Traditionally, exercise routines are being directed face-to-face by a trained individual. With the advent of technology bringing healthcare into the home, voice assistant systems (e.g., Amazon Alexa, Google Assistant, and Apple Siri) provide a platform for the delivery of prescribed exercise programs to older adults in their homes.[86,87] Feasibility studies thus far include mostly community-dwelling adults comfortable with technology; therefore, in terms of frailty treatment and prevention, future research needs to explore applications along the frailty spectrum and consider older adults' access to voice assistant system devices and underlying healthcare disparities.

105.4 SPECIAL CONSIDERATION: SARCOPENIC OBESITY

The complexity of interactions between sarcopenic obesity and functional outcomes highlights the need for a balance between weight loss, proper nutrition, and exercise. Unlike renourishment approaches for malnutrition-related sarcopenia and frailty, caloric restriction and weight loss are pillars of treatment in sarcopenic obesity, using exercise and protein supplementation to minimize the loss of healthy muscle mass.[87] A study by Villareal et al. suggests that combined exercise with caloric restriction can achieve weight loss (9%; -8.5 ± 0.5 kg, $p < 0.001$) with preservation of muscle mass and improved strength.[88] Caloric restrictions of 500–1000 calories/day and a goal of ~0.5 kg/week weight loss are reasonable treatment goals.[87]

In attempts to minimize muscle mass loss during weight loss, protein supplementation during weight loss may mitigate the loss of healthy muscle mass; however, the optimal amount and or pattern of supplementation is unclear.[20,89] It is imperative for individuals with sarcopenic obesity to have adequate protein supplementation to promote an anabolic state after exercise, which is postulated to be 1.0–1.5 g/kg/day, being mindful of renal function at higher supplemental doses.[87] A review by Gilmartin et al. noted improvements in appendicular muscle mass and decreases in truncal fat mass and inflammatory markers in females with sarcopenic obesity after 18 weeks of whey supplementation coupled with three times weekly resistance training.[90] Similarly, a low-calorie diet (1000 kcal/day) with whey and leucine supplementation maintained muscle mass and improved strength in women with sarcopenic obesity.[91] There is currently a randomized control trial investigating the impact of different specific amino acids and exercise on sarcopenic obesity and more studies like these need to focus on individualizing

dietary and exercise routines to best balance weight loss with maintenance of muscle mass.[92] This suggests there are specific roles for specific exercise types for sarcopenic obesity treatment and a need to better understand how to maintain adequate muscle synthesis with effective aerobic exercise.

105.5 CONCLUSION

Healthy aging is an individualized experience requiring individualized approaches. Physical function has a significant impact on quality of life among older adults. Thus, identifying methods of primary and secondary prevention of sarcopenia and frailty is key to helping older adults achieve their desired quality of life. While specific diet components were highlighted within the chapter, dietary patterns combined with mixed exercise regimens will likely be most effective in reducing disease burden and improving physical function in those with sarcopenia and frailty and those at risk of developing these geriatric syndromes. We acknowledge that there are other components needed to promote healthy aging (e.g., community, mental health, cognition); however, these were deemed outside the scope of this chapter. To move prevention efforts forward, it is essential for future research to explore the impact of dietary patterns with exercise regimens, alternative exercise regimens (e.g., yoga and tai chi), and specific macronutrient and micronutrient supplementation amounts on sarcopenia, frailty, and sarcopenic obesity trajectories.

CLINICAL APPLICATIONS

- Healthy aging involves lifestyle interventions that preserve and improve mobility. Approaches to primary and secondary prevention largely overlap as a result of similar underlying pathophysiological mechanisms of sarcopenia and frailty.
- Higher protein diets (1–1.2 g/kg/day) with protein supplementation may delay the development of sarcopenia and show promise for secondary prevention when coupled with mixed exercise regimens.
- There is an urgent need for randomized controlled trials and longitudinal studies to explore the impacts of dietary patterns (e.g., Mediterranean and DASH) when coupled with exercise on sarcopenia and frailty outcomes.
- Older adults should be encouraged to engage in a combination of moderate-intensity resistance and aerobic activity for at least 150 minutes each week with a progressively difficult resistance regimen, individualized to the adult. Practicing yoga and tai chi may be beneficial for older adults.
- Individuals with sarcopenic obesity need individualized dietary and exercise regimens that optimize weight loss while minimizing the loss of healthy muscle mass.

106 Reducing Cognitive Decline through Lifestyle Medicine

Mark Shehata, MD, MBA and Susan M. Friedman, MD, MPH

KEY POINTS

- Cerebral atrophy is a normal part of aging, but lifestyle factors can serve to increase or decrease this rate of change.
- Mild cognitive impairment (MCI) and dementia are clinical diagnoses with structural correlates.
- MCI and dementia, including Alzheimer's type, have a strong association with vascular disease and risk factors, including diabetes, heart disease, hyperlipidemia, and stroke.
- APOE ε4 allele carriers are at significantly increased risk but this risk can still be mitigated through lifestyle factors.
- Each of the six pillars of lifestyle medicine has a role in reducing cognitive decline.

106.1 NORMAL AGING OF THE BRAIN

In order to understand what is normal and what is pathologic in regard to cognitive decline with age, one must first understand how the brain ages. Changes are wide-ranging, occurring at the molecular, cellular, vascular, and structural levels. It has been observed that the brain loses volume at a rate of about 5% per decade from age 40, with the year-to-year rate accelerating later in life. Volume loss is primarily from the gray matter, where neuronal cell bodies reside, but this is also accompanied by loss of protein and phospholipid in the brain, due in part to the loss of myelin from nerve sheaths within the white matter.[1]

Volume loss does not occur proportionally in all regions. A review of studies comparing magnetic resonance images (MRIs) of younger subjects with older subjects noted that the prefrontal cortex is most affected, followed by the striatum, and by other regions including the temporal lobe, hippocampus, and cerebellar vermis. The occipital cortex was most preserved.[2] This has important phenotypic implications as the prefrontal cortex is the primary region responsible for executive function.[3] The hippocampus is heavily involved in conscious memory formation such as learning facts or a new skill and is often noted to be particularly diminished in size in dementia syndromes. The striatal memory systems are involved in habitual processes and the systems are known to interact, as a newly learned task typically begins in the hippocampus and is then encoded in the medial dorsal striatum through practice and repetition.[4] Other changes include loss of axonal length, a decrease in the size of individual neurons, a decrease in the number of synapses, and accumulation of lipofuscin pigment, a byproduct of lipid breakdown.[5]

Another crucial mechanism of age-related cognitive change is the concept of cerebrovascular aging. The brain, receiving 15% of total cardiac output, depends on the vascular system for both the delivery of nutrients and the removal of waste products.[6] A defining feature of the cerebral vasculature is the blood–brain barrier (BBB), formed of membrane components, tight junctions, and specialized cells to prevent harmful molecules from entering the brain.[7] Regulation of flow is dynamic and achieved through smooth muscle control of arteries, long permeating arterioles, and capillary beds in response to carbon dioxide pressure in the blood (PaCO2), input from the autonomic nervous system, and other factors.[7] A number of changes occur with cerebrovascular aging. Loss of compliance of arteries occurs due to the displacement of elastic tissue with collagen and results in an increase in systolic pulse valve velocity, describing pressure exerted on the brain during systole. Endothelial cell senescence occurs, making small vessels less adaptive and thus more prone to thrombotic occlusion and oxidative damage. Luminal narrowing of the vessels and rarefaction (a loss of density) of the microvasculature have been described.[7] These processes can be accelerated by chronic oxidative stress (related to the concept of "inflammaging") and mitochondrial dysfunction inherent to multiple lifestyle and chronic disease risk factors. The downstream consequence is a loss in the above-described BBB and of the brain's ability to autoregulate, two defining hallmarks in how normal cognitive aging is superseded by cognitive impairment or dementia.

Throughout this chapter, a number of animal studies will be referenced in addition to both observational studies and randomized controlled trials (RCT) in human subjects. Dementia is known to be the endpoint of decades of accumulated damage in the brain, a time course making mechanistic study difficult in humans. Animal models are well suited to this role given shared pathogenesis in an accelerated chronology, with rodent models most commonly used.[8] A number of distinct models have been developed to mimic both normal cognitive aging and particular disease states. Such models are limited in their ability to characterize the

DOI: 10.1201/9781003227793-124

full spectrum of cognitive and behavioral implications of such changes and thus complement the evidence obtainable in human studies.[8] This blended approach to evaluating evidence has previously been proposed as an optimal way to understand the relationship of lifestyle to chronic disease.[9]

106.2 DEFINITIONS

106.2.1 Cognitive Domains

The cognitive activities of the brain are often organized into functional "domains". While domains are not mutually exclusive, they are often handled by distinct parts of the brain and thus are a useful way to conceptualize both the function and dysfunction of cognitive processes. These domains include sensation, perception, motor skills and construction, memory, executive functioning, processing speed, and language/verbal skills. Executive function encompasses tasks of planning and problem-solving and involves complex coordination of inputs from other cognitive domains.

106.2.2 Age-Associated Memory Impairment

Most individuals can expect to experience age-associated memory impairment (AAMI) through normal aging. This is thought to be primarily due to changes within the hippocampus and the frontal and temporal lobes of the cerebral cortex.[10] Of the four types of memory—episodic, semantic, procedural, and working memory—episodic and semantic memory are most affected by AAMI, collectively known as declarative or explicit memory. Episodic memory refers to memories associated with events in personal experiences, such as a college graduation, a memorable birthday, or a successful day at work. These memories include information on the time and location of the episode. Semantic memory refers to general accumulated world knowledge, such as universal facts or concepts not unique to an individual's own experience.[10] Nondeclarative or implicit memory is generally preserved in normal aging but can be affected in the disease state. This includes procedural memory, a form of long-term memory involved in the performance of actions and skilled tasks such as tying shoes, and working memory, a short-term form of memory that facilitates the performance of complex tasks.

106.2.3 Mild Cognitive Impairment

Mild cognitive impairment (MCI) is defined by more severe changes than those expected with normal aging but an absence of functional impairment. MCI often affects cognitive domains that are preserved in normal aging and often shares a mechanistic cause with dementia, such as accumulation of tau proteins and neurofibrillary tangles or cerebrovascular disease. The incidence of MCI increases in each decade after age 60 and carries an estimated 15% yearly risk of progression to frank dementia.[11] Cognitive function is screened for by various scales (such as the Montreal Cognitive Assessment, Mini-Mental State Examination, and St Louis University Mental Status scale) and score cutoffs have been employed in distinguishing probable MCI from dementia but ultimately it is the presence or absence of functional impairment due to cognitive decline that distinguishes the two conditions.[12]

106.3 RISK FACTORS FOR COGNITIVE DECLINE AND DEMENTIA

An increase in the incidence and prevalence of cognitive impairment and dementia has been noted consistently year to year in the United States.[13] Given higher prevalence per age cohort, increased life expectancy alone cannot account for the increase. As is the case with many of the diseases discussed in this text, it has been increasingly recognized that many modifiable lifestyle-related risk factors influence the risk and extent of cognitive decline.

The 2020 Lancet commission identified 12 potentially modifiable risk factors for accelerated cognitive decline and dementia. These were estimated to have a weighted population attributable fraction (PAF) for dementia of 39.7%, meaning approximately 40% of dementia cases were calculated to be due to these risk factors.[14] They are summarized in Table 106.1. These factors will be discussed further in the context of the six pillars of lifestyle medicine in the next section. This list is not exhaustive of all modifiable risks.

The greatest non-modifiable risk factor and greatest risk factor overall for cognitive decline is age with risk approximately doubling every ten years of life from age 60.[15] Among genetic risk factors, the APOE ε4 allele is the most well-known. Strength of association has varied widely in the literature but has been generally estimated at a two- to three-fold increase in dementia for individuals with one allele and 8–12 times greater risk for those with two alleles.[16,17] Approximately 25% of people carry one copy of

TABLE 106.1

Traumatic brain injury
Hypertension
Alcohol abuse (>21 drinks per week)
Obesity (body mass index ≥30)
Smoking
Depression
Social isolation
Physical activity
Diabetes
Air pollution

APOE ε4 and 2–3% carry two copies.[18] This association is true for both MCI and dementia. A number of additional genetic risk factors have been identified including but not limited to mutations in amyloid precursor protein (APP) on chromosome 21q, Presenilin 1 (PSEN1) on chromosome 14q, and Presenilin 2 (PSEN2) on chromosome 1q.[19] These are associated with early-onset Alzheimer's disease in particular. The APOE ε2 allele has been found to be associated with a decreased risk of cognitive decline.[20] This was demonstrated in a number of case-control studies and more recently reinforced in analyses of multiple centenarian genetic databases.[21]

The above-described factors contribute to the cumulative risk of cognitive decline in an individual. A number of factors and activities can conversely mitigate the risk. An important concept to define in this context is "cognitive reserve". Cognitive reserve can be defined as an individual's resilience to cognitive aging.[22] This concept will be referenced throughout the remainder of this chapter.

106.4 SIX PILLARS

106.4.1 Nutrition

The consequences of the standard American diet accelerate cognitive aging in a number of ways. Broadly, cerebrovascular aging is accelerated in the same contexts as systemic cardiovascular disease, through chronic inflammation, oxidative stress, and atherosclerosis. The Honolulu Aging Study, best known for characterizing the types of lesions seen on brain autopsies in sufferers of dementia, also noted that Japanese Americans had a considerably higher rate of cognitive impairment than inhabitants of mainland Japan, thought to be in large part due to dietary and other lifestyle differences.[23] Dementia rates in China have been found to increase in correlation with rising obesity rates in China, as Western influence continues to impact diet.[24] Additional disease-specific pathways have been noted. In a study of Drosophila flies and in vitro neuroblastoma cells, it was noted that increased insulin resistance leads to increased tau phosphorylation and thus decreased clearance from the brain through insulin receptor-dependent kinases.[25] In a 2016 study of rats, exposure to a "Western-style diet" (characterized as high in fat and sugar) compared with typical chow-fed rats was associated with increased permeability of the BBB with a dose-dependent relationship to time of exposure to the Western-style diet.[26]

A number of epidemiological studies have demonstrated an association between low dietary omega-3 fatty acids (O3FA) and risk of cognitive impairment. Docosahexaenoic (DHA), a type of O3FA, has been noted to produce neuroprotective metabolites and participate in neuroprotective signaling pathways. It also has been found to limit the production and accumulation of tau proteins and phosphorylation of β amyloid.[27] A recent randomized controlled trial comparing serum and CSF DHA levels found that APOE ε4 carriers experienced a lower rise in CSF DHA after DHA consumption, further supporting the protective role of DHA in cognitive aging.[28] Clinical trials have thus far failed to strongly support a real-world benefit of supplementation of O3FAs. A Cochrane review of three RCTs including 4080 participants aged 60 or older found no differences in cognitive function scores in those receiving O3FA supplements versus those receiving placebo for a minimum of six months.[29] While results may have been influenced by the length of the treatment period or age at treatment, at this time data is insufficient to recommend supplementation. Thus, whole food sources of O3FAs should be recommended. These are rich in fatty fish such as salmon. Plant-based sources include flax seeds, chia seeds, brussels sprouts, and walnuts.[30]

Numerous vitamins and micronutrients have been studied with regard to cognitive decline. Vitamin D has been noted to be protective through a variety of mechanisms. Vitamin D, a steroid prohormone, is known for its primary role in regulating bone health and serum calcium but has been increasingly recognized for its antioxidant and anti-inflammatory roles. Vitamin D crosses the BBB and receptors are present on neurons in multiple structures of the brain. It has been found to promote the production of nerve growth factors (NGF), an important neurotrophic factor.[31] In rat studies, this has been correlated with increased hippocampal volume. Other roles of vitamin D in the brain include regulating various neurotransmitters, reducing tau phosphorylation, reducing the formation of amyloid oligomers (which are more difficult to clear from the brain), and promoting clearance of neurotoxins. While a causal relationship is difficult to demonstrate, numerous observational studies have found an increased prevalence of vitamin D deficiency in individuals with cognitive decline and dementia and have correlated low vitamin D levels with brain volume loss, particularly in the hippocampus.[31] Animal studies have noted a decrease in NGF and glial-derived neurotrophic factor in rats born to vitamin D-deficient mothers and in young rats exposed to a transient vitamin D deficiency. Impairment in attentional tasks was also noted compared with control group rats.[32] B vitamins have also been shown to be protective against cognitive decline. B12 is well known to be associated with dementia and demyelination leading to the syndrome of subacute combined degeneration. B12, B6, and folate have additionally all been found to decrease homocysteine levels, a molecule associated with cognitive decline.[33] An RCT randomized subjects with above average homocysteine level to receive a daily dose of 0.8 mg folic acid, 0.5 mg vitamin B12, and 20 mg vitamin B6 versus placebo for two years and demonstrated reduced homocysteine levels and improved scores in measures of semantic memory, episodic memory, and global cognition in the intervention group.[34]

A 2014 review published in the journal *Neurobiology of Aging* proposed seven dietary and lifestyle guidelines based on available evidence for the prevention of cognitive decline.[35] These are as follows. (1) Minimize intake of saturated and trans-fat due to the strong association

of dyslipidemia with cognitive decline. (2) Vegetables, legumes, fruits, and whole grains should replace meat and dairy as these foods were found in the Chicago Health and Aging Project to be associated with a reduced risk of cognitive decline. (3) Vitamin E should come from foods rather than supplements, as dietary sources (such as leafy greens, nuts, and seeds) have been associated with decreased risk but supplements have not. (4) Daily recommendations of B12 should be reliably met and levels should be checked regularly due to many factors that may impair absorption. (5) If using multivitamins, ones without iron and copper should be chosen unless directed by a physician as studies have linked excessive iron and copper intake to cognitive decline in some individuals. (6) Consider avoiding exposure to aluminum, including through cookware and antacids, as, while evidence is not yet definitive, increased prevalence of Alzheimer's disease has been noted in areas with higher aluminum content in water and aluminum has been noted in brain biopsies of individuals with the disease. (7) Incorporate aerobic exercise equivalent to 40 minutes of brisk walking four times per week. The benefits of exercise are discussed separately in this chapter.

Several diets have been trialed in relation to cognitive decline, with the Mediterranean diet being the most studied. A 2016 systematic review noted the consistency in which studies have demonstrated a linear relationship between adherence to a Mediterranean diet and performance on cognitive scales. A lower incidence of cognitive impairment was also noted in longitudinal cohorts.[36] In 2015, a diet combining the Mediterranean and DASH diet, the Mediterranean-DASH diet intervention for neurogenerative delay (MIND), was published. Differences from the standard Mediterranean diet included an increased emphasis on berry consumption and leafy green vegetables and a framework of ten brain-healthy and five brain-unhealthy foods. These are summarized in Table 106.2. In a cohort of 960 participants, adherence was associated with a slower decline in global cognitive scores as well as in multiple domains. This was described as the equivalent of being 7.5 years younger in age, in terms of the rate of decline between the highest and lowest quartile for compliance. The highest adherence group was found to have a 35% risk reduction for cognitive impairment, and the moderate adherence group had an 18% risk reduction. Mediterranean and DASH diet compliance scores were also measured and found to have a protective effect but a weaker association than that observed with MIND adherence.[37]

A 12-year prospective case-control study (n = 842) published in 2021 sought to further characterize food and microbiota with a protective effect against cognitive decline through serum analysis.[38] Metabolite analysis was done and modeled against performance on multiple cognitive tests. A protective association was found from multiple metabolites of polyphenols (found in deeply colored fruits and vegetables and in green tea), cocoa, coffee, mushrooms, and wine (including resveratrol), supporting plant-based nutrition. The artificial sweeteners acesulfame and saccharin and elevated serum alcohol were found to be associated with increased risk.[38] A particularly rich polyphenolic compound that deserves special mention is curcumin, found in the spice turmeric. Curcumin has potent anti-inflammatory effects in part through modulation of the transcription factor NF-κB, an important regulator of inflammation. Animal studies have found a dose-dependent decrease in markers of oxidative stress within the hippocampus and early human studies have found improvements in mood, attention, and working memory, though optimal dosing remains to be determined.[39]

TABLE 106.2
Food Groups Classified as Brain Healthy or Unhealthy in the MIND Diet Study

Brain healthy
Green leafy vegetables
Other vegetables
Nuts
Berries
Beans
Whole Grains
Fish
Poultry
Olive Oil
Wine
Brain unhealthy
Red meats
Butter and stick margarine
Cheese
Pastries and sweets
Fried and fast food

106.4.2 Exercise

Exercise is one of the most potent tools to combat both long-term cognitive decline and improve mood and cognition day to day. In addition to the numerous benefits to cardiovascular risk which as discussed informs risk of cognitive decline, exercise has been shown to improve functioning across numerous cognitive domains. Numerous interventional trials have demonstrated a slowed risk of cognitive decline in older adults exposed to exercise in multiple geographic regions.[40] Aerobic exercise has been more strongly supported in the literature. A randomized trial assigning previously sedentary older adults aged 60–74 to either a walking program or a stretching and toning program found that only the aerobic group (walking) showed improvement in cognitive tasks of executive function after six months. A 5.1% increase in VO_2 max was also noted, a measure known to correlate with improved cognition.[41] Findings were corroborated in a later study comparing a 12-week aerobic exercise program, consisting of 40 minutes three times

weekly of progressive activity (beginning with walking and progressing to running by the end of the trial period) with one hour, three times weekly stretching sessions, and found improved executive function measured by the Wisconsin Card Sorting Test and improved heart rate variability, thought to reflect general cardiovascular fitness, in only the aerobic exercise group.[42]

Exercise exerts its benefits through a variety of mechanisms including angiogenesis, neurogenesis, and synaptogenesis. Animal studies have demonstrated an increase in BDNF, a crucial neurotrophic factor, and insulin-like growth factor 1 (IGF-1) in the CSF.[43] Exercise-induced increase in BDNF was found to not only reduce loss but even increase hippocampus volume in MRI studies. Loss of hippocampal volume is one of the hallmarks of cognitive aging. More recent studies have found an increase in brain activity as measured by functional MRI as well.[44] A 2018 animal study found that aerobic exercise led to increased expression of Klotho in the brain and kidney, a gene involved in the clearance of reactive oxidative species.[45]

The benefits of exercise in cognition are not limited to primary prevention. A systematic review of 46 randomized trials explored the effects of exercise in individuals with a pre-existing diagnosis of MCI or dementia.[46] Exercise was found to be beneficial for global cognition and in particular cognitive functions including working memory and, less strongly, language. In other studied domains, studies often did not show an improvement from baseline but did show a slower decline in function compared with controls, supporting a disease-modifying effect. Behavioral problems were significantly reduced as assessed by the Neuropsychiatric Inventory. While specific protocols varied widely between studies, noted trends included a greater benefit from aerobic training than from resistance training and a greater benefit with increased intensity of training. It was also found that those with more severe cognitive decline had a more pronounced benefit in global cognition attributed to the expected faster rate of decline at more advanced stages during study periods. Observed adverse events were few and all but one trial noted a greater than 60% attendance rate in exercise classes. Overall meta-analysis of data found a 44% reduction in decline in global cognition compared with controls.[46]

106.4.3 Stress

The importance of stress management has gained recognition in slowing cognitive aging. The allostatic load model postulates that chronic stress leads to dysregulation of the hypothalamic-pituitary-adrenal (HPA) axis and glucocorticoid release.[47] This glucocorticoid excess has downstream effects including disruption of cellular metabolism through glutamate accumulation, increase in insulin resistance and other risk factors of cerebrovascular aging, and disruption of BDNF expression via epigenetic changes. Over time, this has been shown to lead to hippocampal volume loss, leading to cognitive decline and decreased ability to respond to emotional distress. In mouse models, increased plasma cortisol has also been shown to result in accelerated amyloid-β plaque deposition, further increasing the risk for cognitive decline.[48] This is mechanistically related to increased amyloid-β production due to neuronal excitation and increased formation of oligomers and plaques through HPA-mediated pathways.[49]

Meditation has been shown to protect against hippocampal volume loss. A study comparing 50 meditators with 50 controls found increased hippocampal volume in a dose-dependent relationship with the number of years of meditation. This was particularly pronounced within the subiculum region of the hippocampus, important in the regulation of stress, thus suggesting a protective role against stress hormone release and neurotoxicity.[50] Other benefits noted in the literature from mindfulness-focused interventions have included improved attention, increased working memory, and improved performance on tasks of executive function.[51] While protocols varied, there is sufficient evidence to recommend prioritizing stress reduction in general according to patient preferences.

106.4.4 Substances

The negative impacts of smoking on the circulatory system are well documented and cerebrovascular aging is no exception. Analysis of a ten-year cohort from the Whitehall II study noted an accelerated cognitive decline in tests of memory, reasoning, and fluency in male middle-aged smokers. The mean age at first assessment was 59. Effect size was 20–50%. Of note, differences were not seen in females or in those who had stopped smoking at least ten years prior. This may be due to the later onset of diseases of aging in women in general. It also highlights the importance of early smoking cessation.[52] A prospective British study of adults between 43 and 53 years of age found an increase in cognitive decline in midlife in tasks of verbal memory and visual search speeds, with a greater divergence from non-smokers in older participants. Regression predicted this trend would continue later in life.[53]

Shedding light on the mechanisms of these changes was an animal study in which rats were exposed to doses of oral nicotine and cigarette smoke approximating doses used by humans for short-term (four weeks) and long-term (12 weeks) durations. Observations included a dose-dependent increase in anxious and depressive behavior, cognitive interference, neurodegeneration, and DNA damage in the cerebral cortex. Molecular and signaling changes included increased oxidative stress, overexpression of BDNF and dopamine, increased tyrosine hydroxylase, and downregulation of ascorbate (which plays an antioxidant role) and nuclear erythroid factor 2 (Nrf2, a transcription factor involved in resilience against oxidative and metabolic stress).[54]

Data from the Whitehall II cohort was also analyzed with regard to alcohol's effects on cognitive decline in early old age. The mean age in this analysis was 56 years with

5044 men and 2099 women included. Light and moderate use (defined in the study as under 20 g daily) was not associated with accelerated cognitive decline in men but heavy consumption, ≥36 g/day was associated with accelerated decline in all domains. In women, impact was noted at ≥19 g/day on average.[55] One standard drink contains roughly 14 g of alcohol. Thus, patients wishing to minimize the risk of cognitive decline should be advised to drink no more than one standard drink daily for women and no more than two for men. Findings were supported by an analysis of eight-year cohort data from the Ginkgo Evaluation of Memory Study. This included 3021 participants with a mean age of 72 with or without a diagnosis of MCI. Heavy alcohol use (≥14 drinks weekly) was associated with a rate of cognitive decline and a 72% increased risk of progression from MCI to frank dementia in those with MCI at the start of the study. This effect was not modified by the APOE genotype. An increased risk was not observed for alcohol use within recommended limits.[56]

Mechanisms of alcohol's effects on the brain include upregulation of glutamate, and down regulation of GABA and dopamine. This leads to, among other effects, accelerated cell apoptosis in the CNS. The metabolite of alcohol acetaldehyde is also known to be directly neurotoxic. Excess alcohol consumption has also been shown to lead to an increase in pro-inflammatory cytokines and oxidative stress. The effects of thiamine deficiency also bear mentioning given impaired absorption and malnutrition in chronic alcoholism including Wernicke syndrome, characterized by acute ataxia, confusion, and ophthalmoplegia, Korsakoff syndrome, characterized by chronic anterograde amnesia, and Marchiafava–Bignami syndrome, causing seizures and alterations in consciousness due to damage to the corpus callosum.[57] Structural changes on autopsy and imaging study have included volume loss, fiber tract degeneration, cerebellar atrophy, thinning of the corpus callosum, and loss of pyramidal cells in the frontal cortex.[57]

106.4.5 Sleep

The CDC estimates that 35% of all adults and 26% of those above the age of 65 get insufficient sleep, defined as under seven hours nightly on average.[58] This figure has consistently been found to be higher in those suffering from cognitive decline.[59,60] Seen alongside this trend is an exaggeration of age-related sleep changes, including earlier sleep phase, increased fragmentation of sleep, and decrease in slow wave sleep.[61] Disrupted sleep is both a cause and consequence of cognitive decline. Several studies have linked poor sleep to deficits in domains including memory, attention, and executive function in both the short and long term, as well as to increased prevalence of behavioral symptoms.[62,63] Sleep is also known to be crucial in memory formation and thus poor sleep across the lifespan can be surmised to decrease cognitive reserves.[64] One meta-analysis found a 53% increased risk of all-cause dementia in those with insomnia.[65] Research correlating polysomnography with MRI and lumbar puncture noted an increase in CSF amyloid β in cognitively normal older adults with disrupted slow wave sleep, further supporting the link between poor sleep and cognitive decline.[66]

Sleep, among many other roles, serves to facilitate the clearance of neurotoxic substances from the brain. This has been described as the "glymphatic system", a perivascular system in which metabolic waste products are cleared from the CNS. In addition to sleep duration and quality, alcohol consumption, exercise, omega-3 consumption, diet, and chronic stress have all been found to influence glymphatic clearance.[67] In addition to amyloid β, increased levels of tau and various inflammatory markers have been shown to be increased in those with sleep deprivation. In an animal model, amyloid β was also shown to directly impair melatonin synthesis in the pineal gland and interfere with melatonin receptor signaling.[68] Sleep deprivation has also been shown to decrease levels of BDNF, thought to be in part due to disruption of the hypothalamic-pituitary-adrenal (HPA) axis.[69] Thus, prioritizing sufficient high-quality sleep is essential in reducing cognitive aging. A summary of measures to support sleep hygiene is found in Table 106.3.[70]

106.4.6 Relationships

Social interactions are among the most cognitively challenging scenarios one can have day to day and the role of relationships and socialization has been shown to improve cognitive reserve. A 2020 meta-analysis analyzed data from 31 cohort studies exploring the link between social relationships and cognitive decline found that poor social relationships increased the risk of cognitive decline, with a 1.11 odds ratio noted.[71] A 2022 analysis of Framingham Study cohort data found a hazard ratio of 1.54 for ten-year dementia risk for those noted to have loneliness at least three days per week as noted on the Center for Epidemiologic Studies Depression Scale. The hazard ratio was even greater in those without APOE ε4 alleles. Loneliness was also associated with impaired executive function, lower total cerebral

TABLE 106.3
Lifestyle Modifications to Support Healthy Sleep

Sleep Hygiene Measures

Go to sleep and wake up at consistent times
Avoid meals within two hours of bed
Refrain from electronic use in bed
Avoid caffeine in the afternoon
Seek sunlight exposure on waking

volume, and increased white matter injury on MRI, suggesting a role in pathogenesis.[72]

On a day-to-day basis, a study explored how daily social interactions related to the results of mobile cognitive testing and found that an increase in daily interactions and interactions that were rated as more pleasant led to improved cognitive performance on the same day and subsequent two days. Higher interaction scores across the study period predicted higher average cognitive testing scores as well.[73] These supports emphasize positive social interaction as both a preventive and a therapeutic measure relating to cognitive decline.

106.5 HEARING LOSS

The role of hearing loss in accelerated cognitive decline deserves special mention. One of the 12 modifiable risk factors highlighted by the 2020 Lancet commission as noted above, hearing loss in midlife was associated with a relative risk of 1.9 for dementia, tied with depression late in life for the highest risk.[14] This was defined by a threshold of 25 dB loss and a dose-dependent response was noted for worsening loss. While the mechanism is not fully known, a prospective cohort study of middle-aged adults with mean follow-up of 19 years noted that in subjects without baseline cognitive impairment, those with hearing loss demonstrated an accelerated loss of temporal volume on MRI.[74] Several hypotheses have been proposed. The cognitive load hypothesis postulates that untreated hearing loss causes the brain to divert energy toward auditory perception, at the expense of other cognitive processes, leading to accelerated neuronal degeneration.[75] The psychosocial hypothesis theorizes that hearing loss leads to increased depression and social isolation, two known independent risk factors for cognitive decline.[76] While there is an association between hearing loss and depression, a 2017 systematic review found that the status of hearing loss as a risk factor remained when such factors were controlled for.[77]

Fortunately for those experiencing hearing loss, the use of hearing aids has been repeatedly shown to greatly mitigate the risk of cognitive decline. A 25-year prospective cohort study of 1289 older adults (≥65) with hearing loss and 2290 with normal hearing at the start of the study found an association between hearing loss and dementia, depression, and disability only in those who were not using hearing aids.[78] An 18-year study of adults over 50 with cognitive testing every other year found a decrease in the rate of deterioration of immediate and delayed recall starting from the initiation of hearing aids.[79]

106.6 FINGER STUDY

A comprehensive multimodal intervention was tested in the Finnish Geriatric Intervention Study to Prevent Cognitive Decline (FINGER). This double-blind RCT targeted older adults aged 60–77 who were identified to be at risk for cognitive decline as defined by a CAIDE score of at least six and a cognitive score at the mean or slightly below level expected for age. Participants were assigned to either a multidomain intervention including diet, exercise, cognitive training, and monitoring and treatment of vascular risk factors or to a control group receiving general health advice: 1260 participants were randomized and followed over two years. Significant differences were noted in the primary outcome of overall cognition on neuropsychiatric testing as well as secondary outcomes including executive function, processing speed, BMI, dietary habits, and physical activity. The intervention group had good adherence and a low incidence of complications.[80] The promising results of this trial led to the formation of the World-Wide FINGERS network with representation from research teams in over 40 countries to expand clinical research of similar multidomain approaches in combating cognitive decline in different populations.[81]

CLINICAL APPLICATIONS

- Western-style diets characterized by high saturated fat and sugar intake and low fresh fruit and vegetable intake have been repeatedly implicated in accelerated cognitive decline. Diets rich in fruits, vegetables, dietary fiber, and omega-3 fatty acids such as a whole-food plant-based diet, the Mediterranean diet, and the MIND diet should be recommended.
- Exercise has been shown to both protect against cognitive decline and improve memory in those already experiencing cognitive decline, with aerobic exercise having the strongest benefit.
- Stress management protects against cognitive decline through regulation of the hypothalamic-pituitary axis.
- Sleep is vital for the brain's ability to clear toxins, with chronically inadequate sleep leading to accelerated amyloid deposition and cerebral volume loss.
- Healthy social interaction is vital to developing cognitive reserves.
- Hearing loss should be diagnosed and treated early as hearing loss in middle age is associated with cognitive decline later in life.

107 Medication Management in Older Adults

Rohit Moghe, PharmD, MSPH, DipACLM, CDCES

KEY POINTS

- Medication management in older adults is a balance between evidence-based treatment guidance and shared decision-making related to a patient's healthcare goals, taking into account the benefits and risks of each medication.
- Medication harms can occur due to the physiology of aging in the presence of chronic conditions, healthcare systems in which the patients are provided care, and breakdowns in patient and medication safety as part of the medication use process.
- Deprescribing is the systematic process of identifying and providing supervision to discontinue medications when existing or potential harms outweigh benefits.
- Medication management, with a focus on deprescribing, supports the other "Ms" of the 4M model, namely, mentation, mobility, and what matters most.
- Future research will focus on the interaction between lifestyle medicine and deprescribing to determine the best approaches to integrating these two interventions to optimize outcomes.

107.1 INTRODUCTION

Medication management in the older adult population requires balancing evidence-based treatment guidance with shared decision-making. This is even more important when there is a significant lack of representation among older adults in medical research. When there is inadequate evidence for the treatment of certain conditions in older adults, and limited guidance from medical societies, medical management becomes a balance of benefits and risks. It is the intersection of the art and science of medicine. Given the broad scope of medications used in the older adult population, the focus of this chapter will be limited to those who are community-dwelling rather than in congregate settings such as hospitals, skilled nursing and long-term care facilities, and inpatient psychiatric facilities. However, the application of the 4Ms of Age-Friendly Healthcare Systems from the Institute of Healthcare Improvement,[1] as described in Chapter 104, has relevance to all patient care settings. This chapter discusses one of the 4Ms, namely, medication. The adoption of the principles of deprescribing will be discussed.

DEFINITION

Deprescribing is the systematic process of identifying and discontinuing drugs in instances in which existing or potential harms outweigh existing or potential benefits. It is supervised by a healthcare professional with the intent of reducing polypharmacy and improving outcomes. It is not denying care, but rather a patient-centered risk mitigation strategy, where thoughtful discussion occurs between the care team and patients and their caregivers on the balance regarding the risks or harms done by continuing a medication, compared with stopping it.[2]

107.2 PROBLEM—THE WHAT AND THE WHY: FACTORS THAT CAUSE MEDICATION-RELATED HARMS IN OLDER ADULTS

Many factors either by themselves and/or in conjunction with others contribute to medication-related harms in older adults. These factors can be broadly divided into the physiology of aging in the presence of chronic conditions, healthcare systems in which the patients are provided care, and breakdowns in patient and medication safety as part of the medication use process.

107.2.1 Polypharmacy

Prescribing medications for various ailments leads to polypharmacy, defined as greater than five chronic medications, or hyper-polypharmacy, greater than ten chronic medications for greater than 90 days.[3] A systematic review of polypharmacy stated that its causes are complex and conflicting, however, there are notable increased associations in terms of adverse drug events (ADEs), disability and functional decline, frailty, multimorbidity, and malnutrition.[4] According to the Centers for Medicare and Medicaid Services (CMS), the average number of prescriptions over a ten-year period has increased per beneficiary. Patients who take ≥4 medications and ≥10 medications are 21% and 50% more likely to experience falls, respectively, as

DOI: 10.1201/9781003227793-125

well as at higher risk for avoidable healthcare utilization (emergency care, hospitalizations, rehospitalizations, long-term care) and mortality.[5] Multiple factors increase the risk for polypharmacy in older adults and are broadly categorized into patient-specific (e.g., multiple chronic conditions, mental health conditions, cognitive impairment, care under multiple specialists) or health system-related (e.g., poor communication between care providers or care transitions, prescribing to meet quality metrics, and use of automated refill systems).[6] When an older adult has multiple chronic conditions, the likelihood of polypharmacy and hyper-polypharmacy is increased.

107.2.2 Changing Physiology Affecting Medications in the Older Adult

As a person ages, many homeostatic and physiologic functions continue to change in tandem with their overall health and the severity of chronic conditions. Historically, most medications were small molecule compounds, but increasingly, many medications are biological and immunotherapies that could elicit targeted cellular responses. There are four components to be generally aware of when addressing medications in the older adult: pharmacology, pharmacokinetics, pharmaceutics, and pharmacoepidemiology.

Pharmacology or more specifically, pharmacodynamics, refers to what the medication does in the body; the site of action; specific or non-specific receptors or proteins affected. The physicochemical properties of medications are what lead to the intended effects of the medication(s). Pharmacokinetics is what the body does to the medication—absorption of the medication; distribution to the site(s) of action(s); metabolic transformation by various pathways; and elimination from the body. Some medications are prodrugs and require metabolic pathways in order to become active while others can have more active metabolites than the parent compound. Both pharmacology and pharmacokinetics exhibit inter- and intra-patient variability.[7]

Pharmaceutics is the science of formulating a medication for optimal delivery: either systemically, topically, a targeted delivery to the site of action, or delayed or sustained release formulation that enables the medication to be delivered over a period of time. The end product may require special instruction(s) for preparation and administration. This can add to the complexity and cause end-user errors if not properly instructed. A particular formulation of a medication, along with the pharmacokinetic profile can affect how long it takes to achieve maximum concentration (Tmax), the maximum concentration (Cmax), and how long the medication persists in the body, also known as area under the curve (AUC).

Pharmacoepidemiology is the known effects—both intended and unintended—of a specific medication or class of medications based on length of exposure often not studied as part of randomized controlled trials (RCTs) that were conducted for the medication's approval process. This typically happens months to years after the medication has been on the market, and it provides real-world evidence of the benefits and risks associated with medications beyond the RCTs. More often than not, this is where long-term negative impacts of medications on the human body are ascertained, which can further add to the complexity of the aging process. Furthermore, long-term exposure to multiple medications and their interactions may worsen the response of each other as well as cause damage to the human body.[8]

In an aging person, adrenergic receptor density changes, and function of baroreceptors and venous valves within the cardiovascular system also have notable changes. The blood–brain barrier may also weaken with age, allowing for more medications to pass through, increasing the exposure to the central nervous system (CNS). Medications may have enhanced effects on these receptors, increasing an older adult's likelihood of adverse drug reactions (ADRs) due to changes in blood pressure, heart rate, respiratory rate, and/or cognition. The liver utilizes a complex system of a family of enzymes for the metabolism of all chemicals, including medications called cytochrome P450 (CYP450). There are many isoenzymes with some of these displaying genetic variations that affect the capacity of medication metabolism. Of the two key enzymatic processes, CYP450 is responsible for the oxidation and reduction (Phase I) stage of the medication metabolism. This capability significantly declines with age. Phase II is responsible for chemical modification that increases the ability for the medication to be excreted by the kidneys. This typically remains intact with age. The liver also has synthetic functions such as the production of clotting factors, and proteins such as albumin and globulins. Many medications are bound to circulating proteins such as albumin, which affects distribution to sites of target and/or storage in tissue. Medications that are highly protein-bound in a person with reduced synthetic capacity in the liver may result in higher concentrations of unbound medication leading to accumulation and subsequent additive effects in the body. Glomerular filtration rate tends to decrease by 10 ml/min per decade after 40 years of age. Certain chronic conditions such as hypertension and diabetes can further reduce renal function. Structural as well as age-related changes affecting kidney function will result in slower elimination of the medication, accumulation in the bloodstream, and enhanced effects or toxicities at other sites. Furthermore, some medications may cause direct toxicity to the kidneys, resulting in acute kidney injury.

107.2.3 Medication Safety

Medication safety is an evolving field within patient safety and has been challenging to study due to inadequacy of research methodology, lack of documentation in patient medical records, organizational culture, and many other reasons. However, mandates from accreditation organizations as well as local and state requirements are enforcing patient and medication safety through continuous quality improvement within healthcare organizations. Furthermore,

the adoption of electronic health records (EHR), with computerized prescriber order entry (CPOE), has allowed for better data collection around both patient and medication safety. This data now exists within an organization or a local, state, or national registry, which can be used for both research and quality improvement practices.

A 2016 study estimated that medical errors contributed to more than 250,000 annual deaths in 2013 based on the coding of the diagnoses at the time of death.[9] This data, when compared with the National Center of Health Statistics (NCHS) at the Centers for Disease Control and Prevention (CDC), made death due to medical errors the third leading cause of death. A 2017 joint report from the Institute for Healthcare Improvement (IHI), National Patient Safety Foundation (NPSF), and the University of Chicago showed that 41% of 2536 patients who responded to a survey had experienced a medical error, of which 59% was a misdiagnosis.[10] A misdiagnosis may lead to inappropriate treatment(s). The Institute for Safe Medication Practices (ISMP) has a national database of medication errors reported by individual practitioners as well as healthcare organizations. The ISMP has compiled a list of high-alert medications, those responsible for the highest likelihood of errors that can cause harm, temporary or permanent, or be fatal in patients. The high-alert medication lists vary based on the site of care (e.g., hospitals, long-term care facilities, or ambulatory/community). In the ambulatory/community setting, the medications of greatest concern for the geriatric population are opioid analgesics, antithrombotics/anticoagulants, insulin formulations, sulfonylureas, anticonvulsants, cancer chemotherapeutic agents (especially oral), and immunosuppressants.[11]

The medication use system typically includes five distinct components per the Food and Drug Administration (FDA): prescribing, packaging/re-packaging, dispensing, administering, and monitoring. Even though many studies show a significant variation between propensity for errors committed in each component, the prescribing component contributes the most to errors and downstream medication-related problems.[12] This stage requires a lot of patient education and discussion of benefits, risks, and expectations of treatment, as well as lifestyle-related factors to allow for shared decision-making to treat a medical condition with an appropriate medication. A potentially inappropriate medication (PIM) may be prescribed if a comprehensive review of ailments is not conducted, an inappropriate diagnosis is made, or if a thorough assessment of patient-related factors such as medication adherence and persistence, administration techniques, ADRs, and even treatment cost burdens is not completed. A PIM may also be started as a trade-off if the patient is unwilling or incapable of making lifestyle changes necessary to treat a medical condition with a high response rate to modifiable risk factors. Furthermore, a prescribing cascade (Figure 107.1) can be introduced when a patient complains about a new problem that may be attributable to a new ADR, for which a new medication is prescribed, and this cycle continues to be repeated in subsequent encounters. At this stage, it is important to weigh the comparative benefits and risks of initiating medication(s). Implementing CPOE and utilizing pharmacists' ability to intervene and educate providers and patients has been shown to reduce errors at the point of prescribing.[13]

Adverse drug reactions (ADRs) are unintended or excessive effects of a medication. In some cases, these ADRs are tolerable, such as a dry cough with an angiotensin-converting enzyme inhibitor (ACEI), yet still should be noted by both the patient as well as their providers. However, when the ADRs become excessive and impact a patient's quality of life, they often need to be addressed with alternative options.

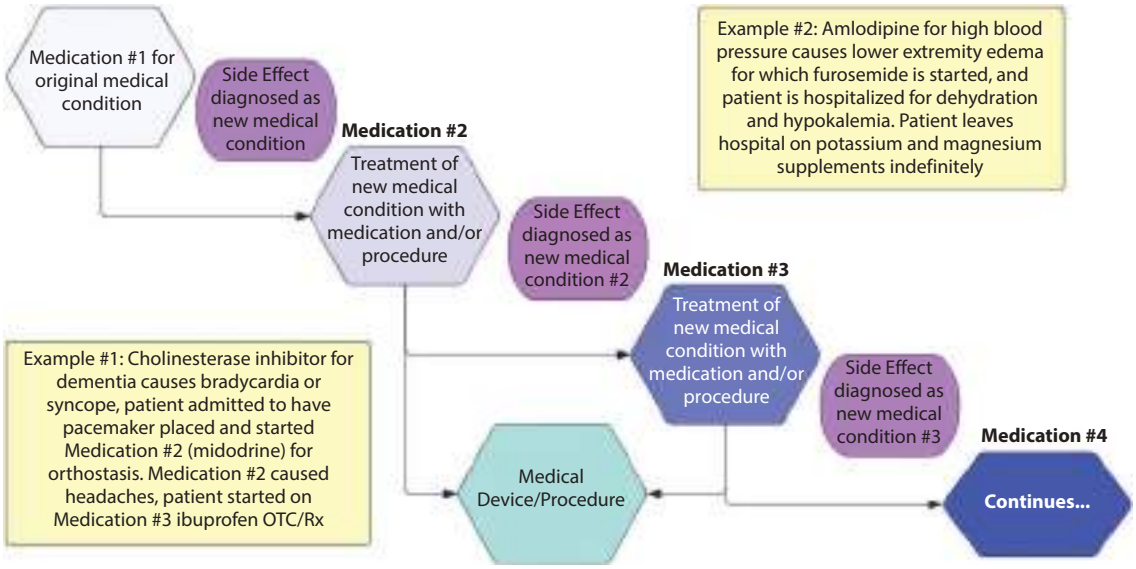

FIGURE 107.1 The prescribing cascade that leads to polypharmacy (adapted from Rochon PA, Gurwitz GH "The prescribing cascade revisited". *Lancet* 2017;389:1778–1780).

Other stages where errors are especially important in the medication use process are administering it to oneself or by a caregiver to the patient. Monitoring of therapy, both for expected outcomes (i.e., benefits) balanced with ADRs (risks), with appropriate laboratory and genetic tests (i.e., precision medicine), may help the older adult achieve their health goals. Thorough patient education is necessary across all aspects of the medication use process including the dispensing component.

107.2.4 Intensification of Medical Guidelines

Guidelines are usually coordinated and published by medical organizations to manage a chronic medical condition in a standardized manner. They establish the standard of care, which may be used as a target for assessing the quality of care provided to a patient. This is especially helpful when a patient has an acute exacerbation of a chronic condition such as hypertensive urgency/emergency, congestive heart failure, asthma, chronic obstructive pulmonary disease (COPD), diabetes, and so on. Standardization can help unify the approach to medical care, reduce inefficiencies, and may help reduce healthcare costs. The downside of standardized guideline-directed therapy could be its inability to take patients' goals, beliefs, and wishes into the decision-making process. Furthermore, a significant lack of older adults (>65 years of age) participating in RCTs further adds to the lack of appropriate inclusion and treatment recommendations established in guidelines. Although some guidelines consider co-occurring chronic conditions (e.g., diabetes and hypertension), often guidelines are mostly disease-specific, intensify based on disease severity, and do not take into account the presence and severity of other chronic conditions.

Therefore, the management of a chronic medical condition occurs in a silo, i.e., treating to a number or a goal and/or to meet performance measures for quality of care. Since most of the guidelines run in parallel with each other, it increases the likelihood of them being applied in a mutually exclusive manner, especially in the setting of having multiple specialists, without a provider who is coordinating care and complexity. This increases the risk for aggressive management which may lead to polypharmacy and hyper-polypharmacy.

When comparing key guidelines for chronic care management, the balance of intensification versus deintensification of treatment must be ascertained. Based on a study of seven of the largest medical guideline developers in the United States, it was found that the majority of them focus mostly on the intensification of treatment (79%) in comparison with the deintensification of treatment (21%).[14] The authors cited the major reason for this is that the majority of guidelines utilize data from RCTs to generate recommendations for treatment and its intensity. Another reason was inconsistency with the balance of benefit to harm, i.e., the number needed to treat (NNT) versus the number needed to harm (NNH). This imbalance is what is not accounted for when metrics are utilized to measure the performance of the quality of care provided.

For example, treating a patient with essential hypertension to a goal of 120/80 mmHg or less, without untoward side effects is based on the guideline goal-directed therapy. This was demonstrated in previous randomized controlled trials over the decades and re-demonstrated in the Systolic Blood Pressure Intervention Trial (SPRINT).[15] The SPRINT series of RCTs was focused on understanding long-term outcomes of intensive versus less intensive blood pressure control in people over 50 years old. While the SPRINT series of trials demonstrated cardiovascular benefit in many, including those with mild cognitive impairment, and reduced brain lesions in the intensive treatment arms of the SPRINT-MIND cohort, the message that is often missed is that only one-third of the patients were >75 years old, and the majority of the participants were generally healthy for their age, as frailty was not assessed.[16] Furthermore, the earlier blood pressure was controlled, the better the intended outcomes with an enduring effect. However, the results may not be generalizable to older people with multimorbidity and frailty. A recent observational study by van Dalen et al showed that blood pressure associations with incident risk for dementia followed a U-shaped curve based on age strata and the very elderly fared better with looser control than the younger.[17] In light of such evidence, should we continue to aggressively manage an older adult's blood pressure to <120/80 mmHg in the presence of multimorbidity and frailty?

In another example, how would we manage a 69-year-old male patient who has type 2 diabetes with an A1C of 9.5%, stage III CKD (eGFR <60 ml/min), with a blood pressure of 152/86 mmHg who is morbidly obese (BMI 38 kg/m2), newly diagnosed with Stage 1 (NYHA) or Stage A (ACC/AHA) heart failure and an ejection fraction of 45%? This person also has osteoarthritis of both knees, states he is in pain, his mood is horrible, and he has trouble falling asleep at night. Which guideline-directed therapy should we access first? How do we prioritize our treatment goals? Where does lifestyle fit in? If we follow the guidelines as they are written, this patient would be on three to five medications for the management of his type 2 diabetes, three to five medications for his hypertension and heart failure, and to meet performance measurement quality metrics, required to be on a statin medication. It is now possible to see how by following guideline-directed therapy, following quality metrics, and treating pain and mental health, it is conceivable to see him on 15 medications. Furthermore, some of these medications may cause side effects, which may result in additional medications to treat them, possibly creating a prescribing cascade. There is a significant risk for polypharmacy and hyper-polypharmacy. In such a patient, would offering options through lifestyle medicine provide additional help while enabling them to deprescribe some medications along the way?

107.3 HOW TO ASSESS IF A PROBLEM EXISTS

A systematic approach that aligns with the Medication component of the Age-Friendly Health Systems (AFHS) from the IHI should be utilized with patients that will help identify patients at risk for drug-related problems (DRP), as well as a comprehensive review of their medical conditions, procedures, and medications, and the patient's health goals. The key drivers are appropriate assessment and determining a solution, which can include medication(s) as long as there is a proper indication, a favorable benefit-risk ratio, and the medication does not interfere with the other three Ms: What Matters, Mobility, or Mentation across care settings.[1]

Many providers encounter patients who already have medication regimens. In such cases, we must assess for drug therapy problems (DTPs).

> Pro Tip: This offers the opportunity to work in an interprofessional manner with trainees (students, residents), nurses, and especially pharmacists. The goal is to make it as simple and seamless as possible in your practice. See Table 107.1.

In addition to the assessment process to identify DTPs, there are additional tools that help identify if certain therapies or regimens a patient is receiving provide low-value care. Table 107.2 shows selected Choosing Wisely recommendations that pertain to geriatric populations regardless of care setting. For the sake of simplicity, only recommendations pertaining to community-dwelling older people were included. To learn more about additional recommendations in the geriatric population in acute, post-acute, and long-term care, refer to the Choosing Wisely website (www.choosingwisely.org) to learn about medication use recommendations by the American Society of Consultant Pharmacists (ASCP), the American Society of Health-Systems Pharmacists (ASHP), and the American Medical Directors Association (AMDA).

During the care process, the other three elements of the 4Ms are typically reviewed in detail: what matters to the patient and their caregivers/family members; their mentation; and their mobility. High-risk medications as defined by multiple stakeholder organizations (IHI, ISMP, AGS, etc.) typically include psychotropic agents (benzodiazepines, antipsychotics, sedatives, tricyclic antidepressants), opioids, anticholinergic agents (especially antihistamines like diphenhydramine), and muscle relaxants. These medications not only affect mentation but can increase the risk of falls, especially in those with frailty.[25] Deprescribing them to either the lowest dose, or completely tapered off, is ideal and safe for patients. To align this with "What Matters", the care team should ask the patient and/or their caregiver about what is the most important thing they would like for their care team to help them with, both short-term as well as long-term. Medications that affect mentation can cause drowsiness, impair cognitive function, and cause significant mood disturbance, all of which may impair their gait, and hence, mobility. They may experience a fall as a result and require additional medical attention due to fractures and/or physical/occupational therapy. Each aspect of the 4Ms is intertwined with the other. If a patient's mentation is significantly affected, it may impair their ability to communicate what matters to them the most.

The 4Ms process encourages creating both deprescribing champions as well as algorithms and guidance within the organization. By putting continuous quality improvement processes in place, there may be an adequate amount of real-world experience that could be published and shared with other institutions that are looking for guidance and support in their efforts to create an age-friendly healthcare system.

107.4 HOW TO FIX THE PROBLEM

According to a review in the American Association of Family Practice on polypharmacy, deprescribing starts with judicious prescribing, i.e., an off-ramp must be deliberated along with the on-ramp when initiating medications (Table 107.3).

When caring for patients with existing extensive medication regimens, an algorithm by Scott et al. (see Figure 107.2) can help determine which medication(s) to consider deprescribing.[26] A thorough assessment should include appropriate indications for medications; identification of any existence of prescribing cascades; balancing actual or potential harms over benefits; evaluation of current symptoms; benefits of medications present in the lifespan remaining of the patient; as well as treatment burdens.

Certain medications cannot be immediately discontinued and will require a slow withdrawal or taper to minimize any withdrawal reactions due to physical and/or psychological dependence on the medication, as well as the symptoms they may have been trying to control. This applies especially to psychotropic, antiepileptics, and neuroleptic medications; opioid analgesics; antihypertensive agents, antidiabetic agents, adrenergic agents, and immunosuppressants. Since this is unique to each medication and/or medication class, it is outside the scope of this chapter. Instead, please refer to the resources section.

107.5 COLLABORATION IS KEY TO SUCCESS

Successful deprescribing initiatives focused on the medication component of the 4Ms model require partnership with all stakeholders, especially pharmacists. As the breadth and scope of practice of pharmacists continue to grow and evolve, it is important to include them in the care process of deprescribing. Pharmacists will also need to work with other members of the care team to better understand how medications may be influential on a patient's mobility or mentation. There is extensive literature on pharmacists playing key roles in providing deprescribing initiatives through their usual practice during patient care encounters.[27–29]

TABLE 107.1

Process to Identify Drug Therapy Problems in Patients with Polypharmacy

Task	Tools (Examples)
1. Perform a thorough medication reconciliation to ensure all medications are appropriately accounted for	• Electronic Health Record (EHR) • Reviewing and reconciling multiple sources of medical records
2. Assess adherence and understand barriers to adherence such as costs, concerns about side effects, or commitment to chronic care management	• ASK-12 Questionnaire[20] • Medication Regimen Complexity Index (MRCI)[21] • Review of prescription fill/refill records, claims, or utilization
3. Identify drug-drug interactions (DDI)	• Available databases already available in EHRs or online at your institution (eMicromedex, UpToDate, Dynamed, etc.) • Serious DDIs include QT prolongation, coagulation/bleeding, psychotropic medications, serotonin syndrome
4. Identify drug-disease interactions	• For example, NSAIDs use in CKD or CHF
5. Identify overtreatment and/or accumulating therapies	• Duplicate therapies • Additive effects (e.g., BP control, anticoagulation/antithrombotics) • ChoosingWisely Initiatives (www.choosingwisely.org)
6. Identify high-risk drugs in older adults ○ Both criteria help identify high-risk drugs and disease states ○ Assess if medications are appropriately prescribed	• American Geriatrics Society Beer's Criteria[24] • STOPP/START Criteria[22]
7. Identify the use of herbal supplements and OTC products ○ May need to identify drug-herb interactions	• Efficacy and benefits can be reviewed on the Memorial Sloan Kettering herbal database (Free) (www.mskcc.org/cancer-care/diagnosis-treatment/symptom-management/integrative-medicine/herbs) • Natural Medicines database (subscription required) https://naturalmedicines.therapeuticresearch.com/
8. Identify medication monitoring for safety and efficacy, as well as adverse drug effects the patient may be experiencing	• Best practice alerts in EHRs • Professional guidelines
9. Assess if any medications are eligible for deprescribing, the patient requests it, and/or the risk-benefit ratio is no longer favorable	• Clinical pharmacist consult for CMM (if available)

ASK-12, Adherence Starts with Knowledge, 12-item questionnaire; STOPP, Screening tool for older person's prescriptions, identifies PIMs; START, Screening Tool to Alert Treatment Prescription, identifies potential prescribing omissions; CMM, comprehensive medication management. Adapted from references [18] and [19].

TABLE 107.2
Selected Choosing Wisely Recommendations for Medication Use in Geriatrics

Sponsoring organization	Recommendations	Rationale
AGS	Do not use antipsychotics as the first choice to treat behavioral and psychological symptoms of dementia.	Inconsistency of benefits and increased risk for falls, cognitive impairment, sedation, stroke, and death.
AGS	Avoid using medications other than metformin to achieve hemoglobin A1c <7.5% in most older adults; moderate control is generally better.	A1C control <7% is associated with an increased risk for hypoglycemia and mortality. Given the long timeframe to achieve the theorized microvascular benefits of tight control, glycemic targets should reflect patient goals, health status, and life expectancy. Reasonable glycemic targets would be 7.0–7.5% in healthy older adults with long life expectancy, 7.5–8.0% in those with moderate comorbidity and a life expectancy <10 years, and 8.0–9.0% in those with multiple morbidities and shorter life expectancy.
AGS, AMDA	Do not use benzodiazepines or other sedative-hypnotics in older adults as the first choice for insomnia, agitation, or delirium.	Large-scale studies consistently show that the risk of motor vehicle accidents, falls, and hip fractures leading to hospitalization and death can more than double in older adults taking benzodiazepines and other sedative-hypnotics.
AGS, AMDA	Do not use antimicrobials to treat bacteriuria in older adults unless specific urinary tract symptoms are present.	Cohort studies have found no adverse outcomes for older men or women associated with asymptomatic bacteriuria. Antimicrobial treatment studies for asymptomatic bacteriuria in older adults demonstrate no benefits and show increased adverse antimicrobial effects
AGS	Do not prescribe cholinesterase inhibitors for dementia without periodic assessment for perceived cognitive benefits and adverse gastrointestinal effects.	Although some RCTs suggest that cholinesterase inhibitors may improve cognitive testing results, it is unclear if it is clinically meaningful. It is uncertain whether these medicines delay institutionalization, improve quality of life, or lessen caregiver burden. No studies have investigated benefits beyond a year nor clarified the risks and benefits of long-term therapy. AMDA also has similar recommendations
AGS	Avoid using prescription appetite stimulants or high-calorie supplements for the treatment of anorexia or cachexia in older adults; instead, optimize social supports, discontinue medications that may interfere with eating, provide appealing food and feeding assistance, and clarify patient goals and expectations.	Megestrol and cyproheptadine are on the AGS Beer's Criteria and ineffective for weight gain. Mirtazapine can stimulate appetite with modest weight gain but should only be used if a patient has clinically diagnosed depression.
AGS, ASCP, ASHP	Do not prescribe a medication without conducting a drug regimen review.	Similar recommendations also come from pharmacy organizations (ASCP and ASHP) as well as AMDA. This is to reduce the risk of polypharmacy.

AGSP, American Geriatrics Society; ASCP, American Society of Consultant Pharmacists; ASHP, American Society of Health-Systems Pharmacists; AMDA, American Medical Directors Association. Adapted from Choosing Wisely Website: www.choosingwisely.org.

107.6 THE INTERPLAY BETWEEN RESEARCH AND REAL-WORLD EVIDENCE

Since much of the deprescribing initiatives and the attention to the details of medications in the 4Ms model is based on quality improvement in the care delivery process, balancing safety with what matters to our patients, it is important to note that the preponderance of research in terms of randomized controlled trials is still an emerging science. The first place to start research on deprescribing medications is with patient safety or quality improvement projects within health systems.[30,31] Usually, this research shows identification and quantifiable reductions in harmful or inappropriate medications.[32] They can expand from there to qualitative research including various stakeholders such as providers, patients, and caregivers to understand what they value in this process.[32–35] One of the largest qualitative studies conducted by Green et al. involved attitudes toward language used in deprescribing medications based on clinical vignettes in the elderly ≥65 years. In both scenarios, the patients preferred language of side effects over questionable clinical efficacy to help them consider having their medications deprescribed.[36]

The Shed-MEDS, D-Prescribe, and OPTIMIZE trials are examples of pragmatic real-world approaches to patient-centered care processes conducted in a traditional

TABLE 107.3
Considerations for Judicious Prescribing

Before starting any new medication ask:

- Are there underlying causes for the issues or symptoms the patient is experiencing that should be addressed first?
- Is the new medication/treatment necessary for the patient's condition?
- Are there nonpharmacologic therapies that can be considered? This is a place where lifestyle medicine may serve an impactful role.
- Are there preventive measures that can be tried first?
- Are there benefits? Are there proven outcomes? When will the benefit be seen?
- What are the risks?
- What are the patient's/caregiver's goals of therapy?
- What are my goals (as the primary care provider) of therapy?
- What is the patient's estimated life expectancy when considering age and comorbidities? Will the patient be alive long enough to experience any benefits?
- Have I discussed this with the patient for shared decision-making?
- Is the patient adherent to currently prescribed medications? Can the patient adhere to this medication?

Consider the complexity of regimen and any visual, dexterity, or cognitive impairments the patient has.

- Can the patient afford this medication?
- When starting any new medications, consider it a trial rather than a permanent addition.

Follow-up with the patient in a timely manner after adding medications.

Assess for effectiveness and safety at follow-up visits.

- When renewing refills, consider the benefits vs. the risks of continuation (long term and short term).

Adapted from reference [19].

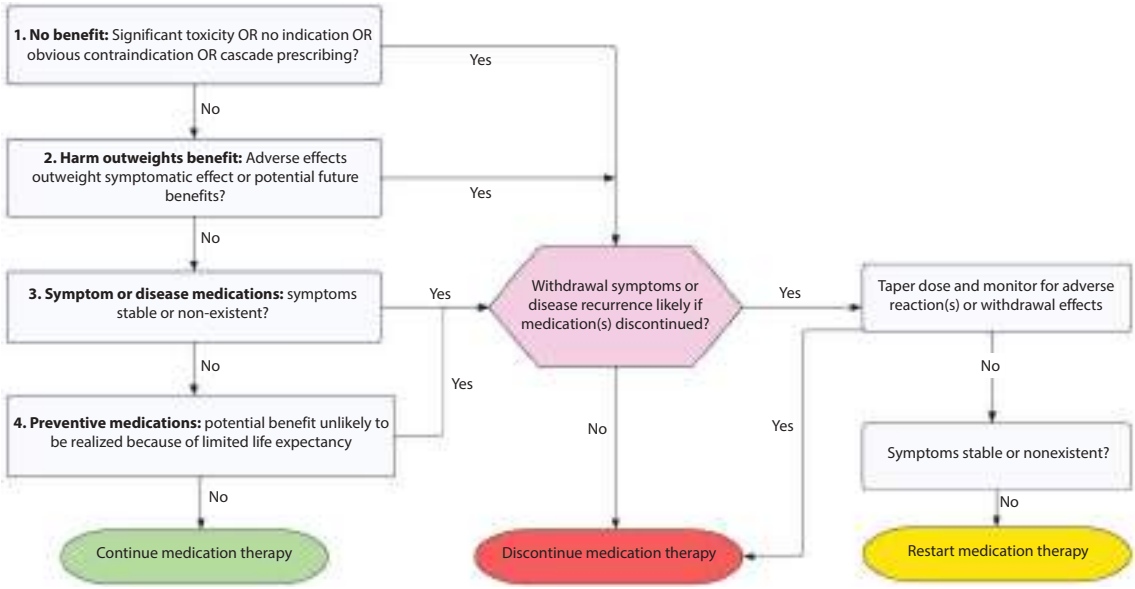

FIGURE 107.2 Deprescribing algorithm (adapted from Scott et al. *JAMA Intern Med* 2015;175(5):827–834.

randomized controlled trial setting.[37–39] The Shed-MEDS trials were conducted on patients ≥50 years of age discharged from a hospital to a post-acute care (PAC) facility such as a skilled nursing or inpatient-rehab facility. The patients were followed up at 7, 60, and 90 days post-discharge from the PAC with a primary endpoint of percent reduction in the total number of medications. Secondary endpoints included the number of medications associated with geriatric syndromes, drug burden index, medication adherence, the prevalence and severity of geriatric syndromes, and functional health status.[37]

The D-Prescribe trial was conducted in Canada and focused on pharmacist-led educational programming for the elderly population in the community pharmacy setting.[37] The patients were randomized at the pharmacy level and received educational materials that discussed options for deprescribing medications based on the American Geriatrics Society Beer's Criteria of PIM versus usual care. At the end of six months, more patients had their medications deprescribed in the pharmacist group (43%) versus the usual care group (12%). Both of these studies demonstrate that not only can the construct of the 4Ms

model be applied in different care settings, but so can the interventions.

The OPTIMIZE trial was a cluster randomized RCT that targeted outpatient clinics in an integrated healthcare delivery network over 12 months. Patients and their providers were provided with educational information to deprescribe unnecessary or risky medications in 3012 patients ≥65 years of age with dementia or mild cognitive impairment with at least one additional chronic condition and taking ≥5 chronic medications.[39] Patients and clinics were randomized to receive deprescribing education (1433) versus usual care (1579). While this study showed modest increases in deprescribing in the intervention group compared with the usual care, it demonstrated the manner in which the education is delivered and who is delivering it. Since clinics and providers were aware that their patients may receive this information, having the intervention come directly from the provider or care team rather than research study education materials could have had an impact on the rates of deprescribing.

Successful research can drive practice when helping patients make decisions that matter to them. As a result, many such trials are currently being undertaken for deprescribing interventions. The United States Deprescribing Research Network (www.deprescribingresearch.org) is a great place to start reviewing studies in progress as well as new research opportunities.

107.7 QUESTIONS AND FUTURE DIRECTIONS

Most of the research is focused on what happens when medications are deprescribed safely under appropriate circumstances taking into consideration risks versus benefits, patient beliefs and expectations, as well as overuse or low-value care. The research is still in its infancy when two approaches are combined into one—lifestyle medicine and deprescribing. How can deprescribing be utilized as a tool in lifestyle medicine in a systematic way?

As patients are encouraged, coached, and enabled to make healthier choices in mitigating, preventing, or even reversing their chronic medical conditions, what is an optimal dose of each component of lifestyle medicine—diet, healthy activity, restful sleep, managing stress, reducing risky behaviors/substances, and positive social connectedness—individually or in a combination? How would we study the individual effects of lifestyle as medicine interventions in patients who are on concurrent medications and the impact of deprescribing them in a stepwise process? Which medications should we start with first, and which ones should be reserved to deprescribe last? Where does deprescribing fit in with biologic therapies and immunotherapies in autoimmune conditions? This is where there is a need to blend both the art and the science of medicine into something practical and useful for our patients.

CLINICAL APPLICATIONS

- Managing medications in older adults requires balancing what is known from research and evidence-based guidelines with the patient's goals of care.
- Polypharmacy is defined as taking more than five chronic medications, and hyper-polypharmacy is defined as taking more than ten chronic medications for greater than 90 days. It is associated with an increased risk of adverse drug events, falls, functional decline, healthcare utilization, and mortality.
- A prescribing cascade can occur when a patient experiences a new problem that may be attributable to a new adverse drug reaction and is treated with a new medication to address that reaction. This can compound the risks of polypharmacy.
- Guidelines are usually targeted toward single chronic conditions, and do not take into account the complexity of the older adult, which may include multiple conditions and individual patient goals. This may lead to an increased risk for polypharmacy. Furthermore, they are often based on studies that have not enrolled frail older adults, so the findings are not applicable to a frail and complex older patient.
- Appropriate prescribing requires determining that there is a proper indication for a medication, a favorable benefit-risk ratio, and that the medication does not interfere with the other three Ms: What Matters Most to the patient, Mobility, or Mentation.
- A framework for considering deprescribing includes identifying appropriate indications for medications; identifying the existence of prescribing cascades; balancing actual or potential harms over benefits; evaluating current symptoms; determining benefits of medications based on life expectancy; and understanding treatment burdens.

108 What Matters: Geriatrics, Lifestyle Medicine, and Palliative Care

Deborah Kempe Ames, MD, MPP, HMDC

KEY POINTS

- Palliative care is holistic care for those with complex, chronic, or terminal illnesses. It addresses the physical, functional, psychological, practical, and spiritual consequences of a serious illness.
- The goal of palliative care is to discover what gives meaning to people's lives in order to create a plan of care to support them in improving their quality of life and meeting their goals.
- The goal of palliative care is to support the patient and all who love and care for them. This includes supporting patient autonomy and patient empowerment for informed consent in all medical decisions.
- Lifestyle interventions can help palliative care patients and other older adults achieve what matters to them, including personal growth, achievement of life milestones, maximal possible self-sufficiency, satisfaction with life, and symptom management.

108.1 WHAT IS PALLIATIVE CARE?

Palliative care is the care of patients with chronic illness, often multiple complex chronic illnesses, or terminal illnesses. It is care of the whole person and centers itself on what matters to the patient, their goals of care, and relief of suffering. For an older person receiving palliative care, improving their self-efficacy, and personal or spiritual growth is often as important as maintaining their functional status and relief of the symptoms of their disease.

> *Palliative care focuses on expert assessment and management of pain and other symptoms, assessment and support of caregiver needs, and coordination of care. Palliative care attends to the physical, functional, psychological, practical, and spiritual consequences of a serious illness. It is a person- and family-centered approach to care, providing people living with serious illness relief from the symptoms and stress of an illness. Through early integration into the care plan for the seriously ill, palliative care improves quality of life for the patient and the family.*
>
> Source: National Coalition for Hospice and Palliative Care, Clinical Practice Guidelines for Quality Palliative Care, Fourth edition, 2018.[1]

Six principles are central to providing optimal palliative care: clarifying goals of care; improving quality of life; identifying the unit of care as the patient and all who love and care for them; recognizing that the patient's path through illness and care is unique to them; documenting the patient's condition, options, decisions, interventions, and needed supports in a plan of care; and planning to support the patient with the interdisciplinary team across healthcare settings. These principles are listed in Table 108.1 and are further described below.

108.2 PATIENT AUTONOMY AND GOALS OF CARE

A typical goal of care, what matters most, is the improvement of quality of life, regardless of prognosis. The goals of care will typically reflect the individual's values about what represents an improved quality of life. This allows a level of freedom to prioritize the patient's autonomy and choices, rather than reflexively following the standards of care that may no longer be appropriate to the patient's age or stage of disease.

The Age-Friendly Health Systems initiative defines "What Matters" as "knowing and aligning care with each older adult's specific health outcome goals and care preferences including, but not limited to end-of-life care, and across settings of care".[2] The "What Matters to Older Adults Toolkit" produced by the Institute for Healthcare Improvement (IHI) Age Friendly Healthcare initiative has concrete steps a clinician can take to hold productive and supportive conversations with their patients at appropriate touch-points in their care. This patient care, as described by the IHI, is consistent with high-quality palliative care goals-of-care conversations and may serve as an accessible entry point for clinicians unfamiliar with goals-of-care conversations.

What matters most to patients often becomes starkly transparent as the patient's internal resources are exhausted by illness or treatment, consistent with the IHI

DOI: 10.1201/9781003227793-126

TABLE 108.1
Six Principles of Palliative Care:

- Clarify goals of care
- Improve quality of life
- Identify the unit of care as the patient and all who love and care for them
- Recognize that the patient's path through illness and care is unique to them
- Document the patient's condition, options, decisions, interventions, and needed supports in a plan of care
- Plan to support the patient with the interdisciplinary team across healthcare settings

recommendation to explore "what matters" with a change in health status or during chronic disease management. As repeat hospitalizations and multiple medical visits consume more of a patient's time and energy, the options for refocusing efforts on quality of life often become more attractive to patients. This may mean less stringent medical control over their clinical conditions, such as hypertension or diabetes. This may also lead to choices to limit invasive interventions or hospitalizations. It may also mean, for some patients, the choice to discontinue all or most conventional medical interventions for chronic or terminal illnesses. When possible, an in-person, linguistically, and culturally competent interpreter is invaluable in any circumstance where the patient and clinician do not share a common primary language and culture and where goals of care or treatment are being discussed or decisions are being made.

The goals of care discussion often reveal what matters most to patients, their values, and what gives their life meaning. These goals may be as concrete as going on vacation at the beach, living to see a grandchild graduate, being able to walk their daughter down the aisle at her wedding, being able to walk to the bathroom independently, having less pain, or completing one last road trip. Or the goal may be as amorphous as improved sleep at night, less anxiety about the future, a deeper connection to the Divine, or self-forgiveness. It may also be an open-ended goal that can never be completed, such as continuing to provide resources that keep their family from becoming homeless. When eliciting and documenting the goals of care, it is helpful to have an openness to the full range of patient priorities: physical, emotional, social, and spiritual. Specificity in documenting the individual goals and what matters most to them with concrete examples or quotes can be exceedingly helpful for the continued appropriate care of the patient.

Guidance on eliciting and documenting these goals of care is provided in the IHI "What Matters to Older Adults Toolkit". Common questions that are more commonly used in palliative care, and not contained in the "What Matters" toolkit, are questions such as: "If you knew you had only a short time left to live, where and how would you want to spend your time?" and "What is an unacceptable quality of life/death for you?" Other tough questions may include, "If you are unable to return to your prior level of functioning/place of residence, what care do you want to receive, from whom?" Many of these questions are based on both the need for care planning and clinical experience working with patients who are facing tough decisions. In addition, there exists an acknowledged potential for personal growth or development in the setting of the suffering experienced by many palliative care patients, often referred to as post-traumatic growth. Such personal growth may be a goal of the patient and more easily achieved when the patient's suffering is managed or relieved.[3–5]

108.3 DEFINING QUALITY OF LIFE

The patient's capacity to achieve these goals is often limited by their terminal illness or complex or severe chronic disease. With limited intrinsic resources, choosing interventions becomes a balancing act of figuring out which interventions have the greatest chance of improving the patient's quality of life with the least burden to the patient. For instance, pulmonary patients who are in chronic hypoxic respiratory failure are not typically good candidates for intensive inpatient physical rehabilitation, though they may welcome information about eating a low-inflammatory diet, "eating the rainbow" with a wide variety of fruits and vegetables as part of their own engagement in their health and well-being,[6] along with cessation of tobacco and breathing exercises to reduce anxiety due to dyspnea. Massage and passive or supported range of motion may also help decrease musculoskeletal pain associated with decreased mobility. All of these modalities can improve symptom management, and thereby improve the patient's quality of life and opportunity for post-traumatic growth, which can further aid in achieving even more of their goals of care. Finding out from the patient what is important to them to address first, and any larger goals, can aid in developing an effective plan of care.

There are numerous measures of quality of life in advanced disease used in clinical research. Some of these measures are disease-specific and some are more general, applying to all patients, including those with severe or chronic illness. The clinician's perspective is determinative in the formulation of most instruments used to measure quality of life. However, the responses are frequently highly subjective and may change as disease or debility progresses. As Davis and Hui point out in their article from 2017:

> Patient perspectives when queried about QOL include the following perspectives: Fulfillment of personal goals, good control of physical symptoms, emotional well-being, the

> ability to lead a normal life and maintain a sense of self, sociability (role within the family and society), existential and transcendent fulfillment, finding meaning in life, adaptability or resiliency, changing values or recalibration of goals with the disease trajectory.[7]

Alleviating physical symptoms and improving functional status can provide the conditions necessary for the exploration of other goals. It could be said that the real work at the end of life begins when the physical suffering abates. This work can involve the deep and important work of attaining social, psychological, and spiritual peace or growth. The team must remain sensitive to what matters to the patient to provide or facilitate the most appropriate support for these goals.

108.4 THE UNIT OF CARE

Choosing the interventions that are likely to have the greatest effect on quality of life often leads to involving the patient's family, friends, and care providers. For an effective plan of care, the unit of care is often the patient and all who love and care for them. For instance, one of the most effective interventions for comfort in end-stage cardiac disease or end-stage liver disease is decreased sodium intake. This can be the difference between a bounce-back to the cardiac care unit after a trip to a fast food restaurant or decreased dyspnea with improved lower extremity edema at home on fewer medications. For this intervention to be effective, the patient and all who care for the patient need to be aware of how important it is and what it means. A home visit that reviews foods immediately present can be a useful intervention for patients, family, and caregivers, with an opportunity to educate about the milligrams of sodium in a serving or container. For many patients, this is not the first time that they have heard this, but the recognition that they are running out of disease-directed treatment options appears to focus many patients on taking back control over this part of their medical condition. Even then, it remains a shared decision-making process, with openly discussed, respectful plans for the management of increased symptoms when the patient chooses not to follow the recommended nutritional interventions. These variations in the plans of care are often for special events, like family celebrations or holidays, where the patient prioritizes the goals of reconnecting or celebrating their connection with those they love. For those patients, fully recognizing their autonomy may involve finding alternative ways for them to improve their symptoms, such as elevation of their legs, lymph drainage massage, temporary increases in their medications, or walking in a pool to relieve lower extremity swelling. Informing the patient of these potential interventions and working with them, and their caregivers, to create the least burdensome plan of care can support the patient's sense of self-efficacy, which may have a unique contribution to quality of life.

Older adult patients living in care facilities sometimes face additional challenges and have additional benefits. Many care facilities do not offer heart-healthy meals, such as low sodium, Mediterranean diet, vegan, vegetarian, or DASH diet options. Other options that are often difficult for patients to navigate in facility settings are changes such as avoiding all dairy or a low-fat diet to treat chronic diarrhea or abdominal discomfort. Many older adults with chronic diarrhea or irritable bowel syndrome demonstrate symptomatic improvement with the avoidance of dairy or the addition of lactase with dairy-containing foods.[8] Likewise, older adults, especially those with biliary dysfunction or status post cholecystectomy, may see relief of diarrhea with a reduced fat diet. Coordination of these interventions can involve the patient's other clinical care providers, as well as family members and other patient advocates, with the patient designating the person they would like to have involved in the efforts on their behalf. Other interventions that often benefit from facility participation include restorative aid services for light exercise or range of motion, physical therapy, occupational therapy, music therapy, art therapy, religious services/observances, social events, exercise classes, dances, and organized outings. With the patient's goals always as the guiding principle, care facilities may have, or know how to access, many elements of robust lifestyle interventions.

108.4.1 Alternative Decision-Makers

At times, due to individual patient preference, culture, language, or health condition, patients may indicate they wish to designate an alternative person to receive their health information and make decisions about goals of care and interventions or they may lack the capacity to make some or all decisions. The designation of an alternative decision-maker may have been made prior to the patient's inability to make decisions or be made by state law in some states and situations. Substituted decision-making is frequently utilized by asking the alternative decision-maker to explain what they believe the patient would have wanted if the patient could choose for themself. Alternatives to substituted decision-making include the best interest of the patient based on community norms and narrative techniques emphasizing patient dignity and individuality.[9] State law varies in how alternative decision-makers are designated and the extent to which they are empowered to make decisions for a non-decisional patient.

In the situation where the patient is capable of making medical decisions and is deferring to another or desires the assistance of another in making medical decisions, as long as the patient's designation is clearly made when provided privacy to express their sincere wishes, it is often not necessary to burden the patient with every detail of their condition and options for treatment, if they designate that information to be given to another person. State law may vary in how these designations are viewed. Formulation of care plans with the patient and their caregivers is an example of the type of shared decision-making common to palliative care medicine.

In all circumstances, the patient should be encouraged to define the important relationships in their lives. The patient

designates who is important, how they should be addressed, and what access they should have to medical information. As the IHI "What Matters" toolkit points out, the level of formality and type of address with the patient should have also been elicited, so as not to offend the patient. When referring to people important to the patient, a husband should not be referred to as a "significant other" and should be addressed with the formality with which he is introduced. A rabbi is not a "priest". And an unrelated person of a certain age may be an aunt, not a "friend of the family". This can make explicit charting more important, and it is an important step in honoring and supporting the patient's goals of maintaining important relationships and social roles. Enjoyment of these relationships is often a primary goal for patients when they are asked about what makes their lives sweet, or if they are asked about how they would like to spend their time if they knew it was limited.

108.5 INDIVIDUALIZED PLANS OF CARE AND WALKING THE PATH WITH THE PATIENT

There is a recognition that the patient's path through illness and care is unique to them. This requires recognition and communication of all options for treatments and interventions, including those of lifestyle medicine, as part of informed consent for their care plan. Formulation of care plans with the patient and their caregivers is an example of the type of shared decision-making common to palliative care medicine.

108.5.1 What Matters: Maslow's Hierarchy as a Bidirectional Cycle

Maslow's hierarchy is typically depicted as a pyramid built on a broad base of essential needs, such as our physiologic needs, with our needs for safety, then love and belonging, following as less foundational, and abstract problem-solving representing the fulfillment of our self-actualization. (See Figure 108.1.) In palliative care, these dimensions of life demonstrate themselves to be a more self-reinforcing bidirectional cycle, with gains in each area supporting gains in the next. An example would be problem-solving frequently aiding the patient in solving difficulties such as access to food, fluids, or the bathroom. Frequently, increased connection to others is seen to lead to gains in all categories, making the lifestyle medicine pillar of positive connections to others clearly key to achieving the highest quality of life for most patients. Having noted that, there is still a level at which patients do need food, shelter, care, and safety before any palliative plan of care can be effective, therefore the palliative care plan of care must include and accommodate preferences for living and caregiving environments as well as the realities of the need for care and available resources of the patient and their family.

108.5.2 Independence

Almost all older adults who receive palliative care services have previously lived independently. Continuing or regaining this independence in driving, living in one's chosen home or community, and completing one's activities of daily living independently is often a goal of older adults. Assisting older adults in creating a plan of care that provides nutrition, exercise, rest, reflection, and sleep, and supports their relationships can assist the older adults in achieving their highest goals of care. Even in older adults with advanced illness, mild-moderate routine physical activity is frequently observed to both bring joy as well as support their independence and there is some indication that it may restrain cancer progression.[10] Examples of activities that patients enjoy that appear to support their continued

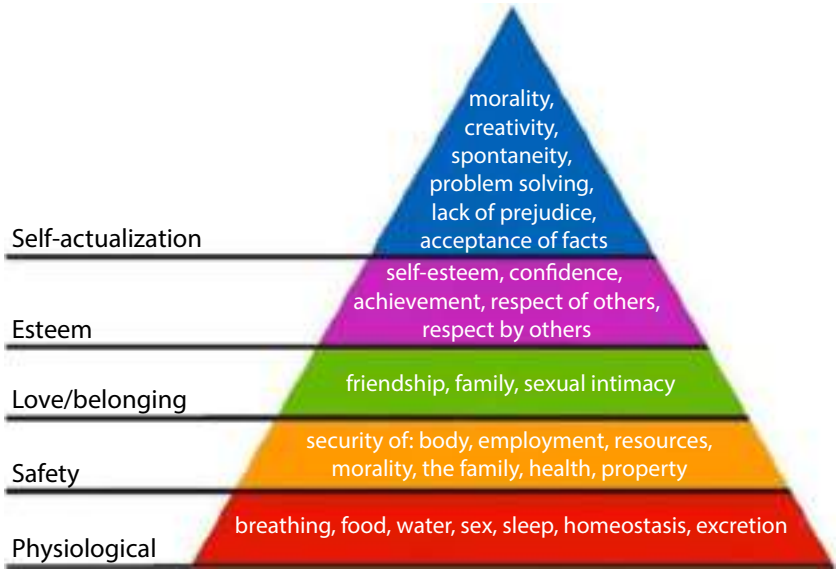

FIGURE 108.1 Maslow's hierarchy.

well-being include gardening, walking (even short distances), and running errands, such as grocery shopping.

Provision of food, shopping, and cooking are aspects of daily living that are essential to wellness and independence. Accommodating changing nutritional needs, nutritional recommendations, and capacity for self-care may force older adults to reexamine their habits, creating both opportunities and barriers to lifestyle interventions. As a source of comfort, having familiar foods may be important to the older adult, at times to the extent that even effective nutritional lifestyle interventions may not be consistent with the older adult's goals of care. In addition, community-based nutritional support, such as community food banks, congregate meal sites, and Meals-on-Wheels cannot typically accommodate specific nutritional requests.

When the plan of care cannot safely include the older adult remaining fully independent, their relationships with others often become how, where, and from whom they receive care. This can be a shift for older adults who have previously defined themselves as care providers. The decline in an older adult's ability to fulfill their activities of daily living can be a source of shame. Those who have highly prized their independence and may have believed themselves invulnerable to disability seem to be at increased risk of shame about the need for assistance in activities of daily living, such as eating and toileting. From Brene Brown, "Far from being an effective shield, the illusion of invulnerability undermines the very response that would have supplied genuine protection".[11] According to Brene Brown, the antidote to shame is resilience, and resilience comes from connection. The connection the older adult often forms with their care providers, whether friends, family, paid caregivers in the home, or custodial care providers can be that antidote to shame. Supporting the adult in creating, renewing, and strengthening these relationships is often key to their sense of well-being and adjustment to their changing social roles and physical status.

108.6 PLAN FOR SUPPORT ACROSS MULTIPLE CARE ENVIRONMENTS

The stress of severe chronic or terminal illness can be addressed through many of the interventions of lifestyle medicine, including meditation, spirituality, positive connections to others, and exercise. Support for these healthy lifestyle changes can take many forms, both within the formal medical system, including hospice, as well as in the broader community. Of particular note, as demonstrated by the meta-analysis by Sawatski 2002[12] there is a significant relationship between engagement in spirituality and quality of life. Per Lindberg 2003,[13] the improvement due to meditation and spirituality extends even to those older adults with dementia and may extend to those in nursing home care. There is a long tradition in hospice of providing spiritual comfort to those enrolled in hospice through regular interactions with a hospice chaplain. The hospice chaplain is considered so important that, per Medicare guidelines, a chaplain is a required member of the hospice care team to formulate and regularly review the plan of care. Many non-hospice hospital-based and home health-based palliative care services have adopted the tradition of providing spiritual care due to the improvement observed in quality of life when older adults and those who love and care for them are supported by chaplains.

108.6.1 Symptom Management

Another requirement of the Medicare benefit which informs palliative care provided in the United States is the requirement of hospices to prioritize treatment for pain, nausea, constipation, and anxiety. As comprehensive lifestyle treatment of these symptoms is widely researched and reported, what will be reviewed here are the modalities that have been commonly observed to provide quick benefit in the alleviation of these symptoms in patients at end of life or with severe disease or disability.

108.6.2 Management of Total Pain

Pain management is often equated with medications, both in the minds of patients and medical professionals. The armamentarium of analgesic medications seems to grow each year, with increasing sophistication in the use of opioid and non-opioid pain medications, each with their specific targets of therapy and side effects. It is outside of the scope of this chapter to address the treatment of symptoms through medication and procedures. However, there are non-pharmaceutical methods of relieving pain that patients and caregivers can incorporate into their lives to relieve some of the pain and distress of prolonged debility and illness.

Addressing any difficulties with sleep, anxiety, emotional pain, and spiritual pain also shows benefits in treating physical pain. Until the other aspects of suffering are addressed, physical pain frequently cannot be adequately alleviated. In palliative care and hospice medicine, there is a concept of "total pain" put forward by the founder of the modern hospice movement, Dame Cicely Saunders. The concept of total pain refers to suffering in the physical, psychological, spiritual, and social domains.[14] The suffering in each domain is understood to amplify the suffering in the other domains. This is part of the reason for the interdisciplinary aspect of hospice and palliative care medicine. It is not uncommon for clinical social workers and chaplains to work extensively with patients and their families to address current and past sources of non-physical suffering. All care providers, especially the nursing staff and physicians, can support treatment of the total pain, often by as little as offering a hand to hold or an ear to listen. These small acts of kindness and attention allow patients to make human connections that are an essential part of the high-touch medicine of palliative care.

The first and foremost intervention for physical pain that patients frequently note is that they want to get out of bed

and move around. This can require the direct assistance of physical therapy, restorative aid services, nurses, or attentive family members or friends. The goal is not exercise, per se, it is movement to relieve muscle spasms and joint pain due to immobility, as well as the pain of pressure injuries. Physical therapy and occupational therapy can be key in helping patients safely return to a level of activity that allows patients to do those things that matter the most to them. Even in patients who cannot rise from bed, range of motion exercises and massage can aid in increasing the patient's sense of well-being and are often reported to decrease pain. Integration of a moisturizer massage into a bed-bound patient's daily hygiene routine appears to provide significant comfort to patients, as well as maintaining the health of their skin. Positioning for support and comfort can include not only pressure relief but also specific pain-relieving postures such as 90/90 positioning: 90/90 positioning involves the patient lying on their back or side with a fully supported 90-degree flexion at hip and knee to relieve nerve compression and pain in the lumbar spine for patients with lumbar spinal stenosis or dysfunction. Restorative stretches and restorative yoga may also improve quality of life for some patients. There are specific yoga options that can be appropriate even for people who would not be capable of typical yoga. These options include chair yoga and therapeutic yoga, including integrated movement therapy, a yoga therapy method that helps people make behavior shifts to move toward optimal well-being.

Anti-inflammatory foods and a plant-based diet, especially for inflammatory arthritides such as rheumatoid arthritis and psoriatic arthritis, appear to benefit patients relatively rapidly.[15] Many patients report benefits even with modification of their diet, rather than a complete change in their diet. As addressed elsewhere, management of the pain and progression of multiple sclerosis can be profoundly impacted by dietary choices. The benefits of anti-inflammatory foods or diet are often remarked by patients to be especially notable in morning stiffness and pain. It is not unusual to hear from someone that they are now able to walk downstairs or do other daily tasks with far less pain. One of the changes encouraged is the use of turmeric in food, tea, or golden milk for relief of pain, with the use supported both by patient reports and multiple studies,[16] always with a dash of black pepper to improve absorption. The typical recipe for golden milk, based on plant-based milk with turmeric, pepper, ginger, and sweet spices for additional flavor, may also be helpful for discomfort due to muscle pain and osteoarthritis pain, with research showing specifically the pain-relieving benefits of ginger and turmeric.[17,18]

Meditation, mindful breathing, prayer, and mindfulness in some form are frequently used by patients to treat physical as well as emotional and spiritual pain prior to any instruction by clinicians. In systematic reviews of the research, the use of mindfulness meditation and mindfulness practices has been shown to improve pain, depression symptoms, mobility, functional status, and quality of life.[19,20] Some of the forms these practices take at the bedside of a chronically or severely ill person are the use of breath awareness, breathing techniques, guided imagery, progressive relaxation, singing, prayer, and other techniques that can be easily taught or reinforced at the bedside. The reinforcement of these techniques can be undertaken by all members of the care team, giving the patient more support in actively managing their own pain.

108.6.3 Nausea and Vomiting

Another common source of suffering for patients with severe or terminal illness is nausea. There are myriad sources and types of nausea, including nausea associated with anesthesia, chemotherapy, cancer, radiation therapy, medications, gastroparesis, autonomic changes, constipation, intracranial pressure, heart failure, renal failure, and liver failure. Multiple classes of medications address multiple receptor classes associated with nausea: histaminergic, serotonergic, dopaminergic, and cholinergic. The most potent and commonly used medications for acute nausea are the dopaminergic (haloperidol, olanzapine) for general nausea and the serotonergic (ondansetron) for chemotherapy-related causes, with the mixed receptor phenothiazines (prochlorperazine) and antihistamine (promethazine) used more commonly for chronic or general nausea. All of these medications, with the exception of ondansetron, commonly cause sedation, which is often undesirable by patients. It matters for most patients that they are awake, aware, and able to interact with those around them. Utilizing non-pharmacological treatments for nausea can reduce the need for sedating medications and give the patient control over their symptoms.

Once again, breathing techniques have been shown to bring rapid relief to some patients with postoperative nausea, as well as chronic, recurrent nausea. The technique used by Sites et al.[21] for their research on the treatment of postoperative nausea utilized a pattern of breathing with three seconds of inhalation, three seconds of holding, then three seconds of exhalation, repeated three times. This pattern was found to bring rapid relief, typically after about five minutes, with and without aromatherapy with peppermint. The use of peppermint, other mints, and ginger has long been advocated for the treatment of nausea, with many patients reporting improvement with the inclusion of these foods in their diets or the use of mint teas or ginger-containing lozenges, foods, and drinks.

Reduction in the fat content of meals has also been reported to reduce dyspepsia symptoms, including nausea.[22] The usual advice is to eat small frequent meals, low in fat, and high in easily absorbed carbohydrates. Examples frequently used are culturally appropriate comfort foods, such as rice soup or porridge, noodle soups, and other food combinations with high water content, moderate salt, and starches. This can also include cold foods, such as applesauce and sorbet if desired by the patient. The mechanism of the relief seen may be in part due to the relief of dehydration, as these are all foods that support more rapid gastric

emptying and fluid absorption. For many families, where the cultural tradition could be expressed as "food is love", the ability of the family or other caregivers to support the patient in this way can be an invaluable source of comfort to both the family and the patient.

Increasing fluids with sparkling water may be especially helpful in decreasing dyspepsia, including nausea, as well as constipation.[23] Other sparkling drinks are not as effective in the research, though many patients and families do report improvement with ginger ale or ginger beer, as well as home remedies such as clear sodas. As nausea triggers can be very individual, so can the alleviating foods and drinks. The important message for the family and other caregivers is to honor the patient's desire whether or not to eat or drink, especially if it is related to the natural and normal decrease in oral intake at the end of life.

At this point, caution is warranted as some patients with a history of an intra-abdominal process, such as tumor or adhesions, may have either a partial or complete bowel obstruction as a cause for nausea with vomiting and subsequently no desire to eat or drink. If there is vomiting of unknown cause despite no oral intake, or in the setting of a known intra-abdominal process, bowel obstruction must be ruled out prior to the initiation of other interventions. Treatment of these conditions is outside of the scope of this chapter, though a low residue (low fiber), high fluid content diet may help maintain a patent bowel after restoration of bowel function in a patient with risk for continued or recurrent partial bowel obstruction.

108.6.4 Constipation

As oral intake and mobility decrease, one of the natural consequences can be slowed gastrointestinal motility and dehydration, leading to constipation. Constipation itself can increase nausea, as well as bloating and abdominal discomfort. This makes constipation a high priority for treatment for many patients. Many patients choose to stop medications that can cause constipation, including opiates. Helping patients understand the many other medications that may be playing a role in increasing their risk for constipation can help the patients achieve their goal of relieving their discomfort due to constipation. Common offending medications are the anticholinergics, which include prescription medications as well as over-the-counter sleep medications, urinary frequency medications, and allergy medications. Many of these patients are also noted to be on supplemental iron, calcium, diuretics, anticonvulsants, or antiparkinsonian agents that may contribute to their constipation. Helping the patient consider what matters most to them is a dynamic process that may lead to decreasing or stopping some medications or supplements, or to the use of other interventions or medications to increase bowel motility.

For patients who are tolerating a full diet, encouraging increased fluids and fiber, especially soluble fiber through the inclusion of more whole grains, vegetables, and fruits, can be effective in helping relieve constipation not caused by medications. Increased fluids and fiber are often most difficult to initiate when patients are in custodial care, such as assisted living facilities and nursing homes. For patients who are fully dependent on others for access to fluids, it may be beneficial to clarify with the facility that each caregiver who enters the room should offer fluids with every entry to the room. One frequently well-tolerated, time-honored intervention is prunes, which has been shown to be more effective than supplemental psyllium.[24] This intervention also has the advantage of being commonly available to nursing home residents.

Finally, abdominal massage is a time- and nursing resource-intensive intervention that is effective in stimulating bowel motility. When elderly residents of a nursing home were provided daily 30-minute abdominal massage for symptomatic constipation, significant improvement was seen in constipation, quality of life, physical disability, psychosocial discomfort, anxiety, and satisfaction with treatment.[25] Even patients whose constipation is a result of opiates may benefit from abdominal massage, with improvement noted in discomfort, stool consistency, quality of life, and number of bowel movements.[26] For patients and their care providers, solving the issue of constipation may represent a return to the cyclical nature of care of older adults, typified by problem-solving, relationship building, and management of resources to support the patient in what matters most to them.

108.6.5 Anxiety, Insomnia, and Depression

For patients facing severe chronic illness or terminal illness, some of the primary forms of suffering observed are disturbances of mood and sleep. Medications used to treat pain and other physical symptoms, such as opiates, may also increase the risk of depression and disturbed sleep. While some patients come to this stage in their lives with prior diagnoses of clinical depression, anxiety disorders, post-traumatic stress disorder (PTSD), insomnia, or other mood or psychiatric diagnoses, all patients are at risk for changes in mood and coping. It is not uncommon for patients to experience and express grief, anger, sadness, worry, existential anxiety, helplessness, regret, shame, guilt, loss of meaning, and demoralization. When persistent, these symptoms may meet the criteria of adjustment disorder. Patients, family members, and caregivers also frequently cope with stress related to changing roles, changing functional status, finances, family relationships, disease changes, treatment-related stress, and stress due to physical symptoms.

The use of screening instruments for depression and anxiety can be difficult in patients with severe or life-threatening illnesses due to the inclusion of somatic symptoms in many screening tools. These somatic symptoms may be associated with mood changes, though not necessarily indicative of a primary clinical depression or an anxiety disorder. One of the most effective depression screening

tools used is a simple two-question screening that is 97% sensitive and 67% specific in the general population:[27]

- During the past month, have you often been bothered by feeling down, depressed, or hopeless?
- During the past month, have you often been bothered by little interest or pleasure in doing things?

In practical application with severely ill patients, the question about anhedonia is far more sensitive for differentiation between sadness or grief and clinical depression. For seriously ill patients who are still capable of joy at the presence of a grandchild or the sun on their face in the garden, the use of antidepressants is unlikely to be helpful. Often these patients have not had a chance to do anything that interests them or brings them pleasure for a prolonged period, though they can report joy at imagining the possibilities. In that visualization, they may even begin to have relief of hopelessness or demoralization.

Cognitive strategies that are commonly used to relieve depressed mood and anxiety in seriously ill people include prayer, guided imagery, progressive relaxation, meditation, counseling, and cognitive behavioral therapy. Other strategies that are successful for select people include music and art therapy, touch therapy or massage, exposure to natural sunlight in the morning, gratitude journaling, and working with someone to record their life story. Exercise and movement have even been shown to improve depressive symptoms and improve function in patients with chronic illness.[28] The variety of these interventions reflects the work of the interdisciplinary team and provides increased opportunity to find an intervention that is successful for the specific patient and family.

Many of the interventions for the treatment of depressed mood and anxiety are also effective in treating insomnia. Some of the most reliable responses are seen with exposure to morning daylight, cognitive behavioral therapy, and physical activity.[29]

Other strategies encouraged to improve sleep include avoidance of caffeine and alcohol, as well as avoidance of other psychostimulants or recreational drugs. However, some patients do report improvement in the quality of their sleep with CBD or marijuana, the use of which is now decriminalized in many states. For patients who have delayed onset of sleep, rather than unrefreshing or interrupted sleep, bedtime routines typically recommended for other people also often work well for older adults with severe illness. Specific additions to the usual bedtime routine that have been observed to be effective are online recordings, often accessed through phone apps, for guided sleep meditations, bedtime stories for adults, and music or ambient noise designed to help the person relax and mask sounds that might otherwise interfere with initiation or maintenance of sleep. Similar to gratitude journaling, another strategy that has been successful for some patients is the development of a habit of recalling three positive things that occurred during the day for which the person is grateful.

Of particular note, anxiety is frequently relieved with open and honest discussion about medical conditions and prognosis with the patient and family. Addressing fears about the physical dying process in particular can relieve not only anxiety but also hopelessness and demoralization. Reassurance that the patient and family will continue to be supported on their journey, whether or not they accept any or all medical, surgical, or lifestyle interventions offered, can go far in supporting a sense of control and hope.

108.7 DOCUMENTATION OF THE PLAN AND GOALS OF CARE

Documentation of the plan of care, including what matters most to the patient, their current condition, options, decisions, interventions, and support needed are essential to the process of continued interdisciplinary and cross-specialty communication.

The most effective plan of care is only as effective as the communication across care environments and care providers. At times, this may require a commitment to the education of care providers on the requirements and effectiveness of lifestyle interventions. This may also provide an opportunity for family members and other care providers to seek information or referrals to discuss their own disease risk and lifestyle interventions. A list of accessible resources can be helpful in these situations.

Complete and explicit documentation of what matters, ideally in the patient, family, and caregivers' own words, can also protect the patient from inappropriate care and interventions. This can be achieved through advance directives, a durable power of attorney, a POLST (Physician's Order for Life Sustaining Treatment), or other legal documents appropriate to the jurisdiction and goals of care. Such explicit documentation of the patient's goals of care, and any changes, can also be essential in prioritizing interventions to achieve an improved quality of life. All healthcare providers can assist in this documentation, though it is often a task requested of the members of the palliative care team.

108.8 HOSPICE AND PALLIATIVE CARE INTERVENTIONS IN PULMONARY AND CARDIAC DISEASE

Hospice and palliative care has a greater than 30-year history in the United States. According to the report of the National Hospice and Palliative Care Organization,[30] the principal diagnosis categories that have grown the most since 2014 are stroke, respiratory, and circulatory/heart; while cancer remains the most common diagnosis class, it no longer represents the majority of patients. Those patients who are admitted to hospice with a primary cancer diagnosis frequently also have cardiac and pulmonary comorbidities amenable to lifestyle interventions for improvement in their quality of life.

108.8.1 Lung Disease and Dyspnea

According to the research of Keranis et al.,[31] a randomized trial demonstrated the benefits of increasing fruits and vegetables by one serving per day in the progression of symptoms of COPD. In practical terms, this can mean that a patient who is suffering from severe, chronic dyspnea with advanced COPD, may feel better and, in some cases, live longer than patients who continue to eat a standard American diet. For some patients who feel these effects, they come to crave fruits and vegetables while they associate them with improved ease of breathing. In some patients who adopt this change, weight loss has been observed, which is common in end-stage pulmonary patients due to the caloric demands of their disease process. The advice to balance the intake of fruits and vegetables with higher calorie foods as tolerated, such as avocado, nuts, non-dairy ice creams, and other treats, has typically been well-received.

Breath-based meditation practices, augmented with the use of a pulse oximeter for some patients, have also resulted in decreased patient distress due to dyspnea. Practically, this can look like the nurse at bedside demonstrating pursed lips breathing or square breathing, or it can be the physician using a pulse oximeter and demonstrating that a slowed exhalation breathing pattern improves oxygen saturation and decreases heart rate. Chan and Lehto[32] demonstrated in their research that an eight-week one-hour mind/body meditation course led to improvement in emotional and physical symptoms associated with COPD for most patients. This is consistent with what is seen in one-on-one interactions in the clinical context where the intervention may be more intense, if less systematic.

Home-based pulmonary rehabilitation, specifically including an exercise component at least four times per week, was noted by Gefine[33] to improve health-related quality of life, general fatigue, and anxiety and depressive symptom scores after pulmonary rehabilitation in frail COPD patients with hypoxic respiratory failure. These and other positive effects on functioning were seen at eight weeks and the benefits were particularly notable at eight months in patients who were more frail at the onset of the research.

Finally, whether it is the theobromine, as suggested by some research,[34] or simply the comfort of the sugar content or taste, many patients find the use of dark chocolate to be useful for treating mild-moderate cough, as an alternative to opiates or other cough suppressant medications.

108.8.2 Heart Failure

The final common pathway for many cardiac diseases is heart failure of some type. Heart failure is somewhat unique among the common pathways of terminal illness in that management of the symptoms of heart failure not only improves quality of life but is also frequently consistent with prolonging life. Avoidance of heart failure exacerbations, fluid overload, symptomatic tachycardia, symptomatic bradycardia, hypotension, angina, and severe hypertension are all desirable strategies to improve quality of life. Many of these symptoms are amenable to dietary changes, changes in daily routine, and changes in physical activity.

The current AHA/ACC/HFSA guideline for the management of heart failure were released in May 2022. The classifications of heart disease within the guidelines are both based on the left ventricular ejection fraction and the degree of symptoms, with special attention paid to the increasingly recognized heart disease due to amyloidosis. These guidelines emphasize the importance of palliative care in the treatment of patients at all stages of heart failure. The goal of this recommendation is enhanced communications, prognostication, symptom management, anticipatory guidance for patients and families, and advance care planning with shared decision-making about medically reasonable treatment options.[35]

The symptoms of heart failure that are frequently managed by palliative care or hospice are dyspnea, orthopnea, edema, fatigue, hypotension, angina, nausea, and orthostatic hypotension. Many of these symptoms are secondary to volume overload and are amenable to sodium restriction for a large proportion of heart failure patients. The degree of necessary and tolerated sodium restriction varies, with a common hospice recommendation being 2 g of sodium per day until comfort is achieved, at the same time that the diuretics are titrated for maximum effect and comfort. Recent pilot studies have supported using an even more stringent 1.5 g sodium per day limit to improve quality of life.[36,37] The extent of sodium restriction and how consistently it is followed is clearly a personal choice for patients when they have access to a reduced sodium diet. However, when what matters to the patient is a 4th of July barbecue or Thanksgiving turkey dinner, then it is not uncommon to aid the patient and family in planning for an increased need for diuresis surrounding these events.

For those patients who are able to make the adjustment, the number needed to treat with a Mediterranean Diet in the known presence of coronary artery disease after a myocardial infarction is just 30 for mortality and 18 for repeat MI.[38–40] For those patients who are more familiar or comfortable with the DASH diet, they are encouraged in making those changes. The DASH diet is also recommended in the AHA/ACC/HFSA 2022 guidelines. Most importantly for symptom management, the patients who make positive changes in their diet frequently report more rapid and sustained relief of their heart failure symptoms.

Other lifestyle interventions that appear to improve nocturnal orthopnea and lower extremity edema are elevation of the legs to the level of the heart for as much of the day as tolerated, with or without spiral compression wrapping and lymph drainage massage. Patients frequently report improved sleep and daytime fatigue when both orthopnea and nocturia are improved with more intensive daytime treatment of lower extremity edema. Some patients have also reported improved lower extremity edema with water aerobics or walking in waist or chest-height water.

Optimizing fluid status is often also beneficial to patients with hypotension or orthostatic hypotension. Older adults often benefit symptomatically from a higher blood pressure and heart rate, with an observed decreased risk of falls and fatigue. Through optimization of cardiac function and medication management, it is not uncommon to allow the systolic blood pressure of an older adult to rise above the usual target range for younger adults. Many researchers, including Masoli[41] in a study in 2020 of more than 400,000 frail adults above 75 years old, have found that the lowest mortality risk was at a systolic blood pressure of 140–160 and diastolic of 80–90. Elderly advanced heart failure patients appear to do well symptomatically with blood pressure at the lower end of that range. Some patients have treatment of their heart failure limited by hypotension despite optimization of their fluid status by all means acceptable to the patient. While managing symptoms and side effects of medications, beta blockers and other medications that decrease the heart rate of older adults are often titrated to allow an increased heart rate, including in the setting of atrial fibrillation.

Avoidance of tobacco is also recommended, with all of the other interventions for relief of dyspnea described above in the pulmonary section.

Finally, meta-analyses have shown that cardiac rehabilitation improves functional capacity, exercise tolerance, and health-related quality of life. Many older adults with cardiac disease need to start low and go slow with increasing their physical exertion. The guidance of either a formal cardiac rehabilitation program, inpatient rehabilitation, or home health rehabilitation can benefit patients in regaining and sustaining the highest quality of life possible.

108.9 SUMMARY: WHAT MATTERS

Lifestyle medicine interventions can improve quality of life consistent with the goals of palliative care. The intensity of the interventions or the forms of the interventions may need adjustment for frail and debilitated patients. At all times, with informed consent, the patient's goals—what matters to the patient—must guide the plan of care.

CLINICAL APPLICATIONS

- Palliative care:
  - Is holistic care of those with complex, chronic, or terminal illness, addressing the physical, functional, psychological, practical, and spiritual consequences of a serious illness.
  - Discovers what gives meaning to people's lives and creates a plan of care to support them in improving their quality of life.
  - Supports the patient and those important to them, including supporting patient autonomy and patient empowerment.
- Lifestyle interventions:
  - Contribute to the care of palliative care patients and other older adults by helping them achieve what is meaningful to them, including personal growth, achievement of life milestones, maximal possible self-sufficiency, satisfaction with life, and symptom management.

Palliative lifestyle interventions include:

- Targeted nutritional interventions, when available and consistent with what matters most to the patient.
- Movement adapted to patient condition and goals.
- Mind–body exercises, targeted breathing exercises, and spiritual practices for the management of total pain and suffering.
- Improved sleep and mood with cognitive strategies, mindfulness, and physical activity.
- Limiting or avoiding the use of alcohol, stimulants, and nicotine to improve symptoms, including mood disturbances, insomnia, dyspnea, and cardiac symptoms.
- Support for positive patient relationships with others as essential to meeting patient needs and achieving what matters most to the patient at all levels of self-actualization.

109 Healthy Aging: Impact of Loneliness and Social Isolation

Paul Mulhausen, MD, MHS

She could be lively only in the midst of life; in isolation she dwindled to a shadow.

—— **Stefan Zweig,** ***The Collected Stories of Stefan Zweig***

KEY POINTS

- Loneliness and social isolation are increasingly part of the aging experience.
- Loneliness and social isolation among older adults are influenced by many factors, including sociodemographic attributes, available social resources, and health status—both physical and mental.
- Increasing evidence suggests that perceived social isolation or loneliness is a major risk factor for physical and mental illness in later life.
- Social engagement is a key feature of healthy aging.
- Promoting resilience and high-quality social relationships throughout the lifespan appears to be vital to healthy aging.
- Although our understanding of the effectiveness continues to develop, clinical and social interventions exist for clinicians to implement and promote.

109.1 INTRODUCTION

From July 12 through July 16, 1995, the city of Chicago experienced an unprecedented heat wave, with daytime temperatures ranging between the low 90s and low 100s (Fahrenheit) and nighttime temperatures in the low to mid-80s. On July 13, the daytime temperature reached 106°F, and, with the extremes of humidity, the associated heat index reached 120.[1] During this one week, Chicago experienced at least 700 excess deaths, most of which were classified as heat-related. Those at greatest risk of dying from the heat were people with medical illnesses who were socially isolated and did not have access to air conditioning. In an analysis of the experience, the US Centers for Disease Control noted that "People, especially elderly people, who live alone and do not have networks of social contacts" were at particularly high risk. "During the summer heat wave of 1995 in Chicago, anything that facilitated social contact, even membership in a social club or owning a pet, was associated with a decreased risk of death".[2]

The Chicago heat wave and others like it[3,4] dramatically illustrate the vulnerability of socially isolated older adults to major environmental stressors, but there has also been much work done to better understand the many mechanisms by which social relationships affect health and how the promotion of social connectedness may enhance health and quality of life across the age span.[5]

Since at least the 1980s, social isolation and loneliness have been recognized as having deleterious effects on the health of older adults, rivaling other risk factors that are well-recognized by the medical community.[6] It has become increasingly clear that loneliness and social isolation have a major influence on physical health, mental health, and healthy aging. We now find ourselves in an era in which 25–29% of adults over the age of 70 report feeling lonely[7] and up to half of Americans have only one person or no one to discuss personal matters, especially losing their ties to local neighborhoods and groups.[8] Thought leaders and social commenters refer to our current state of affairs as an "epidemic of loneliness"[9] or a "Loneliness Crisis".[10] Whether a crisis, an epidemic, or merely a sign of the times, it is clear that loneliness and social isolation are increasingly part of the experience of growing old and that social relationships (or lack of social relationships) matter to healthy aging.

109.2 DEFINITIONS: LONELINESS AND SOCIAL ISOLATION

Loneliness and social isolation are distinct concepts: individuals can be lonely without being socially isolated; experience both loneliness and isolation; or be socially isolated without feeling lonely.[11,] How people define loneliness and social isolation is important because it influences how clinicians may measure these concepts. Loneliness has been conceptualized in several different ways but is frequently viewed as a perceived discrepancy between one's desired and actual social relationships.[12] Domains of loneliness include social loneliness (perceived lack of a wider social network) and emotional loneliness (the absence of a specific desired companion). Feelings of loneliness are not synonymous with being alone but rather involve feelings of isolation, disconnectedness, and not belonging.[13] Researchers

DOI: 10.1201/9781003227793-127

have distinguished loneliness from the experience of solitude. The latter reflects a state of social isolation that involves voluntary distancing from one's social network, whereas loneliness is involuntary and more closely associated with deficits in the perceived quality of one's social interactions.[14] Other constructs of loneliness include a perceived deprivation of social contact, perceived social isolation, or a lack of people with whom to share emotional and social experiences.[15]

Social isolation, on the other hand, has, for many, been more difficult to define. Social isolation and social disconnectedness refer to an objective state rather than the subjective experience of loneliness. Social isolation reflects an individual's lack of contacts or ties with others, such as family, friends, acquaintances, and neighbors.[16] It can be conceptualized as a measure of a person's integration and meaningful communication with their community, friends, and family. Constructs of social isolation include the objective experience of being alone, a lack of meaningful social ties, or a lack of integration with social networks.[17]

While these concepts of social isolation and loneliness appear to overlap, research shows that there is only a moderate association between loneliness and social isolation.[18] Individuals vary significantly in how their social circumstances elicit feelings of loneliness. The quality of the individual's social relationships is a stronger predictor of loneliness than the quantity of social contacts.[19] Some people can live what feels to them to be an isolated experience even when around others. Individuals who have a rich and forgiving social environment have more opportunities to meet their emotional need for social connectedness and belonging. For others, loneliness becomes inescapable, and they may need more help making the connections necessary to feel safe, secure, and content with life.[20]

109.3 MEASURING LONELINESS AND SOCIAL ISOLATION

There are several widely used self-report tools to measure loneliness. These include the UCLA Loneliness Scale and the De Jong Greifeld Loneliness Scale. Measures of loneliness and social isolation are of practical significance to any clinical effort to identify those at risk and to assess interventions to mitigate loneliness and/or social isolation. The UCLA Loneliness Scale and the dJG Loneliness Scale have demonstrated reliability and validity, but they have been designed primarily as research tools, and further study is needed to understand their use in older adults.

UCLA Three-Item Loneliness Scale[21]

This scale is comprised of three questions that measure three dimensions of loneliness: relational connectedness, social connectedness, and self-perceived isolation.

1. How often do you feel that you lack companionship?
2. How often do you feel left out?
3. How often do you feel isolated from others?

The scale generally uses three response categories:

Response	Score
Hardly ever	1
Some of the time	2
Often	3

Scoring

Least lonely 1 2 3 4 5 6 7 8 9 Most lonely

A broader range of approaches have been used to measure isolation, including the size of an individual's social networks, levels of social contact, marital status, and household composition.[22] Most of the validated tools measure the size, closeness, and frequency of contact between the individual and their social networks. These tools have been designed primarily for use in research, and include the Lubben Social Network Scale, the Duke Social Support Index, and the Social Disconnectedness Scale.[23] None of these tools have been designed and tested for use in clinical settings and there is an opportunity for research to understand the most effective strategies to identify and measure loneliness and social isolation in the clinic.

109.4 AGING, LONELINESS, AND SOCIAL ISOLATION

Older people are particularly vulnerable to social isolation and loneliness because of common age-related changes and losses. Experiences of loneliness and social isolation are not uniform across the life course: individuals may become lonely or isolated in old age, be lifelong isolates, or experience loneliness and/or social isolation because of a triggering event.[24] Loss of one's partners and friends through death, deteriorating health, institutionalization, and loss of social roles through retirement are common experiences for older adults. There is evidence that emotional closeness in relationships increases with age, but at the same time, the number of social relationships decreases and life events triggering disruptions in ties increase (e.g., death of a parent, death of a spouse, children leaving home).[25] Variables found primarily in cross-sectional studies to be associated with loneliness in older adults include the following: female gender, non-married status, older age, poor income, lower educational level, living alone, low quality of social relationships, poor self-reported health, and poor functional status. Psychological attributes that have been associated with loneliness include poor mental health, low self-efficacy beliefs, negative life events, and cognitive decline. [26] Women may be at greater risk for loneliness than men because of their longer life expectancy and higher burden of many known risk factors. Additionally, women may more readily admit their feelings of loneliness in comparison with men, which can help account for the higher levels of loneliness observed.[27] These individual factors are compounded by social changes that include reduced intergenerational living, greater geographical mobility, and the rise in one-person households.[28]

There are also community and societal factors impacting an individual that can increase their vulnerability to social isolation and loneliness.[29] These include at the community level, high levels of neighborhood crime, high residential mobility, limited opportunities to participate in social activities, and limited access to services and public transport. Society risk factors include the experience of social discrimination or social marginalization, lack of social cohesion, and social norms that discourage activity.[30]

Risk Factors for Social Isolation and Loneliness Among Older Adults[31–34]

Sociodemographic Factors

- Being 75 or older
- Living alone
- Female
- Being a caregiver
- Limited financial resources
- Cognitive vulnerability
- Sensory Impairments (vision and hearing)
- Language barriers
- Having no children

Life Transitions

- Health decline
- Physical disability
- Losing the ability to drive
- Losing a partner

Relationship Level Factors

- Poor quality personal relationships
- Little contact with friends or family
- Personal relationship conflict, disruption, or dysfunction

Community Level Factors

- High levels of neighborhood crime
- High residential mobility
- Limited opportunities for participation in social activities
- Limited access to services and transportation

Societal Level Factors

- Experiencing discrimination and social marginalization
- Lack of social cohesion
- Social norms that discourage activity

109.5 SOCIAL ISOLATION AND LONELINESS: IMPACT ON HEALTH IN OLD AGE

A growing body of evidence indicates that perceived social isolation and/or loneliness are significant risk factors for physical and mental illness in later life, with an impact on par with other known risk factors such as obesity or tobacco use. One meta-analysis of the literature investigating the association between social relationships and mortality found that individuals with adequate social relationships have a 50% greater likelihood of survival over 7.5 years compared with those with poor or insufficient social relationships.[35] The experience and consequences of loneliness and isolation vary with socioeconomic status and culture, but the association with the lowering of broad-based morbidity and mortality appears consistent. Loneliness or the perceived absence of positive social relationships has been linked to diminished longevity, particularly among older individuals in whom declining economic resources, illness, widowhood, and impaired mobility may result in increased risk for social isolation.[36] Unfortunately, most of the available evidence has been generated through cross-sectional studies, which have limited ability to inform the direction of the association between loneliness and social isolation and health. [37] Causal linkages remain modestly uncertain, but loneliness and isolation have been found to be independent predictors of mortality[38] and are associated with a myriad of physical and mental health problems. Their linkages to chronic diseases, declining function, and any number of adverse physical and mental health problems warrant individual attention, clinical attention, and public health attention. Physical health problems associated with loneliness and social isolation include elevated systolic blood pressure, less restorative sleep, diminished immunity, reduced function, cardiovascular disease, and impaired cognitive performance.[39] Loneliness is also associated with hopelessness, depressed mood, lower levels of well-being, psychological distress, psychiatric morbidity, and depression. Loneliness is also a predictor of suicide among older adults.[40]

Adverse Health Outcomes Associated with Loneliness and Social Isolation[34–39]

Physical Health

- Higher mortality
- Elevated systolic blood pressure
- Cardiovascular disease
- Sleep disturbances
- Reduced immune function
- Impaired cognitive function
- Impaired physical function

Mental Health

- Higher levels of hopelessness
- Depressed mood
- Psychological distress
- Increased suicide risk

Compared with our understanding of risk factors such as smoking and obesity, we know much less about the mechanisms through which loneliness and social isolation affect health.[41] There are two prevailing proposed mechanisms by which social relationships may influence health: the stress-buffering model and the main effects model. The stress-buffering model hypothesizes that real or perceived social resources "buffer" the individual from the deleterious influence of stressors on health. The main effects model proposes that high-quality social relationships have a more direct protective effect on health through mechanisms that are not explicitly intended to be supportive. For instance, social relationships may directly or indirectly encourage or discourage healthy behaviors that lead to better health

outcomes.[42] Emerging research has identified candidate neurobiological mechanisms, which include changes in neuroendocrine, cardiovascular, and inflammatory stress responses; elevated vascular resistance, and hypothalamic-pituitary-adrenocortical activity. However, there are significant gaps in our understanding of the impact of loneliness and social isolation on healthy behaviors, social resilience, and any underlying biological mechanisms. [43]

One area of study has been the impact of loneliness and social isolation on healthcare utilization. Both have been implicated in patterns of increased healthcare utilization. Socially isolated and lonely adults are more likely to undergo early admission to residential or nursing care. They have increased physician utilization and have been independently associated with higher rates of emergency hospitalizations and re-hospitalization within one year of discharge.[44]

109.6 REDUCING LONELINESS AND SOCIAL ISOLATION

A key question that remains open to discussion is whether loneliness and social isolation can be alleviated among older adults and whether alleviating these life experiences leads to improved health outcomes. Many factors that reduce loneliness and social isolation are cross-cultural (living with a spouse or partner), but others are culturally bound (e.g., discrimination and social marginalization). Sustainable solutions may need to be culturally appropriate and hinge on the degree to which an intervention improves an individual's social environment and social interactions. [45]

A variety of interventions have been directed toward alleviating loneliness and social isolation in older adults. These interventions have attempted to improve social skills (e.g., through social recreation), enhance social support (e.g., via mentoring, home visits), increase opportunities for social interaction (e.g., telephone outreach, nonverbal communication), and/or address maladaptive social cognition (e.g., psychological reframing or cognitive behavioral therapy).[46]

Researchers have developed six types of interventions that have been explored at a variety of levels: working with individuals, working with groups, service provision, technology-based, neighborhood, and social structures[47]. The heterogeneity of interventions and the multiplicity of measurement tools and outcome measures, alongside poor methodological quality and a focus on subgroups of the population, have all limited researchers' ability to draw definitive conclusions about the effectiveness of interventions.[48] Yet, because of the high prevalence of loneliness and social isolation in older adults and the suffering they cause, clinicians, health systems, and communities are in a perfect position to develop and test methods that identify loneliness and isolation and take steps to mitigate their ill effects.[49]

It is beyond the scope of this review to provide an exhaustive list of interventions and proposed approaches, but any number of specific examples can be found in the medical literature. These include the following approaches.

- Group-based interventions that target a specific group and focus on a shared interest (or on education) and include older individuals in the planning process.
- Improving access to "gateway services" such as transportation and technology that can improve social connectedness.
- "Befriending" approaches where volunteers or paid companions provide one-on-one outreach to high-risk individuals or those identified as socially isolated or lonely.
- Treating sensory deficits (vision and hearing loss) to improve the quality of social interactions.
- "Social prescribing" in which healthcare providers link patients with existing social services programs or facilitate those linkages. These services include volunteer opportunities, community groups, and faith-based organizations.

Models of Social Prescribing[50]

Model 1: Information Service

This service is an information-only service, with advertising and directory access to SP in a primary care practice

Model 2: Information Service and Telephone Line

This service advertises SP on leaflets and noticeboards in a primary care practice. Based on this information, patients can self-initiate a telephone discussion with a worker

Model 3: Primary Care Referral

Primary health care professionals assess patients during consultation and refer them to SP services if appropriate, for example, if patients have non-clinical issues and require psychosocial support. Referrals to SP services are opportunistic.

Model 4: Practice-Based Generic Referral Worker

Primary care patients can be referred by health workers or self-refer to an SP link worker. Clinics are held in the primary care setting so that they can act as a "one-stop shop".

Model 5: Practice-Based Specialist Referral Worker

A specialist worker works from primary care practice and patients can be referred through primary care referral or self-referral. Direct advice and specific services, such as Citizens Advice,[51] may be offered, as well as referral or signposting onwards.

Model 6: Non-Primary Care-Based Referral Worker

Patients are referred to an external referral center by primary care practice staff, offering one-to-one facilitation, for example, an outreach service or community-based resource center.

- Support groups that facilitate social interactions and/or focus on shared common underlying causes of social isolation such as bereavement or widowhood.
- Group activities to promote healthy behaviors or physical activities such as the US Department

of Veterans Affairs GeroFit program[52] or the SilverSneakers® fitness program for older adults.[53]
- Cognitive behavioral therapy may be useful in helping people suffering from loneliness to reframe the way they think about their relationships, their assumptions about others' views, or their expectations of success in overcoming loneliness.[54]
- Health system and payer-based, population health strategies that integrate communication technology engagement, befriending programs, and social hubs with community health workers to help people found to be socially isolated and engage them with social resources.

Though there is strong evidence that loneliness and social isolation pose a risk to the health of older adults, the evidence for effective interventions to mitigate their adverse effects is limited. The evidence base is, however, growing and there are numerous examples of interventions—both simple and complex—that are ripe for study and implementation.[55]

109.7 ENGAGED AND BEFRIENDED: IMPLICATIONS FOR HEALTHY AGING AND LIFESTYLE MEDICINE

In their influential archetype of successful aging, Rowe and Kahn proposed a three-part model in which one of the three key components is active engagement with life. Life engagement is a complex, multidimensional concept, but the Rowe and Kahn model emphasizes social interaction and productive activity. [56] The literature on loneliness and social isolation supports this emphasis and prioritization of social interaction as key to healthy aging.[57] There are numerous challenges to an engaged, supported, and socially fulfilling life across the lifespan. These include personal barriers, geographic barriers, social barriers, built environment barriers, and the inevitable losses experienced across the course of a life lived into old age. But opportunities abound to mitigate these challenges and there are many examples to follow. There are built environments and age-friendly communities that support social engagement and interaction. There are cultures of social engagement like blue zones, which promote quality relationships through active engagement with community, friends, and family. There are group activities, learning opportunities, and communities of faith that can open doors for those suffering from social isolation and loneliness or those who are at risk (which may be all of us). And there are our personal heroes who develop and nurture multigenerational relationships that are supportive and fulfilling and offer social support and resilience across their lifespan.

CLINICAL APPLICATION

- Evidence indicates that perceived social isolation and/or loneliness are significant risk factors for physical and mental illness in later life, with impact on par with other known risk factors such as obesity or tobacco use.
- Clinicians should consider assessing their patients for self-perceived loneliness and social isolation.
- Although a developing science, interventions to mitigate loneliness and social isolation exist for clinicians to implement and/or promote as mitigation strategies.

110 Caregivers: Bringing the Invisible Patient to the Forefront

Kady Goldlist, MD

KEY POINTS

- Caregiver burden is defined as the extent to which caregivers perceive that caregiving has had an adverse effect on their emotional, social, financial, physical, and/or spiritual functioning.
- Many risk factors put caregivers at risk for burden, including female sex, low education level, residing with the care recipient, higher number of hours spent caring, and caring around transitions (e.g., hospital to home).
- The health outcomes of caregiver burden are substantial and include increased risk of depression, anxiety, social isolation, financial stress, weight loss, and death.
- Healthcare providers need to improve caregiver recognition and implement screening tools for caregiver burden.
- Resources exist to help with screening and educating caregivers to improve caregiver well-being and quality of life.
- Public policy is working at a national level to help gain recognition for caregiver burden and address it as a public health initiative.

110.1 INTRODUCTION

As Americans are living longer lives, many live more years with chronic, complex, medical conditions.[1] Management of multimorbidity is a lot for an individual to manage and often needs the support of a caregiver. The caregiver role is common, as one in six Americans can be classified as a caregiver for people over the age of 50 years.[2] Caregivers are prominent and crucial for the well-being of care recipients, yet they are under-recognized. Caregivers have been called the "Isolated Army"[3] or the "invisible patient".[4] Their under-recognition combined with the challenging task of being a caregiver leaves many caregivers stressed, strained, or burdened. This chapter outlines the importance of the public health issue of caregiver burden, including epidemiology, risk factors for burden, and potential health outcomes, and it provides screening tools and resources for the caregiver. Addressing caregiver burden involves principles that align with lifestyle medicine. It is a collaboration that requires the active participation of healthcare providers, their patients, and any caregivers involved in patient care.[5] Healthcare providers can use lifestyle medicine principles to recognize stressors in caregivers and provide individualized support.

110.2 EPIDEMIOLOGY

Caregiving is defined as providing any type of care to another person. Caregivers provide both physical care and emotional care to the care recipient.[6] Care recipients need ongoing assistance with everyday tasks on a regular or daily basis because of chronic illnesses or disabling conditions.[7] Caregivers provide as much as 90% of the in-home long-term care needed by adults in the United States, with their lost wages amounting to approximately $522 billion annually.[6,8] Older adults are the demographic that requires the most caregivers. In fact, 76% of care recipients are over the age of 65 and 25% are 85 years or older. As of 2020, one in six Americans, or 42 million Americans, are caregivers to someone age 50 or older. Additionally, 24% of caregivers care for more than one person. Sixty-one percent of caregivers are women and 62% of caregivers have another job aside from their caregiver role. Non-Hispanic Whites make up most caregivers to those 50 years and older (61%), followed by Hispanic/Latinx caregivers (17%) and then African American caregivers (14%). Five percent of caregivers are Asian American and Pacific Islanders and 3% are another race/ethnicity. Ten percent of caregivers 50 years and older served in the United States Armed Forces and 7% self-identify as LGBTQ.[2]

The average age of a caregiver is 50.1 years old with 56% over 50 years old and 20% over the age of 65. Most older caregivers are providing care to a relative (89%). The caregiver is often providing care to a care recipient who is a parent or relative who is 75 years old, male (60%), and who has multiple chronic medical conditions that are both physical and/or emotional. Memory problems also make up 35% of care recipient conditions that require caregiving. A majority of caregivers 50 years and older have health insurance that is usually provided through an employer.[2]

By 2026, the baby boomers will be in their eighth decade of life, and starting at this age, older adults need the most support and services for performing their activities of daily living (ADLs).[9] ADLs include bathing, dressing, ambulation, toileting, and feeding. Instrumental activities of daily

DOI: 10.1201/9781003227793-128

living (IADLs) are more complex than ADLs and include food preparation, laundry and housework, transportation, telephone use, and managing finances.[10] Caregivers on average assist with 1.7 ADLs and 4.4 IADLS. Additionally, most caregivers aid with medical/ nursing tasks (59%).[2]

Not only do caregivers help with physical and emotional support in the home, but they are often their care recipient's advocate with healthcare providers, community services, and government agencies. In fact, 56% of caregivers report taking on the role of advocate. Women caregivers are more likely to communicate with care professionals (69%) than men and African American and Asian American caregivers are more likely to advocate than White caregivers (63% and 66% vs. 53%).[2]

Perhaps because of increased longevity, caregivers are spending more years in their caregiving role, with 28% providing care for five years or more as compared with 24% in 2015.[2] Most caregivers spent over 20 hours per week working to provide care and 20% of caregivers spent more than 40 hours a week providing care.[4] In the care recipients' last year of life, most caregivers spent up to 66 hours per week caregiving.[11] Many (37%) care recipients cohabit in their caregivers' households. Three in ten caregivers for those 50 years and older provide care on their own without help from anyone else.[2]

110.3 ABOUT CAREGIVING AND CAREGIVERS/CAREGIVER BURDEN

110.3.1 About Caregiving

Caregiving responsibilities include healthcare decision support, care coordination or management, medical and nursing tasks, physical care, emotional support, homemaking, and transportation.[6] Caregivers provide any type of care to another person informally and 90% do not receive financial compensation.[6,12,13]

There are many positive aspects of caregiving. Caregivers may feel emotionally rewarded because it can affirm family ties, honor past service the caregiver received from the person who now needs care, and save family resources.[4] Caregiving is associated with personal satisfaction in caring for another and providing comfort, feeling useful and needed, and may provide more meaning and purpose to life.[3] However, the role is highly individual and it can have a multidimensional toll on the caregiver.[14]

110.3.2 Terminology

Although there are significant associations with stress in the caregiving role, the term caregiver burden is controversial for its negative connotation. Many caregivers may prefer to be asked about their reflection on caregiving rather than the burden of it. A more positive term may be carepartner, especially when they are the spouse of the care recipient. This terminology puts caregivers at the same level as the care recipient instead of in a hierarchy with the care recipient. Instead of asking a caregiver about "burden", it may be wise to use the word "challenges" instead. This chapter uses the terms caregiver and burden throughout, but newer terms may come into favor.

The Healthy Caregiver Phenomenon explains that caregiving (without strain) is associated with decreased mortality. This may suggest that healthier persons are more likely to take on the caregiving role, or that the sense of purpose in the caregiving role may have a positive effect.[8]

110.3.3 Definition of Caregiver Burden

The definition of caregiver burden, or caregiver strain, was established in 1986. Zarit and colleagues coined the term caregiver burden to be, "the extent to which caregivers perceive that caregiving has had an adverse effect on their emotional, social, financial, physical, and spiritual functioning".[4,8] Within the domains of physical, mental, and psychosocial health, the spectrum of stressors for caregivers can range from personal caregiving, chores around the home and transportation needs, to medical care, social care, advocacy, and financial support.[4,15] The strain of caregiving is significant to those caring for chronically ill older adults.[4] However, caregiver burden is not a one-size-fits-all definition, as many caregivers have different capacities for caregiving and different thresholds for feeling stressed or "burdened".[15] Ultimately, caregiver burden not only affects the caregiver but also the perceived quality of care from the recipient and may add to recipient anxiety.[3,16]

110.4 RISK FACTORS FOR CAREGIVERS AND POTENTIAL HEALTH OUTCOMES

110.4.1 Risk Factors

Although there are known benefits to being a caregiver, there is evidence of potential negative health outcomes when the caregiver role becomes very challenging. One-third of all caregivers describe a high burden of care.[3] There is increased stress and strain if the caregiver is not given the choice to assume the caregiver role. Less than half (47%) of caregivers 50 years and older report choosing to be in the caregiver role. Other risk factors for negative health outcomes for caregivers include:[2,4]

- Lower level of education (associated with the highest levels of caregiver burden in many conditions)
- Female sex (twice that of men)
- Low level of education
- Residing with the care recipient
- Higher number of hours spent caring
- High or increasing care needs
- Caring around transitions (e.g., hospital to home)

Caregivers who have an annual household income of less than $50,000 provide more care than those with higher incomes (26.4 hours a week versus 20.1 hours, on average).

Caregivers of color report higher weekly hours of care than White caregivers.[2]

110.4.2 Potential Health Outcomes

Health outcomes of caregiver burden include: [4,17]

- Depression
- Anxiety
- Social isolation
- Financial stress
- Weight loss
- Suicide

Many caregivers have other employment, and there is a significant risk that the caregiving role may take priority over regular employment. Perhaps most alarming is that caregiver burden is identified as an independent predictor of mortality. In fact, compared with non-caregivers, caregiver burden increases the risk of death by 6.3%.[4]

110.5 CARING FOR PERSONS WITH SPECIFIC CONDITIONS

Compared with younger care recipients, older care recipients are more likely to have memory problems or long-term health conditions, while younger care recipients more commonly have emotional or mental health issues or short-term physical conditions.[2] Multimorbidity, or having multiple chronic medical conditions, is also prevalent among care recipients. On average, caregivers are caring for recipients with 1.7 chronic conditions.[2] It is important to study caregiver burden in the context of specific chronic illnesses, as knowing the primary disease of the care recipient can help predict caregiving challenges. Caregivers should partner with physicians in the care of patients to understand the individual approach to specific illnesses. However, physicians alone cannot be the only source of support. An interdisciplinary collaboration, often with social work colleagues at the forefront, is crucial to creating individualized care plans to address caregiver burden.[4]

The following will investigate specific caregiving roles for two chronic illnesses: dementia and cancer. This section will also discuss caregivers with chronic illnesses and the role caregiving has on their own self-care.

110.5.1 Dementia

Caregivers report that 35% of their care recipients have memory concerns.[2] When asked the main challenge of caregiving, 4% of caregivers report that Alzheimer's or other dementias are the care recipient's main challenge.[2] Challenges include behavior disturbances, intense physical tasks, and continued monitoring of care recipients.[3] However, caregivers not only have to manage the disease and associated memory and behavioral changes but also have to manage the loss of the relationship with the person their care recipient used to be.[18]

Dementia patients require more help with their ADLs compared with those without dementia.[2] Support groups or psychoeducational interventions for caregivers of individuals with dementia are helpful to prevent and manage caregiver burden.[3,4] Education through home and telephone-based sessions provides positive supports and tools for caregivers.[3] Multicomponent interventions including education and resiliency training can reduce caregiver burden and improve quality of life.[19] Pharmacologic interventions (that manage the patient's dementia or dementia-related behaviors) reduced caregiver burden.[4] Preferable to medications, caregivers for dementia patients who practiced self-compassion and emotion-focused coping strategies, such as acceptance and emotional adaptability, had lower depression and anxiety.[18]

110.5.2 Cancer

More than half of informal caregivers provide care for older cancer patients (over 65 years).[16] They must provide cancer-specific care, such as monitoring for treatment side effects, managing side effects, and administering medications.[3,20] In one cohort study looking at caregiving for cancer patients, half of the caregivers felt ill-prepared to care for their care recipient's cancer-specific needs and a quarter of those caregivers reported low confidence in the quality of care they provided.[20]

Since cancer is so diverse and personalized, interventions and supports should also be personalized and scalable to reduce caregiver burden across the cancer trajectory. However, with the unpredictability of cancer, many caregivers express concern with the lack of control over their care recipient's illness. Most cancer caregivers are not prepared for the intensity of their role. Caregivers report 22% worse physical health secondary to caring for a cancer patient although they reported good overall quality of life. Twenty-eight percent of caregivers who are caring for their spouse with cancer reported psychological distress.[16]

Cancer patients with greater symptoms or poor performance status resulted in caregivers reporting lower quality of life. One study of lung cancer patients revealed when patients had more symptoms (physical or psychological), it resulted in increased caregiver burden.[16,21]

A meta-analysis of psychoeducational interventions, skills training, and therapeutic counseling for caregivers of cancer patients showed caregiver burden was reduced, but the improvements in caregiver burden were lost with time.[4] Digital engagement and technology-based interventions include:[16]

- Smartphone applications
- Websites
- Multimedia
- Electronic health record patient portals
- Online peer support network
- Visual mobile system
- Online symptom reporting system

These resources provide information facilitation, caregiver social support, and multicomponent caregiver support. A review of this technology showed that these technology-mediated interventions improved cancer caregiver outcomes, including knowledge, self-efficacy, caregiving satisfaction, burden, emotional well-being, and quality of life.[16,22]

Studies have shown that an interdisciplinary palliative care team, educational sessions, and self-care plans, helped reduce the caregiver burden in caregivers for cancer patients.[23]

110.5.3 Caregivers with Chronic Conditions

By nature of the prevalence of chronic disease and the older average age of most caregivers, caregivers may have their own health issues that they must juggle while caring for their care recipients.[2] We know that a caregiver's health and well-being are critical to providing quality care and allowing for the care recipient to remain at home.[3] Most (74%) of caregivers over the age of 50 report that caregiving has not affected their own health, however, 21% of caregivers report that their health is worse from providing care and 5% of caregivers feel their health has improved with caregiving.[2]

When caregivers are burdened, they have a higher risk of serious illness and are less likely to engage in preventative care for themselves.[3] One paper details caregivers with diabetes and the potential toll caregiving takes on managing their own diabetes. The study revealed that when caregivers are strained, they have lower medication adherence with their diabetic regimen. The rationale is that caregivers have less time to manage their own health and well-being when they are caring for another person.[8]

110.6 SCREENING CAREGIVERS

There is a lot of room for improvement in caregiver screening. Only one-third of caregivers recall being asked by their provider about their role; even fewer are asked about what they need to help themselves.[12] In order for providers to manage any issue, it needs to be brought to the provider's attention. Many caregivers may not think to direct the time and attention of the patient's provider to the caregiver's needs. Therefore, healthcare providers need to initiate the conversation to improve recognition of the caregiver burden.

Many resources are available to help providers ask caregivers the most appropriate questions. Questionnaires can help identify caregivers and then determine the level of stress experienced. By simply asking these questions, providers may make caregivers feel seen and supported.

Assessment of caregivers should be performed by a primary care provider or another healthcare team member. These assessments should be triggered once a caregiver is suspected or a patient has an illness that requires a high degree of care or care that the provider can identify needs additional support. Ideally, caregivers and care recipients should be interviewed together and separately to get more accurate responses.[3]

Initial screening questions:[6]

1. Do you provide care to another adult loved one? Who is the adult (friend, spouse, etc.)?
2. Do you feel strained when you are around your loved one?
3. Do you feel you have lost control of your life since you started providing care for your loved one?
4. How burdened do you feel caring for your loved one?

Screening questions to assess caregiver well-being:[15]

1. Can you tell me how you are doing with your caregiver responsibilities?
2. Are there times when you need help but are hesitant to ask?
3. Do you know about community resources that could help support you as a caregiver?

There are many different screening question templates. Table 110.1 has information on different options. It is

advised to use the template that works best for the provider in terms of length and detail.

110.7 ADDRESSING CAREGIVER BURDEN USING THE PILLARS OF LIFESTYLE MEDICINE

Caregivers want information from their healthcare providers about caregiving and self-care.[2] Most (63%) caregivers report interest in obtaining more information on or help with caregiving topics. Despite that, fewer than 30% of caregivers report that healthcare providers have asked them about what they needed to care for their recipient and 13% report that healthcare providers have asked them what they need to care for themselves.[2] As patients need to be engaged and motivated to promote good health, their support system, which may heavily rely on caregivers, must also be enthusiastic and invested.[5]

110.7.1 Pillars of Lifestyle Medicine and Caregiver Burden

The pillars of lifestyle medicine have been studied to evaluate their relationship to caregiver burden. The results of the findings are discussed here:

- *Tobacco.* It is unclear if tobacco use is associated with caregiver burden.[8] However, there is evidence that when caregivers are stressed, they are more likely to use tobacco.[24]
- *Alcohol and other substances.* Similar to tobacco use, binge drinking was seen in stressed caregivers for cancer patients.[24]
- *Nutrition*. Surprisingly, the literature suggests that some caregiver strain resulted in higher adherence to the Mediterranean diet.[8] Increased adherence may be due to caregivers eating similar diets recommended for their care recipients as caregivers may not have time to prepare separate meals for themselves if they are overwhelmed.
- *Physical activity.* Many caregivers 50 years and older (17%) report high physical strain as a result of caregiving.[2] Caregivers with diabetes have lower levels of physical activity.[8] Enrolling in aerobic exercise programs has been shown to reduce caregiver burden and depression.[25]
- *Weight*. Caregiver burden is associated with weight loss.[4] Two possible mechanisms include 1) caregivers may have unintentional weight loss because they are too consumed with caregiving responsibilities to eat enough calories or 2) caregivers may be healthily losing weight because, as mentioned above, they may be eating more healthily.
- *Stress*. Caregiving was reported to be highly emotionally stressful for 36% of caregivers 50 years and older.[2] Stress was directly related to the number of hours spent caregiving and was increased when caregivers were balancing another job while caregiving.[4] Caregivers have increased stress if they are African American, make less than $30,000 per year, co-reside with their recipient, provide care to spouse/partner, or have difficulty affording services for their care recipient.[2] Many caregivers are unpaid and many report increased financial strain (42%).
- *Sleep.* Caregivers have higher rates of insomnia compared with non-caregivers.[3] Many caregivers of cancer patients (23%) report not sleeping enough to feel rested.[24]
- *Emotional well-being.* Caregiver burden increases anxiety, depression, suicide, and death.[3,4] Loneliness is reported in 21% of caregivers 50 years and older.[2] Interestingly, 51% of caregivers feel their role as caregivers gives them a sense of purpose or meaning in life.[2]

Table 110.2 presents examples of available resources to address caregiver burden within each pillar of lifestyle medicine.

There are many other resources for caregivers aside from the above-described. There are many technological resources and apps to help caregivers. AARP.org has many of these options available. Technology ranges from using programs to help organize lists and calendars to websites that help order transportation services without a smartphone.[3]

110.8 CURRENT PUBLIC POLICY TO ADDRESS CAREGIVER BURDEN

Public policy can shape the future of the psychosocial and financial burdens of caregiving in the United States. Most developed countries offer mandatory paid leave, and the United States is starting to show an interest in providing more support to caregivers. The Family and Medical Leave Act now allows employees to take up to 12 weeks of unpaid leave to provide caregiving needs. In nearly every state, care programs, mostly supported by Medicaid, exist for informal caregivers to be paid for the services they provide.[3]

Below are some other advocacy initiatives supportive of caregivers:[6]

1. The Recognize, Assist, Include, Support, and Engage Family Caregivers Act (RAISE) (https://acl.gov/sites/default/files/about-acl/2018-10/PLAW-115publ119%20-%20RAISE.pdf).
2. The RAISE Act, which became law on January 22, 2018, created the RAISE Family Caregiving Advisory Council, managed by the Administration on Community Living (ACL).
3. The ACL webpage for the Advisory Council is https://acl.gov/programs/support-caregivers/raise-family-caregiving-advisory-council.

TABLE 110.2

Using the Pillars of Lifestyle Medicine to Address Aspects of Caregiver Burden[10,30]

Lifestyle Pillar	Resources for Caregivers:
Tobacco	*Smoking cessation*: CDC: www.cdc.gov/tobacco/quit_smoking/index.htm The American Lung Association: www.lung.org
Alcohol and other substances	*Alcohol use reduction/cessation*: Alcohol reduction: www.rethinkingdrinking.niaaa. nih.gov/thinking-about-a-change/strategies-for- cutting-down/tips-to-try.aspx Alcoholics Anonymous: www.aa.org/
Nutrition	*Access/ resources to adhering to the Mediterranean diet*:[5] oldwayspt.org/traditional-diets/mediterranean-diet/ Mediterranean-diet-resources • Schedule meal delivery by family, friend, or organizations:[15] www.mealsonwheelsamerica.org/ *Cookbook*: *Blue Zones Kitchen: 100 Recipes to Live to 100*, by Dan Buettner
Physical activity	*Set up the right environment to thrive:* AARP age-friendly communities: www.aarp.org/livable-communities/network-age-friendly-communities/ Blue zones replications:[5] www.bluezones.com/services/blue-zones-project/#section-2 *Exercise*: Health Moves: home-based exercise program: www.ncoa.org/resources/program-summary- healthy-moves-for-aging-well/ Go4Life: www.nia.nih.gov/health/exercise-physical- activity NCOA: recommended exercise programs (Active Choices, Health Moves) • Virtual exercise classes through youtube.com
Weight	• Refer to resources in the nutrition, sleep, and stress sections.
Stress (including financial stress)	*Respite services/day programs*: Eldercare locator: https://eldercare.acl.gov/ National Adult Day Services Association: www.nadsa.org *Help with transportation*: Area Agency on Aging:[6] http://n4a.org/about-n4a/?fa=aaa-title-VI • Utilize telehealth and mail order pharmacies[15] • Early involvement in palliative care for patients with serious illnesses[3] *Financial/legal support*: National Academy of Elder Law Attorneys: www.naela.org/findlawyer National Alliance for Caregiving: www.caregiving.org/resources
Sleep	*Sleep hygiene*: • Aim for seven to nine hours of restful sleep www.cdc.gov/sleep/about_sleep/sleep_hygiene.html *Phone applications*: • Avoid screen time but use a smartphone to access applications that have guided meditation before bedtime (Headspace, Sleepio, or Calm). *Respite*: National Institute on Aging: www.nia.nih.gov/health/what-respite-care
Emotional well-being	*Books*: *The Soul of Care*, by Dr. Arthur Kleinman *The Gerontologist* volume on caregiving: "Aging—It's Personal" (https://academic.oup.com/gerontologist/issue/57/1) Caregiver support groups (in-person or online):[15] Family Caregiver Alliance: http://caregiver.org Online resources for caregivers: AARP's Prepare to Care: A Planning Guide for Families[31] (www.aarp.org/home-family/caregiving/) Alzheimer's Association tools (useful for caregivers managing care recipients of any disease): www.alz.org/care/alzheimers -dementia-online-tools.asp American Cancer Society: www.cancer.org/treatment/caregivers.html

4. SAGECAP is an expansion of SAGE which provides support and advocacy for lesbian, gay, bisexual, and transgender older adults. SAGECAP was launched to support caregivers. The focus is on New York City and Baltimore (www.sageusa.org /resource-category/caregiving/).

110.9 CONCLUSION

Caregiving is a common role for Americans and although many caregivers are comfortable in their roles, many experience stress and feel unsupported. When caring for patients, healthcare providers need to improve on recognizing

caregiver burden. Individualized approaches to supporting caregivers can be taken based on healthcare providers' practice, the needs of the caregiver, and the health of the care recipient. Many concerns from the caregiver can be addressed using lifestyle medicine approaches. More information, resources, and policies are available now more than ever on supporting the caregiver, and healthcare providers can enable caregivers to improve their quality of life, which will translate to better care for patients.

CLINICAL APPLICATIONS

- Caregiving is defined as providing any type of care to another person and caregiver burden is defined as the extent to which caregiving has a negative effect on the caregiver.
- Caregiver burden increases depression, anxiety, stress, suicide, and death.
- Existing questionnaires and tools can be utilized to increase healthcare provider screening and the recognition of caregiver burden.
- Many resources exist to help caregivers who are experiencing caregiver burden and newer resources rely on technology to address burden.

Part XIX

Health Promotion

Taylor & Francis
Taylor & Francis Group
http://taylorandfrancis.com

111 Introduction to Health Promotion and Lifestyle Medicine

Jane Ellery, PhD and Dee Edington, PhD

KEY POINTS

- Evidence shows that health promotion and lifestyle medicine practices can positively impact patient health. Encouraging patients to make meaningful changes is difficult, but highlighting the value of the investment, using motivational interviewing, and introducing appropriate digital applications can help nudge them toward healthier behaviors.
- Environments matter, and our built environment typically detracts from rather than promotes good health. Working collaboratively to reshape our environments, including diverse teams of professionals and the individuals who will benefit from the intended changes, is key to behaving differently.
- Changing behaviors to encourage healthier living will require a collective effort. As physicians become more adept at using digital tools, and at working with both traditional and non-traditional health professionals in workplace, school, and community settings, new tactics for change will emerge.

This health promotion section is a primer for physicians who are committed to lifestyle medicine in service of their patients. You are likely in this field of health and healthcare because you are passionate about helping others. By focusing on a lifestyle medicine approach to your practice, you are taking steps to introduce and encourage lifestyle changes when appropriate. This step beyond more traditional medical therapies is not an easy task in a medical system that financially supports physicians who do things *to* sick people instead of rewarding practices that promote good health. Our collective challenge is to shift both thinking and practice so we develop a new system that also champions doing things *for* people, *with* people, and empowers people to do things *by themselves*. The chapters in this section will help you think through this *to…for…with…by* strategy.

First, we have to make sure that people stop getting worse! Dr. Dee Edington's landmark book, *Zero Trends: Health as a Serious Economic Strategy*,[1] reminded us that everyone needs to stop getting worse before we can start getting better. By bringing together insight from years of research and data collection, this book expanded our understanding of the benefits of active living and good nutrition. It presented evidence to support how being active, eating well, connecting with others, and creating built and social environment conditions that allow us to take action on our intentions and aspirations are important to healthy living. We also know that different people have different needs when it comes to physical, social, and environmental health and that they have varied resources and opportunities available as they work to adopt healthier habits.

Actions taken on behalf of patients when they have acute, immediate needs are an important part of the healthcare continuum. Doing things *to* people in our emergency departments, crisis management centers, and operating rooms is imperative to survival; and these actions represent a valuable part of our *to…for…with…by* strategy that is not addressed in this health promotion section. The remaining categories, *for…with…*and *by*, come into play when you work with your patients to co-produce long-term solutions that support the primary, secondary, and tertiary prevention needs often associated with health promotion and lifestyle medicine practice.

The chapters in this section focus on evidence-informed thinking designed to help you expand your practice strategies in ways that will allow you to view your patients as a compilation of everything that they have experienced up to that point in their lives and everything that they experience each day in their current environment. We must treat the whole person. We also must encourage change in ways that make sense in the world in which your patients live, keeping in mind that their worlds likely look very different from how you experience the world.

We may not have definitive answers for you, but we can share what we have learned. Our hope is that you can take this knowledge, build on it, talk with your patients and peers, and find meaningful opportunities to have a positive impact on your patients. Here are highlights of how each chapter contributes to this.

In Chapter 118, Parkinson and Doyle introduce a concept of population health that has emerged at the intersection of public health and medicine. They remind us to move beyond viewing wellness and health promotion efforts as an investment in reducing the cost of medical treatment. Instead, we should view our health and wellness-related efforts as an investment in the value these initiatives bring to individuals and the contributions each individual brings to the world. They also highlight the opportunities that

DOI: 10.1201/9781003227793-130

emerge when considering epigenetics, the microbiome, and neuroplasticity; the importance of the mind–body connection; and the role that our built environment and our personal choices play in our overall health.

The Ellerys expand on built and social environment concepts, in Chapter 114, to encourage co-produced change and a shift in thinking that includes a focus on salutogenesis and a sense of coherence in addition to our more traditional pathogenic concentration. This involves shaping the environment in ways that inspire a good life in a safe and nurturing setting as well as promoting activities that help people keep from getting sick. It also encourages diverse teams of practitioners, including planners, employer groups, and individuals who are working to make the changes, to come together to develop and deliver interventions. This chapter closes by drawing attention to the United Nations Sustainable Development Goals and the Healthy People 2030 Social Determinants of Health and how the principles presented in these collective visions can provide guidance as we think about healthier living.

Pitts and Schultz focus on behavior change in Chapter 112 by helping us understand what motivation is and how we can cultivate it among patients. They introduce us to the importance of intrinsic motivation and a compassionate frame of mind as we work to serve our patients. They also remind us of the value of being fully present and authentic during patient counseling, while allowing the voice of each individual to be part of the plan for change. One recommendation to enhance motivation is to use a collaborative, goal-oriented style of communication called motivational interviewing. This approach respects a patient's interests, values, and concerns. It also helps patients maximize their autonomy and freedom of choice while clarifying their strengths and aspirations.

In Chapter 117, Katch reminds us that biological variability is real and that many factors impact the magnitude of response to interventions. We often blame individuals for being non-compliant; however, age, disease conditions, ethnicity, concomitant medication, environmental variables, and genetics can also play a role in how individuals respond to treatment. He highlights the importance of the language we use and encourages us to adjust modalities if the expected positive responses are not achieved under the current treatment plan.

Chapter 113 highlights the rapidly changing digital technology landscape. Chown, Thibodeau, and Kirby draw our attention to the idea that technology can help us individualize our patient care approach. With digital innovations revolutionizing healthcare and allowing us to intervene in new ways, access to data and analytic tools provides predictive opportunities that were not available to us in the past. Wearable technologies provide new opportunities for personalization and for patient-centric care, and phone applications and websites provide participatory opportunities for our patients. Together, these digital tools can help bring health promotion, prevention, and wellness strategies to the forefront of our work, giving lifestyle medicine physicians new tools to use as they nurture individual behavior change efforts.

In Chapter 116, Shultz provides additional support for built environment change and for using technological innovations for measurement and communication. She also advocates having physicians take a more active role in health promotion. To do this, she encourages lifestyle medicine practitioners to consider the issues of health behaviors, environment, values, and culture while overcoming barriers such as disease orientation, reimbursement policies, and conflicting recommendations. As physicians become more adept at using digital tools, and at working with both traditional and non-traditional health professionals in workplace, school, and community settings, new tactics for change will emerge.

In Chapter 115, Burton provides a perspective on international health and lifestyle. As he recaps the emerging severity of chronic disease throughout the world, he reminds us that smoking and outdoor air pollution contribute to morbidity and mortality across the globe. Additionally, the World Health Association predicts depression will be the top cause of worker disability globally by the year 2030. He brings his chapter to a close by highlighting effective strategies that involve culture changes, health literacy, and a healthcare system that includes prevention, early detection, and healthy behavior change initiatives that can positively impact non-communicable diseases.

As a further insight into the potential of lifestyle change practices, we would like to draw your attention to reports and writings compiled by two recent Surgeons General, Dr. Vivek Murthy and Dr. Jerome Adams. In 2021, Murthy released *Protecting Youth Mental Health: The US Surgeon General's Advisory*,[2] stating, "If we seize this moment, step up for children and their families in their moment of need, and lead with inclusion, kindness, and respect, we can lay the foundation for a healthier, more resilient, and more fulfilled nation".[2] His related popular media book, *Together: The Healing Power of Human Connection in a Sometimes Lonely World*,[3] shares the value of connections and highlights three types of loneliness. These include: (1) intimate/emotional loneliness, a longing to share a mutual, trusted bond; (2) relational/social loneliness, a longing for quality friendships and social support; and (3) collective loneliness, the longing for a network or community of people who share a sense of purpose. Cultivating connections among individuals of all ages will start to help minimize our feelings of isolation and help mitigate the negative impact this isolation has on our health and well-being.

Also released in 2021 was the first Surgeon General report on economic prosperity, *Community Health and Economic Prosperity: Engaging Businesses as Stewards and Stakeholders—A Report of the Surgeon General*.[4] In releasing this report, Adams shares that "As a physician, I understand that health happens in communities. The fact is, our environment shapes the opportunities we have, and a lack of opportunity can mean poor health, education,

family and career outcomes".[5] The report focuses on how communities can become places that nurture health, wealth, and well-being and how businesses can help create value for themselves and their communities by helping create the conditions that will allow people to thrive. Highlighted in this report are robust examples of how diverse organizations and individuals can join together to strengthen community health and increase opportunities for all.

Collectively, we have to commit to finding solutions that will allow our patients to move past outsourcing the responsibility for their health to others, even if that is what our current healthcare system promotes. The chapters that follow can guide your thinking as you explore opportunities for evidence-informed, systems-based changes to help create the social and environmental conditions that will allow your patients to live meaningful, healthy lives.

CLINICAL APPLICATIONS

Action	Benefit
Work with your patients to find changes that fit their understanding of the world.	Involving your patients in developing plans that fit their worldview is an important consideration. Coaching, nudging, and reshaping environments can lead to lasting, meaningful change.
Individualize treatment plans.	Everyone is unique, lives under varied conditions, and responds differently to proposed treatments. Working together to find digital tools and using motivational interviewing as you co-produce individualized treatment plans empowers those who will benefit from taking action.
Think globally, act locally.	Following evidence presented across the globe is important in managing and mitigating the impact of poor lifestyle choices. However, all solutions are local, and the current physical and social environments will need to be considered when encouraging action for change.
Encourage connection and involve non-traditional partners.	As humans, we are built for connections, yet we live in environments that lead to deep isolation with most change tactics taking place in "silos". Intentionally developing intimate, social, and community relationships helps bring meaning to our lives and makes life worth living.

112 Motivation as Medicine

Jennifer S. Pitts, PhD and Alyssa B. Schultz, PhD

KEY POINTS

- While many factors influence unhealthy behaviors, intrinsic motivation is the active ingredient for a successful lifestyle change.
- Physicians are uniquely positioned to play an important role in helping patients create conditions for the motivation that can drive the lifestyle change process.
- Deep listening, compassion, and motivational interviewing are strategies that can strengthen the healing relationship between physicians and patients.

112.1 INTRODUCTION

By changing four aspects of the American lifestyle—poor diet, sedentary lifestyle, obesity, and smoking—we could see an 80% reduction in heart disease, a 90% reduction in diabetes, and a 60% reduction in cancer.[1] It is this powerful impact of lifestyle that led David Katz, Founding Director of Yale University's Prevention Research Center, to proclaim that "lifestyle is medicine".[2] While people face many challenges when attempting to improve health-related behaviors, a big factor is motivation—and physicians can be powerful motivators of positive change.[3] There are many ways physicians can help their patients find the motivation to live healthier lives, and medical practice guidelines recommend lifestyle counseling. Yet many physicians do not counsel patients on their lifestyles, and even when they do, they have varying degrees of success.[4]

112.2 BEHAVIORS

Behaviors are driven by numerous determinants including personal beliefs, attitudes, and motivation, as well as social, economic, cultural, and environmental factors. Unhealthy behaviors become habits by repeatedly meeting an immediate need. For example, people smoke to relieve stress and anxiety or eat poor or too much food for comfort or convenience. There is no lack of available information on healthy lifestyle choices. This is one of the most common frustrations of anyone in the health and wellness field. Unhealthy or risky behaviors have a significant impact on today's all too common chronic health conditions, but helping patients make behavioral changes can be a huge challenge. While many people want to lose weight, for example, they often have ambivalence or even animosity toward making actual lifestyle changes. Of course, it is not enough to know that change is needed or even wanted. Dropping old behaviors and persisting with new behaviors in spite of the biological, emotional, cognitive, environmental, social, and cultural forces that challenge our resolve is one of the most profound trials in life and one of the most promising opportunities for the practice of lifestyle medicine.

112.3 MOTIVATION

The Oxford English dictionary defines motivation as: "A reason or reasons for acting or behaving in a particular way. Desire or willingness to do something; enthusiasm". But motivation is nuanced in subtle but important ways. Self-determination theory (SDT)[5] is about human motivation and a core set of human needs that, when met, contribute to living a full and healthy life and make a primary distinction between autonomous motivation and controlled motivation. Autonomous motivation is what a person chooses to do for themselves while controlled motivation involves acting out of a sense of coercion or pressure. Autonomous motivation is associated with deeper learning, greater flexibility and creativity, and greater persistence in behavior change efforts.[6]

According to SDT, people are more autonomously motivated to change their diet or quit smoking if they believe it will help them achieve a valued health outcome. The more autonomous and self-determined the motivation for a behavior, the more likely it will be to persist. Controlled motivation includes the classic "carrot" or "stick" incentives. Telling patients that they will live much longer if they stop smoking (carrot) or using fear tactics like telling them to stop smoking or risk dying of lung cancer (stick) can both be experienced as very controlling. Both involve external pressure or coercion, and both can undermine individual autonomy. Because the impetus for these behaviors is external, it does not feel authentic and fully integrated.

There are two types of autonomous motivation: intrinsic motivation and fully internalized extrinsic motivation. Intrinsic motivation involves doing things purely for their own sake. When we are intrinsically motivated, we function with a high degree of autonomous motivation and we endorse what we are doing and operate at a high level of self-awareness. We understand ourselves in relation to the world at that moment and operate authentically.

Fully internalized extrinsic motivation is different but just as important as intrinsic motivation. As we all know, the realities of life require that we often do important things that we do not find inherently interesting and enjoyable.

DOI: 10.1201/9781003227793-131

Under certain conditions, these external demands can become internalized and integrated into who we are. Integrating an extrinsic prompt is an active process that people must do for themselves and involves identifying the importance of the behavior and integrating it into who they are as human beings.

112.4 EXTRINSIC TO INTRINSIC MOTIVATION

The transition from controlled (extrinsic) to autonomous (intrinsic) motivation can be difficult. Physicians must understand what blocks or erodes a patient's motivation and how to create conditions for successful behavior change. They must also understand what fuels motivation and help patients cultivate their own autonomous and self-determined motivation to engage in healthier lifestyles. This is a skill that is fast becoming a core part of the practice of lifestyle medicine.

By adopting a need-supportive approach, physicians can help patients adopt and internalize healthier lifestyle behaviors. Studies have shown that autonomy support by health care practitioners affects patient motivation and health behaviors, including smoking abstinence,[7] weight loss,[8] diabetic glucose control,[9] and medication adherence.[10] Autonomy support includes asking about and recognizing the preferences and perspectives of patients, offering them choices about treatment options, and giving them relevant information while taking care not to use too much pressure or be too controlling.

112.5 WILLPOWER

In addition to motivation, patients need willpower (i.e. self-control or self-regulation) to choose and maintain healthy habits. Willpower is the energy or will to do the positive things that some part of us does not really want to do, or resist doing negative things that some part of us really wants to indulge in. A popular theory describes willpower as a muscle that can become fatigued if it is overused, but also strengthened through exercise.[11] Many things deplete that source of willpower energy on a daily basis including lack of sleep, resisting temptations to snack, focusing on difficult mental tasks, dealing with difficult people, and many other tasks that require self-control. When depleted, dieters are more likely to eat poorly[12] and smokers smoke more.[13] Habits require less energy, so they are an important strategy for conserving willpower.[14]

112.6 PHYSICIAN INFLUENCE AND STRATEGIES

In the traditional doctor-patient relationship, physicians are seen as experts, and their role is to give advice or administer some form of treatment to the patient. The role of patients often includes being passive recipients of advice and faithfully executing physicians' recommendations. This approach can be felt as controlling and results in passivity or resistance from patients. Likewise, simply giving patients advice to change can be unrewarding and ineffective. Developing strong interpersonal relationships with patients is crucial to effective lifestyle medicine. Physicians must be fully present and authentic in their patient counseling because patients can feel it when physicians truly care about them. They can tell when they are genuinely heard and understood, and when their preferences and needs are respected.

Having a compassionate frame of mind during encounters with patients is also critical. Compassion is at the heart of quality medicine and is comprised of two components: 1) feeling for another person who is suffering and 2) being motivated to help them. Treating patients compassionately has wide-ranging benefits, including improved clinical outcomes, increased patient satisfaction, and enhanced information gathering.[15] Cultivating compassion could be better incorporated into medical training. Physicians can be trained to see patients with a greater sense of generosity, ask what might be driving and supporting patients' poor behaviors, or identify their willingness or ability to change.

Genuinely curious listening is another important part of developing a strong connection with patients. Active listening involves factual listening to learn new information, empathetic listening to see through another person's eyes, and generative listening, which requires setting aside one's own agenda and connecting with the conversation.[16] This type of listening can transform people and their motivation to change. Helping patients tie behavior change to some greater purpose in their lives is also helpful. If patients can name for themselves how the behavior change can help serve a greater purpose they care about, intrinsic motivation will be stronger.

Motivational interviewing (MI) is another approach to enhance patient motivation to change poor lifestyle behaviors. This is a collaborative, goal-oriented style of communication focusing on the patient's point of view, and respecting their interests, values, and concerns.[17]

MI has been effective for many types of change including hypertension control[18] and increased intake of fruits and vegetables.[19] The principles of MI include understanding and accepting patients' perspectives and situations, emphasizing any incongruity between present behavior and goals, changing strategies to assist patients with change, and supporting patients' confidence in their ability to make changes or achieve goals. With MI, physicians work to maximize patient autonomy and freedom of choice, while minimizing resistance to change. They help patients clarify their strengths and aspirations (goals), explore their values, develop their own reasons for change, and collaborate with patients to outline effective change strategies.

MI involves four processes that may occur simultaneously. These include engaging (establishing a connection), focusing (clarifying the direction that a change goal might take), evoking (eliciting a patient's own motivation for change), and planning (details about when and how to change). MI is achieved by developing five communication

skills. These are: asking open-ended questions, affirming the patient's personal strengths and resources, reflective listening which restates what was shared, summarizing the discussion and insights, and offering advice in line with the patient's perspective and needs.

Powerful ways to deepen intrinsic motivation to change unhealthy lifestyles is to help patients tie behavior change to some greater purpose in their lives: engage in empathic and compassionate inquiry to determine what matters most in patients' lives; look for what animates them, what they care most about; help patients name for themselves how the behavior change can help serve this greater purpose; and help patients purposefully connect to their purpose and values in the moment of temptation and bring to mind the short-, moderate-, and longer-term consequences of their actions. Eating the donut may feed an immediate emotional craving (short-term), but sap the energy needed for spending quality time with family later in the day (moderate-term), undermine a goal to finish that long overdue project, or shed the two pounds that would help them feel better in the long-run.

112.7 CONCLUSION

Lifestyle medicine physicians can play a large role in helping patients make healthy lifestyle choices such as regular exercise, adherence to preventive services, consuming a healthy diet, and other behaviors. One important factor is developing intrinsic motivation rather than extrinsic motivation for behavior change. Some strategies for doing that involve understanding the nature of motivation and situational barriers that exist. Deeper healing relationships can be developed through active listening, motivational interviewing, strengthening willpower, and improving compassion. Overcoming the traditional doctor-patient dynamic of giving generalized advice to a patient who is resistant to control is challenging. Forming stronger bonds with patients requires a genuine caring attitude that is conducive to helpful conversations and counseling so that physicians and patients can work together to make plans for improving health behaviors.

CLINICAL APPLICATIONS

- Physicians can be supportive guides that help strengthen patients' motivation to change unhealthy lifestyle behaviors with a better understanding of the nature of motivation and the fundamental human needs that fuel it.
- Embracing a need-supportive approach to helping patients adopt and internalize healthier lifestyle behaviors is key.
- Using motivational interviewing methods can help patients cultivate their own autonomous and self-determined motivation to engage in healthier lifestyles.
- Helping patients understand and strengthen their willpower and more wisely choose their willpower battles can be aided by deep, curious, and authentic listening during patient encounters.

113 Hybrid Health Promotion: Patient-Centric Digital Tools to Support Healthier Lifestyles

Samantha Chown, BSc, MSc, Josée Thibodeau, RDN, and Anne Marie Kirby, CIS

KEY POINTS

- Advancements in technology, along with the COVID-19 pandemic, have resulted in significant growth and innovation in digital health, including in workplace health and wellness programs.
- Digital healthcare (including telehealth and telemedicine) will continue to remain an important part of the healthcare system.
- Healthcare providers should learn about and promote digital health technologies as a facet of healthcare, especially due to its accessibility, simplicity, and more frequent capacity to influence positive health behaviors.
- Healthcare providers can leverage digital tools from the private sector to supplement care for the best interest of their patients and the broader healthcare system.

113.1 INTRODUCTION

Digital health is a broad term that encompasses technologies and their application in health, including e-health, m-health, telehealth and telemedicine, wearable devices, digital therapeutics, and health information technology.[1,2] The addition of digital health to existing health infrastructure had been slowly evolving for many years, due in part to a lack of funding and resistance—primarily from healthcare providers. However, the COVID-19 pandemic accelerated change and led to a substantial increase in innovation and utilization.[6] Although continued growth of digital health relies on a multi-sectoral effort that spans local to global levels,[4] trends strongly suggest that it will strengthen its position as a vital aspect of the health ecosystem, as evidenced by its inclusion in major organizational roadmaps such as The World Health Organization Global Strategy on Digital Health 2020–2025.[40] Digital tools can supplement the care clinicians provide and may establish better methods of healthcare planning, delivery, safety, and quality.[5] Thus, knowledge and recognition of digital health technologies are essential for all healthcare practitioners.[6]

Societal challenges, especially attaining buy-in from existing institutional healthcare stakeholders, have been asserted to be a bigger challenge to adoption than the scientific or technological challenges.[7] Recent evidence supports this as a large proportion of clinicians recognize that digital health is the future but have concerns about how it changes the role of the clinician and the way care is delivered.[6] Irrespective of opinions toward digital health, it is *happening* and many health professionals and patients across the globe are embracing health applications and devices. As stated by Dr. Keith Horvath in reference to artificial intelligence (AI), the following could be more broadly applied to digital health technologies: "AI is not going to replace physicians, but physicians who use AI are going to replace physicians who don't..."[8] Staying current on this frontier is crucial for physicians practicing lifestyle medicine.

113.2 INNOVATIONS IN DIGITAL HEALTH

Investments in digital health have escalated, and new opportunities for innovation within the digital health space have been realized. In fact, the first half of 2021 saw almost $15 billion in venture capital investment in the United States—nearly two times that of the entire 2019 year.[9] The top three funded clinical indications were mental health, cardiovascular disease, and diabetes.[9] Heavily prioritized due to COVID-19 restrictions was virtual care, such as telehealth and telemedicine services, with reports of usage approximately 40 times higher than pre-pandemic levels.[3,10] An increase was also seen in AI applications within healthcare and services, such as digital diagnostics to detect health conditions, as well as wearable technologies and wellness apps.[6,11] Many health and wellness services thought not to be adaptable to remote settings were reimagined, an example being virtual fitness solutions. As such, expected trends in digital health include further uptake of AI and machine learning, telehealth and telemedicine, augmented and virtual reality, wearables and Internet of Things (IoT), and wellness apps.[12–14] Importantly, these innovations can be delivered in various ways, from primary care physicians to workplaces/work plans and communities. Taken together,

DOI: 10.1201/9781003227793-132

innovation in digital health provides new methods for accessing and delivering health support and services.

Advancements in digital health technologies should not only increase availability and access but should also give rise to additional avenues for user engagement. A popular method for increasing health engagement is gamification, which is the application of game design elements to motivate positive health behaviors.[15–17] Benefits of gamification in health and wellness, as noted by Johnson et al. (2016), may include the following: intrinsic motivation for lasting health behavior change; broad accessibility and everyday life fit of smartphones and wearables; appeal of games; applicability for different health conditions and risks; cost-benefit efficiency; and support for overall well-being through accomplishment and engaging relationships with others.[15] The inclusion of gamification is well-represented in health and wellness programs, whose shift toward technology-focused solutions to improve structure and delivery preceded COVID-19.[18] Digital health companies are filling this need by delivering engaging digital experiences that employ gamification to support individuals on their health journeys. For example, Carebook Technologies creates meaningful and engaging experiences from health assessments to interventions that integrate health challenges, self-directed programs, and coaching with digital tools, such as wearables and digital therapeutics. Such digital health and wellness programming allows individuals and organizations to prioritize action, track progress, and evaluate impact over time in a more accessible, personalized, and data-driven manner. Engagement is a typical metric for the success of health and wellness programs, and as more individuals and organizations adopt hybrid and remote solutions, continued research and development in this space will lead to further innovation in digital health technologies.

113.3 DIGITAL HEALTH: GAINS AND BARRIERS

Digital health offers many gains to individuals, organizations, communities, and systems. With projected challenges of population health and health systems that range from healthcare provider shortages to growing aging populations and increases in chronic condition prevalence,[19,20] an opportunity exists for the private sector to play an important role in the complex web that is the healthcare system.[21,22] Over the last few decades, successful programs have arisen when multiple sectors have joined forces. An example that led to effective health promotion initiatives was the collaboration between CoreHealth Technologies (part of the Carebook family) and the Government of British Columbia (Canada). ActNow BC utilized CoreHealth's technology as the central hub for programs and communications to run and track a province-wide activity challenge, as well as to pilot an Integrated Health Network with allied health teams. Advantages to these alliances are continuing to be explored, as seen from patient-centered medical homes (US), which act in sharp contrast to more traditional siloed care that typically lacks continuity and is oftentimes incomplete. Considering that 90% of healthcare leaders agreed that patients are looking for integrated journeys instead of single services,[23] the implementation of digital health is beneficial for population health and health systems at large.

Over the years, health solutions have become more encompassing of the whole self by assuming a holistic approach that considers multiple dimensions of health and wellness targeting nutrition, physical activity, smoking cessation, sleep, financial well-being, stress, mental health, and communicable and non-communicable diseases.[24,25,26] By ensuring people have access to timely, personalized, and accurate lifestyle and health information—along with the tools to help them build healthy habits—digital tools establish ways for individuals to think about their health more often and be empowered in their health and wellness decision-making.[4] For healthcare providers, the relationship with patients will continue to transition to a partnership in health instead of the previous paternalistic approach.[6] In this way, digital tools can supplement the care of healthcare providers by not only augmenting the interventions that would be promoted for preventing and/or managing chronic conditions but also by helping to serve as a conduit for improving health literacy and accessing care.

Debate about whether digital health technologies support health equity has ensued, especially when compared with traditional brick-and-mortar facilities. However, evidence to date has shown positive impacts on health equity. Digital health technologies are becoming easier to use and more accessible for patients and has shown positive impacts on the healthcare they have received. According to a 2021 survey of US adults conducted by the Pew Research Center, 85% own a smartphone while about 75% own a laptop or computer, and these percentages generally remain high across demographic variables.[27] For individuals who do not have access to technology, hospitals and healthcare organizations have initiated opportunities to provide it to those in need.[28,29] By expanding reach, existing barriers, such as lack of transportation for those who live in rural areas, may be mitigated by reducing the need to be in person.[3,4] Additionally, research has shown that the continued uptake of AI and machine learning applications for healthcare providers, such as decision-support tools that utilize large databases encompassing diverse symptom presentations, increases the capacity for individuals to access adequate care with reduced bias.[11] Ultimately, digital health technologies can support health equity and the sustainability of an already strained healthcare system.[30]

Barriers to digital health exist, ranging from strategic alignment and leadership to governance, capacity, change management, and solution design.[5,31] Perhaps unsurprisingly, the challenges are not considered to stem from technology but rather policy.[5] Systems-level decisions must be made that outline regulatory compliance especially as it relates to health data, education and training for healthcare providers and patients/users on appropriate usage, cost and remuneration,

and appraisal of digital tools.[5,31–33] For patients/users, common concerns include health data privacy and user-friendliness of the technology.[33] Additionally, even though 70% of clinicians agreed that the widespread use of digital health technologies will enable the positive transformation of healthcare, about the same percentage feel that it will be a challenging burden.[6] Concerns raised by clinicians include difficulties preserving the quality of care in virtual settings (i.e., demonstrating empathy virtually), as well as increased responsibility and feeling overwhelmed by new technology and mass amounts of data.[6,33] By co-designing and developing digital tools that center on patients/users and communities, the barriers to digital health, such as access and education about its use, can be mitigated.[34,35] In order to fully attain the positive outcomes of digital health technologies, challenges to its growth are necessary considerations in order to carefully integrate digital tools into existing or updated health systems and avoid creating additional barriers to health.

To ensure gains are attained and barriers are overcome, insights about experiences using digital health technologies are vital to meet the diverse needs of users and providers. The patient/user experience is exceptionally important, and it is what 90% of clinicians believe has driven change in the last decade.[6] Data thus far have shown positive user experiences across various digital health technologies. The US Nationwide Telehealth Impact Survey found that 79% of respondents were satisfied with their telehealth visit and 73% expect to continue receiving virtual healthcare services in the future, with high satisfaction across ages, insurance types, and locations (i.e., urban, suburban, or rural).[36] Positive experiences have also been shown among a variety of non-clinical digital health and wellness services, such as coaching. HealthFitness, a Trustmark company that builds and manages comprehensive fitness solutions for leading companies and organizations with options that extend beyond fitness to address total well-being, received valuable feedback on the benefits of their virtual coaching:

> My coach kept me *accountable* with my sleep and financial goals, giving me a *realistic target date* to achieve them by and *checking in regularly* to support the challenge. I felt the check-ins were extremely valuable to my success…
>
> Coach Michele was great! I have come a long way. It has made a *big difference in my lifestyle*, and my coach helps out very much. No matter what my questions were, Michele was always able to assist me. She made me feel like we have known each other for years…
>
> Katie has been fantastic! I knew what I need[ed] to do, but *just getting started is the hardest part*. Having Katie in my corner has been so helpful for me to *maintain consistency* with my goals!

Moreover, healthcare providers' experiences of digital health have also proven positive, especially in terms of improving efficiency and effectiveness in diagnosing, treating, and supporting patients.[6,11,37] A survey of healthcare providers at the height of the pandemic found that 80% indicated telehealth improved the timeliness of care and almost 70% were motivated to increase the use of telehealth in their practices.[38] Of leaders in healthcare, 61% identified that their main purpose in providing digital health services is to improve well-being by improving health outcomes.[23] Essentially, the primary goal for healthcare providers when utilizing digital health technologies is to adopt tools that help them help their patients better. As more digital health tools are created, these insights will be invaluable to inform further development and enhancement for the best interests of patients/users and care providers.

113.4 FUTURE OF DIGITAL HEALTH

The future of digital health is promising for all stakeholders across industries. From healthcare providers to scientists, technology experts to patients/users, there is an opportunity to redefine how health promotion is supported. The growth of digital health and its capacity to be as positively impactful as possible is dependent on patient/user-centered, multisectoral collaboration.[4] With the opportunity to provide improved care and protect health systems and healthcare providers from further strain, digital tools are important to pursue and implement. Our hope is that digital health is carefully embedded in the healthcare system, and—similar to public health—it is woven into the structure of health systems seamlessly and is not necessarily "seen" if it is functioning effectively.

One way that digital health can be integrated into existing healthcare systems is to align with a vision of healthcare known as "P4 medicine," which has been promoted for many years by Dr. Leroy Hood and advocates of systems medicine.[7] Having thought to emerge from the intersection of systems biology and systems medicine, consumer-driven healthcare and social networks, and the digital revolution, the four Ps in P4 medicine are predictive, personalized, participatory, and preventive.[7] Digital health technologies are already aligning with the four Ps. First, digital tools can lead to more predictive data via AI and machine learning applications that can be used to support clinical decisions and lifestyle changes. For instance, blockchain personal health records and AI can help increase access to health data and decision-making support for patients and healthcare providers. Additionally, digital health allows for more personalization, which means individual health needs can be directly addressed in a patient-centered manner that considers multiple dimensions of health and meets people where they are at. Further, digital tools allow patients to be more active participants in their health, which not only increases patient health literacy and engagement in their healthcare decision-making but also alters the patient-healthcare provider relationship in such a way that is collaborative instead of paternalistic. Finally, digital health brings prevention to the fore through early identification and management of risks, while also supporting people further along the health continuum.

As digital health continues to expand, it will become more important to appraise its benefits in order to determine opportunities for improvement. To do so, frameworks have heavily focused on return on investment (ROI);[32]

however, there has been a shift toward inclusion of value on investment (VOI) to evaluate quantitative and qualitative outcomes, such as patient/user satisfaction, time and cost efficiencies, improved productivity, increased engagement, and reduced health risks.[18,32] Health systems have been encouraged to create measurable, accountable, and scalable key performance indicators to evaluate success.[39] To evaluate digital health technologies across all stakeholders, a heavy reliance on community involvement will be needed to move the digital health ecosystem forward.

113.5 CONCLUSION

Beyond diagnosis and throughout intervention prescription that takes place in clinical settings, healthcare practitioners are in a unique position to influence lifestyle for improved health and well-being in a way that is predictive, personalized, participatory, and preventive. Digital tools are multidimensional and accessible and can augment existing care or emphasize areas of concern that may not have been previously known. Digital health is an aspect of the healthcare system that will continue to grow; therefore, learning about, acknowledging, and sharing digital tools serves the best interests of patients and healthcare providers alike. The strain on the healthcare system relies on being able to adequately support patients with all available resources. Thus, the future of health and health promotion includes digital health.

CLINICAL APPLICATIONS

As a physician, partner with your patients by	Benefits
Embracing lifestyle as medicine	Taking small steps in building new habits can have a significant impact on health risks and chronic condition management. Empowerment of patients by building self-efficacy through learning and iterative attempts to change behaviors that are not based on success vs. failure but on a journey to better health.
Supplementing your practice with digital health technologies	Provide education, encourage lifestyle change through habit formation, support disease management, and integrate remote patient monitoring through appointments and prescriptions. If patients use health and wellness apps, they can utilize this information during appointments (i.e., tracking trends of lifestyle and biometrics when relevant).
Acknowledging and promoting engagement in digital health technologies (through the workplace, community, etc.)	Encourage patients to utilize their workplace benefits and/or access community services and tools: • Completing health assessments and onsite screening • Participating in programs and challenges • Accessing allied health professionals and/or health coaching • Reimbursement for therapeutics, medical devices/wearables, etc.
Keeping pace with current and emerging digital health and wellness applications	Recommend personalized applications that are built with a targeted patient in mind (age, sex, gender, lifestyle, condition, accessibility, etc.) Leverage curated libraries that contain objective, expert evaluation based on usability, clinical value, supporting evidence, and data rights: • APA • ORCHA • PsyberGuide • MindTools • Therappx

114 Community as a Catalyst for Healthier Lifestyles

Jane Ellery, PhD and Peter Ellery, PhD

KEY POINTS

- Diverse disciplines contribute to a theoretical foundation that supports a community-engaged change process to enhance health and wellness.
- A shift from pathogenic thinking to salutogenic thinking opens up new opportunities for meaningful change.
- Placemaking is a place-led, person-centered approach to community development, and it can have a positive impact on lifestyle, wellness, and healthy decision-making.
- Involving those who are to benefit from services in the development and delivery of those services has the best chance of resulting in coherent, sustainable change.

114.1 INTRODUCTION

Communities across the United States are beginning to embrace an economic development strategy that focuses on creating great places for people to live and work.[1–3] "If tax breaks were the old recipe for economic development, creating vibrant neighborhoods that can attract people from near and far is the new one".[1] This change represents a seismic shift in economic growth and development. It also offers the medical community an excellent opportunity to expand health and healthcare delivery options beyond the prevention, management, and treatment of disease models often used today. Lifestyle medicine's focus on addressing the underlying lifestyle causes of a disease, and not just the signs and symptoms of it, epitomizes a step in this direction. According to the American College of Lifestyle Medicine:

> Lifestyle Medicine is the therapeutic use of evidence-based lifestyle interventions to treat and prevent lifestyle related diseases in a clinical setting. This approach empowers individuals with the knowledge and life skills to make effective behavior changes that address the underlying causes of disease.[4]

Unfortunately, even when individuals have the knowledge and skills needed to make healthier choices, their environments often prevent them from following through on those behaviors, making healthier lifestyles difficult to sustain. By forming meaningful relationships between medical professionals and the numerous organizations that work to promote economic development and community revitalization, communities can be reimagined and redesigned to promote health rather than detract from it. If the goal is to have a healthy citizenry, then involving members of the community in the creation of healthy places makes it easier for medical professionals to encourage active, vibrant lives for those in their care.

So where do we start as we rethink our approach to improving health and wellness in communities? The purpose of this chapter is to explore the idea that health and wellness can be impacted by something as simple as where you live and how involved you are in your community. To do this, we will:

- Discuss theoretical connections between place, health, and engagement
- Briefly examine sense of coherence (SOC) and generalized resistance resources (GRR)
- Identify opportunities for physicians to co-produce healthy lifestyle changes with their patients

After reading this chapter, you should have a better understanding of the value that comes from expanding beyond the pathogenic, disease-mitigating perspective of health that is too pervasive among medical and health professionals. Incorporating the salutary factors that encourage health and prosperity, especially when strategizing around community-level interventions, provides new opportunities for impacting community health and wellness through placemaking and community development. These place-led, person-centered, salutogenic initiatives transition the focus of our thinking from how to keep individuals from getting sick to bringing people together and shaping the environment so that it promotes a good life that is lived in a safe and nurturing way.

114.2 DETERMINANTS OF HEALTH, SENSE OF COHERENCE, AND CO-PRODUCTION

The lifestyle medicine movement encourages physicians to prioritize lifestyle changes over medical interventions when working with patients.[5] This approach is well matched with efforts in public health and health promotion that are centered around the determinants of health. Community-level

DOI: 10.1201/9781003227793-133

FIGURE 114.1 Healthy People 2030 Social Determinants of Health.

initiatives that focus on systems and environmental changes are being deployed across the country to make the healthiest choices the easiest choices.

According to the World Health Organization (WHO), determinants of health can include the social and economic environment, the physical environment, and a person's individual characteristics and behaviors. WHO notes that the "context of people's lives determine their health, and so blaming individuals for having poor health or crediting them for good health is inappropriate. Individuals are unlikely to be able to directly control many of the determinants of health".[6] Based on a US population, Healthy People 2030 further defines social determinants of health as "the conditions in the environment where people are born, live, work, play, worship, and age that affect a wide range of health functioning, and quality-of-life outcomes and risks". They identify five domains (see Figure 114.1) including economic stability, education access and quality, healthcare access and quality, neighborhood and built environment, and social and community context.[7]

Enhanced healthcare access and quality will continue to be the primary focus of the medical community. At the same time, advocating to expand efforts beyond those specific to disease prevention and risk reduction to also focus on determinants of health is a valuable step forward for lifestyle management professionals. Additional opportunities for meaningful change emerge when practitioners also consider health within the context of an individual's overall life, and a salutogenic orientation facilitates movement from a pathogenic, disease-focus to a salutary, life-enhancing approach.[8,9] Interestingly, as part of his salutogenic thinking, Antonovsky regularly expressed concern that those who have adopted the concept of lifestyle change too often focus solely on risk factors for diseases like smoking, lack of exercise, poor nutrition, unsafe sex, and exposure to injury. While these are important areas to address, this myopic focus keeps intervention strategies squarely within the context of a pathogenic orientation.[8] In contrast, Antonovsky encourages us to focus on engaging in life experiences that help create consistency, load balance, and participation in decision-making.[10,11]

114.3 A SENSE OF COHERENCE AND GENERALIZED RESISTANCE RESOURCES

Just as pathogenesis looks at the origins of disease, salutogenesis explores and promotes the origins of good health and prosperity for individuals. In Latin, the root *salus* represents safety, salvation, and welfare.[12] Antonovsky developed a central construct for salutogenesis that he termed *sense of coherence* (SOC). SOC is determined by the degree to which individuals perceive their lives to be meaningful, manageable, and comprehensible. In a salutogenic context, Antonovsky defines meaningful as the extent to which individuals feel that life makes sense emotionally and that the problems and demands of life are both welcome and worthy of commitment and engagement. Manageable refers to the extent to which individuals perceive that resources are both available and adequate to meet the demands being placed on them by

the environment. Comprehensible is viewed as the extent to which individuals are able to make cognitive sense of the information that they are exposed to within a specific context or environment and the degree to which that information conforms with their worldview.[10]

In addition to SOC, Antonovsky constructed the concept of *generalized resistance resources* (GRRs). GRRs afford individuals the capacity to deal with stressors and situations that can impair health and that represent "phenomena that provide one with sets of life experiences characterized by consistency, participation in shaping outcomes, and an underload-overload balance".[10] Overall, GRRs refer to the characteristics of a person, a group, or a community that facilitate an individual's ability to cope effectively with life's stressors. They can be personal as well as environmental, and both material and non-material in nature. Examples include knowledge and intelligence, individual genetic traits, social support networks and personal ties, cultural stability, and money. GRRs provide an individual with the attributes needed to comprehend, manage, and find meaningfulness in life. In contrast, the absence of GRRs, also referred to as *generalized resistance deficits* (GRDs), can lead to chronic or endemic strain that can negatively impact an individual's health.[10,13–16]

While individuals may have access to the resources available within a specific context, and the ability to use those resources, they also need to be able to draw on GRRs that help them navigate the decision-making processes they encounter each day. This suggests that the availability of adequate resources is essential to moderating the stresses and strains of daily life. Unfortunately, a substantial portion of our society lives in areas that have limited access to the resources they need and few opportunities to develop personal resources of their own. This makes achieving a strong SOC difficult and may lead to the adoption of suboptimal health behaviors. This conceptualization supports the data analytics that identify zip codes as useful predictors of health and longevity[17] and highlights the need for developing both personal and community resources.

114.4 CO-PRODUCING HEALTHY CHANGE

In our quest to live healthier lives, having a strong SOC is an important step. Additionally, people benefit from experiencing a sense of involvement where they feel engaged and valued. While Antonovsky's research highlights the benefit of individual participation in decision-making processes, the importance of involvement is further enhanced when the life's work of political scientist and Nobel laureate, Elinor Ostrom, PhD, is considered. Ostrom explored the co-production of services while examining the polycentric governance of resources that many individuals share and use in different ways (often referred to as the Commons).[18] Co-production describes a relationship where professionals and citizens share power and work together to deliver public services.[19] This concept emerged in the late 1970s to counter the predominant theories of the time that recommended massive centralization, and it continues to receive periodic attention when working to identify opportunities for community-level change.[20] Co-production involves individuals who are impacted by public services in the development and delivery of those services, lending support to the construct of involvement/engagement.

The association between health, engagement, and community is also apparent in the conceptualization of *high-level wellness* offered by Halbert Dunn, MD, PhD, in the 1960s. While working as Chief of the National Office of Vital Statistics, Dunn encouraged medical and public

health practitioners to explore the factors responsible for good health instead of focusing solely on disease and disability. Dunn's recommendation for a new way of thinking about health was "rooted in the changing demographic, social, economic, and political character of civilization".[21] The four factors that he identified as contributing to this need are highlighted in Table 114.1.

When considered collectively, the works of Antonovsky, Ostrom, and Dunn offer an interesting perspective. Although originating from different disciplines, their theoretical underpinnings provide support for new ways of thinking about health and wellness that are finally reaching

TABLE 114.1

Dunn's Four Factors Contributing to the Need for a New Way of Thinking about Health

1. *It is a shrinking world*. Communication time has shrunk to the vanishing point. Knowledge of events can span the world in seconds and can be known to the masses in a matter of hours. Travel time from the farthermost reaches of the earth has diminished from years and months to a matter of days and hours.
2. *It is a crowded world*. Turned loose in an all-out assault upon disease and death, the medical and health sciences have brought about generally falling death rates without a corresponding reduction in birth rates. The consequent "epidemic" of population growth has reached towering proportions in many parts of the world and brings with it new health problems arising from population pressures and the scarcities of materials and living space.
3. *It is an older world, in terms of its people, productivity, and resources*. A consequence of the revolution brought about by the health sciences is that relatively more people live to an older age. The per capita demand for the output of the economic and productive machinery is steadily advancing. Consequently, it is probably a fallacy for us to assume, as so many of us have done, that an expansion in scientific knowledge can indefinitely counterbalance the rapidly dwindling natural resources of the globe.
4. *It is a world of mounting tensions*. The tempo of modern life and its demands on the human being and his society are steadily increasing with no corresponding readjustment and strengthening of the inner man and the fabric of his social organizations.

Goal 1. End poverty in all its forms everywhere
Goal 2. End hunger, achieve food security and improved nutrition and promote sustainable agriculture
Goal 3. Ensure healthy lives and promote well-being for all at all ages
Goal 4. Ensure inclusive and equitable quality education and promote lifelong learning opportunities for all
Goal 5. Achieve gender equality and empower all women and girls
Goal 6. Ensure availability and sustainable management of water and sanitation for all
Goal 7. Ensure access to affordable, reliable, sustainable and modern energy for all
Goal 8. Promote sustained, inclusive and sustainable economic growth, full and productive employment and decent work for all
Goal 9. Build resilient infrastructure, promote inclusive and sustainable industrialization and foster innovation
Goal 10. Reduce inequality within and among countries
Goal 11. Make cities and human settlements inclusive, safe, resilient and sustainable
Goal 12. Ensure sustainable consumption and production patterns
Goal 13. Take urgent action to combat climate change and its impacts
Goal 14. Conserve and sustainably use the oceans, seas and marine resources for sustainable development
Goal 15. Protect, restore and promote sustainable use of terrestrial ecosystems, sustainably manage forests, combat desertification, and halt and reverse land degradation and halt biodiversity loss
Goal 16. Promote peaceful and inclusive societies for sustainable development, provide access to justice for all and build effective, accountable and inclusive institutions at all levels
Goal 17. Strengthen the means of implementation and revitalize the Global Partnership for Sustainable Development

FIGURE 114.2 Sustainable Development Goals, United Nations (source: United Nations; seewww.un.org/sustainabledevelopment/wp-content/uploads/2019/01/SDG_Guidelines_January_2019.pdf for guidelines for use).

the forefront of intervention strategies.[22] Henry Ford has been quoted as saying: *Coming together is the beginning. Keeping together is progress. Working together is success.* As we consider opportunities for future change consistent with the theoretical foundation presented in this section, coming together, keeping together, and working together become key to identifying successful interventions.

114.5 TAKING ACTION

Changes that combine a salutogenic focus with community involvement and co-production models can be initiated by physicians, mayors, urban planners, and many others in communities across the country and throughout the world. Ideally, diverse disciplines will come together to help

realize this change, because it will take everyone working together to create an environment where the healthiest choice is also the easiest and most accessible option. Opportunities for meaningful, community-level change can come in many forms. The shared vision and needs presented in the United Nations' Sustainable Development Goals (Figure 114.2) provide a springboard for thinking about community-level change opportunities.[23] These 17 goals were adopted by world leaders in September 2015 and provide a unique call to action for all countries interested in working to promote prosperity while protecting the planet. They recognize the value of building economic growth while addressing social needs, climate change, and environmental protection.[23]

The connection between Goal 3, *ensure healthy lives and promote well-being for all*, and lifestyle medicine practice is easy to envision. Building on a salutogenic, co-production orientation, ending poverty (Goal 1), achieving food security (Goal 2), providing quality education (Goal 4), empowering women and girls (Goal 5), promoting decent work for all (Goal 8), and reducing inequities (Goal 10) all work to decrease GRDs and enhance GRRs. Built environments can be restructured to ensure that the healthiest choices are also the easiest choices through managing water and sanitation (Goal 6), accessing modern and clean energy (Goal 7), building a resilient infrastructure and fostering innovation (Goal 9), and making human settlements inclusive, safe, resilient, and sustainable (Goal 11). The remaining six goals are equally important because they foster sustainable, natural environments, and global connectedness.

Communities can positively impact individual health and community wellness by adopting change strategies that are engineered to intentionally enhance GRRs and nudge people toward healthier decisions using globally identified improvement goals. This approach can also enhance SOC by helping everyone involved understand how what they are working toward fits within the bigger picture of what is happening in the world around them.

Involving citizens in the change processes is also important to address when working toward co-producing change. Placemaking refers to a collaborative approach to planning, designing, and managing public spaces, and it inspires people to collectively reimagine and reinvent public spaces.[24] Embodying Ostrom's views related to governing the commons, placemaking involves the people living in the community in the process of maximizing the shared value of public spaces. With a focus on designing communities around how people experience public spaces and not just thinking about transportation, buildings, and open space, placemaking "facilitates creative patterns of use, paying particular attention to the physical, cultural, and social identities that define a place and support its ongoing evolution".[24] Placemakers approach community change by facilitating activities that involve individuals in the community and that encourage open conversations about the use of public and open spaces. These activities contribute to an understanding of the needs and aspirations that the people living and working in a community have for both specific spaces and for their community as a whole. The emotional connection that develops between everyday citizens and the places that they share encourages them to take ownership of the public spaces and contribute to the continuous development and activation of these places.[22,25–27]

The importance of thinking globally but acting locally comes into view. While we can learn a lot from others throughout the world, individuals can only make healthier decisions when local conditions support healthier actions. Involving those who are to benefit from services in the development and delivery of those services through placemaking and other participatory approaches has the best chance of resulting in coherent, sustainable change.

114.6 SUMMARY AND CLINICAL APPLICATIONS

As physicians embrace a salutogenic orientation within the context of community to encourage more positive behaviors among their patients, unique opportunities for developing and providing resources that lead individuals toward healthier decision-making will emerge. Based on the foundational thinking presented in this chapter, Table 114.2 represents five strategies that physicians and other lifestyle management professionals could consider as they work to nudge their patients toward happier, healthier lives.

TABLE 114.2
Lifestyle Management Strategies for Physicians

1. Learn about the community and the offerings available to your patients so you can connect individuals with meaningful opportunities for change and the resources they will need to help them grow and develop.
2. Collaborate with local agencies (including community planners, public health practitioners, corporations, social service agencies, and local non-profit groups, to name a few) to ensure that necessary resources that are not currently available in the community are strategically developed, deployed, and accessible.
3. Look beyond standard lifestyle factors like smoking, nutrition, exercise, and injury prevention to also include housing and safety conditions, neighborhood design, resource availability, and community cohesion.
4. Listen carefully to your patients so you gain insight into the context of their life situations and include them in the development of care plans.
5. Work with your patients to co-produce individualized lifestyle plans that bring their current internal resources together with available community resources to create the best opportunities for success.

When it comes to our communities, we often find ourselves living in places that limit our ability to act in ways that support healthy living. By recognizing that where you live impacts your health and wellness, community change efforts have now emerged as an important intervention strategy. Working together, physicians, planners and developers, employer groups, and even citizens themselves can be involved in the creation of great places for people to live, learn, work, and play. This will take new ways of thinking and doing for physicians, but lifestyle medicine will be a key leader in this change effort.

115 International Health and Lifestyle

Wayne N. Burton, MD, FACP, FACOEM

KEY POINTS

- Non-communicable diseases (NCD) are a global issue accounting for about 71% of all deaths around the world.
- Over 80% of all premature NCD deaths globally are the result of cardiovascular diseases, cancers, respiratory diseases, and diabetes mellitus.
- The modifiable health risk factors for NCDs globally include tobacco smoking, excessive sodium intake, alcohol misuse, and physical inactivity.
- WHO predicts depression will be the top cause of worker disability lost time globally by the year 2030.

115.1 OVERVIEW

Health and well-being is a global issue for countries, multi-national employers, and other stakeholders who are focusing on the health and productivity/performance of their populations. Communicable as well as non-communicable diseases vary in prevalence and importance from country to country. Communicable diseases include a wide range of bacterial, viral, fungal, and protozoan infections. For example, the reported number of COVID-19 global pandemic deaths between January 1, 2020, and December 31, 2021, was almost six million. However, the actual number of COVID-19 deaths has been estimated to be from 18.2 million to over 20 million.[1,2] The pandemic has been associated with a decline in global life expectancy for the first time since 1950, by 0.92 years between 2019 and 2020 and by another 0.72 years between 2020 and 2021.[3]

This section will focus on non-communicable diseases (NCDs), which are chronic diseases resulting from a combination of genetic, physiological, environmental, and behavioral factors including cardiovascular diseases, cancer, chronic respiratory diseases, and diabetes among others. NCDs result in the death of 40 million people around the world each year and account for about 70% of all deaths. The cumulative economic impact to the global economy is estimated to be $30 trillion by the year 2030 according to an analysis by the World Economic Forum and the Harvard School of Public Health. NCDs like heart disease can develop in emerging market countries in much younger populations. For example, in India, people aged 25–35 years old have nearly five times the prevalence of heart disease compared with American workers of the same age. American workers tend to develop heart disease in their 40s, 50s, and 60s. The United Nations (UN) has adopted 17 global goals for sustainable development. The good health and well-being goal is to reduce premature mortality from non-communicable diseases by one-third by 2030.[4]

Four medical disorders (see Table 115.1) account for 71% of all premature NCD deaths globally and about 85% of these deaths occur in low- and middle-income countries.[5]

Fifteen million global non-communicable disease deaths (Table 115.2) occur in relatively young adults, ages 30 to 69 years old. The risk factors for these medical conditions include poor diets, physical inactivity, high blood pressure, elevated blood glucose, abnormal blood lipids, and obesity. Cardiovascular disease in large part is attributable to metabolic risk factors (e.g., cholesterol, blood pressure, overweight/ obesity, blood glucose) and is the leading cause of premature NCDs. Cancer accounted for 23.6 million new cancer cases, 10 million deaths, and 250 million disability-adjusted life years (DALYs) in 2019 in 204 countries.[6] In 2019, cancer was second to cardiovascular disease-related DALYs but the leading cause of death.

The United Nations and The World Health Organization announced a goal of a 25% reduction in NCD mortality by 2025 among persons ages 30 to 70 years old.[7]

TABLE 115.1
Global Deaths Associated with Chronic Diseases

Disorder	Global Deaths Annually
Cardiovascular diseases (heart attacks, stroke, etc.)	17.9 million
Cancers	9.3 million
Respiratory diseases (chronic obstructive pulmonary disease, asthma, etc.)	4.1 million
Diabetes	1.5 million

TABLE 115.2
Global Deaths Associated with Health Risks

Health Risk	Global Deaths Annually
Smoking and secondhand smoke	7.2 million
Excess salt/sodium intake	4.1 million
Alcohol misuse	3.3 million
Physical inactivity	1.6 million

DOI: 10.1201/9781003227793-134

- Fifty percent of at-risk people receive drug therapy and counseling to prevent heart attacks and strokes.
- Eighty percent availability of affordable technologies and medications to treat major NCDs.

Despite this continuing dramatic global shift from communicable diseases to non-communicable diseases, especially in lower-income countries, the healthcare systems in poor countries are not prepared for these new challenges.[8,9]

Because people in lower-income countries do not generally have access to preventive and primary care, diseases like vaccine-preventable cervical cancer, complications from diabetes, and hypertension are more likely to develop. Such diseases will result in avoidable morbidity and mortality, especially in the working-age populations.

115.2 HEALTH RISK FACTORS MEASURED GLOBALLY

The Organization for Economic Cooperation and Development (OECD) includes 34 member democratic countries that report comparable data on key indicators of health. Key health risk factors they report include the percentage of the adult population that are smokers, alcohol consumption, overweight/ obesity, and air pollution-associated deaths. Most countries do not report desirable results for one or more of these health risks.[10] Air pollution may cause six to nine million premature deaths worldwide annually by 2060. Outdoor air pollution contributes to the morbidity and mortality of non-communicable diseases.

115.3 MENTAL HEALTH/ ADDICTIVE DISORDERS

Mental health and addictive disorders are common, affecting more than one billion people globally, and represent 19% of all years lived with disability and an estimated 7.4% of the world's measurable burden of disease.[11,12] The World Health Organization (WHO) predicts depression will be the top cause of worker disability globally by the year 2030.[13] Mental health disorders have a peak onset of incidence in the working-age population and therefore have a significant impact on individual's productivity during the peak of a person's career. They are often underdiagnosed and undertreated, resulting in potentially avoidable medical costs, absenteeism, disability, and lost on-the-job productivity (presenteeism). The financial investment in mental health treatment services has been lagging globally.

The WHO European Ministerial Conference on Mental Health was held in 2005 and endorsed the statement "No health without mental health", which emphasized the important linkage between physical and behavioral health.[14]

Internationally, as in the United States, there is an insufficient number of quality mental health providers. The lack of mental health providers is a major barrier to providing adequate behavioral health services in low- and middle-income countries. For example, more than 75% of persons with serious mental illness in less-developed countries do not receive adequate mental health treatment.[14] Appropriate treatment is compounded by the lack of mental health medications in many countries and the cost of these drugs may be prohibitively expensive to much of the population.[15]

115.4 ALCOHOL

Alcohol use disorder (AUD) was the seventh leading risk factor for both deaths and DALYs in 2016. It has been associated with deaths due to infectious diseases, intentional and unintentional injuries, digestive disorders, cancer, and other non-communicable diseases.[16] In the past, light to moderate intake of alcohol was thought to be associated with a lower risk of cardiovascular disease compared with either abstinence or heavy drinking. However, research now indicates that any amount of alcohol use on a regular basis is associated with an increased risk of cardiovascular disease, including hypertension, coronary artery disease, myocardial infarction, stroke, heart failure, and atrial fibrillation.[17,18]

115.5 TOBACCO

Smoking is the single most important avoidable health risk factor in OECD countries and globally. Almost 170 countries signed a tobacco control treaty adopted in 2003 by the WHO. The prevalence of smokers in a population varies from country to country Approximately six million people die globally each year related to smoking including five million from the direct effects of tobacco and over 600,000 who were exposed to secondhand smoke.[19] Smoking is a major risk factor for the development of cardiovascular diseases and several types of cancers. In addition, smoking is a major risk factor for developing respiratory diseases such as chronic obstructive pulmonary disease (COPD).[20] Smoking during pregnancy is associated with the development of low-birth-weight babies.

Many governments, employers, and other organizations offer smoking cessation programs in many countries. Several governments as well as employers prohibit smoking in the workplace because of the health hazards to others from passive inhalation of tobacco smoke. Medications that support smoking cessation are also available but may be cost-prohibitive to people in low- and moderate-income countries.

115.6 OBESITY

Overweight and obesity is known to be a risk factor for numerous health conditions including hypertension, high cholesterol, diabetes, cardiovascular diseases, respiratory conditions, musculoskeletal diseases, and several cancers.[21] The most commonly used measure of overweight and obesity is body mass index (BMI). BMI is defined as an

individual's weight in kilograms divided by their height in meters squared. Overweight is defined as a BMI of 25.0 to 29.9 and obesity as a BMI of 30 and over.[21] This classification may not be appropriate for all ethnic groups who may be at increased risk at lower or higher BMIs. For example, the Asian population is considered by the WHO to have an ideal BMI of less than 23. The prevalence of overweight/obesity in several countries is summarized in Table 115.3. Researchers reported that in 2015, a high BMI contributed to four million deaths and 120 DALYs lost globally.[22]

Governments and employers in many countries are beginning to address the epidemic of obesity through education and other initiatives. Employer initiatives have included offering healthier food choices in workplace cafeterias and vending machines, workplace-based weight loss programs, and even medications that assist in weight loss as part of a comprehensive approach to weight loss. Governments such as Mexico and India have instituted taxation on sugar-sweetened beverages (SSBs) to help lower the incidence of obesity and type 2 diabetes, while others have mandated the display of food calorie counts in restaurants and the construction of walking and bicycle paths to promote physical activity.

115.7 PHYSICAL ACTIVITY

There is now overwhelming evidence on the benefits of regular physical activity including its positive effects on health and well-being.[23] It is now considered the fourth leading risk factor for global mortality. Both the WHO and the US CDC recommend adults aged 18–64 years old do at least 150 minutes of moderate-intensity aerobic physical activity per week or at least 75 minutes of vigorous-intensity aerobic physical activity per week or a combination of the two.[24] Additional benefits may be gained from 300 minutes per week of moderate physical activity, 150 minutes of vigorous physical activity, or a combination of both. The WHO has also recommended reducing sedentary behavior, although they provide no specific guidelines. Any amount of physical activity can be beneficial, and it is important in achieving physical and duration activity goals. However, only about one in five Americans meet the Centers for Disease Control and Prevention physical activity guidelines.[25] Physical activity has been associated with:

- Decreased all cause-mortality,[3] CVD, high blood pressure, stroke, type 2 diabetes, metabolic syndrome, colon and breast cancer, and depression.
- Less risk of hip or vertebral fracture.
- Heathier body mass index.

Physical activity, both recreational and non-recreational, has been associated with a lower risk of mortality and CVD events for people in low-, middle-, and high-income countries. However, more workers are performing primarily sedentary jobs, which has been associated with increased mortality and morbidity.

Several interventions have been used to promote physical activity by governments and in the workplace, including:

- Urban planning to include walking, cycling, and other forms of physical activity which are accessible and safe.
- Facilitating active transportation to work (e.g., walking and cycling). In many US cities, Mexico City, and others, rental bicycles are available for transportation.
- Including bike and walking paths on employer office campuses.
- Worksite fitness centers are available to employees in various countries at little or no cost.
- Coaching employees on developing a physical activity program.
- Employee activity competitions with incentives that might include pedometers to measure steps taken per day. A common goal is 10,000 steps per day.

115.8 COUNTRY-SPECIFIC HEALTH AND WELL-BEING PROGRAMS

There are a number of organizations that offer resources for organizations that develop health and well-being programs tailored to the needs of a particular country. They include

TABLE 115.3
Health Risk Factor Prevalence in Selected OECD Countries[10]

Country	Smoking (percent smoking daily)	Overweight/Obese (BMI 25 and over)	Alcohol Consumption (liters/capita)	Deaths per 100,000 Population (outdoor air pollution)
Canada	10.3%	59.8%	8.0	10
US	10.9%	73.1%	8.9	15
UK	15.8%	64.2%	9.7	21
France	24.0%	49.0%	11.4	20
Israel	16.4%	50.9%	3.1	27
Japan	16.7%	27.2%	7.1	31
Poland	17.1%	56.7%	11	73
All OECD countries	16.5%	56.4%	8.7	29

TABLE 115.4
Responsibilities of Stakeholders

Stakeholder	Prevention	Detection	Treatment
Government/employers	Anti-tobacco policy Reduction in salt intake Food labeling High-sugar beverages Promotion of physical activity Alcoholic beverages	Awareness of NCDs, signs and symptoms, early detection	Access to affordable medications
Clinicians	Education of patients on health risk factor reduction (e.g., smoking cessation)	Screening and detection of health risk factors	Evidenced-based treatment of health risk factors and NCDs
Health care system	Detection and treatment of NCDs (e.g., blood pressure and blood sugar control)	Screening and detection of health risk factors	Evidenced-based treatment of health risk factors and NCDs

ministries of health, health education and advocacy organizations, the WHO, OECD, and employer wellness councils/organizations among a growing list of others.

Data is important to determine the major health risks and medical conditions for a particular country and for an organization to determine, plan, and evaluate the effectiveness of country-specific interventions. The types of data that are available vary greatly from country to country. Population health data may include biometric risk factors (blood pressure, body mass index, glucose), vaccination rates (influenza, hepatitis, childhood immunizations, etc.), the prevalence of chronic diseases (diabetes, depression, asthma, cancer, high blood pressure, heart disease, etc.), and the prevalence of lifestyle health risk factors (alcohol misuse, overweight / obesity, physical inactivity, stress, etc.)

115.9 APPROACH TO PREVENTION AND CONTROL STRATEGIES

There are three components to comprehensive effective strategies for the prevention and control of NCDs in countries including:

- Cultural, which encourages people to make and maintain healthier choices.
- Health literacy to educate people on how to improve their health.
- Healthcare, which focuses on early detection and the management of health risk factors and NCDs.

Table 115.4 summarizes the responsibilities of various stakeholders in addressing NCDs.

115.10 CONCLUSIONS

All countries are now interdependent in the growing global economy. With the ease of global travel, there are constant threats of communicable diseases such as has occurred in recent years with SARS-COVID-2, Ebola, Zika, drug-resistant tuberculosis, human immunodeficiency virus (HIV/AIDS), and a long list of others. However, the increasing prevalence of NCDs is negatively affecting the health and productivity of country populations and the global economy.[26]

It is important for international healthcare providers and countries to place a higher priority on health promotion and disease prevention in order to reduce modifiable health risk factors that lead to NCDs and mortality. Many countries including the United States and Mexico have made remarkable progress over the past few decades in reducing smoking. However, these same countries have relatively high rates of overweight and obesity, which continue to increase at an alarming rate.

It is essential that healthcare providers, governments, employers, and others implement evidence-based interventions to address the worldwide epidemic of NCDs for the global economy to prosper. Global- and country-specific actions will be needed to achieve the WHO goal of a 25% reduction in the rate of premature death from NCDs.

CLINICAL APPLICATIONS

- Health risk factor targets for blood pressure, cholesterol, blood glucose, and body mass index may vary by country from the generally accepted targets in the United States.
- While risk factor screenings are generally covered by private and government-sponsored health insurance in the United States, such coverage varies significantly internationally.

116 Future Directions of Health Promotion: The Role of the Physician

Alyssa B. Schultz, PhD

KEY POINTS

- Health can be defined as a complete state of physical, mental, and social well-being, and not merely the absence of disease or infirmity; moving the population to thriving, healthy, high-performing, and sustainable outcomes requires earlier and consistent interventions.
- Health promotion professionals, including physicians, must understand the environments in which patients live and work and what connections are needed between the clinical system and changes that are easily supported by communities.
- Health promotion can utilize technological innovations in wearable technology, communication portals, and other tools to more easily support and encourage healthy lifestyles.

116.1 INTRODUCTION

Wellness is defined by the Oxford English Dictionary as "the state of being in good health, especially as an actively pursued goal", and its usage has gone from approximately zero in 1950 to a word used every day in a multitude of ways by 2022. Internet search queries for "wellness" increased 20% year over year from 2018 to 2020[1] and interest in health promotion continues to grow today. The Global Wellness Institute estimated that worldwide spending on wellness in 2020 was $4.4 trillion, including categories as diverse as physical activity, personal care and beauty, wellness tourism, healthy eating, public health, prevention, complementary medicine, personalized medicine, and more.[2]

Health promotion programs, activities, and environments aimed at improving wellness occur in many settings today.[3] Each person may exist in several overlapping settings—home, community, workplace, and physician's office—and individuals may receive different messages in each of these settings. In the workplace, the health promotion message and expected outcomes have traditionally focused on behavior change and the positive impact of healthy lifestyles on healthcare and disability costs, time away from work, and job performance. On the other hand, community and physician-provided health promotion messages may focus on improving healthy behaviors in order to prevent morbidity or mortality or prescribing medicine to combat a wide range of health conditions.

Health and wellness are influenced by contextual and environmental factors, which is why a multi-site approach to health promotion encourages interventions and wellness messaging across the social, cultural, and physical places in which people live, work, and play. This approach has been popularized and applied to health-promoting schools, cities, workplaces, and even islands. What logically follows this approach is a range of actions intended to address the physical, social, organizational, and cultural factors influencing health in any given environment.

Settings such as the workplace or physician's office are more than just convenient locations for reaching target groups; they are also social systems that can support health and provide avenues for changing societies, not just individuals. The types of outcomes expected from working in this way include changes in environments, policy, skills, and organizational processes, as well as changes related to specific health problems. This approach to health promotion and wellness does not preclude a focus on specific health issues. Such an integrated approach ensures greater coordination in negotiating with stakeholders and compiling resource materials and may reduce duplication of effort and competition between programs.[4]

116.2 WELLNESS REAL ESTATE

One area of health promotion that is growing in popularity is wellness real estate. These are planned homes and communities designed to support healthy lifestyles. The COVID-19 pandemic sparked a trend for people to work from home more than ever, allowing them to choose a place to live that is independent of their worksite. This trend also triggered more interest in wellness real estate, which seeks to blend home, work, wellness, and a focus on nature. These wellness developments include new technology and building designs to create "well" environments. Examples include places that put mental and spiritual health at their center such as Gravity in Columbus, OH, communities centered on farms such as Agrihood in Santa Clara, CA, and multi-generational age-in-place communities such as Cantina near Austin, TX. It is easy to see how lifestyle medicine physicians can integrate into these communities

DOI: 10.1201/9781003227793-135

to support the health-promoting lifestyles their residents are seeking.

116.3 TOOLS

Technology innovation occurs in all areas of life and health promotion is no exception. Wearable technology designed to inform and promote health is commonplace today. Patient portals are another advancement that allows patients and care providers to aggregate information such as test results, prescriptions, and messaging in one place and ease collaboration among providers while giving patients direct access to their health and wellness metrics. Other devices such as wireless blood glucose meters and smart pillboxes continue to improve patients' abilities to manage their own health. Electronic medical records (EMR) can play a key role in helping physicians address health promotion among their patients. EMRs can prompt certain information about family history or suggest a measurement of exercise as one of the vital signs.

116.4 BEHAVIOR CHANGE

A core principle in health promotion is making the healthy choice the easy choice. Putting this motto into practice requires removing barriers that individuals face when trying to live a healthy lifestyle. This requires that physicians really get to know their patients; looking closely at exercise levels and home life or environmental factors that cause strain and identifying sources of problems rather than just the problems themselves. One challenge to health promotion in any setting is that the ability to achieve health behavior improvement is dependent on an individual's willingness to implement change consistently.

Behavioral design may help people find useful tools and tactics for making healthy lifestyle changes. It also helps determine how able and ready a person is to make a change and what triggers are most likely to instigate that change. If patients are resistant to change, physicians can enlist the expertise of others by looking at what the community can offer. There may be diet- and exercise-tracking apps, free nutritional and wellness counseling, cooking classes, sports clubs, and even community or church groups that could help patients make positive lifestyle changes once they leave the physician's office.

Work in the field of behavioral economics has led to a better understanding of the role of emotions and intuitions in shaping decision-making. While intuition and emotions can serve important functions, they can also bias decisions in several important ways. Insights from the field of behavioral economics have relevance for the future of health promotion. By understanding the social, cognitive, and emotional influences on decision-making and behavior, it will be possible to develop more effective initiatives and approaches. In the future, physicians need a way of understanding how to measure environmental determinants and how to speak to patients about them. The health promotion field must find a way to effectively relate to each patient individually to ascertain how they can fit healthy habits into their everyday routines, and then identify what changes individuals are willing to make. Then those changes can be simplified to guide patients through monitoring their own actions against an overall goal. Resistance to change is to be expected. Instead of challenging this resistance, respect it and encourage patients to drive toward their own goal-oriented solutions.

116.5 PHYSICIANS' FUTURE ROLE IN HEALTH PROMOTION

A major aspect of any health promotion program is the involvement of physicians because they have high credibility on health issues. In a healthy city or community program, physicians can contribute by sitting on advisory boards or networking with community leaders. Outcome measures will continue to focus on health behaviors, risks, and disease prevention but will also expand to include the impact of additional elements such as well-being, emotional health, psychology, and organizational health on the health of individuals and populations.

Tomorrow's physicians, insurance plans, and best practice guidelines have to re-orient their mindset from the traditional treatment of illness and disease to the promotion of good health and wellness, which is much more than the absence of disease. In health promotion, physicians must consider the issues of health behaviors, environment, values, and culture while overcoming barriers such as disease orientation, reimbursement policies, and conflicting recommendations to take a more active role in health promotion.

The importance of integrating health into the environment and culture is one of the most important future trends in health promotion. Some studies indicate that the culture of an organization or population has the potential for a larger impact on the health of an employee population than the health promotion programming offered by that organization.[5–7] The current model of health promotion will continue to evolve with the integration of psychology, organizational health, technology, integrated medicine, and other fields over time.

The American Medical Association (AMA) states that "health promotion should be a collaborative, patient-centered process that promotes trust and recognizes patients' self-directed roles and responsibilities in maintaining health".[8] They also recommend several things that physicians can do to promote health and wellness. These include:

- Staying up to date on evidence-supported preventive care guidelines and encouraging patients to comply with appropriate vaccinations and screenings.
- Educating patients about modifiable health risk factors.
- Dialoguing with patients about circumstances that impact chronic conditions or wellness such as

transportation, work/home environment, and support systems.
- Delegating health promotion activities to other professionals or community resources as needed.[5]

Further guidance from the AMA is for physician groups and medical schools. These include:

- Including health promotion and disease prevention training in medical school, residency, and continuing education.
- Advocating for health and wellness in schools, workplaces, and communities.
- Supporting or contributing to research for disease prevention and health promotion.

To evolve, the field of health promotion must embrace a new set of measures and metrics for success and apply better methods for measuring the impact of initiatives. Although sometimes hotly debated, the more traditional indicator of a program's value has been return on investment (ROI). However, an improved understanding of what works best and for whom is dependent on measures of the overall value of more comprehensive population-level strategies. This will require adopting a thoughtful framework for understanding the environmental and cultural factors that can influence all individuals in a population. It will also require a new set of metrics that help connect the environment and culture and the leading and lagging indicators of the impact on health and well-being.

To carry the field forward, program planners should continuously assess the support for health in their environments and cultures, track both participation and engagement in programs, and measure self-directed behavior change. The value of traditional health risk assessments can be improved by adding measures of positive outlook (e.g., resilience, optimism, perceived control) and by regularly measuring changes in these important precursors to health. Advances in technology make it possible to more frequently monitor and report on these and other important outcomes with minimal burden on the population.

116.6 CONCLUSION

For the medical community to be successful in helping promote health in the population, it is crucial to approach prevention differently. To ultimately produce good health, we must make investments in the personal lives of patients—understanding the environments they live and work in and what connection is needed between the clinical system and changes that are easily supported by communities. We have an opportunity to help the primary care system promote change among individuals, empowering them to restore and maintain healthy lifestyles, and we have tools available to help us guide the necessary conversations to effect change.

CLINICAL APPLICATIONS

- Tomorrow's physicians may have to re-orient their mindset from the traditional treatment of illness and disease to the promotion of good health, which is so much more than just the absence of disease.
- It is important to bridge the gap between the medical model of the physician's office and the individual's experience in the home, workplace, and community.
- Physicians should learn successful methods to assist patients in sustainable behavior change and make use of the latest technologies such as wearables and patient portals to automatically monitor and encourage good health with more consistent communication between providers and patients.

117 "Responders" and "Non-Responders" in Exercise Studies

Victor L. Katch, Professor Emeritus

KEY POINTS

- Humans exhibit large individual variability in response to exercise training. Some experience larger improvements, while others exhibit either no or negative responses.
- Individual responses to exercise training result from a combination of "true" inter-individual differences, intra-individual differences (within-subject biological variability), and measurement error.
- Biological variability is a fact of life and can be ascribed to many factors including genotype, nutritional status, lifestyle habits, and individual history of exercise training.
- The extent to which a non-response to exercise training is true or false, static or changing, probably depends on exercise modality and what metrics are being observed.

117.1 INTRODUCTION

Establishing an effective individual or group program to improve health outcomes is never perfect. Research on the effectiveness of different intervention strategies that include "structured lifestyle interventions" to increase individual and group success is mixed.[1–8]

Most structured interventions include group or individual education meetings, behavior change techniques, self-monitoring, written information, or even telephone and online counseling. Now, there has been a flood of new "wearable" technologies that, when paired with a smartphone, can track, report, and prescribe all sorts of performance and health information metrics as well as provide extrinsic motivation techniques. Each of these interventions is thought to be an effective tool for enhancing outcome measures used to justify program goals and program funding.

Decisions regarding program effectiveness are based on group comparisons using statistical tests of significance. Deciding whether an observed difference between two sets of data should be interpreted as simply a reflection of "sampling error" (null hypothesis) or a "real effect" (alternate hypothesis), statisticians have devised the t-test, the F-test, the Chi-squared test, and so on. The underlying philosophy of these tests is that the established critical magnitude of the t, F, and x^2 that divides statistical significance from non-significance is a value that yields a 5% (or 1%) probability in support of the null hypothesis.[9]

While these probability tests are appropriate when reporting group differences in research journals and may give insights for the development of "best practice" guidelines, they do not explain the wide array of individual responses to different exercise/diet interventions. Researchers often report such variations by reporting standard deviations or standard errors—which is important, of course—but gives little insight into both quantifying and understanding individual variations to specific outcome variables.[10]

117.2 INDIVIDUAL RESPONSES TO EXERCISE ARE VARIABLE

In the exercise area, initial studies exploring the individual response to aerobic training were published in the mid-1980s. In one important study,[11] ten monozygotic twin pairs were recruited to participate in a 20-week endurance training program, with pre- and post-intervention measures of maximal aerobic power (VO_{2max}) and ventilatory aerobic threshold (V_T). Results showed training increased post-training measures by 12% for VO_{2max} and 20% for V_T, but there was considerable variation among subjects. The magnitude of improvements in VO_{2max} ranged from 0 to 41%. Subsequent studies replicated these initial findings.[12,13] In another study from the same group, 720 subjects underwent a 20-week aerobic training program, completing a battery of pre-training and post-training tests.[14] Again, results showed significant individual variation for VO_{2max} expressed in $mL \times kg^{-1} \times min^{-1}$ with some subjects experiencing improvements of over 1000 ml $VO_2 \times min^{-1}$!

Similar results have been reported in resistance training studies[15–18] and studies examining other exercise modalities, such as sprint interval training.[19,20]

It has been shown that about 10% of subjects demonstrate an adverse response to exercise training—i.e., subjects exhibit a post-test change greater than twice the technical error of measurement, in the negative direction. Such findings are problematic—if certain individuals cannot improve—or, even worsen their health or fitness following exercise training, the implication is that for some people, exercise may be ineffective, potentially even increasing their disease risk.

DOI: 10.1201/9781003227793-136

117.3 NON-RESPONDER, RESPONDER, SUPER-RESPONDER

Interestingly, just as some experience adverse effects to an intervention, there are those who respond as expected (responder) and those who might be considered super-responders—those who respond way off the charts. Sometimes an individual is a non-responder to one intervention and a super-responder to another intervention, and it is nearly impossible to predict the outcome. This not only becomes important when reporting research findings but also in the clinical setting where an individual can become disappointed and discouraged with their post-test scores and are labeled a non-responder.

If an individual is truly a non-responder, they should receive urgent attention, particularly with respect to diet and exercise intervention strategies. Researchers need to determine if non-responders would revert to a more positive response if exposed to more individualized intervention strategies.

117.4 TERMINOLOGY IMPORTANT

The term "non-responder" has been employed to describe those who fail to exhibit positive changes following an intervention.[21,22] This term, however, may promote a misleading perception that exercise is not universally beneficial, which goes against the well-established dictum of the positive effects of regular exercise training on reducing obesity risk,[23] enhancing cardiometabolic health, increasing function in the elderly,[24] improving mental health,[25] and reducing the risk of various disease states.[26]

It may entirely be possible that for an individual any observed non-response to exercise training is modality-specific. That is, subjects exhibiting a non-response in one modality may well show a positive in another modality. In other words, improvements and non-responses are not systematic.[20,27,28] That non-response may be modality-specific points to whether or not training responsiveness to any given intervention is a permanent or a temporary phenomenon. If a given intervention were to be repeated using the same population, would the same individuals also classify as non-responders with a different exercise modality? Since exercise intervention studies tend not to be repeated using the same subjects, this issue remains unresolved. Thus, it is not clear whether a non-response or an adverse response to one exercise modality remains static and unchangeable when repeated with another modality.

Therefore, it may be preferable to label individuals exhibiting no measurable improvement in a given variable as those who "did not respond", rather than "non-responders".

117.5 ARE NON-RESPONDERS (DID NOT RESPOND) COMMON?

In most studies, a "did not respond" result is common, particularly in drug intervention studies. Listings of adverse drug reactions that occur are ubiquitous.[29] This is an admission that sometimes during drug testing, someone (or many) individuals experience adverse drug reactions.

The prevalence of adverse responses in exercise studies is not often considered nor well reported, as we all assume that everyone responds to exercise in about the same way, but to different degrees. As research shows, this is not true.

A recent study[30] looked at the prevalence of adverse responses across six well-known and highly cited exercise intervention studies that tested exercise effects on different cardiometabolic risk factors. Adverse responses ranged from 8.3% for exercise training-induced changes in fasting insulin to 13.3% for changes in high-density lipoprotein levels. About 7% of participants experienced adverse changes in two or more biological risk factors consequent to exercise training.

117.6 COMPLEXITIES OF THE NON-RESPONDER PHENOMENA

There are many reasons people do not respond as expected to an intervention. We often blame the individuals for being non-compliant, the most often cited reason for a null response.[31] When non-compliance is ruled out, we look for other explanations like age,[32] disease conditions[33] ethnicity,[34] concomitant medication use,[35] and environmental variables.[36] Also, recent studies reveal a far greater impact of genetics in determining the magnitude of inter- and intra-individual responses to various classes of drugs and different types of exercise and nutrition interventions.[22]

One of the best examples of variable response to an intervention is in clinical weight loss studies. Aside from the growing reliance on drugs, the standard weight-loss prescription primarily includes calorie restriction of some kind, (high carb, low carb, no carb, etc.). Sometimes caloric expenditure (exercise) is included. But either one of these interventions or in combination is only effective for about 5% to 15% of the population.[37] What then can explain the large number of people who fail to respond to the exercise (and diet) intervention? Obesity and overweight is actually a collection of different conditions each with distinct etiologies and a shared spectrum of symptoms reported by individuals. No wonder there is such diversity in responses between, and perhaps, within individuals!

117.7 INTRA-INDIVIDUAL DIFFERENCES (BIOLOGICAL VARIABILITY)

An often-neglected aspect of understanding the phenomenon of non-responders is the little-appreciated fact that most individuals' biological response to an intervention is variable from time to time. In fact, the inherent tendency of an individual to biologically vary is common for all human variables and may in fact constitute the largest source of variability in a data set. Biological variability should not be treated the same as technological error, which can be

controlled to a certain degree. In contrast to technical error, biological variability is not controllable, although it may be increased or decreased under certain conditions (e.g., disease training). Biological fluctuation has theoretical importance in and of itself. It also becomes important, however, when evaluating changes due to an experimental intervention. For example, suppose an individual started a new exercise program to help reduce elevated cholesterol level, from say 300 mg×dl^{-1} to below the recommended 200 mg×dl^{-1} level. Research shows that tested cholesterol of 300 mg×dl^{-1} is really only an estimate of the "real" value. In most experiments of this type, usually, one cholesterol test is taken before and following the intervention. Little mention is ever provided regarding the error range for an individual cholesterol test. Test-retest cholesterol testing reveals a reliability of about r = ≤92 for cholesterol and its subfraction estimates, depending on the lab, techniques, fasting versus non-fasting, and age,[33,38–40] with a standard error of estimate of about ±8%. In other words, the measured cholesterol of 300 mg×dl^{-1} will fluctuate between 276 mg×dl^{-1} and 341 mg×dl^{-1} for any individual. This is termed intra-individual differences, within-subject variability, or biological variability.[41–43]

Biological fluctuations result from many factors related to how the body responds from time to time and day to day. Biological variability for cholesterol, for example, is based on intrinsic factors related to liver synthesis and tissue utilization, as regulated by genetic factors and their interactions with extrinsic factors like time of day, age, gender, time of year, biological set point, type of food in the gut, and even psychological set. For exercise responses, biological variability is probably influenced by the same variable set but would also include variability in the percentage and type of muscles activated for different types of exercise (aerobic versus glycolytic-dependent exercise). Some individuals exhibit greater and some lower levels of biological variability, depending on the variable being measured. Finding the extent of biological variability for any individual requires multiple tests on the individual and the ability to obtain accurate estimates of equipment and other measurement errors. This is seldom done or reported.

Many examples of measuring biological variability have been reported in the literature, but its magnitude and effects on clinical results and the designation of responders and non-responders are often overlooked[44] but need to be considered.

VO_{2max} and other cardiovascular variables[43,45,46] measuring biological variability can have a large impact on study interpretations, often resulting in faulty conclusions, particularly with respect to identifying the presence of non-responders. For example, in one study[46] biological variability for VO_{2max} was estimated to vary within a range of ±5.6%, 68% of the time, and 98% of the time it could vary within a range of ±11.2%, regardless of whether or not there is an experimental treatment effect, as determined by hypothesis testing. This represents a rather large effect, stated in these terms, when compared with the range of VO_{2max} changes reported resulting from physical training.[47] This biological variability could certainly mask the identification of "true" non-responders. The magnitude of biological variability has also been reported for other cardiovascular metrics used to evaluate exercise training effects.

CLINICAL APPLICATIONS

- There are large individual variations in response to exercise training, with some subjects experiencing larger improvements than others while others appear to exhibit either no or a negative response to exercise training.
- Individual responses to exercise training are a combination of "true" inter-individual differences, intra-individual differences (within-subject biological variability), and technical measurement error.
- Biological variability is a fact of life and can be ascribed to many factors including genotype and individual history, among other factors.
- The extent to which a non-response, i.e., non-responder, to exercise training is true or false, static or changing, probably depends on exercise modality and the metrics being analyzed.

118 Health Promotion: History and Emerging Trends

Michael D. Parkinson, MD, MPH, FACPM and
Stephen T. Doyle, MS, MBA, RCEP

KEY POINTS

- Understanding the historical schism between "medicine" and "public health" informs the creation of a new era of integration acknowledging the social determinants of health.
- Multidimensional, integrated models are required to achieve population health objectives.
- Defining the value of wellness, health promotion, and disease management programs requires a shift from narrow medical cost "ROI" to a comprehensive employer and societal "VOI".
- Understanding the transitions from wellness to well-being, health, and productivity.
- The future is now: emerging trends, technologies, and transdisciplinary research offer a promising way forward for impactful population health initiatives.
- Accelerating clinical alignment should embrace the growing science and practice of lifestyle medicine.

118.1 INTRODUCTION: HISTORICAL SCHISMS AND A NEW ERA OF INTEGRATION.

The roots of "health promotion" conceptually derive from the early 20th-century historical schism between *clinical medicine* (treatment of the individual patient) and *public health* (prevention of disease in populations).[1] As defined in the 1979 Report of the Surgeon General, *Healthy People*, health promotion "seeks the development of community and individual measures which can help … [people] to develop lifestyles that can maintain and enhance the state of well-being".[2] The core scientific models of medicine are best represented by Koch's postulates, which define a deterministic, linear proof for an organism to cause disease.[3] Public health has at its core the paradigm of multifactorial interaction described by the epidemiological triad of "agent-host-environment" to understand disease causality.

Similarly, the division between mental and physical health in the 20th century created a philosophical and practice separation of the *mind* (behavioral and psychological health) from the *body* (medical specialties with ever-narrowing fields of expertise). The *epidemiology* of both medical care costs and public health were historically uninformed by the principles and practice of the science of *economics*. Environmental, architectural, policy, and social psychological (how *individuals* impact and are impacted by *groups*) influences were similarly disconnected from an integrated framework that could explain why individuals and populations behave as they do (or do not) with respect to health, care, costs, performance, and productivity. Emerging science now provides new insights and integrated models can define systematic approaches and best practices to improve "population health".

118.2 INTEGRATED MODELS OF POPULATION HEALTH

The goal of having the longest life possible without suffering premature death, disease, or disability has been termed the "compression of morbidity".[4] It is a useful and compelling epidemiological construct that is understood broadly and sought by individuals and organizations who strive for a healthy and productive life. Both international and US population-based studies and models acknowledge the primary contributory role of social determinants of health which traditionally were inadequately addressed in early health promotion programs whether they be sponsored by private (employer) or public (health agency) entities.[5–8] The Robert Wood Johnson Foundation multiyear effort said it succinctly and best, "how long and well we live is determined by where and how we live, learn, work and play".[9] Early health promotion programs emphasized an individually focused, behavioral, and biometric risk-based approach that was often delivered largely out of context from the community, employer, or organizational culture and determinants of health. As the appreciation of the multifactorial causes of healthy and unhealthy behaviors grew, the terms "culture of health" and "well-being" emerged as better expressing the complexity, comprehensiveness, and more person-centric vision of the goal of health promotion. As more research indicated that the root causes of poor health, excessive medical costs, and lost productivity costs (absenteeism, injuries, disability, workers' compensation) were similar and focused on subpopulations of individuals with elevated health risks, multiple chronic conditions, and high

DOI: 10.1201/9781003227793-137

cost-of-care diseases,[10] the emergence of more integrated environmental, health promotion, disease prevention, care management, decision-making, and productivity-focused models became predominant[11–13].

118.3 WELLNESS, HEALTH PROMOTION, AND DISEASE MANAGEMENT "ROI" AND "VOI"

The ROI ("return on investment") of wellness and health promotion programs to reduce health care costs (particularly in the near term) has intermittently moved from promising[14–16] to pessimistic.[17] Edington's three-decades-long studies indicated that the healthiest and lower-risk individuals had the lowest near- and long-term costs and that moving moderate- and highest-risk groups to lower-risk levels showed a reduction in medical costs generally within 18–36 months after risk level reduction.[14,16] However, program costs were rarely considered in most ROI calculations or captured using any standard methodology. While the lack of standardization in methods also hampered analyses of disease management programs (optimizing self-care for common, expensive chronic diseases such as hypertension, hyperlipidemia, asthma, coronary artery disease, back pain, and diabetes), due to the higher prescription and medical care utilization and costs, program interventions were more likely to demonstrate near-term medical cost savings ("positive ROI"). The RAND Health Quarterly Workplace Wellness Programs Study,[17] one of the largest systematic reviews of health promotion programs, demonstrated that while some health measures did improve, over a five-year period, there was no statistically significant reduction in total monthly medical costs comparing companies with and without workplace wellness programs. Health promotion programs are increasingly being measured by a more comprehensive framework: the "value" of investment. "VOI" was more broadly defined as loyalty to the company; lower turnover, reduction in absenteeism; improvement in job performance ("presenteeism"); reduction in work-related illnesses, injuries, and safety incidents; earlier return-to-work, improved business performance, and lower workers' compensation claims and cost.

118.4 FROM WELLNESS TO WELL-BEING, HEALTH, AND PRODUCTIVITY

As health promotion and disease prevention programs evolved, more emphasis was placed on understanding and aligning environment, culture, policy, programs, and incentives to be more integrated and emphasize comprehensive health, well-being, personal performance, and productivity. The federal government had already created the clinical- and patient-oriented US Preventive Services Task Force[18] and the population-focused US Community Preventive Services Task Force,[19] respectively, to review and rank evidence and make recommendations regarding interventions that improved health on either an individual or group level. The National Institute of Occupational Safety and Health (NIOSH), building on the Integrated Employee Health NASA IOM Report,[11] similarly recognized the need for an integrated model of intervention that aligned health promotion with more traditional "health protection" (occupational safety and health) to create the Total Worker Health™ initiative.[20]

This initiative provides new tools, frameworks, and integrated metrics to assess and improve the "environment", which can promote or detract from improving health and business performance.[12,21–27]

118.5 EMERGING TRENDS AND TECHNOLOGIES

New scientific and economic evidence is emerging and being applied to systems and technologies to initiate and sustain healthy behaviors for both individuals and populations.

The clinical practice of *lifestyle medicine*, rooted in the rapidly evolving understanding of *epigenetics*, *microbiome, and neuroplasticity* represents a major new front in the prevention, treatment, and reversal of common disease.[28,29] Basic science research has demonstrated that inflammation is the common etiologic pathway for the majority of chronic diseases. Growing evidence demonstrates that plant-based eating, physical activity, stress reduction, restorative sleep, addiction reduction/cessation, and meaningful social connection are clinically effective and create new opportunities for linkages and synergies with environmental and population-based strategies[29]

A better understanding of the *mind–body continuum*, including the neuro-humoral science of "happiness" and the production of dopamine/endorphins by multiple stimuli, has led to an augmented appreciation of the chemistry and pathways to enhanced well-being.[29] The power of *social connection*, which underlies the phenomena of connection and contagion,[30] and intrinsic motivators, which can be very personal and strong (purpose, passion, mission), are also being described and deployed.[21]

Built environments that design healthy architectural and human support systems that naturally promote productivity as well as the deployment of *choice architecture*, which makes the "right thing to do the easy thing to do", are becoming more mainstream in creating and sustaining a culture of health. Re-connecting individuals and home, school, worksite, and healthcare settings to the *natural outdoor environment*[30–32] has been shown to improve both public health and human functioning.

Behavioral economics[33,34] and thoughtful alignment and application of incentives have increasingly informed the design and deployment of comprehensive health management programs.

Personal biomeasurement with real- or near-time feedback using wearable technologies tethered to social media support for ongoing behavior change and optimal self-care

is promising and appeals to an increasingly "wired" generation. *Physicians prescribing coaching* using electronic medical records (EMRs) and the trusted "power of the white coat" to produce better outcomes, increase patient engagement, and improve provider satisfaction are being implemented[35, 36].

Healthcare financing and delivery innovations occurring through the Affordable Care Act (ACA) and employer purchasing coalitions and broader use of *value-based incentivized health reimbursement arrangements and health savings accounts* have further accelerated the adoption and impact of wellness strategies. The "volume to value transformation" has led to the emergence of *accountable population healthcare models* designed to meet the "Triple Aim"[37] of improving health, enhancing patient experience, and reducing the per capita cost of care. *Growing consumerism and transparency* in healthcare appropriateness, quality, and costs can further accelerate the prevention, treatment, and even reversal of disease versus "usual care" models characterized by ineffective, inefficient, overutilized, and costly care. *Consumer and patient activation* to improve health and medical care can be measured using validated tools and deployed on a population basis.[38] And *shared decision-making* is increasingly accepted as foundational to producing better outcomes at lower cost using evidence-based decision aids.[39] *Moving care and caring "forward"* to on-site, near-site, homes, schools, and worksites for both coaching and medical care delivery where it is more accessible, engaging, integrated, and lower cost is rapidly accelerating, particularly among large, self-insured employers.

CLINICAL APPLICATIONS

Physicians, as the most trusted agent in healthcare, will be expected by employers initially and other purchasers over time to become competent in lifestyle medicine to prevent, treat, and reverse common chronic diseases.

- Clinicians increasingly will be expected not only to understand epigenetics in causing common, chronic inflammatory-mediated diseases but also to apply brief motivational interviewing techniques to better engage patients in lifestyle interventions.
- Clinical practice workflows, EMRs, and telehealth utilization accelerated by the COVID-19 pandemic will increasingly be linked to consumer-, employer-, and community-centric health behavior coaching programs, online tools, monitoring/feedback technologies, and support groups delivered outside the traditional office setting.

119 Mind/Body Interactions in the Exercise Domain

Stressing the Body to Improve Psychophysiological Functioning

Allyson G. Box, PhD, Jonathan R. North, MS, and Steven J. Petruzzello, PhD

KEY POINTS

- Examining important psychological constructs (e.g., stress, behavioral motivation) across multiple levels (e.g., psychological, biological) will yield much more meaningful answers to mind–body problems than single-level analysis.
- There is a need to focus on the multifaceted nature of the stress response, including the influence of psychological determinants, as the complete stress response and the underlying mechanisms have yet to be fully unraveled in humans.
- Promising evidence indicates the stress response can be "trained" through regular exercise behavior, but there is a need for understanding how individual differences mediate the "toughening" effect of exercise.

119.1 MONISM VERSUS DUALISM

In the previous editions of this chapter,[1–3] we discussed at length what "mind/body" means, how it could be studied, and how it has been studied in the exercise domain through a biological psychology perspective. Biological psychology is "the study of the physiological, evolutionary, and developmental mechanisms of behavior and experience … and emphasizes the goal to relate biology to issues of psychology" (p. 5).[4] Biological psychology assumes mental activity and brain activity are inseparable, a single unit (i.e., monism), and progress in this field has been exponential. This monistic assumption is a departure from the dualistic approach wherein mind and body are treated as separate entities. As Cacioppo, Tassinary, and Berntson[5] noted:

> Monism has replaced any lingering notions of dualism, as psychological states are more likely to be conceived as represented in and acting through cortical, limbic, and brain stem regions, with influences on autonomic, neuroendocrine, and immune activity, which in turn serve to modulate crucial cellular and molecular processes. Afferent information, in turn, travels from the peripheral to the central nervous system to influence the brain and behavior in social contexts. (p. 2)

However, dualistic thinking continues to dominate the field of exercise science. This is likely because much of the research conducted within the exercise domain focuses purely on physiological adaptations (e.g., musculoskeletal, cardiorespiratory, metabolism), psychological outcomes (e.g., self-reported anxiety, depression, well-being), or behavior promotion, intentionally or unintentionally separating the mind and body. However, the emergence of cross-level analysis (i.e., examination across biological and psychological levels), what we referred to in the previous work as "seedlings of change", continues in exercise research, providing foundational evidence of the mind/body phenomena prior to, during, and following acute and long-term exercise. The present chapter aims to give the reader an updated sampling of work utilizing a mind/body approach in the exercise domain since the previous edition of *Lifestyle Medicine*,[3] while focusing on the stress response, exercise as a stressor, promotion of exercise as a health behavior, and the psychophysiological benefits of regular exercise.

119.2 OUR BODIES UNDER STRESS

"Stress" is a feature of daily life, but what is "stress"? Hans Selye,[6] credited with coining the term "stress" as we know it today, defined stress as a "non-specific response of the body to a demand". Selye adopted the term "stress" from the field of physics, which generally defined stress as total force per unit area. In physics, stress can take different names—tensile, compressive, bulk—all of which refer to disruption of the structure of a material. Thus, it is conceivable for human stress to be psychological, physiological, environmental, and so on, as long as it disrupts bodily equilibrium or "homeostasis". Homeostasis, coined by Walter Cannon,[7] refers to the relatively narrow limits within which our internal bodily systems (e.g., nervous, cardiovascular, respiratory, endocrine) automatically coordinate to maintain a relatively steady, functional internal

DOI: 10.1201/9781003227793-139

state. With developments in research, stress has been more recently defined as a "state in which homeostasis is actually threatened or perceived to be so" by adverse forces (p. 374).[8] These adverse forces, more commonly referred to as *stressors*, may be internal or external, real, or perceived. It is when these stressors are of great enough intensity, duration, or frequency (i.e., temporality) to exceed one's regulatory capacity that the organism's stress system is activated, resulting in a cascade of internal system changes with the singular goal of re-establishing homeostasis.[9,10] For example, temporality refers to a stressor that could occur for 20 seconds every minute or a two-second interval that occurs ten times in a minute. There is consensus that the stress response is natural, protective, and necessary to function, but an overactive or dysfunctional stress response, especially when prolonged, results in major negative health consequences.

While stress can be both positive (i.e., eustress) or negative (i.e., distress), how an individual appraises a stimulus (i.e., potential stressor) will influence their regulatory control.[11] Only a stressor that is perceived to exceed an organism's natural regulatory capacity (e.g., an unpredictable and/or uncontrollable stimulus) has the potential to induce a stress response.[12] Moreover, emerging evidence within animal studies suggests the stress response is "demand specific", signifying specific conditions or environmental signals that elicit a patterned array of hormonal and neural responses to ready the organism for the specific behavioral demand (e.g., fighting, fleeing, defending, submitting, or hunting).[13] However, this demand specificity has yet to be unraveled in humans, leaving a great deal of room for individual variability in stress appraisal, reactivity, and recovery. We know the human stress response is psychophysiological, involving patterned physiological alterations to aid in preparing the organism to neutralize a perceived threat (e.g., the appraised demands of the stressor outweigh available resources). Outlined below is a summary of a physiological response to non-specific stressors.

The stress response begins when a threat, real or perceived, activates the cerebral cortex in areas such as the dorsolateral prefrontal cortex (dlPFC), ventromedial prefrontal cortex (vmPFC), orbitofrontal cortex (OFC), anterior cingulate cortex (ACC), and somatosensory cortex. The information is processed and directed to subcortical structures, including the amygdala, ventral basal ganglia, and thalamus, all of which "communicate" with the hypothalamus. A signal conveying sensory information (e.g., pain, danger) can also be sent directly to the amygdala prior to it being processed in the cortex, allowing for a faster response to life-threatening stimuli. The hypothalamus is then responsible for evoking the stress response by "directing" signals through two neuroendocrine pathways: the sympathetic-adrenal-medullary (SAM) axis and the hypothalamic-pituitary-adrenocortical (HPA) axis. The SAM axis is considered a fast response and is most directly related to the "fight, flight, or freeze" behavioral response. Activation of the SAM-axis pathway begins with hypothalamic stimulation following a "stressor", where the preganglionic sympathetic neuron is activated to directly stimulate the adrenal medulla (of the adrenal glands; an endocrine organ structured atop the kidneys) to release catecholamines (norepinephrine, epinephrine) into the bloodstream toward target organs. The release of nor/epinephrine is responsible for increasing heart rate (and cardiac contractility), metabolic rate, blood pressure, muscle tension, and respiration, for pupil and bronchial dilation, and for blood to be shunted from the gut to the muscles; all of which facilitate the coordination of internal systems for an appropriate behavioral response to a stressor. It is generally believed the activation of the SAM axis optimizes functioning. Indeed, evidence suggests a fast, large increase in nor/epinephrine response from baseline to stressor is positively related to task performance. In addition, when this large increase of nor/epinephrine following stressor onset was coupled with a relatively fast (within minutes) decline of nor/epinephrine following stressor cessation, less anxious feelings were reported, and the individual tended to have greater trait emotional stability.[14]

In contrast, activation of the HPA axis is a slower, more prolonged stress response, which can lead to undesirable health conditions, often associated with stress, if left unchecked. The HPA axis response begins with stimulation of the hypothalamus, the integrative center of the autonomic nervous system (ANS), following a "stressor". However, instead of ganglionic activation, this pathway begins with the release of corticotropin-releasing hormone (CRH) from the hypothalamus into hypothalamic-pituitary circulation. CRH targets corticotropic cells within the anterior pituitary gland to release adrenocorticotropic hormone (ACTH) into the bloodstream. ACTH, in turn, stimulates the adrenal cortex, resulting in the synthesis and release of glucocorticoids (e.g., cortisol) and mineralocorticoids (e.g., aldosterone). Cortisol, considered the primary stress hormone, mobilizes fuels (glucose) for energy use. Acutely, cortisol acts to benefit the organism, but prolonged or overexposure to cortisol can disrupt almost all internal body systems, resulting in pathogenesis.[15,16] Thus, the stress response system is natural and ultimately helpful to mobilize an organism to effectively deal with a stressor. However, even while most individuals in modern Western civilization are not regularly exposed to life-threatening stressors, perceived stress and the associated negative health consequences resulting from overexposure to stress (and cortisol) are on the rise. There is an apparent need to focus attention on the stress response. Is it possible to train individuals to appraise stressors differently in an era of increasing, yet non-life threatening, distress? Better yet, can the internal, collaborative physiological systems be trained to react and recover more efficiently to stressors?

119.3 EXERCISE AS A CONTROLLED STRESSOR

The consequences of an inappropriate stress response (e.g., prolonged stress response or delayed recovery) have been

related to increases in physiological (e.g., cardiovascular, metabolic, immune, digestive) and psychological (e.g., anxiety, depression, fatigue) diseases and disorders.[17] Because exercise has been shown to positively impact all of these outcomes, exercise scientists have examined how exercise can alter an individual's response to stress and found compelling evidence that exercise can diminish exaggerated stress reactivity and combat stress-related health effects.[18,19] Indeed, Dienstbier[14] proposed exercise as a self-regulatory method to promote "active toughening" (i.e., effective adaptation) of the stress response systems. He suggested an introduction of controllable, intermittent stressors (such as regular exercise behavior) as a way to "physiologically toughen" an individual's stress response and increase stress tolerance.

Recall that a cascade of internal physiological alterations occurs when an organism is stressed, and Selye believed this cascade of events was a "non-specific" response to a given demand. With this foundation, research has been dedicated to examining how a stressor can induce adaptations of the stress response systems and improve the stress response given a similar stressor. With evidence of an acute bout of exercise eliciting a physiological stress response (e.g., increase in plasma catecholamines, cortisol), exercise was confirmed a stressor. Exercise scientists furthered this exploration by testing whether an exercise stressor could evoke not only physiological adaptations to similar exercise stressors but also to psychosocial stressors like public speaking and memory tasks.

The cross-stressor adaptation hypothesis (CSAH) posits that continued or repeated exposure to a specific stressor (e.g., exercise) will induce an adaptation of the stress response system(s), and thus decrease stress reactivity to a similar stressor and reduce sensitivity to dissimilar stressors, highlighting the importance of habituation. Sothmann and colleagues[20] posed that an exercise stressor of sufficient intensity and/or duration (i.e., exercise that exceeds the regulatory capacity of the organism) shares a similar physiological stress response to a psychological/mental stressor (e.g., public speaking, timed mathematic equations). This led to research aimed at understanding whether exercise adaptations are homotypic (i.e., exercise stressor produces habituation and sensitization only to exercise stressors of similar duration and/or intensity) or heterotypic (i.e., exercise stressors provide adaptations across differing psychosocial stressors). Researchers have found that an exercise stressor can induce adaptations to similar exercise stressors, and, while findings are inconsistent, there is some evidence exercise stressors also improve stress responses to psychosocial stressors.

119.3.1 Stressing the Endocrine System through Exercise

Research has primarily focused on the stress-buffering effects of regular aerobic exercise. A systematic review by Mücke et al.[21] reviewed research examining the influence of regular physical activity and fitness on various indices of stress reactivity, including cortisol. As they argue, previous research has used a wide variety of stressor tasks, ranging from physical to cognitive, to socioevaluative, each of which might elicit varying physiological responses. As such, reviewing studies that have used a fairly standardized stressor, namely the Trier Social Stress Test (TSST),[22] Mücke et al. found that ten of the 12 studies included found either full or at least partial support for reduced HPA reactivity (i.e., smaller cortisol response) to the TSST in those who were either more active or more fit. Another way of examining the exercise-stress relationship is to determine to what extent an acute bout of exercise might impact stress reactivity. For example, Zschucke and colleagues[23] examined stress reactivity (via cortisol and α-amylase) following a mental stressor task in young (~24.5 years) sedentary or trained males after they completed a 30-minute aerobic activity of the same relative intensity (60–70% VO_{2max}). All participants, regardless of fitness level, had a blunted cortisol response to the mental stressor task following the bout of exercise compared with a light stretching condition. Zschucke et al. also found that cardiorespiratory fitness was inversely related to cortisol response to the mental stressor ($r = -0.39$). using a slightly different approach, Caplin et al.[24] randomly assigned healthy male participants to one of three different exercise intensity conditions (light, moderate, vigorous) and examined cortisol responses to a subsequent mental stressor (the TSST). There was a dose-dependent cortisol response to the TSST, with the vigorous intensity group showing a slower rise and lower peak in cortisol response along with a more rapid return to pre-stressor levels. These findings[21, 23] suggest an acute bout of exercise reduces or blunts the stress response to a follow-up mental task, perhaps through a negative feedback loop.[23,24]

Taking a different perspective, Gerber, Ludyga, Mücke, Colledge, Brand, and Pühse[25] proposed that general perceptions of stress (i.e., low vs. high) may interact with physical activity levels to impact the neuroendocrine response following a stressor. They studied cortisol activity following a brief psychosocial stressor (10 minutes TSST) between groups of individuals engaging in low (<20 minutes at least 3·week^{-1}) versus high levels of vigorous exercise (≥20 minutes at least 3·week^{-1}) and found more cortisol reactivity for those engaging in less vigorous exercise in response to the TSST. They also observed that this cortisol reactivity was mediated by the individual's perception of stress, where those who perceived greater levels of general stress had greater cortisol reactivity, but much more so in those who did not engage in sufficient levels of vigorous physical activity. This suggests psychological interpretation or "appraisal" of a stressor impacts the physiological stress response but engaging in regular vigorous physical activity can work to offset this reactivity. Indeed, Lazarus and his colleagues have theorized and tested the stressor-appraisal-response chain dynamics and found these "intra-individual differences" in cognitive appraisal, such as perceiving a stressor as a challenge versus a threat, are associated with differing psychophysical outcomes following a stressor.[26,27]

119.3.2 Stressing the Cardiovascular System through Exercise

It has been known for some time that cardiovascular reactivity to psychosocial stressors increases risk for cardiovascular disease. There is also evidence of greater cardiovascular reactivity negatively impacting hippocampal gray matter and amygdala volume, brain structures important for controlling cardiovascular responses during stress, a year after the cardiovascular reactivity measures were taken.[28] Evidence suggests those who are more aerobically fit have less cardiovascular reactivity to a given stressor.[18] Heart rate (HR) and blood pressure (BP) responses have been extensively examined, with the consensus being those with greater aerobic fitness levels have attenuated stress reactivity (as indexed by smaller HR and BP responses to a stressor).[29,30] It has also been postulated that, rather than directly influencing reactivity, aerobic fitness leads to faster cardiorespiratory system recovery following a stressor.[31] Additionally, the individual's perception of the stressor (e.g., as a challenge vs. threat) can elicit differing cardiovascular system responses (challenge is associated with increased vasodilation while threat is associated with vasoconstriction).[11] This led to considering how the nervous and cardiovascular systems interacted. Heart rate variability (HRV) is one method used to better understand whether autonomic nervous system (ANS) adaptations were indeed occurring alongside cardiovascular adaptations. Briefly, the heart is innervated by both parasympathetic (vagus nerve) and sympathetic fibers. When an organism is within parasympathetic dominance, the more activated vagus nerve results in greater vagal tone. Vagal tone is associated with less psychophysiological arousal and is indicative of an individual at rest. However, even at rest, an individual's parasympathetic and sympathetic nervous systems are working simultaneously, and a stressor, real or imagined, can lead to parasympathetic withdrawal (reduction in vagal tone) or activation of sympathetic fibers, resulting in increased psychophysiological arousal, HR, BP, and so on.

Ultimately, HRV is simply a measure of the time intervals between subsequent heartbeats (the intervals between R-spikes, or interbeat intervals [IBIs] found within an electrocardiogram). Greater variability in IBIs while at rest is associated with greater vagal tone (i.e., parasympathetic dominance), while less variability (i.e., more consistent heartbeats) is associated with less vagal tone (i.e., parasympathetic withdrawal). As such, HRV can be viewed as a physiological marker of stress directly associated with PNS activity.[32,33] Indeed, HRV has been used as an index of morbidity and mortality, with research demonstrating that more consistent IBIs (i.e., less HRV) are predictive of dysfunction in the cardiovascular and immune systems as well as mental health challenges like anxiety, depression, and stress regulation.[34]

This evidence led to the question of whether and how exercise alters HRV, as an increase in HRV would provide some evidence of beneficial nervous system adaptations. A few studies have examined the impact of varying exercise modalities on HRV, with mixed findings on the effects of aerobic, resistance, and mindfulness exercises (e.g., yoga) on HRV improvements.[31,35,36].In a more real-life setting, von Haaren and colleagues[37] randomly assigned 61 college-aged male engineering students to either a 20-week aerobic exercise intervention (two sessions·week^{-1} for ~30 minutes per session) or a control group. Participants in the exercise training group had greater HRV compared with the control group during a real-life stressor (i.e., academic exams). There is a consistent association between fitness and greater HRV, but isolating exercise behavior as the reason for HRV improvements remains relatively elusive. In part, this is because HRV has primarily been used to reflect training load and overreaching in athletes. However, it seems HRV research is fostering attention in other aspects of the exercise domain. Research in this area may soon result in a better understanding of HRV as an indicator of psychophysiological reactivity and recovery following exercise and psychosocial stressors.

119.3.3 Stressing the Immune System through Exercise

As for immune system reactivity, circulating inflammatory markers are of interest.[38–40] A review of the literature by Slavish and colleagues[38] differentiated salivary inflammatory markers according to varying stressors (e.g., exercise, psychosocial). Their findings indicated that fluctuations in interleukin-1 beta (IL-1β), tumor necrosis factor-alpha (TNF-α), and interleukin-6 (IL-6) are fairly consistent across exercise and psychosocial stressors (refer to reference [38] for inflammatory marker characteristics). They did note that a lack of consistent methodology across studies requires caution in broad-stroke interpretations. Moreover, Pedersen and Hoffman-Goetz[41] iterate in detail the acute, immunosuppressant effect of an exercise stressor, while also discussing observed immunological adaptations that can occur over time for regular exercisers. Consistent evidence illuminates the potential for acute immunosuppression following exercise, especially if the exercise stressor is intense and prolonged. However, regular bouts of moderate-intensity exercise have been shown to be "immuno-protective", where proper recovery between intermittent exercise stressors is essential to gain such immunoprotective effects.[42] This exercise-inducing immune-protective effect is thought to be a result of, in part, reductions in inflammation, thymic mass maintenance, and enhanced immunosurveillance.

119.3.4 Stressing the Mind through Exercise

Beyond the focus on physiological stress, it is also important to consider a few additional points, namely mental resistance and resilience (see reference [43]). Mental resistance refers to how effectively an individual regulates stress before the deleterious effects of the stressor would have a negative impact. An increase in mental resistance would

allow greater levels of a stressor to be experienced (i.e., in either intensity, duration, or temporality) without detrimental effects. Mental resilience is the ability to recover from a stressor once experienced. As Levinsohn and Ross[44] put it, the notion of resilience has been used to describe the "mental elasticity of rebounding from adversity" (p. 89). Future work examining the ability of regular exercise to develop greater mental resistance is needed, as is the examination of whether exercise can enhance mental resilience to life's adversities (see reference [45]). Building mental resistance and resilience can aid in "toughening" an individual[14] such that an individual is more likely to: (1) perceive a stressor as a challenge rather than a threat; and (2) develop and employ effective coping mechanisms to recover more quickly from a stressor. As stated previously, one's cognitive appraisal of a stressor as well as one's ability to "bounce back" following a stressor influences the intensity and duration of the stress response.

Cognitive appraisal refers to both primary and secondary appraisals.[26] Primary appraisal indicates an individual's evaluation of the "encounter" (i.e., stressor) and determines whether there is potential for harm or benefit to life, a loved one, self-esteem, values, goals, and so on. Meanwhile, secondary appraisal refers to the evaluation of "control" or whether the individual can do anything to prevent harm or increase benefit, such as employment of coping strategies like acceptance, information seeking, social engagement, and behavior/social inhibition. If an individual perceives a benefit in some way, and the individual believes they have control or strategies that can increase the benefit, then the stressor is perceived as a "challenge"; this is ideal for an appropriate, healthy stress response. However, if an individual perceives a stressor as harmful or aversive, they will consider strategies and potentially begin coping, defined as "the person's constantly changing cognitive and behavioral efforts to manage specific external and/or internal demands that are appraised as taxing or exceeding the person's resources" (p. 993)[26] to reduce harm. An individual's cognitive appraisal of a stressor and its accompanying arousal can mediate their cardiovascular output to that stressor. Jamieson, Nock, and Mendes showed that individuals who were instructed to reappraise a stressor as adaptive and aiding in performance (i.e., viewing the stressor and its arousal as a challenge) had increased cardiac efficiency (i.e., greater cardiac output, decreased vascular resistance) when compared with those who received no reappraisal instruction (i.e., viewed the stressor and its arousal as more threatening).[11] This is where Dienstbier's[14] proposal of "active toughening" could impact not only the physiological systems but the psyche (or mind) as well. Regular exercise behavior, when considered from a macro behavior perspective, could build general mental resistance across stressor types; individuals are more likely to appraise a given stressor as a challenge versus a threat. There is a sound basis for such reframing or reappraisal of stressors and the arousal it brings.[46] Exercise behavior could also build mental resilience such that beneficial coping strategies are more readily used to recover from uncontrollable stressors. However, even with cross-sectional studies providing initial insight into the positive relationship between physical fitness and mental resilience, the empirical evidence supporting this view is limited and is worth further exploration.

In conclusion, previous work in the exercise domain has shown that: (a) physical stress, like exercise, can lead to activation of the HPA axis;[47] (b) those who exercise regularly show reductions of adrenocortical system activity at the same absolute exercise workload compared with inactive or untrained individuals;[48] and (c) HPA axis adaptations occurring as a result of regular exercise can translate (i.e., cross-over) to psychosocial stressors.[49] These adaptations may be reflected in either a smaller response magnitude (i.e., habituation) to submaximal load or an enhanced response to maximal demands (i.e., sensitization).

119.4 EXERCISE PROMOTION FROM A MIND/BODY PERSPECTIVE

The vast majority of exercise psychology literature, especially that related to behavior promotion, emphasizes theoretical frameworks that are strictly cognitive (i.e., "mind" only) based, all but ignoring "body"-based influences. The temporal self-regulation theory (TST), a framework that incorporates neurobiological factors to explain exercise behavior, incorporates higher-order cognitive functioning as an important psychophysiological factor for behavior engagement.[50,51] The set of higher-order cognitive processes is often referred to as "executive functioning". This includes cognitive flexibility (i.e., ability to switch from one concept to another), planning, attentional inhibition (i.e., suppression of stimuli that are irrelevant to the task at hand), working memory (i.e., storing and managing information to complete learning, reasoning, and decision-making behavior), and scheduling. As noted by Hall and Fong, substantial existing evidence[52–57] has shown that exercise results in improvements in executive function (e.g., cognitive control, mental flexibility, working memory). Moreover, higher levels of executive functioning can increase engagement in behaviors that require consistent, controlled effort, like that needed for exercise. Thus, Hall and Fong[50,51] propose that a positive feedback loop exists such that individuals with stronger executive functioning can more consistently engage in an exercise routine, which serves to further strengthen executive functioning and the neural circuitry (e.g., prefrontal cortex, anterior cingulate cortex) subserving it. Recall that the stress response begins in brain areas such as the dorsolateral prefrontal cortex (dlPFC), ventromedial prefrontal cortex (vmPFC), orbitofrontal cortex (OFC), and anterior cingulate cortex (ACC). These structures are where executive functioning and other cognitive processing occur. Thus, the TST's emphasis on executive functioning and neural circuits provides a neurobiological mechanism responsible for one's "self-regulation capacity", and this self-regulation capacity is thought to be a major determinant of stress reactivity and recovery as well as

future behavior. While a relatively novel theory with a need for more empirical investigation, there is some additional psychophysiological evidence to support the TST for exercise behavior promotion.

Recall the cortex of the brain is structurally divided by the longitudinal fissure into symmetrical left and right hemispheres. Thus, a typical cortex contains two dorsolateral prefrontal cortices (dlPFC); one in the left hemisphere and the other in the right hemisphere. This is important because, with advances in the field of neuroscience, there is evidence that a relatively more active right dlPFC is associated with emotional dysregulation, while a relatively more active left dlPFC is associated with emotion regulation. The valence-motivation model[58,59] postulates that resting, frontal cortical activity reflects a biological disposition to respond with more positive affect in the presence of relatively greater left frontal hemispheric activation or more negative affect with relatively greater right frontal hemispheric activation. Further, such frontal cortical hemispheric asymmetries in activation reflect a disposition to approach versus withdraw from given stressors that exceed the individual's self-regulatory threshold. In sum, aligning with the evidence of the left versus right dlPFC, a relatively more activated left frontal cortex predicts positive affective states, approach motivation, and appetitive behavior, but a relatively more activated right frontal cortex predicts negative affective states, withdraw motivation, and aversive behavior.

Taken together, the TST provides a psychophysiological theory proposing deliberate, consistent behavior as a consequence of an individual's self-regulation capacity, which is formed by the individual's neural circuity (e.g., dlPFC, ACC) and associated executive functioning. This neural circuitry and associated executive functioning can be developed through a positive feedback loop, so that better executive functioning leads to more exercise engagement, and regular engagement in exercise leads to better executive functioning. There also appears to be a dispositional (or trait) attribute for self-regulation capacity, in which greater relative activation of the left anterior hemisphere is predictive of a positive, approach orientation to engage in exercise behaviors. According to the TST, this should be trainable given sufficient engagement in exercise stressors of sufficient intensity and/or duration.

119.5 EXERCISE FOR PSYCHOPHYSIOLOGICAL FUNCTIONING

The study of cognitive and affective (feeling) states has grown exponentially over the past 30 years, especially in the exercise domain. However, affective and cognitive responses to exercise have almost exclusively been examined separately, leaving the interplay of these two processes less understood. Although core affect has been defined as a general affective state that occurs without the need for cognitive processing, emotions and moods are defined by the need for some type of cognitive appraisal.[60] Meanwhile, cognitive function is an umbrella term associated with a variety of things including, but not limited to, concentration, attention, learning and memory, planning, and problem-solving. Within exercise psychology, executive functioning has been extensively studied to better understand the influence of exercise on cognitive functioning. Executive functioning, as mentioned previously, has been linked to brain areas in the frontal lobe, specifically within the prefrontal cortex, as well as subcortical structures linked to memory (e.g., hippocampus). While there is a recent emergence of literature in biological psychology addressing affective-cognitive processing (i.e., how affective states interact with cognitive processing), there is a gap in the literature addressing the affective-cognitive dysregulation that can occur under prolonged distress. For example, traumatic or prolonged stress can increase one's risk of physical health disorders (e.g., hypertension, headaches) as well as mental health disorders (e.g., anxiety, depression). There is evidence that emotional reactivity as well as cognitive processing is hindered for those diagnosed with physical and mental health disorders. However, there is a relatively sparse literature addressing how affective and cognitive processing interact to influence dysregulation. Examining cognition independently from affect and vice versa is limiting and provides an incomplete picture. Given the relative lack of theoretical and mechanistic approaches regarding the reciprocal interplay between cognition and affect as it relates to exercise behavior, the scarce research that is attempting to assess the affective-cognitive mind, especially while in dysregulation (e.g., anxiety, depression) deserves to be examined.

A reasonable question is whether an affective disorder results in deficits in executive function or do deficits in executive function result in undesirable affective states. For example, a common symptom of depression (a mood disorder) is the inability to think clearly, concentrate, or make decisions.[61] These symptoms suggest a deficit in cognitive function, including executive function. As noted earlier, the anterior cingulate cortex (ACC) and dorsolateral prefrontal cortex (dlPFC) are primary brain structures involved in executive functioning. However, in depressed individuals, the connections between these brain structures are altered, resulting in reductions in certain executive functioning tasks.[62] Whether increases or decreases in neural activity are observed, it has become generally established that depressed individuals differ in their cognitive processing abilities.[63] Similarly, evidence suggests that greater anxiety results in variations in cognitive control processing.[64] Anxiety is considered an aversive emotional state occurring in the presence, or perception, of a threatening stressor that typically evokes a psychophysiological and behavioral response.[65] For individuals with higher levels of anxiety, increased neural activation occurs in the inferior frontal cortex in response to negative affective stimuli (e.g., fear); individuals with lower levels of anxiety have greater neural activation in response to more positive affective stimuli (e.g., happy)[66] In sum, both depression and anxiety are accompanied by alterations in

cortical activity and functioning: depression negatively impacts cognitive processing; anxiety increases attention to threat-related stimuli, reducing cognitive processing efficiency (i.e., attentional control).[65]

Some research has been done to compare changes in attention, a component of executive function, and depressive symptoms (e.g., rumination) between individuals clinically diagnosed with major depressive disorder (MDD) and "healthy" controls following exercise (e.g., focused meditation, aerobic training). In this limited work, depressive symptoms have been shown to decrease, while at the same time, cognitive control improves, but more so for those with MDD.[67–69] Additionally, Olson et al.[68] suggest that exercise may offer a neurobehavioral treatment for enhancing cognitive control and attenuating depressive symptoms. Although this is an intriguing initial foray into the affective-cognitive interplay within the exercise domain, this needs to become a focus of future research. There is a lack of exercise literature examining changes in anxiety, depression, and other affective functioning in conjunction with cognitive functioning, and vice versa. Such work is needed to understand the reciprocal roles of affective and cognitive function as it relates to exercise behavior and individual health.

119.6 SUMMARY

As we had stated earlier, it is difficult to argue that "mind" and "body" are not inextricably linked. The simultaneous examination of mind/body from multiple levels (e.g., psychological, biological, sociological) will result in a far greater informational yield than will persisting in the examination of mind or body separately and/or from single levels of analysis.[5] The most important point, as always, is to begin with specific, testable research questions. These will lead to innovative research designs and careful and proper selection of the best tools to use in answering these questions. Such an approach will increase the likelihood of uncovering the patterns and meaning in mind/body relationships (i.e., strong inference) rather than just adding more bricks to the brickyard.[70]

As chronic stress has been directly linked to a broad range of diseases and disorders,[17,71] it is imperative to understand the mechanisms underlying the stress response, and further, to determine preventive and treatment practices that can slow the disease process, as well as provide an avenue for improved health. As such, understanding the mechanistic changes following an exercise stressor is an avenue of important focus, as exercise has consistently been shown to improve the systematic functioning of all body systems. However, methodological approaches are inconsistent and differ widely when examining both exercise and psychosocial stressors. A need for consistency in methodology and conceptual sophistication has been deemed necessary to better understand the impact of stress, as well as the role exercise plays in (a) preventing and/or mediating stress reactivity and (b) leading to greater stress tolerance, resilience, and stress recovery.

In conclusion, stress reactivity and recovery are important areas of research, as overwhelming levels of stress are more likely today than ever. There is an accumulation of evidence suggesting exercise, as long as the exercise bout is appraised as a challenge and sufficient recovery is implemented, can "toughen" the individual, increase self-regulation capacity, and ultimately increase future exercise behavior. However, the potential for individual differences in appraisal, demand specificity, and biological mechanisms remain unanswered questions.

CLINICAL APPLICATION

Psychophysiology offers great promise for providing a better understanding of the prominent clinical issues in exercise psychology. The techniques, tools, and methodologies allow for the examination of clinically important questions (e.g., how does exercise improve psychophysiological stress reactivity and recovery). As research continues to produce relevant findings, these can be used to optimize individual treatment plans.

120 Genetic Influences on Regular Exercise Behavior

Eco J.C. de Geus, PhD and Matthijs D. van der Zee, MSc

KEY POINTS

- Despite broad knowledge that regular moderate to vigorous physical activity decreases the risk for morbidity and mortality, a large proportion of the population in industrialized societies does not engage in regular leisure-time exercise activities.
- A growing body of twin and family studies show that genetic factors explain around 45% of the individual differences in the adoption and maintenance of regular exercise, with clear changes in the heritability estimates across the lifespan.
- In childhood, genetic factors (♀25%–♂36%) and the shared family environment (♂52%–♀63%) are the main causes of the observed variance in regular exercise behavior.
- In adolescence, genetic factors (♀♂49%) and the shared family environment (♂23%–♀31%) are the main causes of the observed variance in regular exercise behavior.
- In adulthood, genetic factors (♂48%–♀50%) and environmental factors (♀♂44%) unique to the individual are the main causes of the observed variance in regular exercise behavior.
- Ongoing large-scale gene-finding efforts are rendering important clues on the biological pathways underlying regular exercise to improve the success of interventions on this crucial health behavior.

120.1 INTRODUCTION

Regular engagement in physical activity lowers the risk for morbidity and mortality through cardiovascular disease (CVD), type 2 diabetes, and cancer.[1–4] Despite these well-documented benefits of physical activity, a large proportion of adults worldwide do not engage in such activities regularly.[5,6] Consequently, a physically inactive lifestyle remains a major threat to health in modern-day society, with substantial economic costs.[7] This is reflected in public health recommendations worldwide, which unanimously include an encouragement to a more active lifestyle.[8–11]

Correlates and determinants of a physically active lifestyle have been studied intensively over the past three decades to define optimal targets for intervention. Over 30 years ago, Dishman and colleagues stated that "one barrier to developing effective methods to encourage physical activity (…) is the lack of knowledge of the determinants of regular physical activity".[12] Since then, researchers have identified numerous potential determinants in cross-sectional or longitudinal studies that contribute to the adoption and maintenance of physical activity. Physical activity encompasses a broad domain of activities at work, at home, during transportation, and in leisure time. In this chapter, the emphasis is on voluntary exercise activities in leisure time such as jogging, swimming, exercising at fitness clubs, and participation in recreational or competitive team and individual sports. Such voluntary exercise activities are often specifically aimed at improving skills, fitness, and health and are rapidly becoming the major source of physical activity of moderate to vigorous intensity in many industrialized countries. Furthermore, whereas many aspects of physical activity, such as activity at work or physically active transportation, may be very situational and hard to modify, the readily modifiable nature of voluntary exercise activities makes it a prime target for behavioral intervention.

The bulk of studies devoted to the determinants of voluntary exercise behavior have attempted to explain low exercise prevalence in terms of social and environmental barriers. These include, among others, poor access to facilities,[13] low socioeconomic status,[14,15] non-Caucasian race,[16] high job strain,[17] subjective "lack of time",[18] low belief in health benefits,[14] and low social support by family, peers, or colleagues.[18,19] Although these social factors are important, they explain only a small part of the individual differences in voluntary exercise behavior. In this chapter, we review the evidence from twin and family studies that genetic factors play an important role too.

120.2 DEFINITIONS OF VOLUNTARY EXERCISE BEHAVIOR

Heritability estimates of behavioral phenotypes are sensitive to the exact definition of the phenotype. We will therefore first give an overview of how voluntary exercise behavior has been defined in the studies used in this review. The four important characteristics of the studies presented in Table 120.1 and Figures 120.1–120.4 are that the reported exercise activities were performed regularly, voluntarily, in leisure time, and in the context of fitness or sports. We stress

This table was constructed using 78,525 unique individuals. For over half of these individuals, multiple data points were available, some of which could fall into the same age-bin. Data from these participants were weighted per age-bin such that the total weight per participant was 1 within each age-bin. N, number of unique participants (i.e., sum of weights) with valid data; SD, weighted standard deviation; IQR, weighted inter-quantile range; vigorous exercisers are defined as subjects with a METhours score over 35 (i.e., at least five hours per week vigorous [MET=7] activity).

that this definition of voluntary exercise behavior is different from total physical activity, even when a restriction is made to leisure-time physical activity (LTPA), or more narrowly to LTPA that is of moderate to vigorous intensity. Such LTPA measures will encompass almost all voluntary exercise behavior but may additionally include gardening, dancing, or active transportation by walking or bicycling to school/work, none of which are considered to fall under voluntary exercise behavior in our definition. We further exclude obligatory exercise activities like physical education classes or job-related sports and exercise (military boot camps; firefighter training) and activities that are done infrequently like sailing, surfing, or skiing during a limited number of days per year. We note that our definition of voluntary exercise behavior also *excludes* accelerometer/step counter-based physical activity. Without additional self-reporting, these activity counts cannot distinguish between voluntary exercise activities or other forms of moderate to

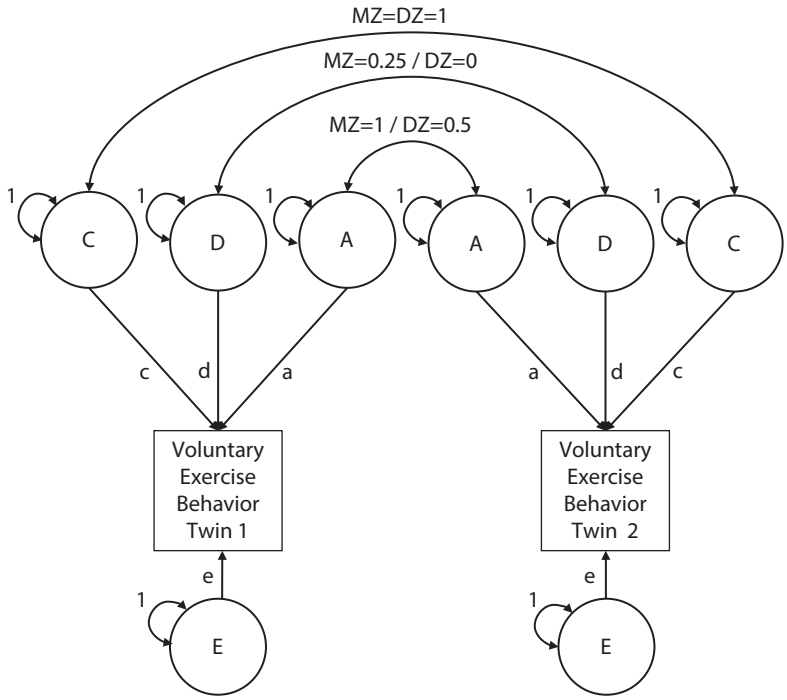

FIGURE 120.1 Path diagram depicting the correlated latent factors that can cause twin resemblance in voluntary exercise behavior. Note: These are the additive (A) and non-additive (D) genetic factors and shared environmental (C) factors. Based on biometrical theory we can set the correlation of the latent additive genetic factors for MZ twins to 1, and for DZ twins to 0.5. The non-additive genetic factors are correlated 1 in MZ twins and 0.25 in DZ twins or lower if there is much epistasis.[68] The correlation of shared environmental factors is set to 1 for both types of twins. The latent unique environmental factors are (per definition) uncorrelated in both DZ and MZ twins. Unobserved latent variables have no scale: their variance is arbitrarily set to 1 (the double arrows that start and end in the latent factors). Path coefficients a, c, d, and e represent the factor loadings of voluntary exercise behavior on the latent factors. In a classical twin study, only three of the four a, c, d, and e path coefficients can be estimated simultaneously. As a rule of thumb, a, c, and e are estimated, unless the MZ correlation is much larger than twice the DZ correlation, pointing to genetic non-additivity.

vigorous activity (e.g., vacuum cleaning, bicycling, stair climbing).

Studies on regular voluntary leisure-time sports and exercise activities all used self-reporting, but the exact methods have greatly differed across studies. Some studies used surveys, whereas others used interviews. Exercise behavior was assessed with only a single "YES/NO participation" question[20] or by presenting subjects with a list of specific exercise activities,[21,22] whereas still others allowed all exercise activities to be reported in a free response format.[23] The quantitative metrics for exercise behavior have differed accordingly. Some studies use a categorical scale classifying participants in a dichotomy of "regular exercisers and non-exercisers", sometimes adding an additional level of moderate exercisers, but using different thresholds for the minimum frequency and the minimum intensity of the exercise activities to separate regular exercisers from moderate or non-exercisers. Ideally, the volume of voluntary exercise behavior is expressed as the energy expenditure in exercise activities across a fixed time interval (e.g., METhours per week). This can be done by multiplying frequency per week, duration in hours, and the estimated intensity for each activity and then summing across all reported exercise activities. Unfortunately, the type, duration, frequency, and intensity of multiple possible exercise activities have not always been assessed or reported in detail in all studies.

120.3 PREVALENCE OF VOLUNTARY EXERCISE BEHAVIOR

In the Netherlands Twin Register, data on exercise behavior has been collected by virtually the same methods through surveys of large numbers of twins, their parents, siblings, spouses, and the children of twins and siblings.[24] To assess the volume of voluntary exercise behavior, we ask whether the participant exercised regularly in their leisure time ("Yes" or "No"). If the participants (or their parental informant) responded affirmative, they were asked to indicate all the exercise activities done regularly. For each exercise activity reported, they noted the number of months per year, weekly frequency, and average duration in minutes of the activity. Depending on the age of the participants (≤16 vs >16 years), Ainsworth's Compendium of Physical Activity[25] or the adaptation for children by Ridley[26] was used to assign a metabolic equivalent of task (MET) value to each exercise activity. This reflects its energy expenditure as a multiple of the basal energy

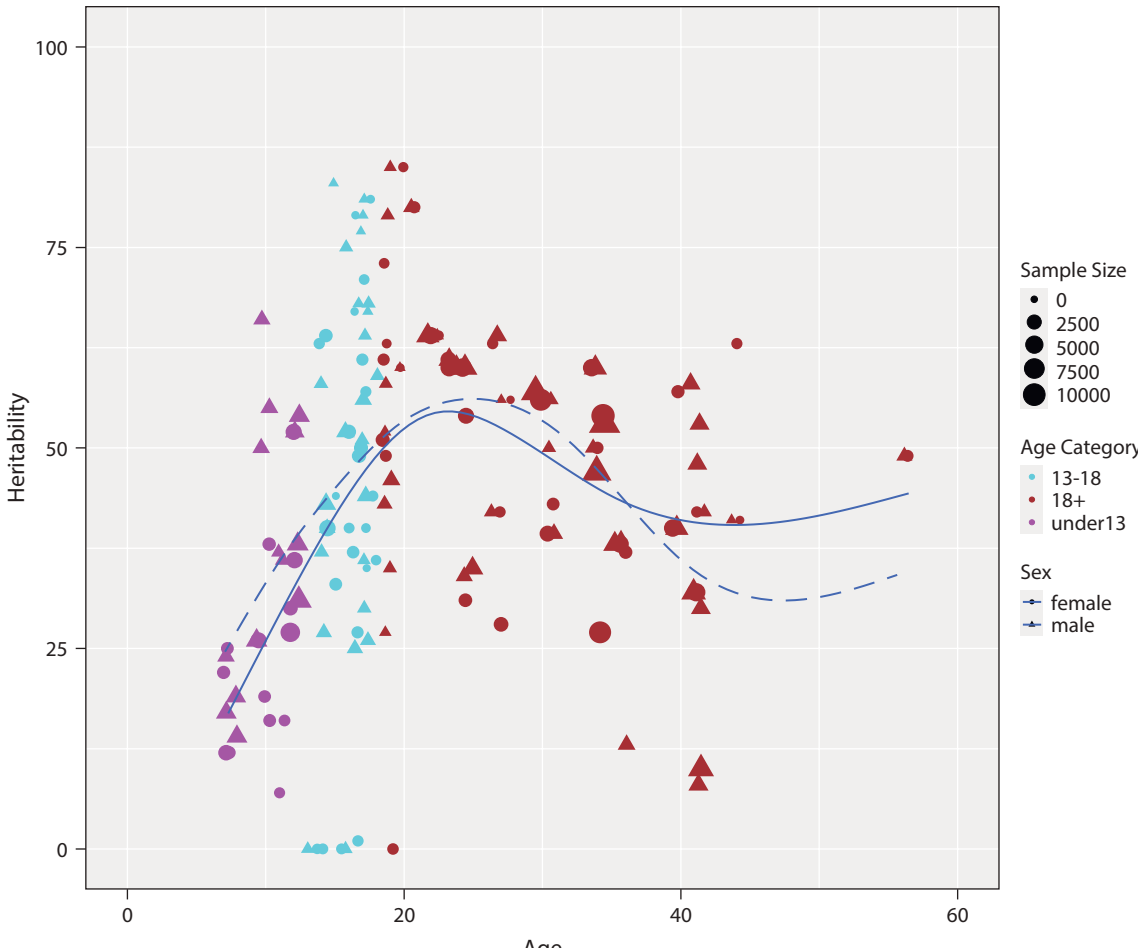

FIGURE 120.2 Heritability estimates for voluntary exercise behavior as a function of age. Note: The scatterplot depicts 168 heritability estimates (on a 0% to 100% scale) from 28 twin studies. Coding indicates whether the estimate derives from samples with mean twin age under 13 (light), between 13 and 18 (medium), and over 18 (dark). Different shapes indicate males (triangle) and females (circle). The size of the circle/triangle is weighted by the square root of the sample size. The two fit lines are the GAM functions around the male (dashed line) and female (solid line) estimates, which also take the study weight into account.

expenditure (approximately 1 kcal/kg/hour) in an average person engaged in that activity. For each participant, a total weekly METhours value was computed across all exercise activities by summing the products of the number of hours spent weekly on each exercise activity and its MET value. Activities were only scored if that participant had engaged in them for at least three months during the past year. For children and adolescents, exercise during obligatory physical education classes at school was not included in the weekly METhours value for voluntary exercise behavior. The six-month test–retest reliability of the weekly METhours value was found to be 0.91[27] and we also found substantial tracking over time using follow-up periods of up to 20 years.[28]

Amassing data across a 30-year period of research in the Netherlands Twin Register results in 162,286 observations from 78,525 unique participants (54.4% females) from 23,681 nuclear families (see Table 120.1). The mean age of the sample was 29.7 (SD = 17.6). A total of 67.3% of these participants engaged in regular voluntary exercise activities, whereas 32.7% were classified as non-exercisers. When considering the frequency and intensity of the exercise activities in METs, little over half of the population (62.4%) engaged in moderate to vigorous exercise activities (4 MET or more) for at least 60 minutes per week, and only 12% could be considered vigorous exercisers (i.e., engaging in vigorous exercise activities [7 MET or more] for at least 300 minutes per week).

In Table 120.1, we illustrate the effects of two of the best-known determinants, age and sex, on the prevalence of voluntary exercise behavior. We furthermore report exercise behavior separately for the twins, their singleton siblings, and, in the older age groups, for the parents and spouses. As many participants took our surveys multiple times, even in a single age-bin, the data were weighted such that the sum of weights per unique participant is one (e.g., if three observations are available for a participant in the age-bin 45–55, the weight of each would be one-third). This means that sample overlap between age bins is possible in

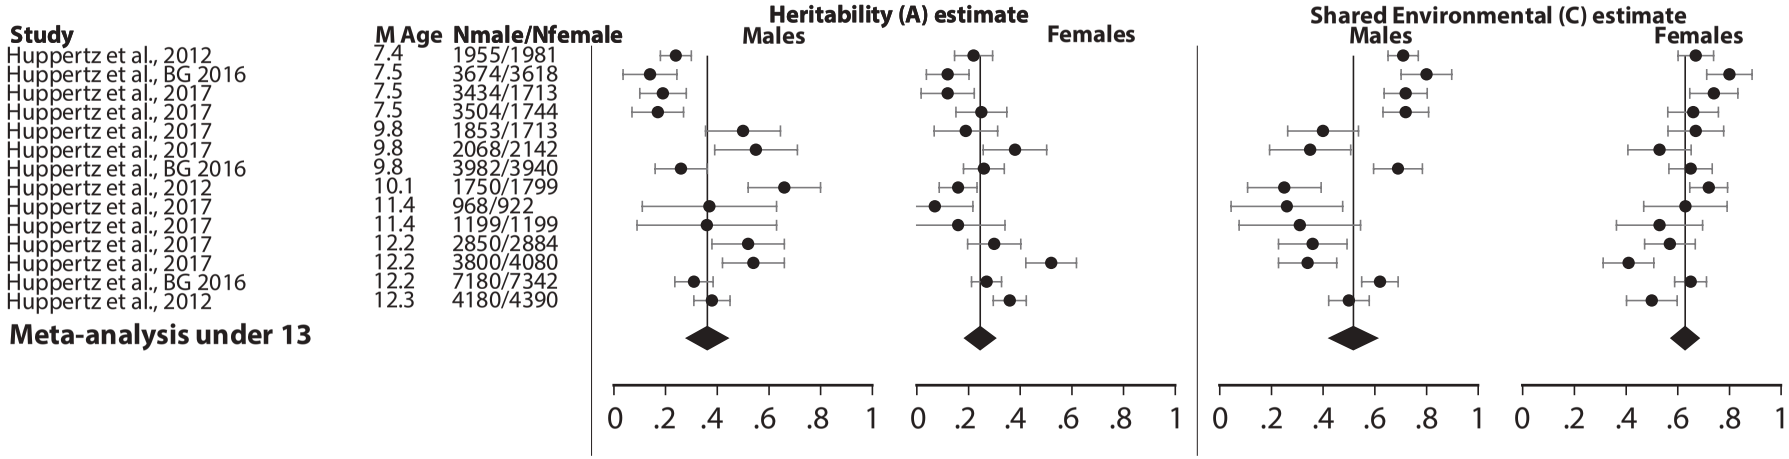

FIGURE 120.3 Forest plot and meta-analytic estimate of the contribution of additive genetic (A) and common environmental (C) factors to the variance in voluntary exercise behavior in childhood.

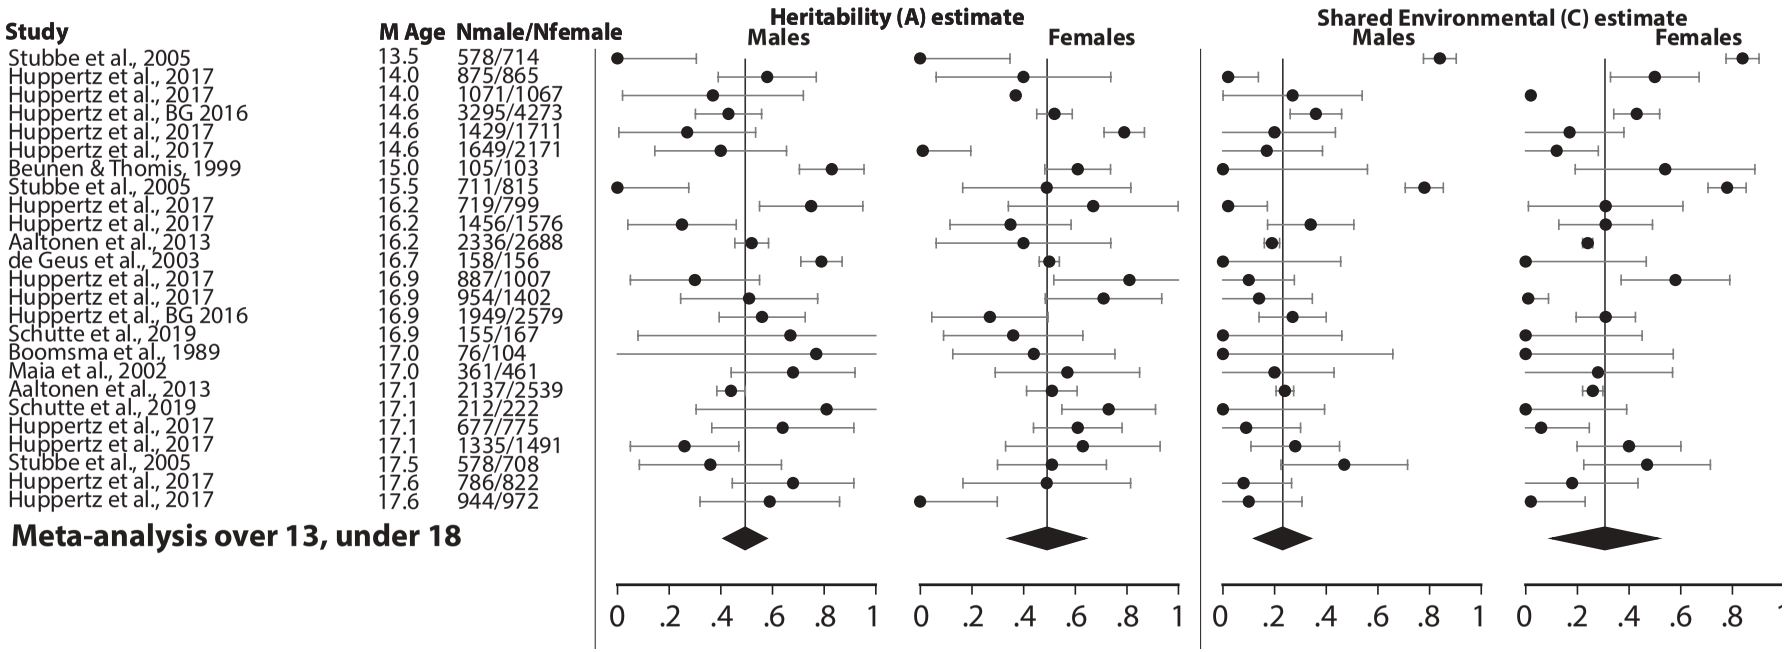

FIGURE 120.4 Forest plot and meta-analytic estimate of the contribution of additive genetic (A) and common environmental (C) factors to the variance in voluntary exercise behavior in adolescence.

Table 120.1, but after weighting there is no sample overlap within age-bin.

We found a lower volume of exercise behavior in young children (<9) compared with older children and adolescents. This contrasts with findings for total physical activity, which is known to decrease from the highest level in early childhood to lower levels in late childhood and adolescence.[29] We interpret this to reflect the predominance of play in determining the total physical activity of young children.[30] In keeping with previous reports, the volume of voluntary exercise behavior in leisure time is lower in females than in males and shows a general decline after adolescence in both sexes. For example, 75.3% of the male youngsters between 15 and 18 years old engage in some form of regular exercise and 37.3% engage in regular vigorous exercise, whereas in adults over 55 years, these numbers have dropped to 46.3% and 9.2%. Formal testing of the linear and quadratic effects of age (in years) and sex (females coded 1) and their interaction on weekly METhours in weighted general equation estimation (GEE) models, accounting for the nested (family) structure of the data, revealed an effect of sex, with males showing higher levels of exercise ($\beta = -0.47$, SE = 0.01, $p < 10^{-99}$). There was also a linear decrease in exercise with age ($\beta = -0.01$, SE = 0.001, $p = 1.8\times10^{-16}$) as well as an additional quadratic age effect ($\beta = -1.19\times10^{-4}$, SE = 1.88×10^{-5}, $p = 2.09\times10^{-10}$). A significant interaction between age and sex ($\beta = 0.004$, SE = 0.0004, $p = 2.31\times10^{-14}$) shows that the decrease in exercise after adolescence is less pronounced in females, compared with males, which is in line with previous findings.[23]

To reconfirm that exercise behaviors do not differ between twins and non-twins,[23] we selected families with same-sex twins where at least one non-twin sibling of the same sex had also participated. We then compared the voluntary exercise behavior of twins with their non-twin siblings, by rerunning the weighted regression mentioned previously with the addition of variables for monozygotic (MZ) and dizygotic (DZ) status separately or a combined twin-status variable. These regressions revealed no significant differences with non-twin siblings for either MZ twins ($\beta = 0.01$, SE =0.02, $p = 0.35$) or DZ twins ($\beta = 0.02$, SE = 0.02, SE = 0.02, $p = 0.15$).

Overall, a clear picture arises from Table 120.1 for the Dutch population. Despite its well-documented benefits, a large group of people do not engage in voluntary exercise on a regular basis, particularly in adulthood. These findings are very much in line with those from other European countries.[21] Furthermore, worldwide, the prevalence of a complete lack of regular voluntary exercise behavior in adults varies between 21% and 53%, depending on the exact age group and the assessment methods used.[6,31] What factors cause exercisers to exercise and, more importantly, what keeps non-exercisers from doing the same? The remainder of this chapter will review evidence from twin and family studies for a significant genetic contribution to voluntary exercise behavior.

120.4 TWIN STUDIES ON VOLUNTARY EXERCISE BEHAVIOR

As with many other traits, exercise behavior appears to run in the family. The familial resemblance observed for exercise can represent genetic influences ("nature") or they can represent environmental influences that are shared within a family ("nurture"). Twin studies can separate these two mechanisms by comparing the resemblance in MZ or identical twins to the resemblance in dizygotic DZ or fraternal twins. MZ twins are the result of the division of a single fertilized egg during an early stage in embryonic development, whereas DZ twins result from two separate fertilized eggs. When twins are reared together, they share part of their environment, and this sharing of the family environment is the same for MZ and DZ twins. The important difference between MZ and DZ twins is that the former share (very close to) all of their genetic variants, whereas the latter share on average only half of the genetic variation segregating in the family.[32,33]

If the resemblance in exercise behavior within MZ pairs is about twice as large as in DZ pairs, which can be tested by comparing the MZ (rMZ) and DZ (rDZ) twin correlations, this suggests that additive genetic factors (A) influence exercise behavior. Additive genetic factors represent the sum of all linear effects of the genetic loci that influence the trait of interest. The contribution of additive genetic variance to the total variance is known as the narrow sense heritability. If the MZ resemblance is more than twice as large as the DZ resemblance, this suggests the additional influence of non-additive genetic factors (D), due to allelic interactions within (dominance) and across genes (epistasis). The contribution of all genetic variance, additive and non-additive, to the total variance is called broad sense heritability. If the MZ twin correlation is less than twice the DZ correlation, this points to the additional influence of common environmental (C) factors contributing to the twin resemblance. Common environmental factors are defined as those environmental factors that are shared within a family, such as parenting behaviors, family functioning, neighborhood, or socioeconomic status. The extent to which even genetically identical MZ twins raised in the same family do not resemble each other is ascribed to the unique (or non-shared) environmental factors (E). These include all unique experiences for each twin separately, like differential jobs or lifestyles, accidents, or other life events, and in childhood, differential treatment by the parents, going to different schools, and having non-shared friends and peers, but also somatic mutations and the stochastic part of epigenetic changes. Measurement error will also be subsumed by the unique environmental factor.

The effect of genetic and environmental factors on exercise behavior in a sample of MZ and DZ pairs can be graphically depicted in a path diagram (Figure 120.5). However, because the additive and non-additive genetic factors cannot be estimated simultaneously with shared environmental factors, at least not using only data from twins, a model

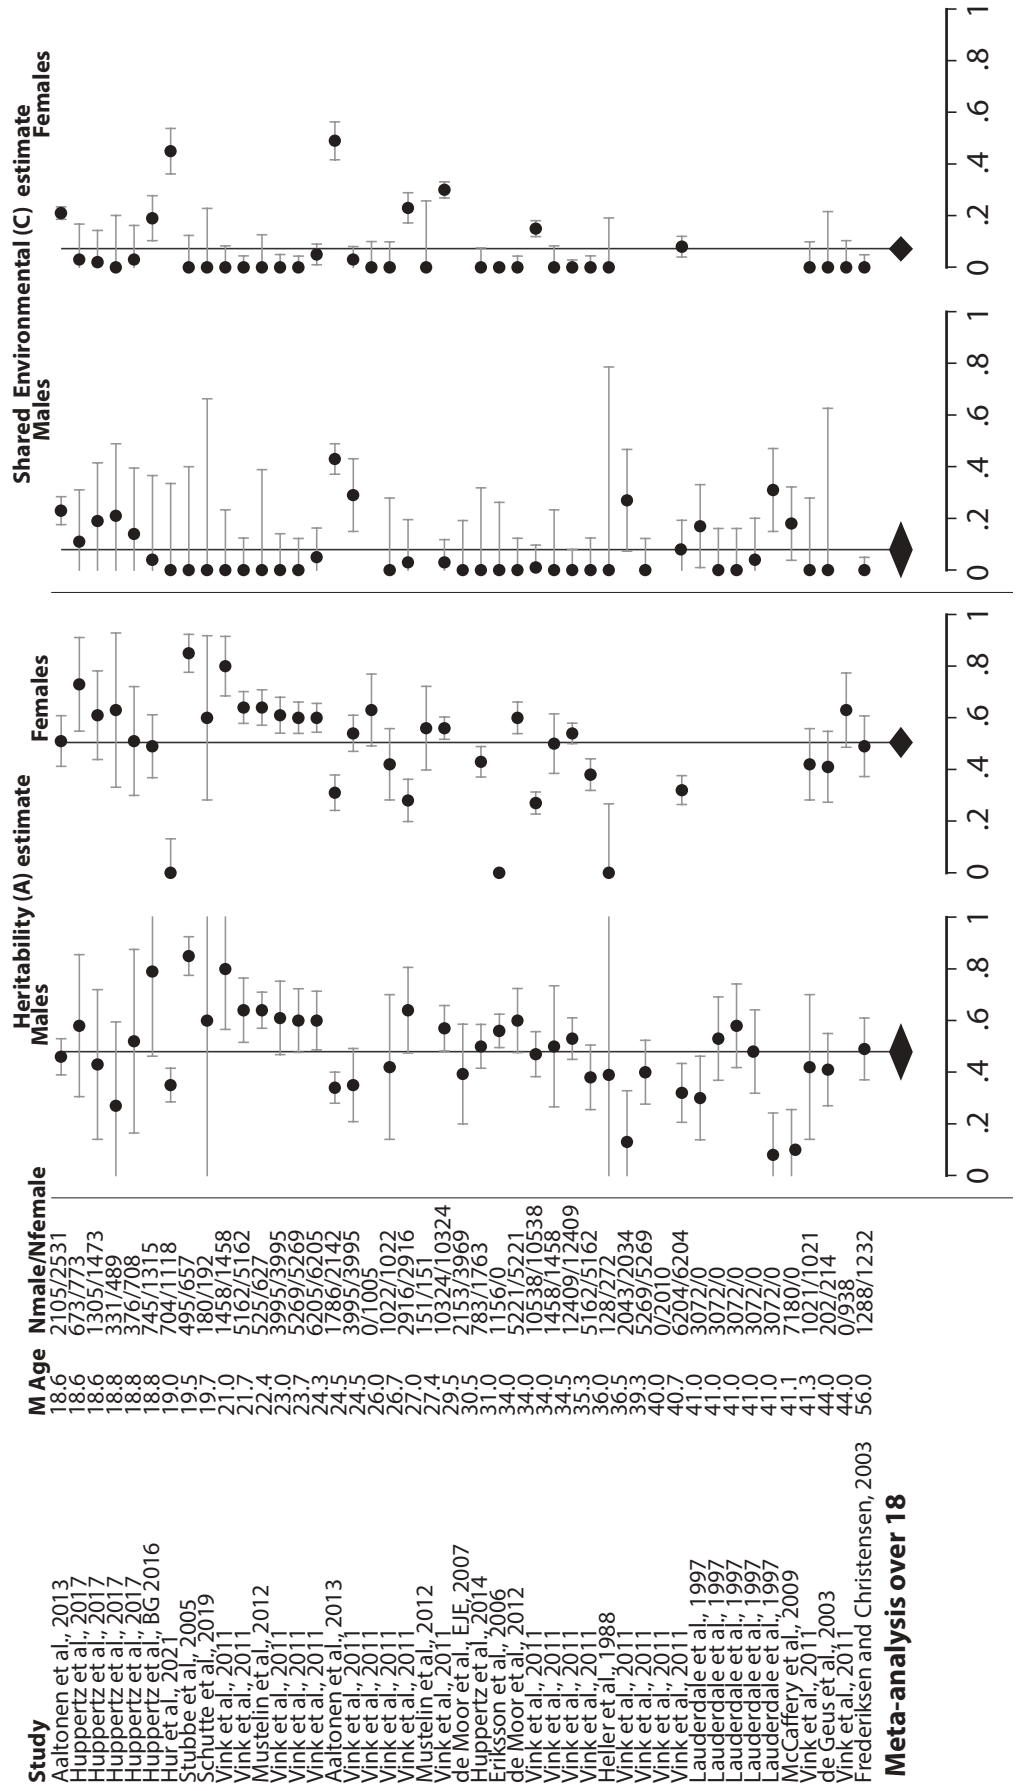

FIGURE 120.5 Forest plot and meta-analytic estimate of the contribution of additive genetic (A) and common environmental (C) factors to the variance in voluntary exercise behavior in adulthood.

estimating A, C, and E for exercise behavior is usually preferred over an ADE model. Non-additivity is left unmodeled because the MZ correlation for exercise behavior is rarely larger than twice the DZ correlation. In terms of the parameter estimates obtained from fitting the twin model to the data, the heritability can be expressed as $a^2/(a^2 + c^2 + e^2)$. This heritability can also be represented as a percentage by multiplying this ratio by 100. The proportions of variance ascribed to shared environmental and unique environmental factors can be computed in a similar manner and are given by, respectively, $c^2/(a^2 + c^2 + e^2)$ and $e^2/(a^2 + c^2 + e^2)$.

An overview of heritability estimates from twin studies conducted on voluntary exercise behavior is given in Figure 120.1. These studies converge on the finding that exercise behavior is heritable across the lifespan, despite substantial heterogeneity in the measures used within and across studies, comprising of: a dichotomy of yes/no sports or regular exercise participation;[20,34–43] time spent weekly on sports;[44,45] the Sports Index from the Baecke questionnaire;[46–49] daily energy expenditure on exercise activities;[50] weekly METhours/minutes spent on sports and exercise activities with intensity higher than 3 or 4 MET;[45,51–54] or categories (e.g., sedentary, moderate, vigorous) based on weekly METhours/minutes[55] or weekly exercise frequency.[56, 57] Figure 120.1 shows remarkable age-related changes in the relative contribution of genetic factors to the total population variance in exercise behavior, which are very similar for males and females. To capture this age dependence and arrive at more stable estimates across multiple studies and multiple measures within single studies, we conducted an inverse variance-weighted meta-analysis on the reported estimates for A and C separately across childhood (mean sample age between seven and 13), adolescence (mean sample age between 13 and 18), and adulthood (ages 18 and over). Results are depicted in Figures 120.2 to 120.4, with the column labeled "M" denoting the mean age of the sample.

Meta-analysis of samples with mean age under 13 estimates male heritability at 36% and female heritability at 25%. In parallel, the estimated variance explained by shared environmental factors was 52% for males and 63% for females. Large changes in genetic and environmental contributions to regular exercise behavior occur in the transition from childhood to adolescence. For example, Huppertz et al.[55] used a combination of univariate modeling on a very large cross-sectional set of Dutch twins (birth year ranged between 1986 and 2004) and a genetic simplex model on the subset of twins that had longitudinal data across multiple ages. Heritability was found to be low in seven-year-olds (14% in males and 12% in females), but gradually increased up to age 18 (79% in males and 49% in females). In contrast, the initially very high relative contribution of the common environment to the variance in childhood exercise behavior rapidly waned when children grew into adolescence and young adulthood (from 80% to 4% in males and from 80% to 19% in females). This pattern of findings was confirmed in studies using slightly different exercise measures and taking into account possible interactions of genetic factors with parental education.[45,58]

That common environmental factors shared by (twin) siblings play a large role in childhood is likely explained by the important role of the parents at this age. Parental modeling has been invoked to explain the correlation between the exercise behaviors of parents and offspring,[59,60] meaning that children copy the behavioral example of their parents. However, actual modeling of the parental phenotype as a common environment shared by twins showed such parental modeling to be absent or small at best.[41] Other effects of sharing the family environment are needed to explain the strong common environmental effects in childhood. These influences include encouragement by parents and siblings to be active, giving exercise activities priority over other leisure time activities, praising the child's activity and/or performance, watching the child be active, telling the child that exercise is beneficial, and enrolling the child in exercise programs or sports clubs, providing transportation to sports venues and supplying the child with equipment and financial support.[61] Such parental support is more strongly correlated to children's exercise behavior than the exercise behavior of the parents themselves.[59,62]

Meta-analysis of samples with a mean age between 12 and 18 estimates both female and male heritability at 49%. The estimated variance explained by common environmental factors in adolescence is about halved from childhood to 23% for males and 31% for females. Twin studies in the Netherlands, Finland, Sweden, and Belgium all show this age-moderation of the genetic and common environmental effects on exercise behaviors[44,56,63] and, independent of country, common environmental factors are a bit more important in early adolescence for girls than for boys. These results suggest that the influence of the family environment and parents becomes less prominent, giving way to increased influence from peers and coaches[64] while simultaneously the influence of genetic factors becomes more important, possibly related to enjoyment and ability. A large body of literature has confirmed self-efficacy, the belief that one can perform a given activity at an adequate level of performance, is a powerful determinant of whether someone engages in and adheres to an exercise program.[65,66] Self-efficacy may be an especially strong factor in adolescence, when the sensitivity to one's own relative ranking among peers may be the largest.

Meta-analysis of samples with mean age above 18 estimates male and female heritability at 48% and 50%, respectively. The remaining variation in adult exercise behavior is influenced by environmental factors unique to a single twin, whereas the common environment that the twins shared early in life, including a shared womb, no longer plays a role of importance. Results from the largest study on voluntary exercise behavior using an extended twin pedigree design[54] suggested that the common environment shared by siblings explains 4% of the variance in adult exercise behavior and the common environment shared by twins

explains 8%. During adulthood, genetic factors influencing performance level and intrinsic enjoyment of exercise will remain important, but extrinsic motivation derived from esthetic and health benefits may also become important. Interestingly we found that sharing a household with a spouse, which should be considered part of the unique environment of a person, yielded high (20–24%) contributions to the variance in exercise behavior. Because an extended family study encompasses partner/spouse relationships of different durations, this effect could be attributed to the increasing resemblance in partners' exercise behavior that occurs over time through marital interaction. Other unique environmental factors that come into play in adulthood and can impact on exercising are increasing job demands and child caretaking obligations, or lower exercise capability due to increasing health problems.

The results from the twin studies in Figures 120.1 to 120.4 demonstrate convincingly that heritable factors are present at all ages. The heritability of voluntary exercise behavior peaks during late adolescence and young adulthood but remains substantial throughout adulthood. Taken together, these results imply that family-based interventions are useful to increase this health behavior in children, whereas individually based interventions, taking into account innate differences in exercise capability and enjoyment, might be better suited for adolescents. Furthermore, as identified in our extended twin-family study, there is a growing influence of spouses on each other's exercise behaviors over time, which suggests that simultaneously targeting the spouses in partner programs is a useful strategy.

120.5 FAMILY STUDIES ON VOLUNTARY EXERCISE BEHAVIOR

The estimation of A, C, and E from the crucial comparison of MZ and DZ resemblance in the twin design makes various, often untested, assumptions. These include the equal environment assumption,[67] random mating assumption,[68] and absence of gene-by-environment correlation.[69] The equal environment assumption states that the MZ twins do not share a larger amount of common environment than DZ twins, based on people's change in treatment purely from the perceived zygosity. This would make MZ twins more alike through reasons other than the shared genome. The random mating assumption assumes that parents do not seek each other out as partners based on their exercise behaviors. If assortative mating on exercise behavior is present, the correlation between genetic factors influencing exercise behavior is higher than the theoretical 50% in DZ twins and full siblings, which can cause underestimation of heritability and overestimation of the shared environmental effects. The assumption that there is absence of gene-by-environment correlation (rGC) would be violated if children modeled their exercise behavior after the exercise behaviors of the parents. This would lead to a scenario where parents not only pass on their "genes for exercise behavior" but also create the strongest exercise behavior-shaping environment for their offspring. Such rGC would inflate the C estimation.[70]

Only one twin study has explicitly tested the equal environment assumption for a set of relevant traits, including total physical activity and physical activity at work or in leisure time separately.[47] No evidence for violation of the equal environment assumption was found for any of the physical activity traits. The presence of assortative mating and cultural transmission and how they impact heritability estimates has been actively tested by adding data from more types of relatives to the twin design, such as data from parents, grandparents, spouses, and siblings. Ten studies have employed extended family designs to report on the familial resemblance of voluntary exercise behavior among adolescent offspring (age range 13 to 20 years) and their parents.[41,54,71–78]

Spouse correlations inform on the presence of assortative mating, whereas parent-offspring correlations enable a test for the effects of direct cultural transmission. The spouse correlation for exercise behavior was significant in all these studies and the sample-size weighted mean was $r_{spouses} = 0.28$. However, extended twin-family studies that took assortative mating into account led to nearly the same heritability estimates as the twin-only model.[41] Mean parent-offspring correlations across 51,201 parent-offspring pairs was $r_{par\text{-}off} = 0.19$, which is substantially lower than the mean correlation between 21,900 full sibling pairs ($r_{sibs} = 0.30$). The stronger intragenerational than intergenerational resemblance cannot be attributed to genetic effects as both types of pairings share on average 50% of their genetic variation. It is largely because of a common environment shared by the offspring to which peers and siblings appear to contribute much stronger than parents. This aligns well with findings by de Moor et al.[41] that explicitly modeled environmental effects common to twins and siblings only and those also shared with the parents. In a sample of 3525 adolescent twins and their non-twin siblings (13 to 18 years) and 3138 parents from 1736 families, 42% of the variation in adolescent exercise behavior in boys could be explained by genetic factors and 52% could be explained by common environmental factors shared with co-twins and siblings but not with the parents. In girls, 36% of the variance in exercise was explained by genetic factors and 41% by generation-specific common environmental effects, with little evidence for cultural transmission.

Taken together, the results of extended twin-family studies suggest that heritability estimates for exercise behavior obtained from studies using only twins are not overly biased by assortment or cultural transmission. However, a final source of bias in the classical twin study design comes from the ubiquitous choice to set the non-additive genetic component to zero. As indicated before, a twin study cannot simultaneously model the A, C, D, and E parameters from just two pieces of relevant information (the MZ and DZ correlations). To circumvent this under-identification problem, D is often assumed to be zero. If this assumption is violated,

estimates of A tend to be biased upward and estimates of D and C tend to be biased downward.[79] This issue can also be partly overcome by including multiple different family members. For example, van der Zee et al.[54] constructed 19,543 extended pedigrees in the Netherlands Twin Register that specified all family relations among participants older than 16 years (N = 50,690 individuals). These pedigrees included twins with their non-twin siblings, spouses, children, and parents. Results confirmed the influence of genetic factors on METhours weekly spent on exercise in adulthood, but in contrast to most twin studies, a significant non-additive (D) genetic component (15%) in exercise behavior was found in this extended pedigree study. Progress in the identification of the actual genetic variants underlying the heritability of exercise behavior will help to resolve the exact contribution of additive and non-additive genetic effects.

120.6 GENE-FINDING STUDIES

The heritability of exercise behavior has been well established, but less is known about the actual genetic variants that are associated with this trait. Candidate gene studies in single small-sized cohort studies are now widely distrusted as a reliable source of replicable association because most complex behavioral traits are highly polygenic with only a very low percentage of the variance in the trait explained by a single genetic variant.[80] Instead, the ubiquitous method of choice to identify genetic variants influencing complex traits like exercise behavior is a genome-wide association study (GWAS), simultaneously testing the association of millions of variants across the entire genome.

The first GWAS on exercise that we conducted in 2009[81] tested for an association with leisure-time exercise behavior in two independent samples comprising 1644 Dutch and 978 American subjects. In retrospect unsurprising, neither sample yielded results that withstood the scrutiny of the multiple testing correction that needs to be applied due to the millions of tests performed simultaneously (p-value below 5×10^{-8}). Two more studies in Korea and the US increased the sample size to 8842 and 22,219, but again failed to detect significant associations with leisure-time exercise after the required stringent correction for the multiple testing burden.[82,83] In a follow-up study using the same leisure-time exercise behavior definition as de Moor et al.[81] but now in a ten-fold larger sample of 14,626 Dutch participants, van der Zee et al.[84] still came up empty-handed. A study of 16,016 Japanese adults did report one genome-wide significance for leisure-time exercise behavior.[85]

The number of genome-wide variants detected only went up once GWAS were scaled up to hundreds of thousands of participants by using the unique resource of the UK Biobank (UKB). Klimentidis et al.[86] performed a GWAS in the UKB (N_{max} = 377,234) assessing various physical activity measures with touchscreen-based surveys, among which were included vigorous physical activity (VPA) and strenuous sports or other exercises (SSOE). After applying corrections for work-related physical activity and an indicator of socioeconomic status, a dichotomy of zero versus three days of 25+ minutes of VPA yielded six loci that were associated with variation in this VPA measure. For SSOE, a dichotomy of participants spending no versus at least two days of sports or other exercises for 15+ minutes added another five genome-wide significant loci, with the most strongly associated variant in the *CADM2* gene. The above demonstrates the main truism in the GWAS field. Samples at a scale of 100,000 participants are needed to identify genetic variants in highly polygenetic phenotypes.

Detection of the genetic variants underlying the heritability of voluntary exercise behavior is clearly still in its infancy. It is nonetheless a sure route to increased future understanding of the actual biological pathways underlying the individual differences in the choice for regular exercise behavior, that is, the biology that makes exercisers exercise but keeps non-exercisers from doing the same. Knowledge of these pathways may further help resolve causality in the well-known association of exercise with other lifestyle behaviors such as overeating and smoking, or with physical health problems like cardiovascular and metabolic disease[87] and mental health problems including depression.[88] Finally, large-scale meta-analytic GWAS of regular exercise or other physical activity traits can be used to compute polygenetic risk scores for these traits.[89] These can be exploited in stratified or personalized interventions that take innate biological differences into account and therefore increase the success of an intervention. Following existing models of the use of genetic information in healthcare, polygenetic risk scores for regular exercise behavior could be used to focus our resources for intervention on those who are likely to need the intervention the most,[90] give feedback on where they fall on the genetic risk scale to increase their motivation to engage in the intervention to avert an unwanted (disease) outcome,[91,92] or tailor our interventions to better fit the person's genetic risk profile with regard to injury sensitivity,[93] and whether the focus should be on enjoyment, competitive performance, or what the predicted health benefits are (e.g., with regard to weight loss).

CLINICAL APPLICATIONS

In keeping with the acknowledged importance of the interplay of nature and nurture in many other behavioral traits, future interventions to increase regular exercise behavior should prominently include knowledge of its genetic/biological determinants instead of sole reliance on social/environmental determinants. Although research on the specific genetic/biological determinants is in its early phase, and the use of polygenetic scores is still only a future promise, some recommendations can already be extracted from the twin and family studies reviewed here to increase the success of interventions on regular exercise behavior:

- In childhood, shared environmental influences additionally explain family resemblance in exercise behavior, implying that family-based interventions

provide a meaningful route to increase this health behavior in children.

- In adolescence, shared environmental influences appear to be largely generation-specific and innate factors become a dominant influence. This implies that interventions in adolescence should be tailored to the individual and their relationship with peer groups. A large emphasis on athletic competence, for instance, might be counterproductive for those adolescents at the low end of innate exercise abilities.
- Adulthood sees a substantial decrease in the prevalence of regular exercise behavior, with the increased competition for time by work-related and social roles. Given the increasing resemblance in the exercise behavior of spouses over time, partner programs can be an effective strategy. Despite the increased importance of unique environmental factors, genetic factors remain important in determining who will become/remain an adult exerciser. Enforcing preset levels on the frequency, duration, and intensity of exercise activities in guidelines may not be compatible with variation in the innate ability to enjoy and "feel good" after intense or prolonged exercise.

121 Influence of Physical Activity on Brain Aging and Cognition

James M. Rippe, MD and Steven J. Petruzzello, PhD

KEY POINTS

- Physical activity plays an important role in brain health throughout the lifespan.
- Numerous studies have shown that physical activity enhances cognition throughout the lifespan.
- Physical activity improves biomarkers of brain health.
- Physical activity decreases the likelihood of various dementias including Alzheimer's disease.
- Physical activity plays an important role in improving affect and decreasing anxiety and tension.
- Physical activity plays an important role in multiple aspects of healthy sleep.

121.1 INTRODUCTION

There are strong associations between physical activity and cognition and brain health, in general.[1–16] These associations are particularly relevant as the worldwide population continues to age.

Issues related to brain health and cognition have become increasingly important, particularly in the older population, and across the lifespan. A robust scientific literature has emerged in this area. The concepts in this chapter utilize the same definition of brain health that was adopted by the Physical Activity Guidelines for Americans Advisory Committee 2018 Report (PAGA, 1), which stated that brain health is a concept that involves "optimal or maximal functioning of behavioral and biological measures of the brain and its subjective experiences arising from brain function".[1] This is a very similar definition that has been adopted in the Presidential Advisory Statement from the American Heart Association and American Stroke Association entitled "Optimal Brain Health".[17]

Research in neurobiology has advanced significantly in the last decade. There are multiple aspects of brain health including cognition, reduction of the risk of dementia,[18] perception of quality of life,[19] and sleep.[20] Advances in technology have also allowed the measurement of a variety of biological markers of brain structure and function. Numerous studies have now shown a strong and positive relationship between physical activity and brain health. These studies provide the underpinnings both for the recent focus on this topic from the PAGA 2018[1] and AHA/ASA Presidential Advisory[17] on "Optimizing Brain Health".

Issues of physical activity, brain health, and cognition are critically important to practitioners of lifestyle medicine since physical activity is one of the cornerstones and pillars of lifestyle medicine. The linkages between physical activity and brain health are an important and emerging area of interest in lifestyle medicine. With all of these factors in mind, it is a propitious time to consider issues related to brain health both from an individual and a public health standpoint.

121.2 BACKGROUND ON PHYSICAL ACTIVITY IN BRAIN HEALTH

Important research in the area of physical activity and cognition began to appear in the 1970s, both with animal and human investigations.[21] These studies examined physical activity and its impact on dopamine and reaction time in older and younger subjects. Several researchers reported faster reactivity (shortened reaction times) in older men and women who engaged in regular physical activity.[22–24] These findings contributed to the notion that reaction time was an index of the general integrity of the neurologic system and thus a proxy for cognitive function. Experiments in animal models supported these findings and further advanced this field.[25,26]

The next major breakthrough in human research involved the assessment of physical activity-induced effects on decision-making abilities. Studies showed that both intelligence and reasoning were enhanced by physical activity. Electroencephalography (EEG) technologies, which evolved in the 1990s, allowed more specific evidence concerning how the brain functioned in younger and older men who had high levels of physical activity. These findings led to important studies demonstrating that cognition was enhanced in physically active individuals.

Contributions in this area were buttressed by research utilizing newly available technology, namely magnetic resonance imaging (MRI), which demonstrated positive relationships between brain tissue density and the integrity of white matter and cardiovascular fitness in both men and women.[27] These MRI studies also led to findings that individuals with higher levels of cardiovascular fitness demonstrated resistance to atrophy of the brain with aging.

This line of research ultimately led to additional studies utilizing advances in genetics which showed strong

DOI: 10.1201/9781003227793-141

cognitive benefits of physical activity for carriers of the APOE ε4 genotype. The APOE gene has been strongly associated with a higher risk of Alzheimer's disease (AD).[28] As a result, physical activity has now entered the area of Alzheimer's research and contains enormous potential.

In addition, studies have increasingly been published in the area of aging that explore the potential of reducing cognitive decline through physical activity in middle-aged and older adults. Such studies have led to the concept of "cognitive reserve", which denotes the idea that physical activity and other healthy lifestyle factors throughout the lifespan may, indeed, promote resilience against cognitive decline in old age.[29,30]

121.3 PHYSICAL ACTIVITY AND AGING

The positive role of physical activity on cognition has been most strongly demonstrated in men and women over the age of 60 years.[31] Individuals in this age range are likely to incur age-related decline in central nervous system (CNS) function, potentially due to inflammation or oxidative stress. The research examining physical activity in older adults has shown strong benefits suggestive of protective effects, slowing the cognitive decline typically associated with aging and dementia-related pathology.

It has been well described that as individuals age, changes in multiple organ systems occur. In particular, the effect of aging on the brain includes significant structural changes. These changes include loss of neurons and synaptic plasticity, particularly in the prefrontal cortex, which can result in a less efficient brain as well as decreases in memory and difficulties in "executive function",[32] an aspect of cognitive functioning that includes cognitive control, mental flexibility, and working memory, all of which are largely dependent on the prefrontal cortex. In contrast, knowledge and expertise tend to be well maintained in normal aging. These processes are largely independent of frontal lobe activity.[33]

In addition, decreases in brain volume are seen with normal aging by the seventh decade. Older individuals tend to compensate for reduced brain activity by instituting various aspects of the brain to accomplish tasks.[34] The change in the frontal lobe, and prefrontal cortex, in particular, is demonstrated functionally by a loss of such executive functions as working memory.

One physical change in the brain associated with pathologic aging is the development of amyloid plaque and neurofibrillary tangles (NFTs).[35] These structural changes in the brain may be responsible for initiating the disease process of dementia and ultimately lead to AD.

121.4 BENEFITS OF PHYSICAL ACTIVITY ON BRAIN AND COGNITION

Several biological processes may underlie the benefits of physical activity on cognition. Effects of physical activity on various biological aspects of the brain underscore the ability of physical activity to enhance cognitive reserve.[36] These biological aspects include neurotransmitters and neurotrophic factors THAT allow for increased growth and survival of neurons. In addition, physical activity enhances connections between neurons, classified as synaptogenesis, as well as the growth of new neurons (neurogenesis) and increased cerebral blood flow (angiogenesis).

Research has demonstrated that regular physical activity results in a reduction of age-related brain atrophy, and in some instances, a reversal of neural decline (i.e., neurogenesis, synaptogenesis). Several studies have shown increases in brain volume in both grey and white matter after a six-month aerobic exercise intervention.[37] Various executive functions such as inhibitory control, mental flexibility, and memory decoding have all shown benefits from physical activity.

Physical activity may also delay the symptoms associated with dementia and the normal aging process. The emerging literature on individuals with advanced Alzheimer's disease has shown mixed results in the area of physical activity.[17] However, individuals who have mild cognitive impairment (MCI) demonstrated significant improvement in executive function with increased physical activity. This is important since MCI is thought to be a stage often leading to AD. These studies in MCI patients suggest that physical activity reversed some of the neuropathological properties.[17] The mixed results in Alzheimer's patients suggest that the benefits of physical activity are more likely after long-term interventions. As such, changes in physical activity earlier in life are very important for lowering the risk of AD.

121.5 DEFINING OPTIMAL BRAIN HEALTH

The role of cognitive function and other aspects of brain health provided the underlying rationale for the American Heart Association (AHA) and American Stroke Association (ASA) to issue a joint Presidential Advisory to define "optimal" brain health in adults.[17] This Advisory underscores the concept that cardiovascular risks are also closely associated with brain health for the prevention of dementia in later life. A healthy brain is essential for living a long and full life. Sustaining brain health over the course of a lifetime is essential to maximize one's overall quality of life, functional ability, and independence.

As the AHA-ASA Presidential Advisory notes, most definitions of brain health emphasize the absence of overt vascular or neurogenetic injuries such as from strokes or AD. However, "optimal" brain health extends this concept to include the capacity to function and adapt to the environment. This underscores the important role of cognition.

The recommendations from the AHA-ASA Presidential Advisory emphasize seven metrics to contribute to optimal brain health, including increased physical activity. This is the same framework initially defined by the AHA as "Life's Simple 7".[38] These metrics include not smoking, consuming

a healthy diet, weight management (BMI less than 25 kg/m^2), and a strong emphasis on physical activity. The metrics in "Life's Simple 7" closely mirror the pillars of lifestyle medicine. An added benefit of following these metrics involves the important role they also play in minimizing risk factors for heart disease and stroke, including high blood pressure. The Presidential Advisory notes that physically active individuals have a 35% lower risk of cognitive decline compared with those who are physically inactive. These findings are very similar to those published in the PAGA 2018.

The role of physical activity in lowering the risk of heart disease and also in maintaining brain health is important for both individuals and public health. Multiple studies have shown that physical activity improves cognitive function throughout the lifespan. It is particularly important for older individuals. It is estimated by the year 2050, the population of adults over age 65 in the United States will reach 83.7 million individuals, which is double the 2012 level of 43.1 million.[1] Physical activity may be both an efficacious and cost-effective approach to improving multiple aspects of health, including cognitive function, in this population.

In the area of dementia and AD, the Alzheimer's Disease Foundation estimates that the annual cost of AD in the United States is approximately $250 billion per year. It has been estimated that in the last five years of life, the cost of dementia per person was $287,000.[39] These costs associated with AD and other dementias may increase to $785 billion per year by 2050. Increased physical activity may be a highly effective approach for lowering both the risk of developing AD as well as mitigating its cost. It has been estimated that 21% of AD cases in the United States are attributed to physical inactivity. If a 25% increase in physical activity could be achieved, it could potentially prevent 230,000 cases of AD.

In addition to its other benefits, increased physical activity improves quality of life (QOL).[40] Low levels of QOL have been linked to higher mortality risk in older individuals as well as greater use of healthcare facilities.

Regular physical activity has also been demonstrated to improve mental health, including reducing risk of depression and anxiety. Both depression and anxiety are common in the adult population in the United States. Increased physical activity has been shown to be as or more effective than pharmaceutical therapy for both of these conditions.

121.6 PHYSICAL ACTIVITY IN COGNITIVE RESERVE

The strong research base on the multiple benefits of physical activity on the brain throughout the lifespan has led a number of investigators to propose the concept of "cognitive reserve". Cognitive reserve refers to the capacity of the mature adult brain to sustain function and resist the effects of disease or injuries sufficient to cause a decline in cognition or the development of clinical dementia. It has been postulated that individuals who experience these declines have less cognitive reserve than individuals who do not and that physical activity helps build and maintain cognitive reserve.[36]

Cognitive reserve may be classified either as active or passive reserve. Active reserve relates to the adaptability of neurocircuits to respond to cognitive challenges. This can be exemplified by compensation and the use of other parts of the brain when confronted with challenges. Passive reserve, in contrast, refers to the structural properties of the brain. This involves brain tissue density, white matter integrity, and vascularity. Research has demonstrated that cognitive reserve is correlated with neurotransmitters and neurotrophic factors as well as an increase in synaptogenesis (generation of new brain synapses) and neurogenesis (generation of new neurons).[41,42] All of these factors appear to be related to increased physical activity.

It should be noted that cerebral blood flow decreases with age and dementia. Physical activity has also been shown to improve blood volume and vasculature in the brain through a process called angiogenesis. This process involves the development of new blood vessels through sprouting of the existing vessels and epithelial cells.

All the above processes are components of cognitive reserve and are positively influenced by physical activity. Thus, physical activity has enormous potential to help delay the onset of deterioration of cognitive function.

121.7 THE ROLE OF PHYSICAL ACTIVITY IN BRAIN HEALTH AND COGNITION

The PAGA 2018 Scientific Report devoted a whole section to the interface between physical activity and brain health, in general, and cognition, in particular.[1] In the area of cognition, improvements from physical activity were demonstrated for academic achievement and processing speed as well as memory, executive function, and decreased risk of dementia. Most of the evidence for these benefits comes from aerobic activity (e.g., brisk walking), although other forms of exercise (e.g., muscle strengthening, sports participation, yoga) may also contribute to these benefits.

Strong evidence also exists that physical activity has transient benefits for various domains of cognition such as working memory and processing speed. These findings have been demonstrated, particularly in children and older adults.[43]

Chronic effects of moderate or vigorous physical activity have been demonstrated, particularly in individuals over the age of 50. These benefits extend to individuals who have evidence of mild impaired cognition and may also be of benefit in conditions such as attention deficit hyperactivity disorder and Parkinson's disease.

The most dramatic improvements in cognitive function based on physical activity have been shown to involve executive function, which relates to impulse control and the ability to plan activities.

121.8 PHYSICAL ACTIVITY AND IMPAIRED COGNITIVE FUNCTION

Cognitive function is vitally important for the ability to plan actions and maintain neural connections which, in turn, are essential to optimize QOL and independence.[17] In essence, a healthy brain is essential for both living a longer and fuller life. Poor brain health may be associated with such underlying disorders as AD, stroke, and other causes of vascular cognitive impairments including brain trauma and neurodegenerative disorders.

The United States has the second largest number of people living with AD (3.9 million people), exceeded only by China (5.4 million people with AD).[44] Worldwide, over seven million new cases of dementia are diagnosed annually, and by 2050, the prevalence of dementia is expected to increase by over 100% in high-income countries and over 250% in low-income countries. It has been estimated that more than 10% of adults over the age of 60 have some component of memory loss and 35% report at least some level of functional difficulty.[45] The PAGA 2018 Scientific Report documents that greater amounts of physical activity are associated with reduced risk of cognitive decline and risk of dementia including AD. Some evidence indicates that physical activity can improve cognitive function, particularly with those who have mild cognitive impairment and perhaps even those who have mild degrees of dementia.

121.9 PHYSICAL ACTIVITY AND QUALITY OF LIFE

The concept of quality of life is based on the way individuals perceive and react to their health status or non-medical aspects of their lives. QOL is typically divided into health-related QOL and non-health-related QOL. The relationship between physical activity and perceived positive QOL is strong and is particularly evident in older adults (over the age of 50) and particularly over the age of 65. Even younger individuals between the ages of 18 and 65 improve health-related QOL based on physical activity compared with treatment control. As such, physical activity is an important contribution to leading productive and happy lives with improved QOL.

121.10 PHYSICAL ACTIVITY AND AFFECT

Affect may be defined as the subjective experience of feeling states including pleasure, displeasure, and arousal.[46] The PAGA 2018 Scientific Report documents that there is strong evidence that there seems to be a relationship between the level of exercise intensity and affect. For example, high levels of intensity of exercise may actually lead to negative affect. There is increasing evidence that the way people feel during physical activity is an important determinant of their continued participation. Physical activity has been demonstrated to reduce acute ("state") anxiety and longer participation in physical activities can reduce "trait" anxiety in both middle-aged and older individuals.[47–51] (See Section 121.11.) Physical activity can also reduce symptoms of depression. (See Section 121.12.)

121.11 PHYSICAL ACTIVITY AND ANXIETY

Anxiety has been defined as a "noticeable psychological, physical, emotional state most characterized by feelings of apprehension, fear or expectation of fear, worry, nervousness and physical expectations arising from activation of the autonomic nervous system". The annual prevalence of significant anxiety disorders is estimated to be approximately 18% in the United States. Females are more likely to experience anxiety than males. Anxiety is considered pathological when it emerges in situations that are not objectively dangerous, are excessively strong, or significantly constrain the life of the individual affected with anxiety. Symptoms of anxiety may also be reflective of high levels of stress in the modern world.

The relationship between physical activity and anxiety and anxiety disorders has been studied in numerous research trials.[47–51] Physically active people are found to have decreased emotional stress. Regular physical activity has been shown to lower anxiety in healthy individuals. Most of the literature is based on aerobic activity, although there is some evidence that decreased anxiety may be found in response to resistance strength training.[52] Physical activity may deflect negative thoughts or emotions. Physical activity carried out in a group may contribute to social interactions, which may contribute to relieving anxiety. There is some evidence that regular physical activity may increase endorphins, which may contribute to its anxiety-reducing benefits. This has been largely speculative in the past, but recent evidence from PET scans has suggested that decreased levels of anxiety correlate with opioid-like binding in several brain areas. These findings, however, are preliminary and need to be confirmed with further studies.

121.12 PHYSICAL ACTIVITY AND DEPRESSION

Major depressive disorders (MDD) annually affect approximately 10% of the population in the United States.[53] The lifetime prevalence of MDD is 10% in men and 15% in women. Even if individuals do not meet diagnostic criteria for MDD, symptoms of even mild depression can have a negative impact on health.

Physical activity has been shown in multiple studies to lower the risk of depressive disorders.[54,55] There is evidence of an inversive relationship between symptoms of depression and physical activity, although the complexity of this relationship suggests that these relationships be treated with caution. Physical activity (particularly aerobic activity) has also been associated with a reduced risk of developing depression. This appears to exhibit a dose-response relationship. One study showed that engaging in more than 30

minutes/day of physical activity reduced the odds of experiencing depression by 48%.[54] Most studies in this area have been based on a model of 12 weeks of physical activity and examining its effects on depression.[56–62]

Studies have shown significant decreases in depressive symptoms throughout the adult lifespan. Physical activity has been shown to be equally effective for lowering symptoms of depression as cognitive behavioral therapy and anti-depressant pharmaceutical therapy.

121.13 PHYSICAL ACTIVITY AND SLEEP

The PAGA 2018 Scientific Report reports strong evidence that both acute and regular bouts of physical activity improve sleep outcomes in adults.[1] There is also evidence that physical activity improves sleep outcomes across age and sex.

Sleep is a pillar of lifestyle medicine and it is important to health and well-being across the lifespan.[63] Sleep plays a critical role in biological functions and it is important in neural development, learning, memory, emotional regulation, cardiovascular health, and metabolic health. Numerous studies have shown that sleep latency (length of time between going to bed and falling asleep), total sleep time, sleep efficiency, sleep quality, daytime sleepiness, insomnia, and obstructive sleep apnea are all improved with regular physical activity.[64–69] These benefits have been shown in a variety of different age groups including young, middle age, and older men and women.

Improvements in sleep carry significant public health benefits. For example, approximately 10% of adults have clinically diagnosed insomnia[70] and 26% of adults between the ages of 30 and 70 suffer from obstructive sleep apnea (OSA).[71] In addition, 25% of the population reports getting insufficient sleep for at least 15 hours every 30 days, and between 25% and 48% of the population report a sleep problem of some kind.[72] Thus, physical activity can play a major role in a variety of conditions. It should also be noted that sleep problems are associated with increased risks of accidents, cardiovascular risk factors, obesity, stroke, and all-cause mortality. It has been estimated that the United States suffers economic costs in excess of $400 billion/year as a result of insufficient sleep.[73]

121.14 SUMMARY

The linkages between physical activity and brain health are wide-ranging and profound. This includes not only cognition but also risk of a variety of chronic diseases and overall quality of life. For this reason, both the PAGA 2018 Scientific Report and Presidential Advisory on "optimal brain health" from the AHA and ASA focus on physical activity and improved brain function and cognition. For all of these reasons, it is incumbent upon lifestyle medicine practitioners to inquire about both physical activity and various aspects of brain function in every clinical encounter.

CLINICAL APPLICATIONS

- Increased physical activity is essential for multiple benefits in virtually every patient.
- The relationship between physical activity and cognition is particularly important and often underemphasized in clinical medicine.
- Emerging evidence has accumulated that regular physical activity is important for many aspects of brain health including cognition.
- Physical activity also positively interacts with several other factors related to brain health including improved mental health, lower risks for anxiety and depression, and improved sleep.
- Physical activity is important not only to brain health maintenance and appropriate cognition but also in decreasing the likelihood of age-related cognitive decline and other forms of dementia.

122 Physical Activity and Anxiety

Katharina Gaudlitz, MSc, Brigitt-Leila von Lindenberger, MSc, Tim Aurich, and Andreas Ströhle, MD

KEY POINTS

- Anxiety disorders are the most common mental disorder, with global estimates calculating a prevalence of up to 25%.
- Anxiety disorders can be treated with psychotherapy, medication, and complementary methods (e.g., exercise), however, demand for more effective treatment remains high.
- Regular physical activity is linked to less anxiety, but more research is needed to show a definitive preventative effect.
- One-time exercise seems to have an acute anxiolytic effect in individuals with and without anxiety disorders.
- The literature is sparse concerning specific disorders, but findings suggest a therapeutic effect in patients with agoraphobia/panic disorder, posttraumatic stress disorder, obsessive-compulsive disorder, generalized anxiety disorder, and social anxiety disorder, but not in specific phobia.
- Both aerobic exercise and resistance exercise show anxiolytic effects.
- Psychological and biological mechanisms seem to mediate the beneficial effects of physical activity on anxiety.

122.1 ANXIETY: DEFINITIONS AND DIAGNOSES

Anxiety, in general, is a normal and even essential human emotion, as it secures survival. In preparing for a fight or flight reaction, it signals (assumed) danger and may so protect the organism from harm. It activates physiological changes (e.g., sweating, faster heartbeat, and breathing), and, consequently, also has cognitive (e.g., dashing thoughts) and behavioral (e.g., leaving the situation) correlates. Panic is differentiated from anxiety by having even faster changes and very quick onset. So, a panic reaction is a fast, defensive reaction, which allows the organism to leave a possibly dangerous situation as quickly as possible.

Anxiety is considered pathological if it emerges in situations not objectively dangerous, if it is excessively strong, and if anticipatory anxiety constrains the life of the affected.[1,2] In this regard, anxiety disorders can be differentiated from "normal" and subclinical anxiety. According to the International Classification of Diseases 11 (ICD-11) of the World Health Organization (WHO), anxiety disorders are grouped within anxiety and fear-related disorders (6B).

We will focus here on diagnoses relevant to the chapter, that is, anxiety disorders and other related disorders that have been studied in association with physical activity. For any other detailed diagnostic criteria, we recommit to the ICD-11.[2]

Generally, the specific diagnoses can be classified by the nature of anxiety. In phobic anxiety disorders, anxiety is evoked only, or predominantly, by well-defined situations, which are not dangerous. As a result, these situations are avoided whenever possible or endured with dread. Furthermore, contemplating entering the phobic situation generates anticipatory anxiety.

Agoraphobia:

- Anxiety in at least two of the following situations: public places, crowds, traveling far away from home, or traveling alone. Agoraphobia is further specified by the existence of a history of panic disorder.

Social anxiety disorders (SAD):

- Anxiety centered around the fear of scrutiny by other people.

Specific (isolated) phobias:

- Anxiety is restricted to highly specific situations such as proximity to particular animals, heights, thunder, and dental treatment, and the phobic stimulus is avoided whenever possible.

In contrast, in the so-called "other anxiety disorders", the manifestation of anxiety is the major symptom and is not restricted to any particular situation or object.

Panic disorder (PD):

- Core features are recurrent attacks of severe anxiety (panic). These are discrete periods of intense fear accompanied by somatic or cognitive symptoms like sweating, trembling, breathlessness, dizziness, fear of losing control, or even mortal fear. Panic attacks are unpredictable as they are

DOI: 10.1201/9781003227793-142

not restricted to any particular situation or circumstance. Although anticipatory anxiety (fear of further panic attacks) is common, people experience intervals without anxiety in between the attacks.

Generalized anxiety disorder (GAD):

- The essential feature is anxiety, which is free-floating, that is generalized and persistent but, again, not restricted to any particular situations or circumstances.
- Furthermore, patients present with worries (e.g., that they or a relative will become ill or have problems), muscular tensions, vegetative hyper-irritability, and other physical symptoms.

Obsessive-compulsive disorder (OCD):

- Essential features are recurrent obsessional thoughts and/or compulsive acts, which are distressing, and the patient often tries to resist them.
- The acts are done to prevent objectively unlikely events, which the patient fears might otherwise occur. Anxiety is almost invariably present and gets worse if compulsive acts are resisted.

Post-traumatic stress disorder (PTSD)

- Differs as to the existence of causative influences. It occurs as a response to a stressful event or situation of an exceptionally threatening or catastrophic nature, which is likely to cause distress in almost anyone.
- Typical features include episodes of reliving the trauma and feelings of emotional "numbness", feeling detached from other people, unresponsiveness to surroundings, anhedonia, and avoidance of activities or situations resembling the trauma. Usually, autonomic arousal with hypervigilance, an enhanced startle reaction, and insomnia are also present.

122.1.1 Anxiety Disorders: Incidence and Impact

Among all mental disorders, anxiety disorders are the most common, and their prevalence and course are reasonably well described. The overall prevalence of anxiety disorders is shown to be high. Global estimates assume a prevalence ranging between 3.8 and 25%[3] Data from the United States suggests considerable variations between the most (specific phobias, 15.6%) to the least prevalent (OCD, 2.3%) disorders. The age of onset is typically in childhood or adolescence, the course is often chronic-recurrent, and anxiety disorders are highly comorbid with each other and with other mental disorders.[4] Furthermore, except for OCD, women are at a significantly higher risk of suffering from anxiety disorders.[5]

The individual and social impact of anxiety disorders has been pointed out repeatedly. Anxiety disorders constitute a major health economic challenge, and their costs might even have been underestimated in the past.[6] The economic costs include psychiatric and non-psychiatric care, emergency care, hospitalization, drug prescription, reduced productivity, absenteeism from work, and suicide.[7] On a more individual level, anxiety disorders predict numerous unfavorable sociodemographic, clinical, and functional outcomes and are especially associated with unfavorable interpersonal outcomes.[8]

122.2 TREATMENT: HOW CAN ANXIETY DISORDERS BE TREATED?

122.2.1 Psychotherapeutic Treatment of Anxiety Disorders

Cognitive behavioral therapy (CBT) is long known to be the gold standard in psychotherapy for anxiety disorders. Its positive effect is one of the best-assured results in psychotherapy research in general. Numerous clinical trials have supported the efficacy of CBT for anxiety disorders. Several meta-analytic results of treatment outcome studies have supported this finding, showing strong effects of CBT for panic disorder and agoraphobia, social phobia, OCD, GAD, and PTSD.[9] Cognitive therapy and exposure therapy alone, in combination, or combined with relaxation training have been shown to be effective across different anxiety disorders, with no differential efficacy for any treatment components for any specific diagnoses.[9] Superior effects for CBT in GAD and PTSD but not for SAD were the only difference in the diagnostic level reported here. In line with these earlier findings is a more recent review of meta-analytic findings on the efficacy of CBT for the treatment of anxiety disorders by Olatunji et al.[10] The authors reviewed contemporary meta-analytic studies and support the finding that CBT procedures, and particularly exposure-based treatment approaches, are highly efficacious.

Self-help efforts have been evaluated, playing a role as an initial basic treatment in stepped-care models of treatment or as a strategy to prevent a disorder from developing. Furthermore, they are promising in meeting the lack of professionals providing evidence-based psychotherapy and the demand for treatment with minimal cost to health services. For a review of the outcomes of self-help efforts, see Morgan and Jorm.[11] Researchers also explored the possibility of using the Internet to deliver CBT (Internet-assisted CBT, ICBT). Recent reviews and meta-analyses report that therapist-supported ICBT appears to be efficacious in treating anxiety in adults and that therapist-supported ICBT may even not be significantly different from face-to-face CBT in reducing anxiety.[12, 13] Newer meta-analyses analyzing the evidence for specific anxiety disorders also show positive results, underlining the potential of ICBT.[14–16]

122.2.2 Pharmacological Treatment of Anxiety Disorders

The pharmacological treatment of anxiety disorders has been studied intensively and clinical trials showing its effectiveness have been well replicated. Selective serotonin reuptake inhibitors (SSRIs) and selective serotonin-norepinephrine reuptake inhibitors (SSNRIs) are recommended as first-line drugs due to their positive benefit/risk balance.[17] Other options include the calcium modulator pregabalin, tricyclic antidepressants (like imipramine and clomipramine), buspirone, moclobemide (selective and reversible inhibitor of monoamine oxidase), the antidepressant agomelatine, and the atypical antipsychotic quetiapine.[17] Benzodiazepines are very effective due to their rapid onset of action and ability to be used on an on-demand basis, although their long-term use is not recommended because of their potential for abuse and dependence and their lack of antidepressant properties.[17] The most recent development in the field of pharmacotherapy for the treatment of anxiety disorders is the antidepressant vortioxetine, which was investigated in controlled studies involving patients with GAD. However, no significant improvement compared to placebo could be demonstrated meta-analytically.[18]

122.2.3 Is a Combination of Pharmaco- and Psychotherapy Even Better?

To increase the efficacy of either psychotherapy or pharmacological treatment, the combination of both has been discussed as an option for faster and more sustained treatment. Although this approach may seem obvious, confirming empirical findings are not.

Pull[19] found little benefit for a combination of psychotherapy and pharmacotherapy for the treatment of anxiety disorders versus monotherapies when taking randomized controlled trials (RCTs), meta-analyses, and reviews into account. Zwanzger et al.[20] found that there might be evidence for the superiority of combination therapy under some conditions, although the authors did not see evidence for the beneficial effects of combined treatment for long-term outcomes. Consistently, Hofmann et al.[21] report in their meta-analysis that pharmacotherapy may be a useful strategy for enhancing acute-phase CBT outcomes, while they do not support the benefit of combination therapy for long-term CBT outcomes. Interestingly, the authors report a significant publication bias in terms of smaller effects in more recent studies, which might be due to more rigorous assessment methods.

The most recent meta-analysis in the field shows that combinations of psychotherapy and pharmacotherapy have a large effect size.[22] However, only a few combination studies were seen as suitable for the comparison due to methodological reasons and some of these had not been conducted with the most powerful drugs.[23] Current treatment recommendations generally list CBT and pharmacotherapy as equally beneficial for panic disorder, agoraphobia, GAD, and social phobia,[24] while the preference of the informed patient is emphasized to be decisive. A combination of both is recommended if monotherapy is not sufficient.[22] For specific phobias, OCD, and PTSD, psychotherapy is seen as superior and recommended as first-line treatment.[23–26]

122.2.4 Complementary Treatment Methods and Add-Ons

Complementary and alternative interventions to treat anxiety are highly popular, and evidence in the past was sparse.[26] There is a growing body of literature, though official guidelines have oftentimes not yet included these treatments.[27] Hypnosis and biofeedback as well as methods of complementary medicine such as acupuncture, osteopathy, or homeopathy are often recommended by healthcare practitioners, however, controlled studies fulfilling basic methodological standards are lacking.[17]

On the side of phytotherapy, inconsistent results have been shown, with lavender oil, kava-kava, *Withania somnifera*, and *Gingko biloba* being among the most promising candidates.[28] However, further research is needed due to methodological shortcomings and to confirm preliminary findings.[28] Meditation, relaxation training, and yoga are shown to be somewhat effective in numerous disorders, even though the potential risk of bias has been pointed out repeatedly.[29,30] Mindfulness-based interventions (MBIs), as an increasingly popular therapeutic approach, have been taken into the scope of research. They seem to be effective in the treatment of anxiety and have been shown to increase the effectiveness of CBT, though further research is warranted.[29, 30]

Exercise has been considered a promising therapeutic option for anxiety disorders, as in a wide range of research it has been shown to have positive effects on major depression.[31] However, recent meta-analyses emphasize that the positive effect of exercise in the treatment of depression might have been overestimated, when taking a closer look into the methodology of confirming studies[32] or when closely compared with psychological treatment or antidepressant medication.[33]

A detailed illustration of evidence-based results for the link between anxiety disorders and physical activity will be given in the following passages.

122.3 WHAT LINKS ANXIETY (DISORDERS) AND PHYSICAL ACTIVITY?

Physical activity has been defined as bodily movements produced by skeletal muscles that result in energy expenditure.[34] It, therefore, includes either leisure activity (jogging, cycling, etc.) which increases fitness, as well as gardening, housework, or walking. Exercise is seen as a subset of physical activity, as it is defined as planned, structured, and repetitive physical activity that has improvement or maintenance of physical fitness as a final or intermediate

goal.[34] Earlier research had focused on the effect of exercise explicitly,[35] while more recent research has also focused on everyday physical activity, which is seen as beneficial for health.[36] In the literature, though, both terms are not always differentiated. In the following, we will review studies on physical activity, exercise (training), and sports.

122.3.1 Physical Activity and the Prevalence and Incidence of Anxiety Disorders

Physical activity is long known to be associated with a range of health benefits and the absence (i.e., inactivity) can have harmful effects on health and well-being as it increases the risk for medical disorders like coronary heart disease, diabetes, certain cancers, obesity, and hypertension, as well as all-cause mortality.[37]

Compared with a wide range of research on the positive effects of physical activity on depression, anxiety disorders have been less frequently studied. Additionally, the diversity of anxiety disorders makes it difficult to generalize from studies on one specific anxiety disorder to others. Furthermore, changes in the diagnostic criteria complicate the interpretation of early studies.

Cross-sectionally, the link between physical activity and anxiety has been intensively studied, and high self-reported levels of physical activity have generally been found to be associated with better mental health, including lower emotional distress and fewer symptoms of anxiety.[38–44]

Concerning different diagnoses in the field of anxiety disorders, Goodwin[45] analyzed the data of the US National Comorbidity Survey and found significant associations between regular physical activity and a lower prevalence of specific phobia, social phobia, panic disorder, and agoraphobia in a representative sample of adults in the United States. A representative, cross-sectional study in Japan[46] including 4000 people showed a positive relation between dislike of physical activity and higher odds ratios for panic attacks and panic disorder, which was found to be especially true for women. A Dutch study reported lower rates of anxiety disorders in individuals who exercised at least one hour per week, without evidence for a linear dose-response relationship.[47] On the other hand, studies can also be found that do not support the association between physical inactivity and symptoms of anxiety.[48–51]

Problems occur when trying to compare these studies as the measurements of anxiety and physical activity are inconsistent. Furthermore, in most studies, fitness was not directly assessed, and measuring exercise habits and anxiety disorders in cross-sectional surveys generally is ambiguous about cause and effect. Prospective longitudinal studies are needed to prove the hypothesis that physical activity has a preventative effect on anxiety but are rare when it comes to anxiety disorders.

McDowell et al.[52] suggest a small preventative effect in their recent review and meta-analysis of prospective cohort studies, although study quality was low-moderate. In line, Teychenne et al. reviewed the literature and found sedentary time to be inversely associated with symptoms of anxiety.[53] In contrast, a newer meta-analysis[54] examining the effectiveness of physical activity in the primary prevention of anxiety found no preventative effect, with study quality being low. Despite results suggesting an association between physical activity and fewer symptoms of anxiety, more high-quality, consistently designed prospective studies and meta-analyses are still needed. Furthermore, it is not yet clear whether there is a causal relationship between physical activity and (less) anxiety, as often is implicitly assumed in population-based studies. It is also conceivable that common genetic factors both influence exercise behavior and anxious symptoms, a possibility supported by evidence from a Dutch study.[55]

122.3.2 Evidence of the Therapeutic Impact of Physical Activity on Anxiety

122.3.2.1 Anxiolytic Effect in Healthy Individuals

The anxiolytic effect of aerobic exercise in healthy individuals has been investigated in numerous studies and several older meta-analyses suggest a fear-reducing effect in healthy people.[56,57] More recent reviews and meta-analyses confirm evidence of an anxiolytic effect of exercise on anxiety symptoms in people without established anxiety disorders.[58] For the anxiolytic effect on trait anxiety, a training period of at least ten weeks and a workout in the aerobic power range seem to be critical,[56] while reductions in state anxiety immediately after performing single bouts of exercise have also been reported.[59,60] Recently, a study examining the anxiolytic effects of resistance exercise also showed promising results, meaning that patients could potentially have more options when it comes to choosing exercise intervention.[61]

122.3.2.2 One-Time Physical Activity and Anxiety

The anxiolytic effect of a one-time physical activity was first described by Orwin.[62] Other early case reports also described the anxiolytic effect of one-time physical activity in patients with specific phobias.[63,64] Symptoms of anxiety in healthy people, in whom panic attacks were experimentally induced by caffeine intake, cholecystokinin tetrapeptide (CCK-4), or CO_2 inhalation, decreased after a single session of physical exercise on the bicycle ergometer or a treadmill.[65–67] Before a CO_2 challenge, 18 panic disorder patients practiced either moderate exercise or very light exercise. Panic reactions were smaller in patients who performed moderate exercise compared with patients in the control condition (very light exercise)[68] In a cross-over design, healthy individuals and patients with panic disorder were studied by Ströhle and colleagues.[69] The effects of rest and 30 minutes of aerobic treadmill exercise were compared with each other after CCK-4-induced panic attacks. It was shown that panic attacks were less frequent in the exercise condition and that 30 minutes of physical

activity caused an acute anti-panic and anxiolytic effect. Similarly, Lindenberger et al.[70] showed an effect of moderate-intense acute aerobic exercise on clinical symptoms in patients with dental phobia. Recent studies suggest that acute exercise is especially helpful in individuals with high baseline anxiety,[71,72] however, not all of them show significant effects.[73] Ensari et al.[59] provide meta-analytic findings driven by high-quality studies over the last 25 years and show that acute exercise can yield small reductions in state anxiety. However, research in this field is still plagued by floor effects associated with missing studies with patients experiencing high baseline anxiety.[59]

122.3.2.3 Long-Term Physical Activity and Anxiety

The effect of physical training in patients with manifest anxiety disorders has received more attention in the last couple of years and the number of eligible studies is growing rapidly. Hence, the evidence that exercise is an effective treatment for patients with anxiety disorders is becoming clearer:

- *Panic disorder.* Early findings of a case series revealed the anxiolytic effect of aerobic endurance training in the treatment of patients with panic disorder.[74] The effectiveness of exercise in reducing symptoms was confirmed by other studies, which, however, also showed the superiority of pharmacotherapy[75,76] and psychotherapy.[77] However, one must not forget the side effects of pharmacotherapy, which are not found in psychotherapy and exercise therapy.[75] One study showed that exercise might have similar effects to relaxation techniques.[76] Gaudlitz et al.[78] showed that the effectiveness of psychotherapy can be augmented with an adjunctive exercise regimen. Newer studies also show similar trends: Plag et al.[79] demonstrated the effectiveness of high-intensity interval training in comparison with a low-intensity exercise regimen in reducing symptoms of panic disorder, with higher intensity leading to stronger effects. Lattari et al.[80] further underline these findings, showing a significant decrease in baseline anxiety following 12 sessions of aerobic exercise. Additionally, Bischoff et al.[81] found that exercise could enhance exposure therapy outcomes. Most recently, Machado et al.[82] reviewed the existing literature and concluded that exercise has positive effects on symptoms of panic disorder. However, the amount of evidence and methodological issues prevent them from recommending exercise as monotherapy for panic disorder.
- *PTSD.* There is growing evidence that patients with PTSD benefit from exercise training, although definitive statements about PTSD cannot be made yet. Rosenbaum et al.[83] conducted a review and meta-analysis of the evidence in 2015 and found that physical activity reduced PTSD symptoms more effectively than control. However, trials with yoga were included, which reduces the significance of this topic, since yoga is considered different from other types of exercise. Conversely, Nordbrandt et al.[84] could not find significant differences between the treatment-as-usual group and the exercise plus treatment-as-usual group in a relatively large RCT with traumatized refugees. However, this also may be because traumatized refugees tend to have smaller treatment effects than other populations.[84] Nevertheless, the overwhelming evidence suggests a positive effect of exercise on PTSD,[85–91] with lower baseline cardiorespiratory fitness potentially predicting a greater symptom reduction through regular exercise.[90]
- *OCD.* Promising effects of exercise for symptom reduction have been reported[92–94] and the potential clinical utility of regular aerobic exercise in conjunction with CBT for these patients has also been confirmed.[95] However, taking these and other studies together, Freedman et al.[96] could only find mixed results in their narrative review, with the only RCT reviewed having negative findings.
- *GAD.* Sparse studies show the anxiolytic effects of exercise,[97–100] with higher-intensity exercise seeming to be more effective than lower-intensity exercise.[99]
- *SAD.* Two studies show that both mindfulness-based stress reduction (MBSR) and exercise have anxiolytic effects,[101,102] with exercise being potentially more effective in individuals with more severe baseline symptoms and MBSR more effective with lower baseline symptoms.[102]
- *Specific phobias.* Patients with specific phobias were examined in studies looking at the effects of exercise on varied anxiety disorders, and the literature suggests a positive effect.[103,104] However, this disorder has not received a lot of attention regarding exercise interventions. Weisman and Rodebaugh[105] found no difference from control when examining the effects of exercise on exposure therapy outcomes in patients with specific phobia, undermining the aforementioned findings.

Most studies have focused on aerobic exercise as an intervention, with resistance exercise receiving less attention. However, this is changing, with newer studies showing comparable effects between both exercise regimens.[104] Exercise also seems to augment cognitive behavioral therapy outcomes in patients with anxiety,[106–108] which could have a significant impact on response rates.

122.3.2.4 Recent Meta-Analytical Findings

Meta-analyses by both Bartley et al.[109] and Pearsall et al.[110] do not support the claim that exercise is effective in treating anxiety symptoms and specific anxiety disorders. However, the overwhelming evidence of other systematic reviews

and meta-analyses shows a different picture. Earlier findings[58,111,112] can now be supported by more recent studies, all of which show evidence of the anxiolytic effect of exercise.[113–117] These effects are seen not only in adults but also in children and young people.[118,119] Wegner et al.[112] as well as Stubbs et al.,[58] suggest that exercise seems to be more effective in improving anxiety symptoms in people with a current diagnosis of an anxiety disorder compared with participants with a non-clinical range of anxiety. Other meta-analyses reviewing patients without anxiety disorders also find anxiolytic results,[116,120] with effect sizes similar to those of pharmacotherapy.[116] All authors agree that the database, although growing, is still sparse and that further well-conducted and methodologically sound RCTs, as well as high-quality meta-analyses, are needed to draw definitive conclusions.

In summary, physical exercise appears to have an "acute" anxiety-dissolving effect and longer-term anxiety-reducing effects when used for appropriate clinical pictures as a therapeutic add-on. Particularly suitable sports cannot be named yet, although both endurance training and resistance exercise seem to have positive effects.[119] To what extent exercise can also be used as the main intervention for anxiety disorders is still an unsettled question, although the growing evidence suggests this possibility. It is, however, certain that athletes are consistently less anxious and depressed than physically inactive people.[121] On the other hand, it is not clear whether sport sustains mental health or whether mental health and engagement in sports have a common basis.

122.3.3 Mechanisms of the Anxiolytic Activity of Exercise

122.3.3.1 Psychological Mechanisms

From a psychological point of view, there is some empirical evidence that the effect of exercise is based on the improvement of perceived coping skills and increased self-efficacy.[122] Anxiety disorders often go hand in hand with the most stressful experience of being trapped, seeing no solution, and helplessly being at the mercy of the symptoms. The possibility to gain relief through exercise opens a way out. Once a person sees a way out of a seemingly hopeless situation, and feels able to exercise control over the events, stress level decreases and the associated symptoms improve. The awareness to have the means to self-regulate improves self-confidence and thereby promotes health.[123]

Other authors believe that the effect of physical activity lies in the deflection of negative thought content.[124] If physical exercise is carried out in a group, social interaction and reinforcement could also contribute to relieving anxiety.

The anxiolytic effect of endurance training in patients with panic disorder can also be regarded as an exposure strategy toward interoceptive cues. Patients often experience normal bodily sensations such as increased heart rate or a fast pulse as dangerous or even life-threatening. If these sensations occur during a panic attack, they are inexplicable and uncontrollable for the patient. However, if these sensations occur repeatedly during exercise, the patient can get used to them, perceive them as natural and not life-threatening, and therefore alter their cognitive and affective reaction to them.[125] In this sense, exercise can be considered a form of interoceptive exposure.[126] Furthermore, exercise seems to contribute positively to the reduction of anxiety sensitivity,[125,127] which is conceptualized as a permanent fear of anxiety and anxiety-related sensations and which is a risk factor as well as a maintaining factor for anxiety-related psychopathology.

For a more detailed overview of psychological mechanisms underlying the effect of exercise on anxiety disorders, see Gaudlitz et al.[128].

122.3.3.2 Biological Mechanisms

Concerning biological mechanisms of action underlying the beneficial effect of exercise for the treatment of anxiety disorders, different mechanisms on neurochemical and physiological levels have been discussed.

It was shown that endurance training leads to a normalization of serotonin receptors[129,130] and increased levels of the neurotransmitter serotonin. This effect has been observed when serotonergic agents are administered via psychopharmacotherapy (SSRIs). Furthermore, exercise-induced changes in endorphins, endogenous peptides that act as opioid receptor agonists and are also related to mood, have long been explored. While for a certain time, these observations had been based entirely on findings of enhanced endorphin levels in the peripheral blood, Boecker and co-workers[131] were able to disclose the central mechanism and identify a relationship between exercise and perceived euphoria during exercise by using PET (positron emission tomography). The level of euphoria was significantly increased after running and was inversely correlated with opioid binding in several brain areas.[131] However, the hypothesis that endorphins mediate exercise-induced anxiety reduction has also been challenged as evidence is mixed.[132]

Exercise also has positive effects on stress reactivity (e.g., the hypothalamus-pituitary-adrenal [HPA] axis). In patients with anxiety disorders, over-activity of the HPA system might be present[133] and lead to a permanently increased release of the stress hormone cortisol into the body. This can have many adverse consequences such as the loss of nerve cells in the hippocampus or the weakening of immune reactions.[134,135] Physical activity seems to be able to reduce cortisol levels in the body or prevent increases in cortisol.[136] This finding is supported by different research results on the effects of endurance training,[137–140] but also on the effects of an acute bout of exercise on patients with specific phobia.[70] Furthermore, atrial natriuretic peptide (ANP) appears to play a role in the modulation of fear and panic and could be responsible for psychological adaptation processes during exercise. Moreover, ANP may be involved in the process of anxiolytic effects of chronic physical activity.[141]

Exercise has also been found to normalize reduced levels of brain-derived neurotrophic factor (BDNF) and therefore has neuroprotective or even neurotrophic effects. BDNF can cause nerve regeneration, particularly in the hippocampus, which is reduced in stress-affected patients. Since antidepressants produce the same effect, it is hypothesized that the antidepressant and anxiolytic effects of physical activity might be mediated by an increased release of BDNF.[132,142–144] Reduced BDNF levels have been associated with both increased general anxiety and anxiety disorders.[132] Meta-analytically driven effect size analysis generally supports the role of exercise as a strategy for enhancing BDNF levels in humans[142] and this could especially be shown for aerobic compared with resistance training interventions.[143] When using exercise therapeutically in patients with anxiety disorders, research on BDNF has been very sparse so far, so more evidence must be generated to draw definitive conclusions. Ströhle et al.[144] showed that moderate-intense exercise significantly increased BDNF concentrations in patients with panic disorder (but not in healthy controls) who had significantly reduced concentrations compared with healthy controls at baseline.

It seems that aerobic exercise modulates hormones, neurotrophic factors, and neurotransmitter levels in humans, but the individual response probably depends on factors such as genes, age, and hormonal status.[145] The latter factors would need to be integrated into future studies considering individual differences and more systematically also in patients with anxiety disorders. For a more detailed overview of biological mechanisms, see DeBoer et al.[132] and Gaudlitz et al.[128]

122.4 CONCLUSION AND RECOMMENDATIONS

Although there are many studies underlining the association between (more) physical activity and (less) anxiety, many questions remain. Also, clinicians are still waiting for answers to questions as to type, frequency, duration, and intensity of exercise to "prescribe" to whom.[146] However, the literature suggests that exercise might be more efficacious in treating anxiety in less-active people[90] and people with a clinical range of anxiety.[58,112] Furthermore, LeBouthillier and Asmundson tested aerobic exercise versus resistance training as transdiagnostic interventions and found both exercise modalities to be efficacious in improving disorder status, while aerobic exercise improved general stress and anxiety and resistance training improved disorder-specific symptoms.[104] Until this and the above-mentioned questions are further clarified, the guidelines of the WHO should be followed: Adults should at least do 150 minutes of moderate-intensity aerobic activity (e.g., brisk walking, household chores), 75 minutes of vigorous-intensity aerobic activity (e.g., running), *or* an equivalent mix of moderate- and vigorous-intensity aerobic activity each week, all performed in bouts of at least ten minutes.[147] Additionally, strengthening exercises of all major muscle groups should be performed at least two days a week.[147] Despite those widely accepted guidelines, which have been in use for almost a decade now, the challenge of implementation, especially for people with mental disorders, must be faced and input is needed from randomized controlled clinical trials. Most recently, Stevens et al.[148] suggest focusing on social identity and self-categorization theories (rather than on individual-level factors like cognition or attitudes) as a new approach that still has to be proven useful in supporting patients in engaging in physical activity.

CLINICAL APPLICATION

Population	Recommendation
Healthy individuals or individuals with a subclinical range of anxiety Individuals with anxiety disorders	Guidelines of the WHO[147]: • At least 150 minutes of moderate-intensity aerobic activity (e.g., brisk walking, household chores) • *or* 75 minutes of vigorous-intensity aerobic activity (e.g., running) • *or* an equivalent mix of moderate- and vigorous-intensity aerobic activity each week, all performed in bouts of at least ten minutes • *and* strengthening exercises of all major muscle groups at least two days per week

123 Physical Activity and Depression

Chad D. Rethorst, PhD, Darragh O'Sullivan, BS, and Matthew P. Herring, PhD, FACSM

KEY POINTS

- Evidence indicates physical activity can be utilized in the treatment and prevention of depression.
- This may be particularly relevant in diseased populations where the depression comorbidity results in significantly poorer outcomes.
- Several potential biological mechanisms underlie the antidepressant effects of exercise. Understanding these mechanisms may facilitate matching patients to effective treatment of depression.
- Future research must continue to evaluate strategies for implementing exercise as a treatment in real-world clinical settings.

123.1 PREVALENCE AND BURDEN OF DEPRESSION

Depressive disorders annually affect approximately 10% of the population in the United States with a lifetime prevalence of 10% in men and 15% in women. Costs associated with depressive disorders have grown, as the annual economic burden of depressive disorders is estimated at $210 billion.[1] Even in individuals who do not meet the diagnostic criteria for major depressive disorder (MDD), depressive symptoms have negative influences on health. Elevated depressive symptoms are associated with an increased risk of MDD,[2] reduced physical and job functioning,[3–5] higher rates of disability,[6] and increased social dysfunction.[4,7]

Further increasing the burden of depressive disorders is the limited accessibility and effectiveness of treatments. Only 55% of people with a depressive disorder receive treatment and only 32% of those receiving treatment experience alleviation of symptoms.[8] Randomized controlled trials (RCTs) have shown the efficacy of three classes of treatment in reducing depressive symptoms: antidepressants, psychotherapy, and neurostimulation.[9] Despite the empirical evidence demonstrating the efficacy of these treatments, the remission rate for initial treatment is approximately 30% and approximately one-third of patients fail to achieve remission even after multiple treatment attempts.[10–14] These data highlight the need for more cost-effective, accessible, and alternative treatments for depressive disorders. Exercise is one potential treatment that has been supported through research.

123.2 CROSS-SECTIONAL AND LONGITUDINAL STUDIES OF EXERCISE

The relationship between physical activity and depressive disorders was first identified in epidemiological work. Higher levels of physical activity and cardiorespiratory fitness have consistently been associated with lower depressive symptoms and risk of depression onset.[15–18] In a recently published meta-analysis of longitudinal associations across 111 studies, the odds of incident cases or an increase in subclinical depressive symptoms were reduced by 21% for individuals meeting WHO physical activity guidelines.[19] While the majority of epidemiological research has focused on aerobic activity, recent cross-sectional studies report lower depressive symptoms among individuals engaging in resistance training.[20–22]

Although there is strong evidence that there is an inverse relationship between symptoms of depression and physical activity, the complex and multi-faceted nature of the relationship requires that researchers gain a better understanding of how other factors may moderate or influence this relationship. Recent studies have identified that this inverse relationship exists in low- to middle-income countries,[23] exists as we age,[24] and may even exist with as little as one hour of physical activity per week.[25] However, there is no consensus on how much physical activity (PA) is protective for depression; the WHO Guideline Development Group revealed that knowledge on dose response, especially optimal dose, from adequately powered studies, is understudied.[26] Though findings have supported stronger depression odds reductions after moderate and vigorous PA which met WHO guidelines[19] the impact of meeting PA guidelines has not been the focus of the majority of available investigations. Research from The Irish Longitudinal Study on Ageing (TILDA) Waves 1 and 2, which is one of only three studies evaluating the association between meeting PA guidelines and depression, showed that meeting PA guidelines was cross-sectionally associated with 40% lower odds of depression, and conferred small-to-moderate protective effects against developing depression (23%).[27]

123.3 RANDOMIZED CONTROLLED TRIALS OF EXERCISE

123.3.1 Efficacy of Aerobic Exercise in Reducing Depressive Symptoms

Building on the findings from epidemiological studies, a number of RCTs have examined the treatment effects of aerobic exercise on depressive symptoms in individuals with MDD. Dunn et al.[28] randomized 80 adults, aged 20–45, to either high-dose aerobic exercise (17.5 kilocalories per kilogram of weight [KKW] at a self-selected intensity), low-dose aerobic exercise (7 KKW at a self-selected intensity), or an exercise placebo group (i.e., stretching). Following 12 weeks, the mean Hamilton Rating Scale for Depression (HRSD) score was reduced by 47% in the high-dose exercise group, which was significantly greater than the reductions in HRSD score observed in the low-dose exercise (30%) and placebo groups (29%).

Blumenthal et al.[29] randomized adults, age 40 and older, with MDD to one of four treatment groups: home-based aerobic exercise, supervised aerobic exercise, antidepressant medication (sertraline), or a placebo pill. Following 16 weeks of treatment, greater remission rates were observed in the home-based (45%) and supervised exercise (40%) compared with a pill placebo (31%).

The Regassa study[30] randomized 946 patients with depression into one of three treatment groups for 12 weeks: exercise, internet-based cognitive behavioral therapy, and 12 weeks of treatment as usual that was delivered by their primary care physician. Among the exercise group, participants were further randomized into one of three types of exercise: light exercise (stretching, yoga, etc.), moderate exercise (moderate-intensity aerobics class), and vigorous exercise (high-intensity aerobics and strength training). Participants in all exercise groups attended hour-long classes three times a week for 12 weeks. At the conclusion of the trial, patients who participated in the exercise classes had significantly reduced Montgomery–Asberg Depression Rating scores than those in the treatment-as-usual group. Building on previous reports of positive long-term effects of exercise as a treatment for depression,[31–33] long-term follow-up data from the Regassa study reported that light and vigorous exercise groups had experienced reduced Montgomery–Asberg scores compared with treatment as usual and moderate exercise, though all groups experienced either stable or reduced depressive symptoms.[34]

123.3.2 Efficacy of Resistance Training Exercise in Reducing Depressive Symptoms

Another group of studies has examined the effect of resistance training exercises on depressive symptoms.

At least five studies of clinically depressed adults have suggested that resistance exercise training may be as or more efficacious for reducing symptom severity compared with aerobic exercise training.[35–40] However, this literature has also been characterized by consistent weaknesses, including small sample sizes, limited post-intervention follow-up, and lack of investigation of putative mechanisms.

A ten-week study found resistance training significantly reduced depressive symptoms compared with an attentional-control group. Furthermore, 59% of the resistance training group had achieved a clinically meaningful response compared with only 26% in the control group.[37] After the ten-week assessments, participants in the resistance training group were instructed to continue engaging in twice-weekly, unsupervised resistance training sessions for another ten weeks. Depressive symptoms remained significantly lower in the resistance training group after this phase and the percentage of participants classified as "non-depressed" was 73% compared with 36% in the control group. The significant difference in depressive symptoms between the groups remained at a 26-month follow-up.[36]

In another trial, older adults were randomized to one of three conditions: high-dose resistance training, low-dose resistance training, or standard care. At the end of eight weeks, the high-dose group had significantly greater reductions in depressive symptoms compared with the other two groups and there was no significant difference between the low-dose and standard care groups. Participants in the high-dose group were also more likely to achieve a clinical response, defined as a 50% reduction in depressive symptoms, as 61% of the high-dose participants achieved a clinical response compared with 29% of the low-dose group and 21% of the standard care group.[35]

123.3.3 Meta-Analyses Examining the Efficacy of Exercise in Reducing Depressive Symptoms

In addition to the studies referenced above, several other trials have examined the effect of exercise interventions in patients with depressive disorders. The results of these studies have been summarized in a number of meta-analyses.[41–44] These meta-analyses report significant effect sizes for the reduction of depressive symptoms following an exercise intervention. The effect sizes reported in these meta-analyses range from 0.83 to 1.39, indicating a large treatment effect. The latest Cochrane Review reported a smaller effect size and recommended further research to clearly illustrate a clear relationship between exercise as a treatment for depression.[45] However, an additional meta-analysis[46] and a critical appraisal highlighted methodological limitations of the Cochrane review and made arguments for including additional studies in the report.[47] Both the critical appraisal and the meta-analysis reported larger effect sizes for exercise as a treatment for major depressive disorder.

Recent meta-analytic evidence supported the efficacy of resistance exercise training for depressive symptoms (d = 0.66), including a large, near one-standard deviation improvement among samples with mild-to-moderate depressive symptoms (d = 0.90) that approximates a 50%

symptom reduction classified as a clinically meaningful treatment response.[48] Even when only the most rigorously designed trials were included, the average reduction in depressive symptoms remained nearly a half-standard deviation in magnitude.

In addition to evaluating depression symptoms, meta-analyses have also explored other secondary outcomes associated with depression, such as quality of life and other psychosocial indicators. One meta-analysis explored the impact that exercise has on quality of life indicators among depressed patients and found that exercise improved overall quality of life, physical quality of life, and psychosocial quality of life.[49]

123.3.4 Exercise versus Established Treatments

The studies described above compare exercise to some version of a control group. Further studies have compared exercise with established treatments for MDD. Results of two studies conducted by Blumenthal et al.[29,50] indicated no significant difference in treatment response to exercise versus SSRI in older adults. However, evaluation of long-term outcomes in these studies suggests a benefit to exercise compared with SSRI.[31–33] Klein et al.[51] found no significant difference in changes in depressive symptoms between exercise and group psychotherapy, while Hallgren et al.[30] found no difference between three exercise intensity groups and internet-based cognitive–behavioral therapy. These findings are further supported by the Rethorst et al.[41] meta-analysis, which also included the results of unpublished studies and reported no difference in effect size in studies comparing exercise with SSRI or psychotherapy.

123.3.5 Exercise as an Adjunctive/Augmentative Therapy

As previously mentioned, Blumenthal et al.[50] examined exercise as an adjunctive treatment by including a group that received both SSRI and aerobic exercise. While this group demonstrated significant reductions in depressive symptoms, this reduction was not significantly different from those who received only SSRIs or aerobic exercise. Two RCTs to date have examined exercise as an augmentative treatment for non-remitted MDD. Mather et al.[52] randomized older adults, who had received at least six weeks of antidepressant medications without a sustained response, to either aerobic exercise or health education classes. Following a ten-week intervention, the exercise group had a significantly higher response rate compared with the health education group. Trivedi et al.[53] compared the efficacy of two doses of aerobic exercise as augmentation for non-remitted MDD. Following the 12-week intervention, both groups had significant increases in remission rates and there was a trend toward higher remission rates in the high-dose exercise group, although the difference between the two groups was not significant.

123.4 EXERCISE PRESCRIPTION

While there is substantial evidence supporting the use of exercise in the treatment of MDD, research has not provided a clear indication of the proper dose of exercise needed to elicit an antidepressant effect. Complicating the matter is the fact that several aspects of the exercise intervention could potentially influence the efficacy of the intervention, including session frequency, session duration, exercise intensity, intervention duration, and exercise modality.[54]

123.4.1 Session Frequency and Duration

Exercise intervention trials in participants with MDD have varied in the frequency of exercise sessions (i.e., the number of sessions per week). Dunn et al.[28] found no difference in effect between groups exercising three times per week versus five times per week. This finding is supported by meta-analytic results demonstrating no difference in effect sizes across trials with different session frequency.[41]

Typically, exercise has been prescribed in terms of session duration, in which participants exercise for a set amount during each session. The session duration used in trials for MDD has usually ranged between 30 and 60 minutes. To date, no trial has directly compared interventions of differing session duration. However, examination of moderating variables in the Rethorst et al.[41] meta-analysis suggests that sessions lasting 45–59 minutes are most effective.

Another approach to prescribing exercise has been through the calculation of caloric expenditure. Dunn et al.[28] compared low dose (7 KKW) with high dose (17.5 KKW). In this trial, 17.5 KKW resulted in greater reductions in depressive symptoms, suggesting that there is a minimum dose of exercise needed to elicit an antidepressant response and that the total amount of exercise dose completed may be more important in determining the optimal exercise dose than the session frequency or session duration.

123.4.2 Exercise Intensity

One shortcoming in previous research in this area is the lack of adequate monitoring of exercise intensity. Some trials have not monitored exercise intensity or have allowed participants to "self-select" exercise intensity. Exercise intensity has ranged from 50% to 85% of HRmax among trials that did monitor intensity. No trial has compared exercise intensities in reducing depressive symptoms, though the Rethorst et al. meta-analysis found no difference in effect size across trials based on exercise intensity.

For resistance training, both trials conducted by Singh et al.[35,37] prescribed resistance training at 80% of 1-RM, though Singh et al.[35] compared this intensity of resistance training with a group given lower-intensity resistance training at 20% of 1-RM. The results of this trial suggest a dose-response relationship between resistance training intensity and changes in depressive symptoms as the high-dose group

had significantly greater reductions in depressive symptoms compared with the low-dose group.

A recent randomized control trial evaluated the effect of exercise intensity on depression symptoms.[30] Helgadóttir, Hallgren, Ekblom, and Forsell[55] randomized adults between the ages of 18 and 67 into one of four groups for a 12-week intervention that targeted depression symptoms: light exercise (yoga), moderate exercise, vigorous exercise, and treatment as usual. There were no significant differences between the exercise groups; however, each of the three exercise groups had significantly lower post-treatment scores when compared with treatment as usual.

123.4.3 Intervention Duration

Previous trials have reported significant reductions in depressive symptoms in as little as four weeks, though most trials have treatment periods of several months. Meta-analytical results suggest that longer intervention durations may be more efficacious in reducing depressive symptoms in patients with MDD. Rethorst et al.[41] report larger effect sizes in trials of ten weeks or longer compared with those trials with intervention durations of four to nine weeks.

123.4.4 Exercise Modality

The majority of trials examining the antidepressant effects of exercise have used aerobic exercise activities. However, as previously noted, other trials have shown the efficacy of resistance training in reducing depressive symptoms.[35,37] A recent meta-analysis confirmed the efficacy of resistance training in reducing depressive symptoms; however, training volume and improvement in strength were not associated with improved depressive symptoms in the included trials.[48] Currently, there is no evidence to indicate that one modality of exercise is more efficacious in treating MDD. One trial has directly compared differing modalities, finding no difference between an aerobic exercise group and a resistance training group,[56] while meta-analytic results have revealed no difference in effect size between the two modalities.[41, 48]

123.4.5 Adherence to Exercise Interventions

Ultimately, the aim of the prescription of exercise as a treatment for MDD is to individualize treatments to optimize patient outcomes. This requires the identification of factors that may influence response to treatment. One of the largest influences on treatment efficacy is treatment adherence. It has been postulated that exercise may be unsuccessful as a treatment for MDD due to the belief that patients with MDD will not adhere to an exercise program. However, in studies that have compared exercise interventions to SSRIs, there are no statistical differences in treatment adherence between the two treatments.[29,50] Furthermore, the Rethorst et al.[41] meta-analysis calculated the adherence rates of trials included and found a dropout rate of 14.6%. This rate is comparable to dropout rates observed in groups receiving SSRIs and psychotherapy.[57,58]

Additional strategies can be used in conjunction with an exercise intervention to improve adherence. First, the intervention itself can be modified to improve adherence. For example, Blumenthal et al.[29] found better adherence to a home-based exercise compared with laboratory-based exercise. In another study, Dunn et al.[28] found altering session frequency (three weeks vs. five weeks) resulted in no difference in adherence. A meta-analysis conducted by Stubbs et al.[59] reported that both patients who are recruited to supervised exercise sessions and recruited out of an inpatient setting are less likely to drop out.

123.5 IMPROVING DEPRESSIVE SYMPTOMS AMONG PERSONS WITH CHRONIC HEALTH CONDITIONS

In addition to trials examining the effect of exercise in individuals with MDD, another group of trials has examined the effect of exercise on depressive symptoms in diseased populations. Comorbid depressive disorders are commonly observed among individuals with chronic diseases. In addition to the burden associated with MDD, the comorbidity of MDD is often associated with poorer disease outcomes due to a reduction in treatment adherence associated with the presence of a depressive disorder.

Across available RCTs among a myriad of chronic illnesses, exercise training resulted in a small but significant mean improvement in depressive symptoms (0.29) across illnesses.[60] Moderator analyses showed stronger improvements among patients with mild-to-moderate depressive symptoms, among those who met recommended levels of physical activity, and among those for whom exercise training also significantly improved functional outcomes.

123.5.1 Cardiovascular Disease

Given the role of exercise in the prevention and treatment of cardiovascular disease, there have been several trials that have examined the effects of an exercise program on depressive symptoms in cardiovascular disease patients. A randomized control trial that was conducted in 82 medical centers in the United States, France, and Canada concluded that heart failure patients randomized to receive supervised aerobic exercise sessions and follow-up home exercise sessions experienced a statistically significant decrease in their Beck Depression Inventory Score (BDI II). Blumenthal et al.[61] found that participants with ischemic heart disease randomized to a 16-week aerobic exercise intervention had significantly lower BDI scores compared with participants receiving usual care. In another trial, participants with chronic heart failure randomized to an aerobic exercise intervention had significantly lower BDI scores compared with the treatment-as-usual (TAU) group.[62] Similarly, Kulcu et al.[63] found a significant decrease in BDI scores

following eight weeks of aerobic exercise in patients with congestive heart failure compared with TAU.

123.5.2 Type 2 Diabetes

Individuals with type 2 diabetes are at increased risk for developing depression. Given their increased risk of reporting depression symptoms,[64] this population can benefit from both the physical and mental health benefits associated with physical activity. A cross-sectional study by Craike et al.[65] not only found that physical activity explained 22% of the variance in depression symptoms among people with type 2 diabetes, but also found differences in the effect of exercise intensity when stratifying the sample by weight status. Normal weight and overweight individuals with type 2 diabetes experienced a negative association between symptoms of depression and vigorous physical activity; however, people classified as obese experienced a negative association for both moderate and vigorous physical activity.

123.5.3 Cancer

In patients with cancer, trials have examined the effects of exercise both during and following treatment. The outcomes of these trials are not always focused on depressive symptoms and the results of those trials that did assess depressive symptoms are equivocal.[66] However, there are clear psychological benefits from exercise in cancer patients including decreased fatigue, increases in positive mood, and improved quality of life.[67]

A few studies have explored the effect of exercise on depression in patients undergoing treatment for cancer or cancer survivors. A meta-analysis that explored the relationship between cancer-related fatigue and exercise measured depression as a secondary outcome and reported that exercise had a moderate effect on depression symptoms.[68] Another study randomized breast cancer patients into either high-dose aerobic exercise, standard aerobic exercise, or a combination of aerobic exercise and resistance training.[69] This trial reported among all patients, higher doses and a combination of aerobic and resistance training were not superior to standard aerobic exercise. However, patients who reported symptoms of depression at baseline were more responsive when randomized into the combination group. Although patients who reported baseline depression and were assigned to the high-dose group did not have statistically significant reductions in depression symptoms compared with those assigned to the standard group, the authors did report meaningful effect sizes for those in the high-dose group.[69]

123.5.4 Neurologic Disorders

In a meta-analysis of 26 trials of individuals with neurologic disorders (Alzheimer's disease, migraine, multiple sclerosis, Parkinson's disease, spinal cord injury, stroke, and traumatic brain injury), exercise was found to reduce depressive symptoms.[70] The majority of work done in this area has focused on individuals with multiple sclerosis. A more recent meta-analysis of 14 trials found exercise reduces depressive symptoms among individuals with multiple sclerosis. Furthermore, this effect was moderated by improvement in fatigue; studies in which exercise improved fatigue demonstrated significantly larger decreases in depressive symptoms.[71]

123.5.5 Other Diseases

While the number of trials in other diseased populations is not as large as in cardiovascular disease, research has examined the effects of exercise on depressive symptoms in patient populations.[72] As an example, patients with fibromyalgia display lower levels of depressive symptoms following exercise interventions.[73,74] Similarly, patients with COPD have reductions in depressive symptoms following an exercise intervention.[75,76]

123.6 MECHANISMS OF THE ANTIDEPRESSANT ACTION OF EXERCISE

Several mechanisms have been proposed to explain the antidepressant action of exercise. These mechanisms typically fall into one of two categories: neurobiological markers and psychosocial factors.

123.6.1 Serotonin

Serotonin is the neurobiological marker most commonly associated with MDD. Low levels of plasma serotonin (5-HT) have been widely observed in patients with MDD,[77] while SSRIs are the most commonly prescribed medication for the treatment of MDD. SSRIs inhibit 5-HT transport,[78] ultimately reducing plasma, serum, and whole-blood serotonin levels.[79,80] Results of animal studies indicate that exercise increases the neural discharge of serotonin,[77,81] tryptophan levels in the raphe nucleus[82–84] and hippocampus,[81] and serotonin metabolism.[85–87]

In animal models, exercise-induced alterations have been linked to reductions in depression-like behavior. Kim et al.[88] induced a depressive state through a series of foot shocks, which also reduced the expression of serotonin in the dorsal raphe and reduced the expression of 5-HT1A receptors. Subsequent treadmill exercise increased 5-HT and 5-HT1A expression. These increases were associated with reduced depressive symptoms. Exercise prior to stress exposure also protects against a detrimental reduction in serotonergic functioning. Ten weeks of swimming exercise prior to foot shock increased 5-HT in the hippocampus and reduced behavioral consequences of stress exposure.

A study by Otsuka et al.[89] suggests intensity alters the effects of exercise on serotonergic functioning.

Treadmill running at a low speed (15/m/min) increased c-Fos expression in 5-HT dorsal raphe nucleus neurons and reduced depression and anxiety behaviors. However, running at a faster speed (25 m/min) did not significantly alter serotonergic functioning or depression/anxiety behaviors.

Less evidence exists regarding the effects of exercise on serotonergic functioning in humans. Acute exercise increases plasma tryptophan, while exercise training increases plasma prolactin, 5-HTT, and 5-HT2A receptors,[90] but decreases serum serotonin levels.[91]

123.6.2 Inflammation

Additionally, inflammatory processes may directly and indirectly affect the pathophysiology of depression by influencing neurotransmitter systems.[92] Inflammatory factors are thought to negatively interact with other pathways to induce monoamine dysfunction, which is characteristic of the etiology of depression. Inflammation may contribute to reduced serotonin synthesis through reductions in circulating tryptophan, the precursor of serotonin, and increased neurotoxic byproducts (i.e., kynurenine) known to induce depression.[93] Immune activation by cytokines induces indoleamine 2,3-dioxygenase, an alternative metabolic pathway for tryptophan, leading to a relative depletion of tryptophan and serotonin.[92] Further, kynurenine is metabolized to kynurenic acid, which activates α7 nicotinic receptors, reducing dopamine release, and quinolinic acid, which activates glutamate NMDA receptors.[92]

Importantly, the repetitive skeletal muscle action involved in exercise alters serotonin release and metabolism in the brain through increased free fatty acid levels and the use of branched-chain amino acids during exercise that stimulate the potential for enhanced serotonin synthesis.[94] Additionally, elevated peroxisome proliferator-activated receptor-gamma coactivator-1α increases skeletal muscle expression of kynurenine aminotransferase enzymes to ultimately decrease kynurenine levels in the brain.[95] Exercise also alters the number and function of inflammatory factors.[96] For example, the largest RCT of exercise training for depression conducted to date showed that, among 116 of 945 depressed Swedish adults who completed the trial, higher baseline serum IL-6 was significantly associated with reduced depression severity after exercise and reduced IL-6 following exercise was significantly associated with parallel reductions in depression severity.[97] Similarly, in the TREAD study, higher baseline levels of TNF-α were associated with greater improvement in depressive symptoms, while changes in depressive symptoms were positively correlated with changes in IL-1β.[98] However, this innovative and integrative hypothesis remains understudied as a psychobiological mechanism of the protective effects of exercise for depression and warrants further examination at both the population level and in experimental trials.

123.6.3 Brain-Derived Neurotrophic Factor

Research indicates that brain-derived neurotrophic factor (BDNF) is thought to play a role in the development and treatment of MDD. Compared with healthy adults, serum BDNF is lower in untreated MDD patients, and serum BDNF levels are inversely correlated with symptom severity and increase following treatment.[99]

Exercise appears to increase peripheral BDNF level. Two meta-analyses report moderate increases in BDNF following an acute bout of exercise.[100,101] Both analyses found this effect to be moderated by sex, as the post-exercise increase in BDNF was larger in males than females, and Dinoff et al.[100] report greater increases in BDNF following exercise sessions of longer duration. These meta-analyses summarized studies of primarily healthy adults, but similar effects have been observed in studies of patients with MDD.[102,103]

BDNF levels also increase in response to exercise training.[101,104] Only one study included in these analyses was conducted in a sample of patients with MDD. In this study, no significant effect of exercise training on serum levels of BDNF was observed. It is worth noting that in this study, participants had been treated with an SSRI of adequate dose and duration prior to enrollment, which may confound the observed effects on BDNF as SSRI treatment increases peripheral BDNF.[105]

123.6.4 Hypothalamic-Pituitary-Adrenal Axis

Patients with MDD demonstrate elevated levels of cortisol in plasma and urine,[106–108] increased corticotropin-releasing factor (CRF) in cerebral spinal fluid,[109,110] and increased size and activity of the pituitary and adrenal glands.[111] Patients with MDD also demonstrate increased hypothalamic-pituitary-adrenal (HPA) axis reactivity to psychological stress.[112] HPA-axis function normalizes in response to MDD treatment.[113,114]

Evidence also suggests alterations in the HPA axis in response to exercise. Bouts of acute aerobic exercise result in increased cortisol excretion, while chronic aerobic exercise is associated with reduced cortisol excretion.[115] Acute aerobic exercise also reduced cortisol response to the Montreal Imaging Stress Test.[116] Furthermore, physical fitness is associated with reduced cortisol response to stress in the form of exercise[117] and psychological stress.[118] These findings are supported by a wealth of animal research demonstrating altered HPA-axis response to stressors following chronic exercise training.[119–122]

There is also evidence that these exercise-induced alterations in HPA-axis response to stress lead to improvement in depression. Liu et al.[123] induced depression-like behavior in rats through chronic uncontrolled foot shock. Physiologically, this stress increased serum corticosterone. Four weeks of swimming exercise reduced serum corticosterone, which was associated with reductions in depression-like behavior.

123.6.5 Endocannabinoids

Research has implicated endocannabinoids in the etiology and treatment of MDD.[124] Patients with MDD demonstrate lower levels of endocannabinoid ligands serum 2-arachidonylglycerol (2-AG) and anandamide,[125,126] while the level of 2-AG is negatively correlated with the duration of the current depressive episode.[126] Studies in rats indicate that endocannabinoid receptor CB_1 antagonists produce antidepressant effects,[127,128] while administration of fluoxetine results in a decrease in CB_1 gene expression.[129]

A single bout of aerobic exercise in humans increases anandamide, suggesting that exercise activates the endocannabinoid system.[130] Increased AEA following an acute bout of exercise is negatively correlated with depression, tension, and total mood disturbance factors on the Profile of Mood States and positively correlated with vigor.[131] The acute increase of endocannabinoids may be dependent on the intensity of the exercise. Raichlen et al.[132] observed increases in endocannabinoids following moderate-intensity exercise but no change following high- or low-intensity exercise.

Evidence of chronic effects of exercise on endocannabinoids is limited to animal models. CB_1 gene expression is reduced with chronic aerobic exercise,[133] mirroring the effect of fluoxetine of CB_1 gene expression. Exercise also alters CB_1 receptor sensitivity, which provides a protective effect against exposure to stress.[134]

123.6.6 Psychosocial Factors

In addition to the neurobiological mechanisms described above, psychosocial factors may also play a role in the antidepressant effects of exercise. Low self-efficacy is often associated with depressive symptoms.[135] It has been proposed that self-efficacy can be improved through physical activity.[136,137] Trials in patients with MDD consistently report an increase in self-efficacy following chronic exercise[138–140] and these increases in self-efficacy are associated with a decrease in depressive symptoms.[138] Another construct proposed as a mechanism for the antidepressant action of exercise is distraction. It has been postulated that exercise can serve as a distraction from stress and therefore reduce depressive symptoms.[141,142] However, Craft[138] found no significant difference in distraction following an aerobic exercise intervention in women with MDD.

123.7 PREDICTORS OF THE ANTIDEPRESSANT ACTION OF EXERCISE

Ultimately, the study of the antidepressant effects of exercise will inform how exercise can most effectively be used as a treatment. As described previously, the heterogeneity in treatment response indicates the need to tailor treatments to individual patients. One approach to tailor treatments is to attempt to predict treatment response based on pre-treatment patient characteristics. Recent studies have aimed to identify predictors of treatment response to antidepressant medications and psychotherapy.[143–145] A similar approach could inform which patients are most likely to benefit from exercise as a treatment.

A review by Schuch et al.[146] summarized the previous research efforts to identify predictors of treatment response to exercise. In the TREAD study,[53] biological factors associated with better treatment response to exercise included higher baseline levels of BDNF[147] and TNF-α.[98] Lavebratt et al.[97] also report elevated baseline inflammation, specifically IL-6, predicted better treatment response to exercise. Pre-treatment clinical characteristics associated with better response to exercise treatment include better physical health,[148] lower anxiety,[148] and the presence of hypersomnia,[149] and atypical depressive symptoms.[150]

The eventual utility of these predictors will be to differentiate exercise as a treatment among the variety of treatment options available. For example, exercise appears to be most effective as a treatment for individuals with elevated inflammation.[97,98] In contrast, higher levels of inflammation have typically been associated with poorer treatment response to SSRIs.[151,152] This suggests it may be possible for clinicians to choose between different treatments based on patient characteristics. However, it should be noted that the effects of these individual predictors may not be large enough to inform clinical decision-making. As a result, more recent research has attempted to combine multiple factors to predict MDD treatment response.[153]

123.8 FUTURE DIRECTIONS

Several areas for research will further clarify and define the role of exercise in the treatment of MDD. First, while there is evidence for a dose-response relationship, the combination of time, frequency, and intensity of exercise required for the optimal reduction of depressive symptoms has not been identified. Not only will this maximize the treatment effect, but identifying the appropriate dose of exercise is also important to allow physicians to provide a clear exercise prescription to patients.

Current exercise prescription recommendations are based on summaries of previous studies.[54] It should also be noted that there is likely individual variation in response to exercise. Therefore, there is not likely to be a "one size fits all" exercise prescription. Few studies have directly compared multiple exercise doses or intensities, though the results of those studies do suggest different patients respond differently to different exercise programs. This evidence corresponds with studies of physiological mechanisms of differential neurobiological response to varying exercise stimuli. For example, Otsuka et al.[89] reported increases in c-Fos expression in 5-HT neurons following low-speed treadmill running but not high-speed running. Conversely, c-Fos increased in CRF neurons following high-speed treadmill running but not low-speed running.

Researchers should continue to explore the role of exercise as an adjunctive or augmentation treatment. Integrating

exercise with established treatments has the potential to maximize treatment in a population that typically has a modest response to treatment. Results from previous trials suggest that exercise may be especially effective in maintaining treatment effects[31,33,154] and as a treatment for individuals who do not fully respond to initial SSRI treatment.[52,155] Finally, despite epidemiological evidence suggesting the protective effect of physical activity on future MDD, no trial has prospectively examined the preventive effects of exercise.

The role of exercise in the treatment of MDD will ultimately depend on treatment professionals being willing and properly educated to prescribe exercise to their patients. Recent data indicate that only 5% of general practitioners include exercise as one of their most recommended treatments for MDD, compared with 92% for antidepressant medications. This disparity is likely because only 41% of general practitioners believe exercise to be "very effective" or "quite effective" in treating MDD.[156]

Based on the existing evidence, several professional organizations, including the American Psychiatric Association,[157] the Canadian Network for Mood and Anxiety Treatments,[158] the National Institute for Health and Clinic Excellence,[159] and the Royal Australian and New Zealand College of Psychiatrists,[160] now recommend exercise as a treatment for MDD. However, significant shortcomings remain in the recommendation of exercise as a treatment for MDD.[161] Strengthening the evidence supporting exercise as a viable treatment option for depression will require demonstration of effectiveness in real-world settings. As such, researchers have called for a shift from well-controlled randomized controlled trials to pragmatic trials conducted in clinical settings.[162]

CLINICAL APPLICATIONS

Exercise is efficacious in the treatment of depressive disorders as either a monotherapy or as an augmentation to another antidepressant treatment. For patients interested in exercise as part of their treatment, evidence indicates achieving a weekly goal of approximately 150 minutes of moderate-intensity physical activity per week. Aerobic activities and resistance training have both been shown to be effective in reducing depressive symptoms.

Beyond the reduction of depressive symptoms, exercise has the potential to significantly improve the physical health of persons with depression. Compared with general populations, persons with depression are at an increased risk for cardiovascular disease, type 2 diabetes, and certain cancers.[163–166] Overall, meta-analyses have estimated the relative risk of all-cause mortality is increased by 64–81% in persons with depression compared with non-depressed individuals. Conversely, engagement in exercise is associated with a decreased risk of chronic health conditions and reduced mortality risk.[167–169] As such, engagement in exercise has the potential to significantly reduce the burden of depression, not only by reducing depressive symptoms but also by improving the physical health of those with depression.

124 Injuries and Lifestyle Medicine

David A. Sleet, PhD, Michael F. Ballesteros, PhD, and Judith R. Qualters, PhD

KEY POINTS

- Injuries are an enormous public health problem, placing a huge burden on individuals, families, communities, and the health care system.
- Injuries are the leading cause of death for ages 1–44 in the United States, with unintentional injuries as the main cause.
- Injuries are not "accidents"; most injuries are predictable and preventable.
- Acute exposure to energy at levels beyond human tolerance, or the absence of essentials such as oxygen, are the root causes of injury.
- Injury rates vary by geography and socio-demographics such as age, sex, race, and income.
- Injuries are costly to society and such costs can be averted through the use of devices such as seat belts, life jackets, smoke alarms, helmets, product safety devices, environmental safeguards, and behavioral health services for those at risk of suicide.
- Lifestyle medicine practitioners can play an important role in injury prevention by working with patients and communities to improve behaviors, laws, enforcement, environments, and products.
- Many evidence-based strategies for reducing unintentional injuries are available but are infrequently used.
- Lifestyle practitioners have an important role in injury prevention by implementing evidence-based strategies that will save lives.

124.1 INTRODUCTION

Injuries, which include unintentional injuries, violence, and suicide, are a major public health problem affecting patients, families, and the communities in which they live.[1] This chapter will focus primarily on unintentional injuries, which account for two-thirds of the public health injury burden, and will include some information on suicide (see Chapter 129).

Public health shares a common goal with lifestyle medicine to increase awareness of lifestyle-based causes of disease and injury.[2] In addition to the many preventable diseases that are seen in the practice of lifestyle medicine, there is one health threat that the public still accepts as a *fait accompli*—injuries. We have not yet fully integrated injury prevention into lifestyle medicine, and patients are not as educated on how to lower their risks of injury as they are on how to lower their risks of cancer or heart disease. Perhaps this is in part due to the belief by the public that injuries are accidental, acts of fate or bad luck, random events, or acts of God.

124.2 INJURIES OR ACCIDENTS?

An injury is distinct from an accident. Accidents are not generally considered predictable or preventable. Injuries are the medical consequences of an "accident". The Oxford English Dictionary defines the term *accident* as "an unusual event, which proceeds from some unknown cause … unexpected … happening by chance or fortune".[3] The word *injury,* on the other hand, has its root in the Latin term *injuris,* which literally means "not right". The dictionary defines injury as "hurt, damage or loss sustained"—in short, harm of any kind, done or sustained.[4] Public health and medical science favor using the term "crash", "incident", "collision", or "event" instead of "accident" to describe the circumstances that give rise to an injury[5]. The *British Medical Journal* banned the word "accident" from its lexicon in 2001[6] because it fails to distinguish between the event (fall or crash) and the outcome (tissue damage).

Injury in public health is defined as unintentional or intentional damage to the body resulting from acute exposure to thermal, mechanical, electrical, or chemical energy or from the absence of such essentials as heat or oxygen.[7] Most injuries can be prevented through changes to products, behaviors, and environments.[8] Using terms such as *injury prevention* rather than *accident prevention* helps make clear the potential for preventing such events. Lifestyle medicine can be an important source to dispel the myth of "accidents" and help patients and the public recognize that injuries are preventable if only certain steps are taken to reduce the risks at home, on the road, at work, and in the community.[9]

124.3 INJURY AS A PUBLIC HEALTH PROBLEM

The National Academy of Sciences in 1985 pronounced that "injury is the most under-recognized public health problem facing the nation today".[10] The science of injury control demonstrates that using public health and health promotion approaches can be effective in preventing injuries.[11,12]

DOI: 10.1201/9781003227793-145

Injuries, like diseases, result from interactions between persons (host factors), agents or vectors (e.g., energy exchange), and the environment (physical and social environmental factors). This approach is the foundation for understanding injury prevention.[13,14]

Despite the injury burden, injury prevention has received relatively little attention from legislators, teaching institutions, journal editors, and, most strikingly, the healthcare system when compared with other public health issues. While there have been some notable exceptions to this tendency recently (e.g., pediatric traumatic brain injury guidelines, opioid prescribing guidelines, clinical training, and electronic health records (EHRs) decision support tools for injury), more needs to be done to elevate injury prevention in preventive medicine and public health. In addition to focusing on traditional areas in lifestyle medicine (e.g., physical activity, nutrition, tobacco, hypertension), lifestyle medicine practitioners can add preventing injury as part of a comprehensive public health approach to lifestyle change by supporting evidence-based policies, providing community education, and linking clinical care with injury prevention.[9,15,16]

124.4 BURDEN OF INJURIES

In the United States, unintentional injuries are the fourth leading cause of death for people of all ages and the leading cause of years of potential life lost (YPLL) before age 65 years—2.2 times that of malignant neoplasm and 2.4 times that of heart disease.[17]

Figure 124.1 compares the ten leading causes of death in 2020 by rank and age grouping. In the United States, unintentional injuries are among the top ten causes of death in each age group throughout the lifespan and the *leading* cause of death for people ages 1–44 years. Injuries represent the first, second, and third leading causes of death among ages 15–24 and 25–34 and accounted for more deaths than the other seven causes combined. For children and youth ages 1–24, injuries dominate all other causes of death.[18] Motor vehicle injuries predominate as a cause of death among ages 5–34. Suicide is a leading cause of death for those 10–44 years of age.

Table 124.1 presents CDC data on the number, percent, and rate per 100,000 population for unintentional injury deaths and suicide. The top three causes of unintentional injury death are poisonings (drug and non-drug), falls, and traffic injury deaths.[17]

Deaths are only a small part of the problem. Non-fatal unintentional injuries place a heavy burden on the healthcare system and expend valuable pre-hospital, hospital, and rehabilitation resources. In fact, an estimated 2.9 million people were hospitalized, and 22.9 million people were treated in emergency departments (EDs) in 2020.[17] Approximately one-third of all emergency department visits[19] and 6% of all hospital stays[20] are due to injuries.

Table 124.2 shows the estimated number of non-fatal unintentional and self-harm injuries treated in hospital US EDs among all ages, races/ethnicities, and sexes in 2020. The highest numbers and rates were for falls, transportation, and struck by and against injuries, with over 30% of the ED visits due to injuries resulting from falls. Over 480,000 individuals were treated for self-harm injuries, which include suicide attempts.[17]

124.4.1 Costs

The costs of injuries are staggering.[21] In 2019, the total lifetime medical and work-loss costs of injuries in the United States was $4.2 trillion in 2019, including the costs of fatal injuries ($2.2 trillion) and non-fatal injuries ($2 trillion).[22] Over $1.4 trillion of the fatal injury costs were attributed to unintentional injuries, followed by suicide $463 billion, and homicide $209 billion. Among unintentional injury costs, drug poisonings, including prescription drug overdoses, accounted for 45% of fatal injury costs; transportation-related fatal injuries, 28%; falls, 11%; and suffocation, 4%.[17]

124.4.2 Health Disparities

Injuries are not distributed evenly throughout the population. Children, adolescents, males, the elderly, the poor, certain racial/ethnic groups, and those of low SES are at elevated risk.[23] A recent analysis of National Institute of Health-funded research projects addressing unintentional injuries in children found that among 34 grants (between 2011 and 2018), only eight focused on racial and ethnic minority children.[24] Injury epidemiology can be an important tool to help explain these variations, identify groups at higher risk for injury, and target specific interventions to reduce the burden. For example:

- *Age*: Unintentional injury death rates vary by age with the lowest rates among those 5–14 years old (3.8 per 100,000 population in 2020), and the highest rate among those 75 years of age and older (191.2 per 100,000 population).[17]
- *Sex*: Males are 2.3 times more likely to die from an unintentional injury than females (age-adjusted death rates: 80.4 vs. 35.6, respectively)[17]
- *Race and ethnicity*: Unintentional injury death rates also vary by race and ethnicity. The highest death rates are among Non-Hispanic (NH) American Indian and Alaska Natives (99.8) and NH Blacks (66.9). While NH Asians and Hispanic-all races have the lowest rates (18.2 and 41.2, respectively).[17]
- *Suicide*: Suicide death rates are highest among Non-Hispanic American Indian and Alaska Natives (23.9) and Non-Hispanic Whites (16.8).[17]
- *Urbanization level*: Death rates for unintentional injuries in non-metro areas are 1.2 times higher than rates in metro areas (68.8 vs. 55.7, respectively).[17]
- *Poverty*: Unintentional injury death rates for counties with >20% poverty are 79% higher compared

Ten leading causes of death, by age group, all race/ethnicities, both sexes, United States, 2020

with counties with <5% poverty, and this gap has been widening over time.[25]

- *Disability*: Risk of unintentional injury is two to three times higher among youth with a disability.[26]

More research is needed to better understand the key drivers of these disparities and how policy and tailored prevention strategies can be used to achieve injury-related health equity.[27]

124.5 INJURY PREVENTION AND CONTROL

Lifestyle interventions for injury can, and do, work to lower risks.[28–31] In recognition of this, the US Department of Health and Human Services *Healthy People 2030* initiative includes strategies for the prevention and control of injuries in their data-driven national objectives to improve health (https://health.gov/healthypeople). Specific goals and objectives include reducing fatal injuries from traumatic brain injury (TBI), overdose deaths, motor vehicle crashes, self-harm, and falls, and reducing ED visits for non-fatal unintentional injuries. Most, if not all these risks are influenced by lifestyle choices.

Three categories of interventions that can effectively reduce unintentional injuries include education/behavior change, legislation/enforcement, and technology/engineering.[32] Each strategy can enhance the effects of the other. Specific interventions that support prevention include using individual protective devices such as helmets and seat belts; reducing risky driving behaviors such as texting and driving; installing smoke alarms; requiring alcohol interlock devices in the vehicles of offenders; supporting enhanced enforcement such as roadside breath testing for alcohol; and improving practices of physicians, providers, and other healthcare workers such as screening and brief interventions, counseling, and motivational interviewing.[33]

Individual and community actions are required for these strategies to succeed, and they are fostered by education, stimulated by social and organizational change, and encouraged through public policy, legislation, and enforcement activities.[34]

Through the elimination of injury as a cause of death, estimates reveal that the average US life expectancy at birth could be increased by approximately 1.5 years (with notable variations by sex, ethnicity, and race). Under this assumption, an estimated 48,400 injury deaths and $61 billion in medical and work-loss costs could be averted annually.[35]

124.6 HOW LIFESTYLE MEDICINE PRACTITIONERS CAN HELP PREVENT INJURIES

There is an urgent need for lifestyle medicine practitioners (and providers) to effectively link injury prevention approaches and tools to the clinical care of patients. Injury prevention counseling, for instance, can be an effective intervention with patients and families.[36,37] To date, however, office-based counseling has not been universally applied. In the 2016 DocStyles survey, healthcare providers were asked about the use of clinical fall risk assessments in older adults. Overall, only about half of primary care providers reportedly screened for fall risk at wellness visits.[38] A 2021 study asked healthcare providers about their diagnosis and management practices related to driving after a mild TBI, and 52% reported they talked with patients on how to safely return to driving more than 75% of the time. However, they did not consistently screen for risk factors and did not provide patients with written instructions for self-care.[39]

Lifestyle medicine physicians often see patients and their families for treatment after an injury has occurred, but they have the opportunity to go "up-stream" to uncover the root causes, collect injury surveillance data on specific causes, and design preventive interventions for specific populations in the clinical environment. There are also opportunities in patient care to implement interventions such as screening and brief interventions for alcohol or opioid misuse and screening and counseling older patients on fall prevention.[40]

Physicians can also inform decision-makers about the need to strengthen legislation or set healthcare and reimbursement policies that promote and incentivize prevention. Healthcare professionals who serve on medical school or nursing faculty can offer to teach courses on trauma prevention and can also help prepare medical and allied health students with material related to injury prevention.

Reducing injuries will also require a shift in how society thinks about hazards, the environment they live in, their personal risk behaviors, and the value of prevention. Lifestyle medicine can contribute to this shift by engaging in a variety of actions in the community to protect the public, such as:

- Supporting efforts to strengthen policies in your state that prevent injuries such as primary seat belt laws, strong teen driving policies, smoke alarm installation policies, adherence to evidence-based opioid prescribing guidelines, and motorcycle and bicycle safety measures such as helmet use.
- Supporting community drowning prevention strategies such as the use of four-sided fences around residential swimming pools and the use of life jackets while boating.
- Collecting data on the clinical and healthcare costs and consequences of injuries treated in the ED or in private practice settings.
- Strengthening collaboration with local coalitions, such as Safe Kids, Injury Free Coalition for Kids, local drowning prevention coalitions, the National Safety Council, or State Public Health Departments and State Offices of Highway Safety.
- Supporting efforts to build injury prevention into healthcare reform
- Testifying at hearings and town meetings about evidence-based injury prevention strategies.
- Supporting or conducting research on risk and protective factors and interventions to reduce all forms of injury and trauma, including those on and off the job.
- Strengthening pre-hospital care, comprehensive trauma care systems, and trauma registries
- Integrating injury prevention into existing health delivery systems, such as pediatric and rural health clinics, and adding injury assessments and screenings into electronic health records (EHRs).
- Assuring age-appropriate injury prevention information is added to all periodic health examinations and risk assessment systems.

124.7 FUTURE DIRECTIONS

The National Academy of Sciences/Institute of Medicine report *Reducing the Burden of Injury*[41] emphasized the importance of using a scientific approach to injury prevention and called on public health agencies and others to work with medical care organizations, healthcare providers, states and communities, businesses, and other federal agencies to pursue alliances that would help reduce injuries. Injury epidemiologists, behavioral scientists, and lifestyle medicine practitioners can work side-by-side to identify, prevent, and control injuries, and to explore ways to better integrate our public health and healthcare delivery system, strengthen data systems and advance the use of digital technologies to better support health outcomes across the life span, identify risk and protective factors, test culturally appropriate interventions, and conduct evaluations of existing injury prevention efforts.

Injury prevention has evidenced significant progress in the United States in the past 30 years. Fatal and non-fatal injuries have been reduced and funding for injury prevention

and control research and infrastructure support for state programs have all increased.[15] But more work needs to be done. The challenge now is to engage lifestyle medicine and primary care physicians in becoming more active in fostering lifestyle behaviors to prevent injuries.[2,9,42] Rapid advances in clinical decision support systems embedded in electronic health records, use of telehealth services for broader service delivery as was seen during the COVID-19 pandemic, and resources such as CDC's Stopping Elderly Accidents, Deaths, and Injuries (STEADI) toolkit, which supports healthcare providers in fall risk assessment and treatment, provide some ways of addressing this challenge.[43]

Lifestyle medicine practitioners and the Lifestyle Medicine Association are important partners in fostering strategies to prevent injuries. Primary care professionals and other gatekeepers can help make injury-free choices the easiest choices for patients and the public, thus reducing injuries from all causes.[44] And, as integral members of their communities, lifestyle medicine practitioners can play a pivotal role in advancing a culture of safety throughout the life course of patients and families.[45]

124.8 CONCLUSIONS

Although injuries have plagued societies since the beginning of time, injury science has taught us that injuries are both predictable and preventable. Using theory and a combination of environmental, product engineering, and behavioral approaches that target the host, agent, and environment stand the best chance of succeeding.[8,46,47] Approaches will need to be adapted to different populations, lifestyles, and life stages with a particular sensitivity to social determinants of injury. Because there are so many different injuries with varied causes, tailored strategies are necessary. Lifestyle medicine and primary care family practitioners are important allies in encouraging lifestyle choices that reduce injuries.

As the editors of the *American Journal of Lifestyle Medicine* wrote in the introduction to their inaugural issue:[48]

> We need to focus our patients' attention on the important daily practices and habits that can either promote good health or, if these practices are not positive, lead to adverse health consequences. This is one of the great challenges for health care practitioners in the 21st century. (p.9)

Injury prevention can now be added to the list of daily practices and habits that will promote good health.

CLINICAL APPLICATIONS

- Include injury prevention in all your health promotion and disease prevention activities with patients.
- Expand your record-keeping to collect and monitor patient risk factors for injuries (e.g., chart reminders for teens about texting and driving or about opioid-related overdose risk among middle-aged adults).
- Assess the safety practices of patients and their families (e.g., consistent use of seat belts, helmets, and life jackets, avoidance of drinking and driving, and preventive measures to prevent falls in older adults).
- Assess for depression and risk factors for suicide in patients experiencing stress or traumatic life events.
- Set goals for your patients to change risky lifestyles that predispose them to injuries.
- Encourage patients to use protective gear in play and sports.
- Assess the risks of unintentional injury and suicide among racial and ethnic minority groups who are disadvantaged.
- Promote the collection and dissemination of local injury-specific data to help develop effective interventions at the community level.
- Have information available on how patients can access resources in the community for injury and suicide prevention (e.g., CDC, local safety council, state health departments, mental health clinics, suicide helpline, SafeKids chapters, poison control centers, and local prevention coalitions).
- Screen for alcohol misuse and poly-drug use using tools such as brief intervention and motivational interviewing (www.cdc.gov/opioids/providers/training/index.html).
- Advise parents on the correct use of age-appropriate child safety seats and booster seats with their children.
- Support improvements in pre-hospital and hospital care for injured victims and support comprehensive trauma care systems in your community.
- Maximize the use of EHRs for injury data and use prescription drug monitoring programs to improve prescribing practices.

125 Motor Vehicle Crashes, Injuries, and Deaths: Epidemiology and Prevention

Merissa A. Yellman, MPH, Bethany West, MPH, and David A. Sleet, PhD

KEY POINTS

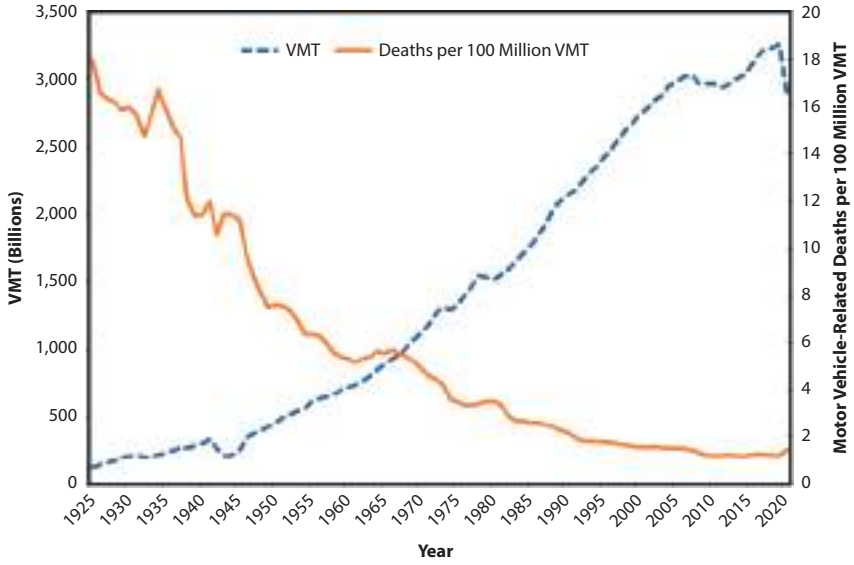
- Motor vehicle crashes (MVCs) are a leading cause of death and a major cause of morbidity in the United States.
- MVC deaths and injuries are costly to society and the healthcare system.
- MVC deaths and injuries to drivers, passengers, motorcyclists, pedestrians, and bicyclists are preventable.
- Effective evidence-based strategies are widely available, but most are not universally implemented.
- Primary prevention holds the most promise for reducing the MVC death/injury burden (e.g., sobriety checkpoints and ignition interlocks).
- Healthcare providers can play an important role in primary prevention by conducting screening and patient education in clinical settings and supporting effective public policies.

125.1 MOTOR VEHICLE CRASH DEATH/INJURY AND LIFESTYLE MEDICINE

Motor vehicle crash (MVC) injury and lifestyle choices are inextricably linked.[1] For many, a healthy lifestyle entails independence that comes with the ability and freedom to drive.[2] Motor vehicle travel continues to be a popular mode of travel in the United States. In the span of 100+ years, the number of registered vehicles in the United States has grown from about 1.3 million in 1913 to about 276 million in 2020.[3] In 2020, about 92% of households had at least one vehicle available to drive.[4] There were about 228 million licensed drivers in the United States in 2020, and each licensed driver drove an average of 12,724 miles on over four million miles of public roads.[5] However, motorization has consequences for crashes, injuries, medical care, and deaths.

MVCs are a leading cause of death for people aged 1–75 years in the United States, and they are the number one cause of death for children, youth, and young adults combined across the age range of 5–24 years.[6] MVCs accounted for approximately 40,000 deaths and more than 2.1 million emergency department visits for non-fatal MVC injuries in 2020.[6] In comparison, 349 people died in non-military airplane crashes in the United States in 2020.[7]

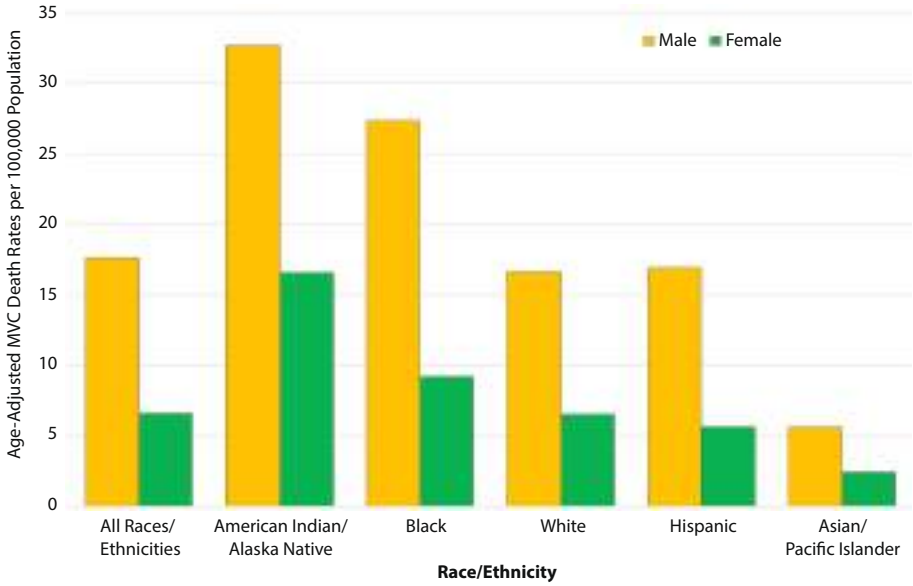
MVCs also result in substantial monetary costs. In 2020, MVC deaths resulted in approximately $430.7 billion in total costs (in 2020 US dollars), including about $537 million in medical costs and about $430.2 billion in cost estimates for lives lost.[6] Additionally, non-fatal transportation injuries resulted in approximately $331.5 billion in total costs (in 2020 US dollars), which included $51.1 billion in medical costs, $15.7 billion in lost productivity costs, and $264.7 billion in quality-of-life loss costs.[6]



Nevertheless, substantial progress has been made. While road environment exposure has increased (as measured by vehicle miles traveled), there has also been a 92% decline in MVC deaths per 100 million vehicle miles traveled between 1925 and 2020[3] (Figure 125.1). Improvements in motor vehicle safety are considered one of the ten greatest public health achievements over the past 100 years. These improvements have been possible primarily due to advances in vehicle safety, road improvements, and driver behavior change,[8–10] which have mitigated many of the negative effects of increased motorization. This achievement is an example of how injury prevention science has played a critical role in reducing MVC deaths without taking cars off the road. Despite these remarkable declines, MVCs remain a leading cause of death among most age groups in the United States.[6]

125.2 HEALTH EQUITY CONSIDERATIONS

Some populations are disproportionately affected by MVCs.



- *Disparities by sex*. Males consistently have higher MVC death rates than females. In 2020, the age-adjusted MVC death rate among males (17.6 per 100,000 males) was about 2.7 times higher than that of females (6.5 deaths per 100,000 females)[6] (Figure 125.2).
- *Disparities by age*. MVC death rates are typically higher among young adults and older adults than among other age groups. In 2020, the highest MVC death rates by age group were among young adults aged 20–24 years (19.4 deaths per 100,000 population), young adults aged 25–29 years (17.9 deaths per 100,000 population), and older adults aged ≥85 years (16.7 deaths per 100,000 population).[6]

DOI: 10.1201/9781003227793-146

Abbreviation: VMT = vehicle miles traveled.
Data Source: https://injuryfacts.nsc.org/motor-vehicle/historical-fatality-trends/deaths-and-rates/.
Note: The National Safety Council (NSC) did not directly provide VMT. VMT were calculated based on the number of motor-vehicle related deaths and the death rates per 100 million VMT provided by NSC. Therefore, VMT estimates in this figure may differ slightly from VMT estimates provided by the Federal Highway Administration (FHWA) due to rounding.

FIGURE 125.1 Annual vehicle miles traveled and motor vehicle-related deaths per vehicle miles traveled—United States, 1925–2020.

Abbreviation: MVC = motor vehicle crash.
Data Source: CDC WISQARS, available at: https://www.cdc.gov/injury/wisqars/.
ICD-10 Codes: V02–V04 (.1,.9), V09.2, V12–V14 (.3–.9), V19 (.4–.6), V20–V28 (.3–.9), V29 (.4–.9), V30–V39 (.4–.9), V40–V49 (.4–.9), V50–V59 (.4–.9), V60–V69 (.4–.9), V70–V79 (.4–.9), V80 (.3–.5), V81.1, V82.1, V83–V86 (.0–.3), V87 (.0–.8), V89.2.
Notes: Data for White, Black, American Indian/Alaska Native, and Asian/Pacific Islander only include Non-Hispanic ethnicity. Data for Hispanic ethnicity include all races. Rates are standardized to the 2000 US population. The race/ethnicity categories are displayed in descending order (from left to right) by overall (not sex-specific) age-adjusted motor vehicle crash death rates in 2020.

FIGURE 125.2 Age-adjusted motor vehicle crash death rates by race/ethnicity and sex—United States, 2020.

- *Disparities by race/ethnicity.* MVC death rates are typically highest among non-Hispanic American Indian and Alaska Native people (AIAN) and are also disproportionately high among non-Hispanic Black people. In 2020, the age-adjusted MVC death rate among AIAN people was 24.4 per 100,000 population, which was 1.4–6.2 times higher than the rates of other racial/ethnic groups. Age-adjusted MVC death rates among Black people (17.7 per 100,000 population) were the second highest when compared with other racial/ethnic groups. Similar disparities exist when examining

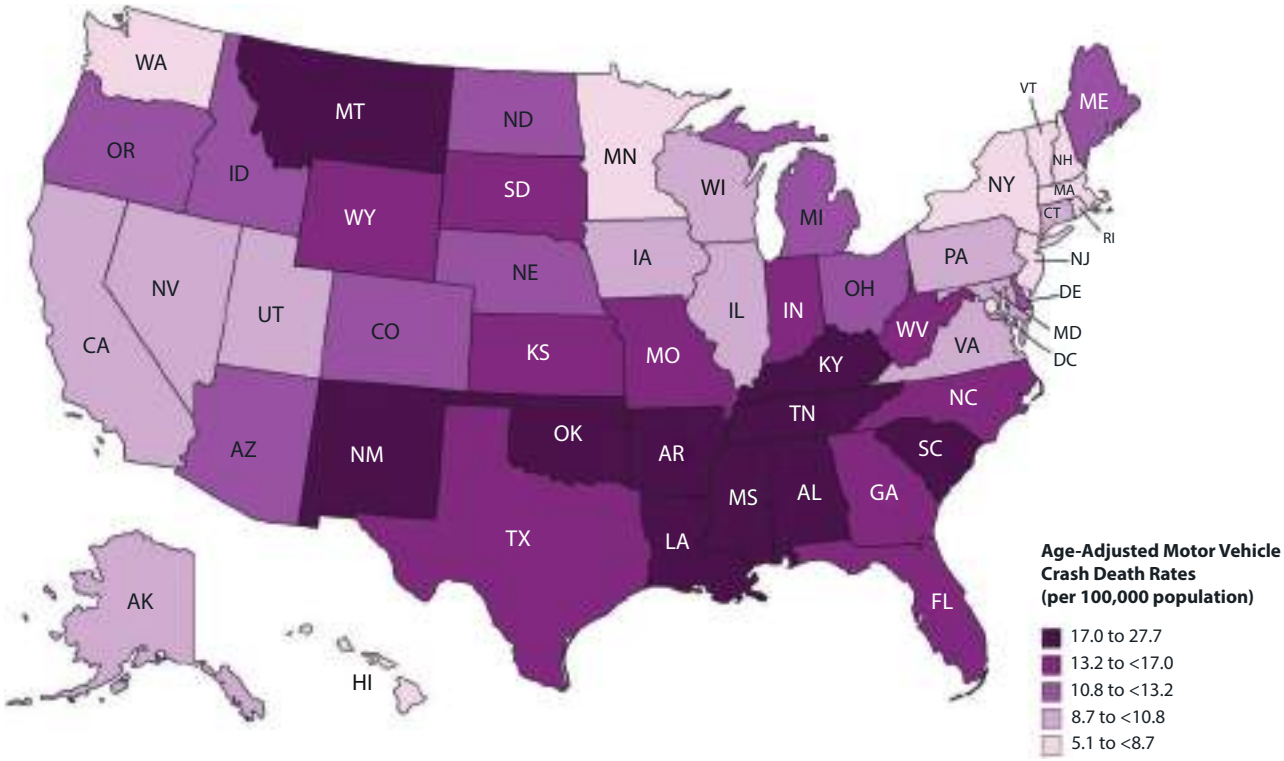
MVC deaths among racial/ethnic groups by sex[6] (Figure 125.2).

- *Disparities by urban/rural status.* Within the United States, disparities persist by rurality, with higher MVC death rates and less restraint use in rural compared with urban areas.[11–13]
- *Disparities by US state.* MVC death rates vary widely by state. In 2020, age-adjusted MVC death rates ranged from a low of 5.1 per 100,000 population in Massachusetts to a high of 27.7 per 100,000 population in Mississippi. Many states with the highest death rates were located in the South, and many states with the lowest death rates were located in the Northeast[6] (Figure 125.3).
- *Disparities among high-income countries.* In 2019, the United States had the highest population-based MVC death rate out of 29 high-income countries. The 2019 US death rate (11.1 per 100,000 population) was 2.3 times higher than the average rate (4.8 per 100,000 population) among 28 other high-income countries. Additionally, the US population-based death rate increased nominally (by 0.1%) from 2015 to 2019, whereas the average percent change among 27 other high-income countries was −10.4%.[14]

While the public health burden of MVCs is large, effective strategies to prevent deaths and injuries exist. Healthcare providers (HCPs) have an opportunity to address motor vehicle safety and discuss what works to keep patients safe on the road. The rest of this chapter will briefly summarize the epidemiology of MVC deaths and injuries by topic and discuss evidence-based strategies to reduce the personal, societal, and healthcare burden they present. At the end of each motor vehicle safety topic section, there is a brief summary with suggestions about what HCPs can do.

125.3 MOTOR VEHICLE INJURY PREVENTION STRATEGIES

125.3.1 Alcohol-Impaired Driving



Alcohol-impaired driving has been a persistent motor vehicle safety problem in the United States. Since the mid-1990s, approximately 30% of MVC deaths each year have involved at least one alcohol-impaired driver.[15,16] The Centers for Disease Control and Prevention's (CDC) Transportation Safety website offers additional information about alcohol-impaired driving.

Screening, interventions, and assessment/treatment programs typically focus primarily on reducing alcohol consumption; however, they can be beneficial for reducing many alcohol-related harms, including alcohol-impaired driving.[17–19] Examples include the following:

- *Screening, brief intervention, and referral to treatment (SBIRT).* These interventions typically focus on identifying people who drink alcohol excessively (but do not have alcohol use disorder) before they commit an alcohol-impaired driving offense. Brief interventions often involve assessing readiness to change as well as motivators and barriers for behavior change. SBIRT has been implemented in hospitals, emergency departments, other clinical settings, and non-clinical settings (e.g., colleges and high schools).[17–19]
- *Electronic screening and brief intervention (e-SBI).* These interventions take advantage of technology (i.e., electronic devices such as computers, cell phones, and tablets) to facilitate the delivery of key elements of face-to-face SBI. At a minimum, e-SBI involves screening individuals for excessive drinking and delivering a brief intervention with personalized feedback about the risks and consequences of excessive drinking.[20] CDC's Alcohol Screening Tool can be used by adults to assess their drinking and create a personal change plan.
- *Alcohol use disorder (AUD) assessment and treatment.* People who have AUD can benefit from referrals to specialized treatment. Long-term programs including close monitoring for alcohol use and tailored treatment are typically most effective.[17] See Chapter 98 in this textbook for more information.
- *Programs for people who are convicted of alcohol-impaired driving offenses.* When people are convicted of alcohol-impaired driving, this is an opportunity to assess drinking patterns and refer them for brief interventions or specialized treatment, as appropriate. These assessment and treatment programs should be implemented in combination with other strategies (e.g., ignition interlocks) and should not be used as a replacement for other sanctions.

Other effective strategies for reducing alcohol-impaired driving include:

- *Publicized sobriety checkpoints and high-visibility saturation patrols.* These law enforcement strategies entail police patrolling locations to find impaired drivers and either randomly or selectively checking drivers for impairment. Times and locations are usually selected based on when and where alcohol-impaired driving and related crashes are more common. These strategies are most effective when well-publicized (e.g., through mass media campaigns) and when conducted regularly.[17,21]
- *Alcohol ignition interlocks for all people convicted of alcohol-impaired driving, including first-time offenders.* Ignition interlocks are devices that can be installed in cars and measure alcohol on the driver's breath. Interlocks prevent the car from starting if the driver has a blood alcohol concentration (BAC)

Data Source: CDC WISQARS, available at: https://www.cdc.gov/injury/wisqars/.
ICD-10 Codes: V02–V04 (.1,.9), V09.2, V12–V14 (.3–.9), V19 (.4–.6), V20–V28 (.3–.9), V29 (.4–.9), V30–V39 (.4–.9), V40–V49 (.4–.9), V50–V59 (.4–.9), V60–V69 (.4–.9), V70–V79 (.4–.9), V80 (.3–.5), V81.1, V82.1, V83–V86 (.0–.3), V87 (.0–.8), V89.2.
Note: Rates are per 100,000 population and are standardized to the 2000 US population.

FIGURE 125.3 Age-adjusted motor vehicle crash death rates by US state—United States, 2020.

above a certain level (usually 0.02 grams/deciliter). These devices are effective for preventing repeat alcohol-impaired driving offenses while they are installed but are less effective for reducing recidivism once they are removed. However, coupling AUD assessment and treatment programs with ignition interlocks has shown benefits for reducing alcohol-impaired driving recidivism even after interlocks are removed.[22] States with all-offender ignition interlock laws have experienced the largest reductions in the number of alcohol-impaired drivers involved in fatal crashes, as compared with states requiring interlocks only for some offenders or no offenders.[23]

- *Lower blood alcohol concentration (BAC) limits.* Forty-nine US states and the District of Columbia (DC) have a BAC limit of 0.08 grams/deciliter (g/dL) for drivers, which means drivers with a BAC ≥0.08 g/dL are considered impaired by the legal definition. However, driver impairment begins at even lower BAC levels.[24] In 2018, Utah implemented a 0.05 g/dL BAC law, resulting in substantial reductions in MVCs, alcohol-involved crashes, and deaths per mile driven.[25] Globally, most high-income countries have BAC laws set at 0.05 g/dL or lower,[14,26] which can reduce alcohol-impaired driving.[24]
- *Other laws that can reduce alcohol-impaired driving.* All US states and DC have zero tolerance laws, which prohibit people aged <21 years from driving with any measurable amount of alcohol in their systems. All states and DC also have minimum legal drinking age laws, which require people to be aged ≥21 years to purchase alcohol. Both laws have been effective in reducing alcohol-impaired driving crashes and related injuries/deaths.[17,24,27,28] Other policies/strategies intended to reduce drinking to impairment by decreasing the availability, accessibility, and affordability of alcohol (e.g., increasing alcohol taxes and regulating alcohol outlet density) can also be beneficial for reducing alcohol-impaired driving.[24]

What HCPs can do:

- Screen patients for excessive alcohol use and AUD. Patients who drink alcohol excessively can benefit from brief behavioral counseling interventions,[29] and patients who have AUD can be referred to more extensive alcohol treatment programs.
- Support effective alcohol-impaired driving prevention strategies, such as lower BAC limits for drivers and ignition interlocks for all people convicted of alcohol-impaired driving.

125.3.2 Drug- and Polysubstance-Impaired Driving

Drug-impaired driving is driving while impaired by any illicit or legal substance (including prescription or over-the-counter medications). Polysubstance-impaired driving is driving while impaired by two or more substances (e.g., alcohol and cannabis). Drug- and polysubstance-impaired driving have become an increasing public health concern in the United States, particularly because of increased state-level legalization of cannabis (medical and/or non-medical) and because of the ongoing opioid overdose epidemic.

After alcohol, cannabis is the most common substance associated with impaired driving.[30,31] Cannabis has negative effects on many skills that are important for safe driving, such as motor coordination, decision-making, judgment, and reaction time.[30,32] Also, acute cannabis intoxication has been associated with MVCs.[32,33] The most common polysubstance-impaired driving combination is alcohol and cannabis, and this combination can impair driving skills even more than either substance alone.[34] Cannabis use is illegal at the federal level; however, as of July 2022, 19 states and DC allow for non-medical adult use and medical use, and 18 additional states allow for medical use.[35]

Many substances (e.g., cannabis) are processed differently in the body than alcohol. Thus, there is typically poor correlation between blood concentrations of non-alcohol substances and impairment. Also, non-alcohol substances often remain in the body much longer than alcohol.[30,32] Polysubstance use is common, and determining each substance's individual as well as combined effects on driving can be difficult.[30] Less is known about the involvement of non-alcohol substances in MVCs since standardized toxicological testing[36] for drivers involved in MVCs is not universally implemented across the United States. CDC's Transportation Safety website offers additional information about drug- and polysubstance-impaired driving.

While less is known about how to reduce drug- and polysubstance-impaired driving, some strategies include:

- *SBIRT.* Screening can be beneficial for identifying people who use substances in a harmful way.[37] Brief interventions could be implemented in some situations for people who use other substances with similar techniques to those used for people who drink excessively.
- *Substance use disorder assessment and treatment.* People with substance use disorders can be linked to specialized treatment. For example, people with opioid use disorder may benefit from treatment with medication such as buprenorphine or methadone.[38]
    - The Substance Abuse and Mental Health Services Administration (SAMHSA) offers a Behavioral Health Treatment Services Locator and an Evidence-Based Practices Resource Center.
    - CDC offers an Addiction Medicine Toolkit where HCPs can learn more about diagnosis and treatment of substance use disorders, linkage to care, stigma reduction, and patient communication strategies.

  SBIRT and assessment/treatment of substance use disorders may help reduce harmful substance use; however, more research is needed to determine if these interventions can reduce drug-impaired driving.
- *Publicized sobriety checkpoints and high-visibility saturation patrols* may have the potential to reduce drug- and polysubstance-impaired driving. There is minimal research to assess their effectiveness specifically for drug-impaired driving.[39] If conducted, they should include *drug recognition experts*—police officers with specialized training who can recognize impairment by substances other than (or in addition to) alcohol.

What HCPs can do:

- Consider screening patients for excessive alcohol use[29] and other substance use[37] simultaneously to maximize time and resources, as well as opportunities for brief interventions or linkage to treatment, as appropriate.
- Counsel patients about the effects of any substances (illicit, prescription, or over-the-counter) they use and how these substances can affect the ability to drive safely.

125.3.3 Child Passenger Safety

In 2020, 607 child passengers aged <13 years died in MVCs[40] and more than 63,000 child passengers were injured.[6] Correct and consistent use of age- and size-appropriate car seats and booster seats is essential to keep children safe when traveling in motor vehicles.[41] Car seats and booster seats are effective in reducing injuries and deaths among children.[41–45] However, many children travel completely unrestrained, are restrained incorrectly, or graduate to the next stage of child passenger safety too early.

CDC's current child passenger safety guidelines are as follows:

- *Stage 1.* From birth until age 2–4, children should be buckled in a *rear-facing car seat with a harness* until they reach the maximum weight or height limit of their car seat. Never place a rear-facing car seat in the front seat of a vehicle. Front passenger airbags are especially dangerous for young children in rear-facing car seats.[41]
- *Stage 2.* After outgrowing their rear-facing car seat and until at least age 5, children should be buckled in a *forward-facing car seat with a harness* until they reach the maximum weight or height limit of their car seat.

- *Stage 3.* After outgrowing their forward-facing car seat, children should use a *belt-positioning booster seat* until the seat belt fits properly without a booster seat, which typically does not occur until children are aged 9–12 years.
- *Stage 4.* Children no longer need to use a booster seat when the *seat belt* fits them properly. A seat belt fits properly when the lap belt is across the upper thighs (not the stomach) and the shoulder belt is across the center of the shoulder and chest (not on the neck/face or off the shoulder). Children aged <13 years should sit in the back seat of the vehicle so that they are not near frontal airbags.[41,46] Airbags are designed to be used in combination with seat belts for adults and can cause serious injuries or death to children.

Effective strategies to increase restraint use among children include the following:

- *Child restraint laws* requiring children to use approved car seats, booster seats, or seat belts appropriate for their weight, height, and age when traveling in motor vehicles increase restraint use.[17,47,48]
  - *Short-term, high-visibility enforcement* of child restraint laws coupled with widespread media advertisements can enhance the effectiveness of child restraint laws.[17,47]
  - *Strengthening/extending current child restraint laws* can also be beneficial for increasing age- and size-appropriate restraint use.
    - *Booster seat provisions.* Child restraint laws requiring children who have outgrown car seats to use booster seats until at least age nine can help reduce injuries and deaths.[13,49–52] As of July 2022, only five US states require children to use booster seats until at least age nine. CDC's Booster Seat Planning Guide can assist with assessing, planning, and implementing improved booster seat laws.[49]
    - *Provisions requiring children to remain rear-facing until at least age two.* Current guidance from CDC and the American Academy of Pediatrics (AAP) recommends that children remain in rear-facing car seats for as long as possible and until they reach the maximum weight and height limits of their car seat.[41,46,53] Most children should be able to ride rear-facing in convertible car seats until they are aged 2–4 years. As of July 2022, 17 US states and DC require children to be rear-facing until age two.
- *Distribution plus education programs* help parents/caregivers obtain new, unused car seats and learn how to properly use and install them. These programs often include hands-on demonstrations. *Incentive and education programs* are similar and reward parents/caregivers for correctly using car seats. Both types of programs typically offer instructional aids such as print materials and videos for parents/caregivers.[17,47,54]

What HCPs can do:

- Reinforce the importance of properly using car seats, booster seats, and seat belts correctly and on every trip. Children aged <13 years should sit in the back seat of the vehicle.
- Share child passenger safety resources with parents/caregivers whose children are aged <13 years, such as CDC's Transportation Safety website and CDC's infographics about the four stages of child passenger safety.
- Suggest that parents/caregivers consider seeking assistance with education and installation of car seats and booster seats from certified Child Passenger Safety Technicians. Parents/caregivers can also attend local car seat inspection stations.[55] These services are usually free.
- Determine if there are local distribution/education programs for families who cannot afford car seats and provide those resources to families.
- Support strengthening/extending current child restraint laws when laws are not on par with best practice.

125.3.4 Restraint Use among Teens and Adults

The use of seat belts is the most effective way to save lives and reduce injuries in crashes[56]—yet millions of teens and adults do not use seat belts on every trip. Seat belts reduce death and serious injury by about half.[56] Nonetheless, about half of occupants aged ≥13 years who are killed in crashes are unrestrained.[57] CDC's Transportation Safety website offers additional information about seat belt use.

Restraint use varies significantly by age, race/ethnicity, location, and other factors.[11,58–61] Compared with other age groups, teens and young adults aged 16–24 years have the lowest seat belt use rates.[58] Additionally, seat belt use in the back seat is substantially lower than in the front seat.[58,62]

Effective strategies for increasing seat belt use include the following:

- *Primary enforcement seat belt laws.* These laws allow police officers to stop and ticket someone just for not using a seat belt. Primary seat belt laws result in higher rates of seat belt use and fewer MVC deaths than secondary seat belt laws,[17,63] which only allow officers to give tickets if a driver is stopped for another reason. Seat belt laws are most effective when they cover occupants in the

front seat and the back seat.[58] As of July 2022, 20 US states and DC have primary enforcement seat belt laws covering all seating positions.

- *Increased penalties.* Increased penalties for violating seat belt laws can increase seat belt use.[17,64] Penalties may include higher fines or negative points on a driver's license.
- *Short-term, high-visibility enforcement.* Efforts such as "Click-It-or-Ticket" involve a short period of increased and highly publicized police efforts. Combining law enforcement and media coverage can be particularly effective for reaching people who typically have lower seat belt use rates (e.g., men, teens, and young adults).[17] Conducting these enforcement efforts at night may have added benefits since seat belt use is lower and other transportation risk behaviors are typically higher at night.[17]

What HCPs can do:

- Remind patients about the effectiveness of seat belts and that it is important to use them on every trip, even for short distances.
- Emphasize the importance of being good role models by using a seat belt, especially for parents/caregivers who want to set a good example for their children.
- Support primary enforcement seat belt laws for all seating positions and other effective strategies for increasing seat belt use.

125.3.5 Teen Driver Safety

MVCs are a leading cause of death for teenagers. In 2020, about 2,700 teenagers (aged 14–19 years) were killed and about 216,000 were non-fatally injured in MVCs.[6] Per mile driven, teen drivers (aged 16–19 years) are approximately three times as likely as drivers aged ≥20 years to be involved in a fatal MVC.[65] Teen drivers are particularly susceptible to being involved in MVCs due to their age and their inexperience behind the wheel.[66] Engaging in risky behaviors such as speeding, impaired driving, non-use of seat belts, and distracted driving puts them at additional risk.

Effective strategies include the following:

Graduated Driver Licensing (GDL) systems help new drivers progressively gain skills and driving experience under lower-risk conditions. The three stages of GDL include 1) learner's permit; 2) intermediate/provisional license; and 3) full licensure.[67] GDL systems exist in all US states and DC, although the strength of laws in each state varies. GDL laws have been repeatedly shown to be effective in reducing teen crashes and deaths.[17,68] Best practice GDL systems include a minimum age of 16 for obtaining a learner's permit, a mandatory learner's permit holding period of 12 months, at least 70 supervised practice hours, no teen/young adult passengers, restrictions against nighttime driving between 10:00 pm and 5:00 am (or longer), and a minimum age of 18 for full licensure.[69–71] CDC's Graduated Driver Licensing System Planning Guide can help states develop plans to strengthen GDL practices. Please see CDC's Transportation Safety website for more information about GDL.

Parental/guardian monitoring, supervision, and involvement have shown some benefits for reducing transportation risk behaviors and increasing safe driving among teen drivers.[72,73] Parents/guardians can restrict driving under high-risk conditions, such as prohibiting nighttime driving and not allowing their teen to drive with any young passengers—even if their state's GDL laws do not have these restrictions. Parents/guardians can also set clear rules and expectations with their teen driver for them to follow GDL practices and not engage in transportation risk behaviors (e.g., impaired driving or distracted driving). They can also formalize a commitment to safe driving practices with their teen through a signed Parent-Teen Driving Agreement, which can be found on CDC's Transportation Safety website. Moreover, parents/guardians can practice with their teen to ensure their teen gets many hours of supervised driving experience under varied conditions.

What HCPs can do:

- Counsel parents/guardians about their responsibility to keep their teens safe on the road, and counsel teens about their responsibility to become safe, responsible drivers.[55,73,74]
- Remind parents/guardians and teens about the importance of GDL systems, and ensure they are familiar with their state's GDL laws. Encourage parents to set additional restrictions if state GDL does not align with best practice.
- Stress the need for parents to practice driving with their teen under varied conditions, monitor their teen's driver behaviors, establish a Parent-Teen Driving Agreement with their teens, and set a good example for their teens by using seat belts and not driving while impaired or distracted.[55]
- Encourage parents/guardians and teens to purchase the safest cars possible within their budget. Parents/guardians can consult a list of safe and affordable vehicles for teens and can read research about the benefits of newer vehicle safety technologies for teen drivers on the Insurance Institute for Highway Safety's website.

125.3.6 Older Adults

The older adult population (aged ≥65 years) in the United States is growing rapidly. The older adult population grew from 41.4 million in 2011 to 55.7 million in 2020, representing a 34.6% increase.[75] During the same period, there was only a 1.3% increase among people aged <65 years.[75] About 86% of older adults (47.7 million) have driver's licenses.[5,75]

Frailty increases with age; therefore, older adults are more likely to be killed or seriously injured if they are involved in MVCs.[76] About 7,500 older adults were killed in MVCs and about 196,000 older adults were treated in emergency departments for non-fatal MVC injuries in 2020.[6]

What HCPs can do:

- Encourage older adult patients to download and use CDC's MyMobility Plan and related resources. The plan and its resources can help older adults plan to stay safe, mobile, and independent as they age, as well as help them reduce injury risks that often come with age.
- Review each patient's prescription and over-the-counter medications to reduce side effects and interactions. CDC's Medicines Risk Fact Sheet contains information about medications that might have side effects associated with MVCs and falls.
- Motivate patients to follow a regular physical activity program to increase strength, balance, and flexibility.
- Recommend that patients have their eyes checked annually and that they wear glasses/corrective lenses as required, which can benefit them as drivers, pedestrians, or bicyclists.
- Encourage older adults to consider potential alternatives to driving, such as riding with a friend/family member, using a ride share service, or using public transportation.

125.3.7 Pedestrians

Pedestrian deaths have increased by almost 50% in the last decade.[6,77] In 2020, about 7,000 pedestrians were killed in MVCs, and approximately 104,000 pedestrians were treated for non-fatal MVC injuries.[6] Risk factors for pedestrian deaths and injuries include walking in urban areas, walking at non-intersections, walking at nighttime, and vehicle speed.[77,78]

Effective interventions to reduce pedestrian deaths and injuries include the following:

- *Reducing vehicle speeds.* An adult pedestrian's risk of dying if struck by a car traveling about 30 miles per hour is <20%, but that same pedestrian would have almost a 60% risk of dying if they were struck at about 50 miles an hour.[79] Therefore, reducing vehicle speeds through roadway design interventions or lower speed limits can be particularly beneficial for pedestrians, especially in urban areas.
- *Roadway countermeasures that enhance the visibility of pedestrians and/or physically separate them from motor vehicles.* Examples include sidewalks, crosswalks (particularly with visibility enhancements), specific types of flashing pedestrian warning signs, medians/pedestrian refuge islands, and leading pedestrian intervals.[80]
- *Increasing visibility, especially at night.* Wearing retroreflective materials (particularly on extremities) or flashing lights can dramatically increase the distance from which a pedestrian can be seen and thus can help to prevent pedestrian deaths and injuries.[17,81]

What HCPs can do:

- Encourage patients to be aware of the risks that pedestrians face and to protect themselves by:
  - Increasing their visibility at night by carrying a flashlight and wearing reflective clothing.
  - Walking on sidewalks or other paths instead of the road. If no sidewalks or paths are available, walk on the shoulder facing traffic.
  - Crossing streets at a crosswalk or intersection.
  - Avoiding the use of electronic devices when walking—especially when crossing the street.
  - Avoiding walking if they have been drinking alcohol and/or using other substances, which can impair judgment and coordination.
- Support implementation of speed reduction countermeasures (e.g., roadway design features and lower speed limits).

125.3.8 Motorcyclists

Almost 5,600 motorcyclists were killed in the United States in 2020,[82,83] and about 181,000 motorcyclists were treated in emergency departments for non-fatal MVC injuries.[6] Riding on motorcycles is inherently more dangerous than riding in motor vehicles, since motorcycles are less stable and lack the protection of a vehicle shell.[82] In 2020, the death rate per vehicle mile traveled among motorcyclists was about 28 times higher than the death rate per vehicle mile traveled for passenger car occupants.[83]

Effective interventions to reduce motorcyclist deaths and injuries include the following:

- *Motorcycle helmet use* reduces the risk of head injury in an MVC by about 69%,[84] and it reduces the risk of death by about 40%.[85] Although motorcycle helmets sold in the United States are required to meet the federal safety standard (as indicated by the "DOT certification" label), noncompliant helmets can be found and are used by some motorcyclists.
- *Universal helmet laws* are the most effective way to increase helmet use. These laws require all motorcyclists (drivers and passengers of all ages) to use helmets.[86–88] Motorcycle helmet use is substantially higher in states with universal helmet laws compared with states that have partial or no motorcycle helmet laws.[89] Also, universal helmet

laws are associated with reductions in motorcyclist crash death rates.[90] As of July 2022, only 18 US states and DC have universal helmet laws.
- *Motorcycle rider training* may be beneficial on the individual level, but effectiveness studies on a population level have had mixed results.[17] Compulsory training programs show some promise,[88] particularly if they incorporate on-the-road skills-building methods.
- *Anti-lock brakes* are required in all new cars but are not required for motorcycles. The use of motorcycles with anti-lock brakes is recommended.[82,91] Fatal crash rates for motorcyclists using motorcycles with anti-lock brakes are 22% lower than fatal crash rates for motorcyclists using motorcycles without anti-lock brakes.[82,91]
- *Use of protective and highly visible clothing* can also have safety benefits.[17,88,92,93]

What HCPs can do:
- Counsel patients on the importance of using federally certified helmets and making sure they are fitted properly.
- Suggest that patients who ride motorcycles take motorcycle rider training, use motorcycles with anti-lock brakes, and use clothing that is protective and highly visible.

125.3.9 Bicyclists

In 2020, 932 bicyclists were killed in MVCs in the United States,[94] and about 131,000 bicyclists were treated in emergency departments for non-fatal MVC injuries.[6] Risk factors for bicyclist deaths and injuries include riding without helmets, riding in urban areas, riding on major roads (other than interstates and freeways) and not at intersections, and using alcohol and/or other impairing substances.[94]

Effective interventions to reduce bicyclist deaths and injuries include the following:

- *Bicycle helmet use* substantially reduces the risk of head and brain injury in a crash.[95–98]
- *Bicycle helmet laws* are effective for increasing helmet use.[17,98,99]
- *Roadway design interventions* that physically separate bicyclists from motor vehicles are also effective. Examples include segregated bike lanes and well-designed and illuminated intersections.[98]

What HCPs can do:
- Reinforce the importance of bicycle helmet use. Encourage patients to make sure that their helmets fit properly.
- Encourage patients to increase their visibility at night by wearing fluorescent and/or retroreflective clothing and adding lighting to bicycles.[17,98,99]

125.3.10 Speed

Speed affects both the likelihood and severity of MVCs. In 2020, 29% of fatal MVCs involved speeding.[100] MVC injuries that occur at high speeds are more severe, particularly for pedestrians and bicyclists. Traffic calming and roadway design measures that compel drivers to slow down can help reduce speeds, including narrowing streets, road diets, curb extensions, speed bumps, roundabouts, and rumble strips.[79,80,101] These measures are often backed up by low speed limits (about 20 miles per hour) in urban areas and/or areas with high pedestrian traffic.[79] Other effective speed-reducing strategies include automated speed enforcement, red light cameras, and variable speed limits.[17,80]

What HCPs can do:
- Remind patients about the importance of not speeding—particularly in areas where there are pedestrians and bicyclists.
- Support efforts to implement automated speed enforcement, red light cameras, lower speed limits, and roadway design features that reduce speeds.

125.3.11 Distracted Driving

Every day, about nine people in the United States are killed in MVCs reported to involve a distracted driver.[102] Distracted driving is any activity that takes the driver's attention away from driving, such as cell phone use, eating, or adjusting radio or climate controls. Any of these distractions can increase the chance of an MVC.

Many US states have enacted laws prohibiting handheld cell phone use or texting while driving bans. In isolation, these laws have had limited effectiveness; however, high-visibility enforcement of these laws has shown promise in helping to address distracted driving. High-visibility enforcement involves increased numbers of police officers patrolling a specific area along with paid and earned media, thereby increasing drivers' perceived risk of getting a ticket.[17]

What HCPs can do:
- Remind patients about the dangers of all types of distractions while driving.
- Remind patients of the distracted driving laws in their state, which can be found on the Insurance Institute for Highway Safety's website.

125.3.12 Technology and Motor Vehicle Safety

New technologies are being implemented every day in vehicles and on roads to improve road safety. The 2020 United Nations General Assembly (UNGA) resolution 74/299 ("Improving global road safety") highlights the role of innovative automotive and digital technology for motor vehicle safety. Vehicle and infrastructure technology are also central components of the Safe System approach.[103]

In the future, fully autonomous vehicles or self-driving cars have vast potential safety benefits; however, they are not currently commercially available. Nonetheless, there are many vehicle safety technologies currently available in modern vehicles that can help reduce transportation risk behaviors, crashes, injuries, and deaths. Examples include the following:

- *Front and rear crash prevention*. Forward collision warning, automatic emergency braking, backup cameras, and rear cross traffic alerts.
- *Lane departure prevention*. Lane departure warning, lane keeping assist, blind spot warning, and side view cameras.
- *Transportation risk behavior reduction*. Passive alcohol detection systems, high speed alerts, and drowsiness alerts.
- *Protection of vulnerable road users*. Bicycle/pedestrian detection and braking systems.
- *Other*: Adaptive cruise control, tire pressure monitoring system, and electronic stability control.

What HCPs can do:

- Advise patients to learn more about vehicle safety technologies and driver assistance technologies at the National Safety Council's My Car Does What website, the National Highway Traffic Safety Administration's Driver Assistance Technologies website, and the Insurance Institute for Highway Safety's Advanced Driver Assistance website.
- Encourage patients to purchase cars with as many vehicle safety technologies as their budget allows and encourage them to prioritize safety technologies over convenience technologies.
- Remind patients that some vehicle technologies (e.g., complex navigation systems) can decrease safety by contributing to driver distraction.

125.3.13 The Safe System Approach, Global Road Safety, and Prevention Efforts

MVCs cause substantial morbidity and mortality worldwide.[26] Globally, approximately 1.35 million people are killed in MVCs every year, and about 93% of those deaths occur in low- and middle-income countries.[26] Additionally, MVCs are the leading cause of death for people aged 5–29 years.[26]

Many current global and domestic efforts to reduce MVC deaths and injuries emphasize widespread adoption of the Safe System approach—which accommodates for human error, accounts for human vulnerability, and works to protect all road users. Its core elements include safe roads, safe vehicles, safe road users, safe speeds, and post-crash care. Multiple high-income countries (such as Australia, the Netherlands, New Zealand, Spain, and Sweden) that have embraced the Safe System approach have had success reducing MVC deaths and injuries.[103]

In the United States, multiple cross-sectoral efforts and initiatives to improve motor vehicle safety are also ongoing. The Road to Zero Coalition's primary goal is to eliminate all US MVC deaths by 2050 and seeks to do this through three approaches: 1) doubling down on what works through proven, evidence-based strategies; 2) advancing life-saving technology in vehicles and infrastructure; and 3) prioritizing safety by adopting the Safe System approach and creating a positive safety culture. Healthy People 2030 has four motor vehicle safety goals and three other transportation-related goals including reducing deaths from MVCs, reducing drunk driving, reducing drowsy driving, and increasing restraint use. The 2021 US Government Bipartisan Infrastructure Law (i.e., the Infrastructure Investment and Jobs Act) authorizes major investments in the US transportation sector, including opportunities to improve motor vehicle safety. The National Roadway Safety Strategy, issued by the US Department of Transportation in 2022, establishes a comprehensive plan that outlines critical actions needed to improve motor vehicle safety.

Globally, the World Health Organization (WHO) established global road safety goals through the initiation of the first Decade of Action for Road Safety (2011–2020). WHO subsequently initiated a second Decade of Action for Road Safety (2021–2030), and the accompanying resolution re-commits to halving MVC deaths and injuries. The first-ever high-level UNGA meeting on improving global road safety was held in mid-2022 and resulted in the adoption of a political declaration detailing actions to accelerate road safety improvements. Additionally, the United Nations Sustainable Development Goals (SDGs) (adopted in 2015) established two road safety-related goals:

- SDG 3.6 called for a 50% reduction in MVC deaths/injuries by 2020.
- SDG 11.2 calls for accessible, safe, affordable, and sustainable transportation systems for all, with an emphasis on meeting the needs of women, children, people with disabilities, and older adults.

What HCPs can do:

- Be aware of and support global and domestic efforts to reduce motor vehicle crash deaths and injuries.
- Support implementation of the Safe System approach.

CLINICAL APPLICATIONS

Each motor vehicle injury prevention strategies section in this chapter has recommendations for healthcare providers specific to each topic. In addition to those recommendations, here are several overarching and cross-cutting clinical applications that apply more broadly to motor vehicle safety.

- Include motor vehicle injury prevention in all your health promotion and disease prevention activities with patients.
  - Encourage lifestyle behaviors that decrease the likelihood of MVCs, injuries, and deaths.
  - Set goals with patients to reduce crash risk by changing behaviors (e.g., using a seat belt on every trip; using helmets when riding on motorcycles or bicycles; not driving after drinking alcohol and/or using other substances).
- Assess and record MVC risk and protective factors regularly when counseling patients and their families and include these risk factor assessments in electronic health records and chart reviews.
- Conduct annual patient medication reviews to assess polypharmacy and drug interactions that might affect driving. This is important for all patients but particularly important for older adults, who commonly take multiple medications.
- Support efforts to strengthen comprehensive trauma systems in your state and improve prehospital care.

126 Drowning Prevention

Tessa Clemens, PhD and Briana Moreland, MPH

KEY POINTS

- Drowning is a leading cause of death among children. From 2011 to 2020 over 4000 people in the United States died from drowning each year and over 8000 people were treated in the emergency department each year for non-fatal drowning.
- Non-Hispanic Black or African American persons and non-Hispanic American Indian or Alaska Native persons have the highest rates of fatal drowning.
- The most common locations of fatal drowning differ by age group. The majority of infant drownings occur in bathtubs, the majority of drownings among children aged one to four years occur in swimming pools, and among persons aged ≥15 years, the majority occur in natural water (Figure 126.1).
- Drowning is preventable. Effective drowning prevention strategies include installing fences that fully enclose swimming pools, learning basic swimming and water safety skills, wearing life jackets while boating, close and constant supervision of children in or near water, and knowing and administering cardiopulmonary resuscitation if drowning does occur. When participating in aquatic activities, avoiding alcohol and staying in lifeguard-supervised settings can help prevent drowning.

126.1 DEFINITION OF DROWNING

The definition of drowning has evolved over time; a previous review identified over 20 definitions for fatal drowning and 13 for non-fatal drowning.[1] In 2002, existing definitions were deemed unsuitable for surveillance and epidemiological research because they included characteristics of the drowning event, pathophysiological changes, as well as the outcome.[2] Using separate definitions for fatal and non-fatal drowning was also identified as a potential contributor to underestimation of the burden of drowning.[2] The following definition was adopted by consensus of the World Congress on Drowning in 2002: "Drowning is the process of experiencing respiratory impairment from submersion/immersion in liquid".[2] Drowning outcomes include death (fatal drowning) and morbidity or no-morbidity (non-fatal drowning).[2] Consistent use of drowning terminology across sectors and disciplines is important to enable adequate comparisons and clear and consistent drowning prevention messaging and advocacy.[3] The term "near-drowning" should be avoided as it implies that a drowning did not occur and that drowning is necessarily fatal. Non-fatal drowning can result in serious long-term morbidity, and correct terminology should be used to describe non-fatal drowning cases so that they can be better studied and prevented.

126.2 EPIDEMIOLOGY OF DROWNING

From 2011 to 2020, on average, over 4000 people in the United States died from drowning each year and there were an additional 8000 estimated emergency department visits for non-fatal drowning annually.[4] Rates of fatal and non-fatal drowning vary by demographic characteristics such as age, sex, and race/ethnicity.[4] Rates of drowning deaths have decreased overall in the past two decades.[5] However, this decrease has been more pronounced in some groups than others. Drowning deaths disproportionately affect Black or African American and American Indian or Alaska Native children and young adults.[5] Persons with certain medical conditions may also have a higher risk of drowning.[6,7] The most frequent locations where drowning deaths occur differ by age, race, and ethnicity.[5]

126.2.1 Age

Children aged one to four years have the highest rates of fatal drowning, and from 2011 to 2020 more children aged one to four years died from drowning than from any other cause except birth defects.[4] From 2011 to 2020, 2.6 per 100,000 children aged one to four years died from drowning.[4] Children aged one to four years also have the highest rates of drowning-related emergency department visits (21.1 per 100,000 children from 2011 to 2020). Drowning was the second leading cause of unintentional injury death among children aged 5–14 years and the third leading cause of unintentional injury deaths among persons aged 15–29 years from 2011 to 2020.[4] Drowning death rates are lower throughout the rest of adulthood and increase among older adults aged ≥65 years (1.5 per 100,000 older adults from 2011 to 2020). Older adults aged ≥65 years have higher drowning death rates than all other age groups except children aged one to four years.[4]

126.2.2 Sex

From 2011 to 2020, males had higher fatal (2.0 per 100,000) and non-fatal (3.1 per 100,000) drowning rates compared

DOI: 10.1201/9781003227793-147

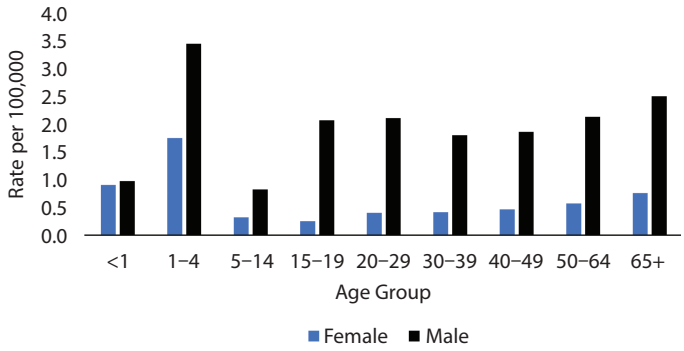

FIGURE 126.1 Fatal drowning rates by age group and sex, National Vital Statistics System, United States 2011–2020. International Classification of Disease 10th revision drowning death codes: W65-W74, V90, V92.

with females (fatal: 0.6 per 100,000; non-fatal: 2.0 per 100,000).[4] Males have higher fatal drowning rates across all age groups except infants aged <1 year where drowning death rates do not differ by sex.[4] Possible reasons for the higher drowning rate among males compared with females include increased exposure, risk-taking behavior, overestimation of swim skills, decreased use of life jackets, and alcohol use.[8–10]

126.2.3 Racial and Ethnic Disparities

There are persistent racial and ethnic disparities present in drowning death rates.[5] Non-Hispanic Black or African American persons aged ≤29 years have fatal drowning rates 1.5 times higher than non-Hispanic White persons of the same age.[5] Non-Hispanic American Indian or Alaska Native persons aged ≤29 years have fatal drowning rates 2.0 times higher than non-Hispanic White persons of the same age.[5] Despite an overall decrease in the rate of fatal drowning over the past 20 years, these disparities persist and may be increasing in some groups.[5] From 2005 to 2019, the drowning death rate ratio between non-Hispanic Black or African American persons aged ≤29 years and non-Hispanic White persons aged ≤29 years significantly increased.[5]

The reasons for racial and ethnic disparities in drowning deaths are not well understood. Some possible explanations for these disparities are lower reported swimming ability among African American youth[11] and increased fear of drowning among Black youth and their parents, leading to potential hesitancy in swim lesson participation.[12] More research is needed to explain the higher rates of drowning deaths among non-Hispanic American Indian or Alaska Native youth and non-Hispanic Black or African American youth.

126.2.4 Medical Conditions

Medical conditions including seizure disorders, autism, and some heart conditions are associated with increased drowning risk.[7,13] Seizure disorders, such as epilepsy, have been associated with increased drowning deaths in children[14] and adults.[15] Persons with epilepsy have 15 to 19 times the risk of drowning deaths as the general population.[16] Drowning is also a leading cause of unintentional injury death among children with autism spectrum disorders.[13,17] Deaths among persons diagnosed with autism were nearly 40 times as likely to be caused by drowning than deaths among the general population.[17] Heart conditions may also be associated with an increased risk of drowning.[7,13] Ischemic heart disease has been associated with an increased risk of drowning[7] and although rare, long QT syndrome, a cardiac condition that causes arrhythmias, can increase the risk of drowning.[18]

126.2.5 Location of Drowning

Overall, most drowning deaths occur in natural water such as lakes, rivers, and oceans (45%) and swimming pools (18%).[19] Children aged one to four years account for over one-third of all fatal drownings in swimming pools;[19] 1.5 per 100,000 children aged one to four years drowned in swimming pools on average from 2011 to 2020.[19] The location of drowning differs by age, race, and ethnicity. Non-Hispanic Black or African American persons have the highest fatal drowning rates in swimming pools.[5] This disparity is most pronounced in youth aged 10–14 years.[5] Non-Hispanic Black or African American youth aged 10–14 years have drowning death rates 7.6 times higher than non-Hispanic White youth aged 10–14 years in swimming pools.[5] Non-Hispanic Black or African American children and young adults aged ≤29 years have drowning rates 1.8 times higher in swimming pools than non-Hispanic White children and young adults.[5]

Fatal drowning in natural water is most common among persons aged ≥15 years.[19] Non-Hispanic American Indian or Alaska Native persons have the highest fatal drowning rates in natural water.[19] Among persons aged ≤29 years, non-Hispanic American Indian or Alaska Native persons had fatal drowning rates 2.7 times higher than non-Hispanic White persons in natural water.[5] This disparity was most pronounced in persons aged 25–29 years.[5] Non-Hispanic American Indian or Alaska Native persons aged 25–29 years had drowning rates 4.0 times higher than non-Hispanic White young adults in natural water[5] (Figure 126.2).

Rates of fatal drowning in bathtubs are highest among infants aged <1 year, accounting for approximately 68% of drowning deaths among infants from 2011 to 2020.[19] Boating-related drowning death rates are highest among adults aged ≥20 years.[19] Although drowning in natural water accounted for the highest percentage of drowning deaths among older adults (aged ≥65 years), older adults had higher percentages of drowning deaths in swimming pools and bathtubs compared with persons aged ≥15 years[4] (Figure 126.3).

Overall, persons living in rural areas have higher rates of fatal drowning compared with those living in urban areas.[19] However, drowning death rates in rural compared with urban areas differ by location of drowning; rates of fatal drowning in natural water and on boats are higher among persons living in rural areas compared with those living in urban areas, while rates of fatal drowning in pools are higher among persons living in urban areas compared to those living in rural areas.[19]

126.3 DROWNING PREVENTION STRATEGIES

Drowning happens quickly and quietly; without immediate intervention, drowning is often fatal or results in serious outcomes with long-term morbidity. Therefore, primary prevention strategies that stop drowning from occurring are most effective. Proven primary prevention strategies for drowning include installing barriers controlling access to water, basic swimming and water safety skills training programs, and wearing life jackets. Close supervision and avoiding alcohol during water-related activities can also reduce drowning risk.[20] If primary prevention strategies fail and the drowning process is started, knowing how to administer cardiopulmonary resuscitation can make a

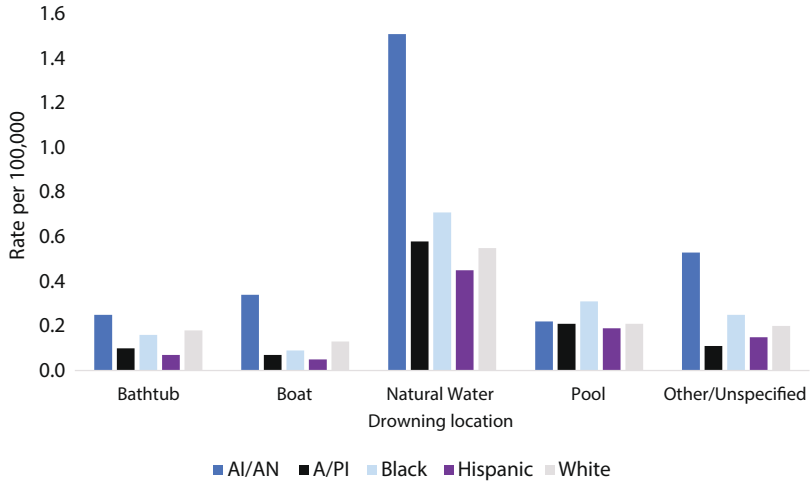

FIGURE 126.2 Fatal drowning rates by location and race/ethnicity, National Vital Statistics System, United States 2011–2020.

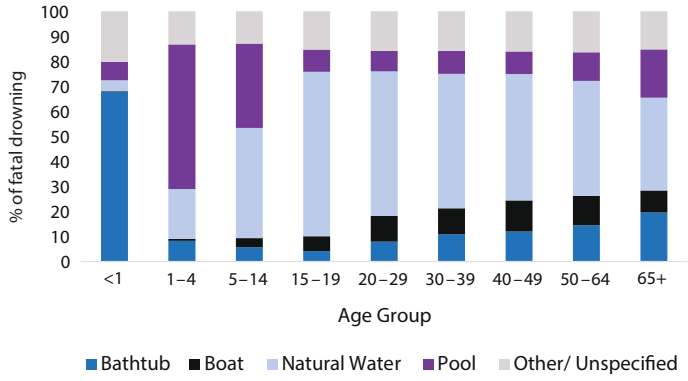

FIGURE 126.3 Percentage of drowning deaths in each location by age group, National Vital Statistics System, United States 2011–2020.

Non-Hispanic American Indian or Alaska Native (AI/AN), non-Hispanic Asian or Pacific Islander (A/PI), non-Hispanic Black or African American (Black), non-Hispanic White (White), Hispanic persons could be of any race International Classification of Disease 10th revision drowning death codes: bathtub: W65, W66; boat: V90, V92; natural water: W69, W70; pool W67, W68; other/unspecified: W73, W74

critical difference during the time it takes emergency medical services to arrive.

126.3.1 Barriers Controlling Access to Water

Barriers that control access to swimming pools can prevent drowning in the event of a lapse in caregiver supervision. Such barriers include pool fencing, pool covers, pool alarms, and door alarms. Pool fencing is the most effective of these measures; a meta-analysis of available studies found the odds ratio (OR) for drowning in a fenced versus unfenced pool to be 0.27 (95% CI: 0.16–0.55), and the OR for four-sided, isolation fencing that completely encloses the pool versus three-sided, perimeter fencing where the house acts as the fourth side of the enclosure to be 0.17 (95% CI: 0.07–0.44).[21] The World Health Organization recommends fully enclosing pools with four-sided isolation fencing with self-closing and self-latching gates and legislating and enforcing such barriers as one of ten actions to reduce drowning.[22] In 2009, Queensland, Australia, introduced new legislation requiring that pools be enclosed with four-sided isolation fencing.[23] Six years after the legislation was introduced, drowning rates among children aged <5 years significantly decreased.[23] To prevent children from climbing over, under, or through them, pool fences should meet the following specifications outlined by the Consumer Product Safety Commission:[24]

- Fence height should be a minimum of four feet (at least five feet is preferable) with less than a four-inch gap under the fence (less than two inches if the fence is on grass or pebbles).
- Vertical bars or slats should not have gaps more than four inches between them.
- Fence construction should limit hand holds that could be used to aid climbing (e.g., horizontal bars should be at least 45 inches apart and should be on the inside of the fence, closest to the pool).
- Fences should have self-closing, self-latching gates. Latches should be at least 54 inches above the bottom of the gate, or the latch release mechanism should be on the swimming pool side of the gate at least three inches below the top of the gate, and the gate and fence should have no opening greater than half an inch within 18 inches of the latch.
- Objects that could be used to climb over the fence should not be placed nearby (e.g., storage boxes, patio furniture).

Pool covers and pool nets that can hold the weight of a child are less likely to be effective because they need to be removed and replaced each time the pool is used, increasing the likelihood that the pool will be unintentionally left unsecured between uses.[13] Pool alarms, designed to sense disturbances of pool water, and wristbands that alarm when exposed to water, have been demonstrated to function properly when tested, but no study has established whether they prevent drowning.[25] The effectiveness of door alarms, intended to alert caregivers that a child has gained access to the pool area by leaving the home, has also not been studied.[13] Pool covers, pool alarms, and door alarms should not be relied on exclusively as barriers but can function as additional layers of protection when used in conjunction with proven barriers such as four-sided isolation fencing that completely encloses the pool.[13]

126.3.2 Basic Swimming and Water Safety Skills Training

Implementation of basic swimming and water safety skills training programs can reduce the risk of drowning.[27] Such programs are recommended by the World Health Organization for children six years of age and older[27] and by the American Academy of Pediatrics for children as young as one year of age and older.[6,13] There is currently no evidence to support a recommendation for infant (<1 year) swim lessons.[13] Introducing swimming training in this age group should be carefully considered by the caregiver and pediatrician as it may increase the risk of gastrointestinal tract infections, dermatitis, acute respiratory illness, hyponatremia, and hypothermia.[13]

The goal of basic swimming and water safety skills training programs is to move participants toward water competency. Water competency is the ability to anticipate, avoid, and survive common drowning situations, as well as the ability to recognize and safely assist a person who is in distress in the water. There are three main components of water competency:[1] water safety skills,[2] basic swimming skills,[3] and helping others.[27]

1. *Water safety skills* include knowing your limitations, avoiding unsafe behaviors (e.g., never swimming alone, only swimming in safe areas, not diving in shallow or unsafe water, always wearing a life jacket while boating, not using alcohol or drugs during aquatic activities), understanding how different physical and environmental conditions (e.g., physical fitness, medical conditions, currents in water) affect swimming in open water, and knowing how to call for help.
2. *Basic swimming skills* include the ability to safely enter and exit water, turn around and orient to safety as well as turnover in the water, float and/or tread water, swim to safety (at least 25 yards), and the ability to perform these skills while clothed.
3. *Helping others* includes always providing close and constant supervision around water, knowing how to recognize a drowning person, knowing safe ways to rescue a drowning person without putting yourself at risk, and knowing CPR.

Despite evidence of the benefits of participating in basic swimming and water safety skills training, inequities in the

adoption and uptake of programs by race, ethnicity, and socioeconomic status exist.[26] For example, Black or African American people have lower self-reported swimming skills than people from other racial and ethnic groups.[11,28,29] Studies have identified structural barriers (i.e., financial constraints, lack of time, and lack of facilities)[30] and attitude and behavioral barriers (e.g., fear of being in and around water)[12,30] for Black or African American people in developing swimming skills. More research is needed to determine how to improve access to basic swimming and water safety skills training programs for communities at increased risk of drowning. Engaging these populations to understand and address barriers to accessing and participating in prevention programs will be critical to developing effective and inclusive drowning prevention strategies.[5]

126.3.3 Personal Floatation Device (Life Jacket) Use

Personal floatation devices (life jackets) reduce the risk of fatal drowning during recreational boating for people of all ages and swimming abilities.[30] US Coast Guard-approved life jackets should be worn properly by boaters at all times and can also be worn by children playing near water and by inexperienced swimmers during other aquatic activities such as swimming or wading.[32] Despite evidence supporting the efficacy of wearing life jackets to reduce drowning and recommendations by national organizations, life jacket use remains low when unmandated. Life jacket use ranges by boat type and age, with the lowest observed rates among recreational motorboat users and adults. A 21-year study from 1999–2019 in the United States reported life jacket wear rates among recreational boaters ranged from 21–25% for all recreational boaters combined (all ages and types of boats). The lowest wear rates were among adults (18 years and older) on open motorboats ranging from 5–7%, and the highest were among youth (less than 18 years) on non-powered paddle craft ranging from 64–93%.[33] Legislation has been shown to increase life jacket wearing. An Australian study indicated that the probability of life jacket use in Victoria increased from 22% to 63% on small-powered vessels after legislation was introduced.[34] Mandatory wear regulations in four lakes in the state of Mississippi resulted in an increase in life jacket use from 13% to 68% three years after the regulations had been introduced.[35]

The safest option is for all boat users, regardless of age, boat type, or activity, to wear a life jacket at all times while boating. The most effective lifejackets are US Coast Guard-approved and have the following specifications:[36]

- Fit snuggly with all clips, zippers, and ties fastened and with loose strap ends tucked in.
- Materials in good condition and do not have holes, rips, or tears.
- Properly fitted for the person wearing it, and when fastened, the life jacket should not be able to ride up over the individual's chin and ears.

126.3.4 Active Supervision of Children

Absent or inadequate supervision has been identified as a contributing factor in pediatric drowning.[37] Although passive interventions that are always in effect (e.g., pool fencing) are more likely to be effective than active interventions that require an action (e.g., caregiver supervision), designating a responsible adult to supervise children closely and constantly when in or near the water provides an important layer of protection; adult supervision should work in conjunction with barriers to reduce the risk of drowning among children.[13] Three commonly described dimensions of supervision are proximity, attention, and continuity:[38]

- Proximity: proximity may be most important for young children and beginner swimmers. Touch supervision, where the adult is within arm's reach and can quickly assist the beginner swimmer, should be used in these cases.[13]
- Attention: adults supervising children during aquatic activities should maintain visual and auditory attention and avoid distracting activities like reading, using the phone, and consuming alcohol or drugs.[13]
- Continuity: drowning happens quickly and quietly, therefore, children and beginner swimmers should be supervised constantly when in and near water.[13]

126.3.5 Alcohol

Alcohol is an important risk factor associated with drowning; 30–70% of individuals who drowned while engaging in recreational aquatic activities had alcohol in their bloodstream.[39] The consumption of alcohol during aquatic activities can result in poor judgment and poor performance, which increases the risk of the drowning process starting in the first place. Additionally, alcohol can have physiological effects that contribute to more severe drowning outcomes such as poor balance and orientation, and increased risk of hypothermia.[40]

Several studies have examined alcohol involvement in recreational boating fatalities. A California study estimated a relative risk of death of 10.7 for boat operators with a blood alcohol concentration (BAC) of about 0.10 g/100mL.[41] A case-control study conducted in Maryland and North Carolina estimated that the odds of death for recreational boat passengers and operators increased at even low levels of BAC; a BAC of 0.01 g/100ml resulted in an OR of 1.3 (95% CI 1.2–1.4). A high BAC of 0.25 g/100ml resulted in an OR of 52.4 (95% CI 25.9–106.1).[40] A case-control study that compared fatal with non-fatal recreational boating injuries in Washington found that fatalities were 70% more likely to have alcohol involved (95% CI 1.1–2.8).[42] Despite evidence that alcohol is a risk factor for recreational boating injury, studies suggested that recreational boaters do not fully perceive this risk. The results of two independent survey studies indicated that recreational boaters believe

that passengers can safely drink more alcohol than operators,[43,44] and that individuals on stopped boats can safely drink more than those on moving boats.[43]

Avoiding alcohol when swimming, boating (for both operators and passengers), or supervising children can reduce the risk of drowning.

126.3.6 Lifeguard Supervision

Lifeguards can serve an important role in both primary and secondary drowning prevention. Lifeguards prevent drowning by enforcing safety rules to prevent injuries, educating swimmers, and monitoring aquatic conditions. In fact, a study demonstrated that rescues only represent 1.9% of lifeguard activity, whereas prevention actions, that prevent the need for a rescue in the first place, comprise the majority of a lifeguard's activities during their time on duty (54.8%).[45] Lifeguards are also trained to identify and rescue persons who get into trouble in the water and/or begin drowning. Lifeguard supervision can reduce drowning in multiple ways:[46]

- The presence of lifeguards may decrease risk-taking behavior near or in the water.
- Lifeguards monitor aquatic environments and alert swimmers to hazards. For example, they may notice dangerous conditions developing (e.g., rip tides, strong waves) that could increase drowning risk and can make swimmers aware of these conditions.
- Lifeguards are trained in safe water rescue techniques and resuscitation and can rescue a person and provide effective treatment prior to the arrival of emergency medical services.

While actively guarding, lifeguards are most effective when focused on the water and not asked to take on other activities, such as selling concessions.[46] Lifeguards are not a substitute for caregiver supervision. Even when a lifeguard is present, close and constant supervision by caregivers can prevent child drownings. Lifeguard-supervised settings are the safest option for all persons, especially those with an increased risk of drowning due to medical conditions or other risk factors.

126.3.7 Cardiopulmonary Resuscitation

The likelihood of surviving a drowning event is improved when immediate rescue and resuscitation are initiated. Bystander cardiopulmonary resuscitation (CPR) has been associated with improved neurologically favorable outcomes in drowning persons.[47] In the event that lifeguards or other trained rescuers are not on site, caregivers and/or witnesses of drowning events play a pivotal role that may determine the outcome of the person who drowned. Without the immediate basic resuscitation (i.e., CPR) that can only be initiated by on-scene bystanders, subsequent advanced resuscitation techniques, such as administering defibrillation and medications, may be of little value.[48] Although compression-only CPR has been recommended as an approach to bystander CPR in some settings,[49] both compression and ventilation are recommended for effective CPR with drowning patients.[13] However, compression-only CPR is still better than not attempting any form of CPR.[50] Being trained in basic CPR is useful for all persons, especially caregivers. Many organizations such as the American Red Cross[51] and the American Heart Association[52] offer CPR training courses, both online and in-person.

CLINICAL APPLICATIONS

- Include drowning prevention and water safety in your health promotion and disease prevention activities with patients.
- Provide age-specific education about drowning prevention for patients and families (e.g., remind caregivers of infants about the importance of supervising closely and constantly in the bathtub, remind caregivers of toddlers that drowning happens quickly and quietly, and provide examples of effective barriers).
- Provide patients who have medical conditions that place them at increased risk of drowning (e.g., seizure disorders, autism, cardiovascular disease) and their families with water safety tips. Encourage people with seizure disorders to shower instead of taking a bath and encourage people with medical conditions to participate in aquatic activities in supervised settings.
- Encourage families to fully enclose home pools, including above-ground pools of either temporary or fixed installation, with four-sided isolation fencing with self-closing, self-latching gates.
- Talk with caregivers about enrolling their children in basic swimming and water safety skills training. Have information available on how families can access these programs in your communities (e.g., YMCA Safety Around Water Program,[53] American Red Cross swim programs[54]).
- Reinforce that wearing properly fitting US Coast Guard-approved life jackets at all times during boating activities can prevent drowning. Remind caregivers that life jackets can also be worn by children and beginner swimmers when in or near water during non-boating-related activities. Discourage the use of foam toys and water wings as floatation devices.
- Screen for alcohol and substance misuse using existing tools such as brief intervention and motivational interviewing to identify the potential for impaired boating. Reinforce that using alcohol and other drugs while participating in aquatic recreation and while supervising children in or near the water are risk factors for drowning.

- Encourage caregivers to take basic cardiopulmonary resuscitation training and have information on hand about how families can access this training in your community or online (e.g., through the American Red Cross[51] or the American Heart Association[52]).
- Identify whether legislation related to drowning prevention measures such as isolation pool fencing and mandatory life jacket wear exists in your state.

127 Improving the Care of Children with Mild Traumatic Brain Injury: CDC's Evidence-Based Pediatric mTBI Guideline

Kelly Sarmiento, MPH, Angela Lumba-Brown, MD, Matthew J Breiding, PhD, David Paulk, EdD, PA-C, Kenneth Vitale, MD, and David Sleet, PhD

KEY POINTS

- Mild traumatic brain injury (mTBI) is caused by a blunt force applied to the head or body that leads the brain to accelerate and decelerate with translational, rotational, and/or angular forces.
- mTBI presents differently among children, relative to adults, due to anatomical, physiological, and cognitive differences.
- Several validated symptom scales are available to healthcare professionals to aid in the diagnosis of mTBI among children.
- Most children with mTBI have a good recovery and no longer experience symptoms one to three months post-injury.
- Certain premorbid conditions and risk factors may suggest a delayed recovery among children with mTBI and should be assessed as part of prognostic counseling.
- Access to social supports and referral to mental healthcare may help reduce mental health sequelae after an mTBI.
- mTBI treatment may include cognitive and vestibular rehabilitation, sleep hygiene, and/or non-narcotic analgesia.

127.1 INTRODUCTION

According to the Centers for Disease Control and Prevention (CDC), approximately 223,000 traumatic brain injury (TBI)-related hospitalizations in 2019 and more than 64,000 TBI-related deaths in 2020 occurred in the United States.[1] These estimates do not include people seen in primary care offices, specialty clinics, federal, military, or US Department of Veterans Affairs settings, or those who do not seek medical care.[2] Developing a national system that standardizes the measurement of TBI to comprehensively capture its incidence, prevalence, and outcomes is needed to better understand the full burden of this injury.[2]

A greater focus on reducing health disparities is critical to preventing TBI among those at greatest risk and minimizing adverse outcomes following this injury. Prior studies have found high levels of lifetime TBI among people who are experiencing homelessness,[3] those who reside in correctional and detention facilities,[4] and women in domestic violence shelters.[5] American Indian/Alaska Native children and adults have higher rates of TBI-related hospitalizations and deaths than other racial or ethnic groups,[6,7] and people living in rural areas have a higher rate of TBI-related death compared with those living in non-rural areas.[8] Research on health disparities and TBI by race and ethnicity also demonstrate inequities in patient evaluation and outcomes based on the intent of injury, namely violence-related TBI.[7,9]

127.2 MILD TRAUMATIC BRAIN INJURY

A TBI is caused by a blunt force applied to the head or body that leads the brain to accelerate and decelerate with translational, rotational, and/or angular forces. These direct or indirect forces lead to a wave of energy that passes through brain tissue, injures it, and triggers neuronal dysfunction that involves a complex cascade of ionic, metabolic, and physiologic events (Figure 127.1).[10,11] This cascade, and microscopic axonal dysfunction, results in clinical signs and symptoms of TBI.[10]

At least 75% of patients with TBI who seek medical care are initially classified as having a mild TBI (mTBI).[12] There are several, somewhat varying definitions of mTBI in the published literature. Moreover, debate exists regarding whether the term "concussion" is synonymous with mTBI or is a subset of it. In a systematic review containing research on mTBI over a 25-year period, CDC defined mTBI to include patients with "GCS [Glasgow Coma Scale] scores of 13 to 15 with or without the complication of intracranial injury (ICI) on neuroimaging, and regardless of potentially requiring a hospital admission and/or neurosurgical intervention".[13] For the sake of consistency, this chapter will use the CDC Systematic Review definition of

DOI: 10.1201/9781003227793-148

FIGURE 127.1 The mechanism of mTBI.

mTBI, and the term concussion is utilized when referencing studies that used the term.

127.2.1 mTBI among Children

Children are at particular risk for an mTBI in part due to participating in contact sports[14] and their still-developing gross motor skills (e.g., learning to walk), which can make them more susceptible to a fall. Unique anatomic and physiologic factors, such as larger head-to-body size ratio, weaker neck muscles, and differences in cerebral blood flow and metabolism may also increase their vulnerability to an mTBI and a potentially prolonged recovery.[15,16]

During the acute period, children with mTBI commonly present with one or more non-specific signs or symptoms that fall into broad categories (Table 127.1).[17] These categories or subtypes are not mutually exclusive and may include:[17]

- Somatic symptoms (e.g., headache, balance disruption)
- Cognitive symptoms (e.g., amnesia, disorientation)
- Mood/affective symptoms (e.g., irritability, fatigue)
- Sleep-related symptoms (e.g., trouble falling asleep)

127.2.2 Indications of Deteriorating Neurological Function

Children should be carefully observed by reliable caregivers during the first 24–48 hours following a potential mTBI. Healthcare professionals should advise parents that any severe or worsening signs and symptoms warrant immediate medical attention. These may include:

- Decreasing levels or any loss of consciousness.
- Focal neurologic deficit (e.g., weakness or numbness in any extremity).
- Repeated vomiting or increasing severity of symptoms.
- Seizures, slurred speech, increasing confusion, unusual behavioral change, or irritability.
- Significant cervical pain with tenderness and/or loss of range of motion, paresthesias, or weakness.
- Blood or fluid drainage from the nose or ears.
- Bruising under the eyes or behind the ears.

127.3 EVIDENCE-BASED PRACTICES FOR CARING FOR CHILDREN WITH AN mTBI

CDC published the Pediatric mTBI Guideline in September 2018 to provide evidence-based guidance for healthcare professionals on the care of pediatric patients with mTBI seen in primary care, outpatient specialty, inpatient, and emergency care settings.[18] The CDC Guideline contains 19 sets of clinical recommendations on diagnosis, prognosis, and management and treatment (Tables 127.2–127.4) developed based on best practices outlined in a report by the National Academies of Sciences, Engineering, and Medicine.[19] Details on the literature research, systematic review, and overall methodology used to develop the CDC Guideline are available at www.cdc.gov/TraumaticBrainInjury.

127.3.1 mTBI Diagnosis

CDC Guideline recommendations for diagnosing mTBI among children are provided in Table 127.2. Diagnosing an mTBI may be challenging as some symptoms are common to other conditions, such as headache syndromes, and may be present without any injury at all (e.g., feeling fatigued, being forgetful).[20–22] Further, children with disabilities and younger children may not be able to recognize or verbalize their symptoms. Thus, assessing each patient completely and systematically is essential. Components of an initial evaluation for mTBI generally should consist of a physical exam to identify: 1) indications of ICI and deteriorating neurological function (e.g., hemotympanum, pupillary asymmetry); 2) factors that impact mTBI management (e.g., concurrent injuries or baseline deficits, vestibular and/or oculomotor dysfunction); and 3) characteristics and circumstances of the injury, and symptom type and severity level.[23] Evaluating common conditions (e.g., early signs of viral infection, poor sleep) is useful to help rule out other contributing factors (e.g., cervical tenderness, scalp hematoma).

A primary objective of an initial clinical evaluation for a pediatric patient with an mTBI is to identify the risk for ICI.

TABLE 127.1
Clinical Presentation of mTBI in Children

Somatic	Cognitive	Mood/Affective	Sleep
• Headache • Dizziness • Balance disruption • Nausea/vomiting • Visual disturbances (photophobia, blurry/double vision) • Phonophobia	• Confusion • Anterograde amnesia • Retrograde amnesia • Loss of consciousness • Disorientation • Feeling mentally "foggy" • Vacant stare • Inability to focus • Delayed verbal and motor responses • Slurred/incoherent speech • Excessive drowsiness	• Emotional lability • Irritability • Fatigue • Anxiety • Sadness	• Trouble falling asleep • Sleeping more than usual • Sleeping less than usual

TABLE 127.2
Recommendations for Diagnosing mTBI among Children

Neuroimaging

Clinical evaluation of a child with a possible mTBI includes balancing potentially devastating complications of a more severe injury against the risks associated with head computed tomography (CT).

- Healthcare professionals *should not* routinely obtain head CT for diagnostic purposes among children with mTBI.
- Healthcare professionals *should* use validated clinical decision rules to identify children at low risk for ICI, among whom head CT is not indicated, and identify children who may be at higher risk for significant ICI and, therefore, may need head CT. Existing decision rules combine a variety of factors that might indicate higher risk, including the following:
  - Age <2 years old
  - Vomiting
  - Loss of consciousness
  - Severe injury
  - Severe or worsening headache
  - Amnesia
  - Non-frontal scalp hematoma
  - Glasgow Coma Score <15
  - Clinical suspicion of skull fracture

Neuropsychological Tools

Several validated tools can be applied quickly and inexpensively. Evidence to determine whether baseline testing among children better identifies mTBI as compared with post-injury scores alone is insufficient.

- Healthcare professionals *should* use an age-appropriate, validated symptom rating scale as a component of the diagnostic evaluation for children presenting with acute mTBI.
- Healthcare professionals *may* use validated, age-appropriate computerized cognitive testing in the acute period of injury as a component of an mTBI diagnosis.

Serum Biomarkers

Current evidence for recommending any of the studied biomarkers for an mTBI diagnosis among children is insufficient.

- Healthcare professionals *should not* perform these tests outside of a research setting, at this time, for the diagnosis of children with mTBI.

Patients at elevated risk for ICI should undergo neuroimaging and may need immediate neurosurgical intervention. The CDC Guideline recommends that healthcare professionals use validated clinical decision rules to identify patients at risk for ICI.[18] The goal of decision rules is to help healthcare professionals avoid exposing patients to unnecessary radiation resulting from a head CT, while also ensuring that children with increased risk for ICI receive needed imaging and interventions. The Pediatric Emergency Care Applied Research Network (PECARN) decision rules is a tool validated for use with pediatric patients.[24] Several studies support the effectiveness of the PECARN rules in identifying pediatric patients with head injury at risk for ICI.[25–28]

The CDC Guideline does not recommend that healthcare professionals routinely image a pediatric patient with suspected mTBI for diagnostic purposes.[18] This includes the use of CT, MRI, SPECT, and skull X-ray. Instead, healthcare professionals should use age-appropriate, validated symptom-rating scales to assess for mTBI.[18] These

scales are designed to assess symptom type and severity level during the acute period and should not be used in isolation.[29] Examples of validated scales include the Post-Concussion Symptom Inventory (embedded within the Acute Concussion Evaluation tool),[30,31] Health and Behavior Inventory (HBI) (embedded in the Child-Sport Concussion Assessment Tool),[32,33] Sport Concussion Assessment Tool (SCAT),[33,34] and the Post-Concussion Symptom Scale.[32] Importantly, most scales are not validated for use among children ages ten years and under and some symptoms commonly reported by young children (e.g., changes in appetite, increased dependence on parents) may not be represented.[35,36] When using these scales, healthcare professionals may consider factors such as the testing venue (e.g., noise, distractions) and fatigue (e.g., sleep disturbance, time of day), which may affect a patient's performance.[35,36]

127.3.2 mTBI Prognosis

CDC Guideline recommendations on the prognosis of mTBI among children are provided in Table 127.3. The length of recovery following an mTBI is unique to the characteristics of the injury and the child. Most longitudinal studies show some children will have persistent symptoms one-month post-injury, but most symptoms resolve within three months to one-year post-injury.[37,38] Few children with mTBI (2%)[37] experience symptoms one-year post-injury. The length of recovery for a child may vary based on factors such as previous history of mTBI,[39] sex,[40] more severe initial presentation of an mTBI,[37,41] and the presence of pre-existing comorbid conditions (e.g., mood and learning disorders, migraine headaches).[13,16,42] Other risk factors for delayed recovery described in the CDC Guideline include Hispanic ethnicity, lower socioeconomic status, current neurological or psychiatric disorder, and family and social stressors.[18] Children who are at higher risk for delayed recovery are more likely to need additional interventions and referral to a specialist.

Healthcare professionals should conduct a clinical history and screen for identifiable risk factors for poor prognosis using validated prediction rules.[18] No single assessment tool can predict outcomes. Instead, healthcare professionals should use a combination of tools to assess recovery among children with mTBI. These tools may include both cognitive and balance tests and validated symptom scales. The CDC Guideline states that comprehensive neuropsychological evaluations (e.g., cognitive, social, and behavioral assessments) can assist in determining the etiology of cognitive impairment and can direct treatment for such impairment based on the patient's symptoms.[18] Further, healthcare professionals may assess and monitor for mental health sequelae. Ledoux and colleagues found that children with mTBI are more likely to experience mental health issues (e.g., psychiatric hospitalization and self-harm) compared with children who receive care for an orthopedic injury.[43] Improved access to social supports (e.g., emotional support,

TABLE 127.3
Recommendations for Prognosis of mTBI among Children

General Healthcare Professional Counseling for Prognosis

Evidence shows that education and clear communication from healthcare professionals can optimize outcomes.

- Healthcare professionals *should* counsel patients and families that most children with mTBI do not show significant difficulties that last more than one to three months post-injury.

Prognosis Related to Premorbid Conditions

Increased risk of delayed recovery or prolonged symptoms are associated with certain premorbid conditions among children with mTBI.

- Healthcare professionals *should* assess the premorbid history of children to assist in determining the prognosis for mTBI. This assessment should occur either prior to injury as part of pre-participation athletic examinations or as soon as possible post-injury.

Assessment of Cumulative Risk Factors and Prognosis

Evidence shows that various demographic and injury-related factors predict outcomes for children with mTBI.

- Healthcare professionals *should* screen for various known risk factors for persistent symptoms among children with mTBI.

No single risk factor is strongly predictive of outcome. However, evidence suggests symptoms may last longer for:

- Older children/adolescents
- Children of Hispanic ethnicity
- Children from lower socioeconomic status
- Children with more severe presentations of mTBI (including those associated with intracranial injury)
- Children who report higher levels of acute post-concussion symptoms

Assessment Tools and Prognosis

Healthcare professionals can more effectively counsel patients with mTBI when they have assessed risk factors for outcome and recovery. However, no single assessment tool can predict outcomes.

- Healthcare professionals *should* use a combination of tools to assess recovery among children with mTBI.

Interventions for mTBI with Poor Prognosis

While most mTBI symptoms resolve within one to three months, some children are at risk for persistent symptoms or delayed recovery which may require further interventions.

- Healthcare professionals *should* monitor children with mTBI at high risk for persistent symptoms based on premorbid history, demographics, and/or injury characteristics.

problem-solving advice) and referral to mental healthcare—a key element of recovery that warrants attention from healthcare professionals—may help reduce mental health sequelae after an mTBI.[44,45]

127.3.2 mTBI Management and Treatment

CDC Guideline recommendations on managing and treating mTBI among children are provided in Table 127.4. To promote a good recovery, they recommend that healthcare professionals provide assurance and information to families about the warning signs for more severe injury, symptom-monitoring tips, the return to activity process (such as return to school and sports), and when to follow up for additional care.[18] Further, children and their families should be made aware that mTBI symptoms may not appear right away and may evolve (e.g., "wax and wane") during recovery, but these changes are part of the normal recovery process.[20] Previous studies show that nearly 25% of pediatric patients with mTBI experience psychological distress after concussion.[46] Patient education, reassurance about the likelihood of a good recovery, and understanding among families regarding the importance of post-injury care and what to expect may ease patient and family concerns and improve outcomes.[47]

Following two to three days of rest post-mTBI, the CDC Guideline recommends a gradual return to cognitive and non-strenuous physical activities that do not substantially exacerbate symptoms (Figure 127.2).[18] This includes returning to school. Too much rest and social isolation during a child's initial recovery period may worsen symptoms, lead to emotional sequelae, and prolong recovery.[48] Healthcare professionals may provide discharge instructions customized to a patient's symptoms that include when to return to activity and should advise children to avoid activities that put them at risk for another injury to the head and brain throughout the course of recovery.[18,42,49]

Some students will not need any adjustments to their schedule or academic workload when they return to school. However, others may struggle with symptom exacerbation when they begin to increase cognitive activities at school.[20] To support a child's return to school, healthcare professionals may provide written communication to school staff regarding the child's type and severity of symptoms and recommended accommodations.[18] This may include a return-to-school letter that outlines breaks and recommended adjustments.[18] Example adjustments include environmental modifications (e.g., using headphones to reduce noise distractions), curriculum changes (e.g., reduced workload), activity limits (e.g., short rest breaks), and presentation strategies (e.g., paper materials versus a smartboard for light-sensitive students).[44] These adjustments may be kept in place until the child can engage in regular school activities without significant exacerbation of symptoms (i.e., has returned to their pre-injury symptom baseline).

Complete recovery is when a child participates in their regular non-sports-related daily activities and remains free

TABLE 127.4
Recommendations for Managing and Treating mTBI among Children

General Areas of Treatment for Patients and Families

Health outcomes are generally optimized through patient health literacy and the resulting behavior modification. In addition, evidence shows that rest or reducing cognitive and physical activity is beneficial immediately following an mTBI.

- In providing education and reassurance to the family, the healthcare professional *should* include the following information:
  - Warning signs indicating more serious injury
  - Expected course of symptoms and recovery
  - Instructions on monitoring post-concussive symptoms
  - Prevention of further injury
  - Management of cognitive and physical activity/rest
  - Instructions regarding return to school and return to play/recreation
  - Clear follow-up instructions
- Healthcare professionals *should* counsel patients and families on how to gradually increase scheduled activity after the first several days of rest that does not exacerbate symptoms and closely monitor symptom expression (number, severity).
- To assist children returning to school following an mTBI, medical and school-based teams *should* counsel the student and family on how to gradually increase the duration and intensity of academic activities as tolerated to expand participation without significantly exacerbating symptoms.

Symptom and Problem-Specific Treatment and Management

Painful headache, dizziness, sleep problems, and cognitive dysfunction are common symptoms among children after mTBI and intervention may be necessary.

- Healthcare professionals and caregivers *should* offer non-narcotic analgesia to children with painful headache following acute mTBI, but also provide counseling to the family regarding the risks of analgesic overuse, including rebound headache.
- Healthcare professionals *may* refer children with subjective or objective evidence of persistent vestibulo-ocular motor dysfunction, following an mTBI, to vestibular rehabilitation.
- Healthcare professionals *should* provide guidance on proper sleep hygiene methods to facilitate recovery from pediatric mTBI.
- Healthcare professionals *should* recommend treatment for cognitive dysfunction that reflects its presumed etiology.

FIGURE 127.2 Steps for return to activity plan for children following an mTBI.

of symptoms. The return to sports should only be initiated once the child has complete recovery, and per requirements in most state laws, has obtained approval from a healthcare professional to return to sports.[49] The CDC Guideline and the Consensus Statement on Concussion in Sport describe a gradual, stepwise progression that should be followed to safely return an athlete to sports participation.[49] The return to sports process is best achieved using a team approach that includes coaches, parents, and athletic trainers (when available).[42,49]

Painful headache, dizziness, sleep problems, and cognitive dysfunction are common symptoms among children after an mTBI, and intervention may be necessary.[18] The CDC Guideline recommends that healthcare professionals use non-narcotic analgesia for children with painful headache following mTBI along with counseling regarding the risks of analgesic overuse, including rebound headache.[18] Other treatments for mTBI may include cognitive and vestibular rehabilitation and guidance on sleep hygiene, as needed.[18] Children with mTBI whose symptoms do not resolve as expected with standard care within four to six weeks should be referred to an appropriate specialist for further assessments or interventions.[18]

FUTURE DIRECTIONS

Equally important to the development of an evidence-based guideline is a comprehensive approach to integrating the guideline into clinical practice. CDC created implementation tools and strategies to not only build awareness of the CDC Pediatric mTBI Guideline, but also to encourage its use, and ultimately, achieve integration of the recommendations into standard medical practice. This included customizing educational tools for audiences that play a role in supporting implementation of the recommendations such as the following: healthcare providers; parents; school professionals; sports coaches; and medical organizations. CDC implementation tools are available at www.cdc.gov/HEADSUP. Evaluating the uptake, application, and impact of the CDC Pediatric mTBI Guideline and implementation tools will be critical to understanding their utility in improving the diagnosis and management of mTBI among children. Periodically revisiting and revising the CDC Guideline and implementation tools to incorporate new evidence and a focus on health equity will also be critical.

CLINICAL APPLICATIONS

- Educate and reassure patients and families about the high likelihood of a good recovery.
- Emphasize mental health and social support as key elements of recovery.
- Do not routinely image patients (i.e., CT, MRI, SPECT, and skull X-ray) with suspected mTBI for diagnostic purposes.
- Discuss the risks of head CT in the context of risk factors for ICI with patients and families.

- Assess recovery using a combination of tools (e.g., cognitive and balance tests, symptom-rating scales).
- Use validated clinical decision rules to identify patients at risk for ICI and validated symptom rating scales to diagnose mTBI.
- Advise patients to return to cognitive and nonstrenuous physical activities that do not increase symptoms following two to three days of rest, at most.
- Monitor return to school and academic progress in school to determine if and what adjustments are needed.
- Oversee patients' return to play progression, along with sports coaches, parents, and athletic trainers.
- Refer children with mTBI to an appropriate specialist if their symptoms do not resolve as expected with standard care within four to six weeks.

128 Older Adult Falls: Epidemiology and Effective Injury Prevention Strategies

Robin Lee, PhD, Ramakrishna Kakara, MPH, and Gwen Bergen, PhD

KEY POINTS

- Falls among older adults are a major public health burden in the United States. Each year more than one in four (27.3%) adults aged 65 and older sustain a fall, resulting in 9,000,000 injuries requiring medical treatment or restricted activity.
- In 2015, the estimated medical costs attributable to fatal and nonfatal falls was approximately $50.0 billion.
- Common modifiable risk factors include gait and/or mobility disorders, muscle weakness, balance impairments, impaired cognition, medications (anti-psychotics, tricyclic anti-depressants, selective serotonin reuptake inhibitors, benzodiazepines, etc.), orthostatic hypotension, foot and ankle problems, vision impairment, and environmental or home hazards.
- Many effective interventions can reduce fall risk factors and prevent falls (e.g., strength and balance programs, medication management, cataract surgery).
- Fall prevention activities can be incorporated in multiple clinical settings such as outpatient facilities, inpatient settings, pharmacy services, and rehabilitation centers.
- Lifestyle medicine practitioners can play a unique role in the prevention of older adult falls by identifying patients at high risk, screening them for fall risk, assessing their modifiable fall risk factors, and intervening to reduce identified risk using effective interventions.

128.1 EPIDEMIOLOGY

Each year, in the United States, more than one in four (i.e., 14 million in 2020) older adults (adults ≥ 65 years) report a fall.[1] Around one in ten older adults (i.e., 5 million in 2020) report a fall injury requiring medical treatment or restricted activity for at least one day.[1] As some older adults have multiple falls in a year, in 2020, there were an estimated 36.7 million falls and 8.9 million fall injuries. The older adult population in the United States is projected to increase from 56 million in 2020 to about 98 million in 2060.[2] In 2060, nearly one in four Americans will be at least 65 years of age.[2] If the proportion of older adults who fall each year remains the same, there will be about twice as many older adults experiencing falls or fall injuries in 2060. The number of falls may increase to 70 million and fall injuries to 17 million.

Incidence alone gives an important but incomplete assessment of the problem. Figure 128.1 shows that since the year 2001, the age-adjusted fall death rate has more than doubled. In 2020, more than 36,000 older adults died due to falls, i.e., averaging around 100 deaths every day.[3] Living longer with more chronic conditions may explain some of the observed increase.[4]

These numbers translate into significant costs. In 2015, estimated medical costs attributable to fatal and non-fatal falls were approximately $50 billion.[5] The portion attributed to Medicare for the treatment of non-fatal falls was $28.9 billion.[5] The overall spending for fatal falls was estimated to be $754 million.[5] In a recent study of 2016 healthcare spending, falls ranked among the top 20 most expensive health conditions among older adults, just behind ischemic heart disease.[6]

Fatal and non-fatal fall burden differs by demographics. Figure 128.2 illustrates that although death rates increased consistently for both men and women between 2001 and 2020, men have higher death rates than women. However, a larger number of women die because of a fall compared with men each year.[7] This is due in part to the gender imbalance in the older age groups—older women (31.2 million in 2020) outnumber older men (25.2 million in 2020)[8]—and to the increased susceptibility of women to injury, such as hip fracture, when they fall.[9] Deprey et al. found that hip fractures and head injury were the most common types of fall injury that led to death among older adults.[10]

In addition to fall deaths, non-fatal fall injuries that require medical attention are a growing problem among older adults. In 2020, there were about three million fall-related emergency department (ED) visits and more than 997,000 fall-related hospitalizations.[3] Figure 128.3 illustrates that, like fall-related deaths, fall-related ED visits have been increasing over time for both men and women, with women accounting for a larger proportion of injuries.[3] Fall-related injury among older adults differs from fall-related deaths in that women have a higher injury rate than men.

The rate of falls and fall injuries vary by race and ethnicity. American Indian/Alaska Natives and Non-Hispanic

DOI: 10.1201/9781003227793-149

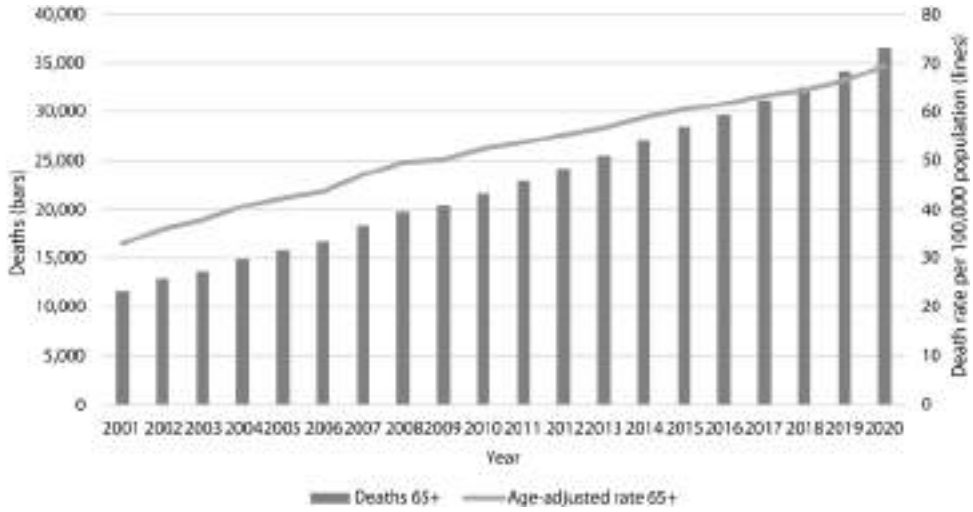

FIGURE 128.1 Number of fall deaths and fall death rates, ages 65 and older, United States, 2001–2020.

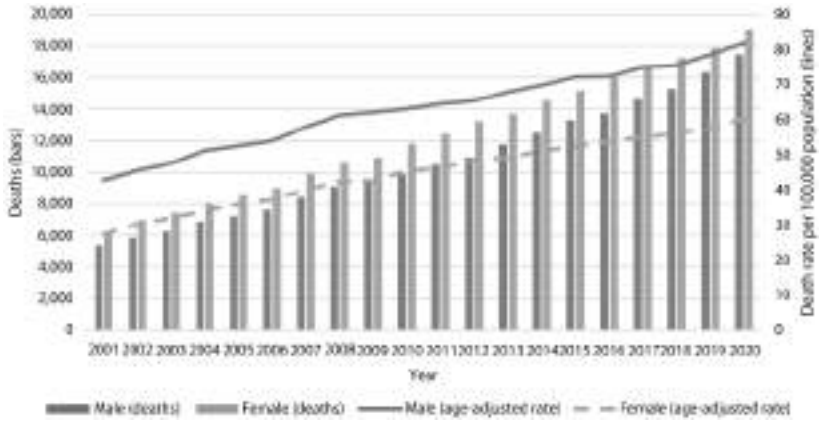

FIGURE 128.2 Number of fall deaths and fall death rates by gender, ages 65 and older, United States, 2001–2020.

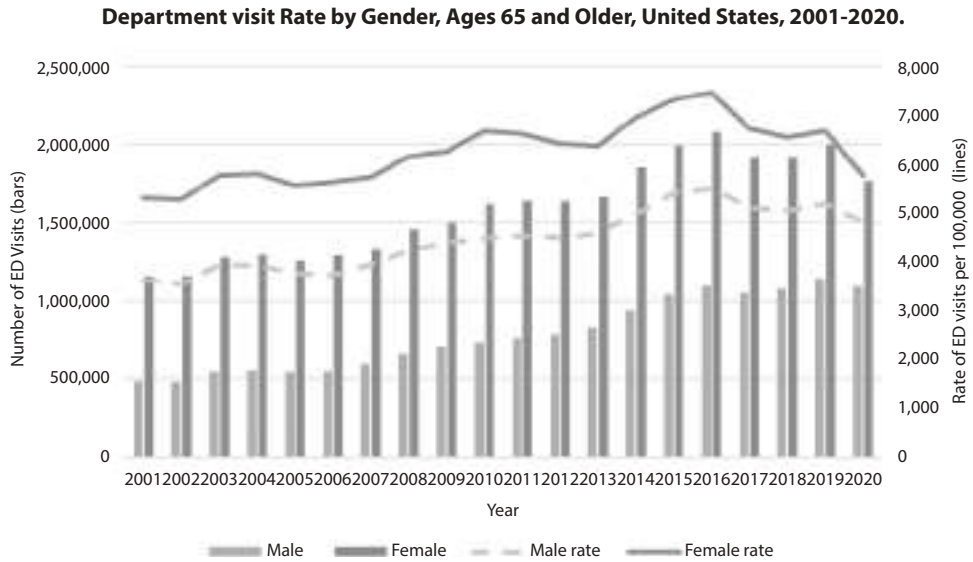

FIGURE 128.3 Number of fall-related ED Visits and fall-related ED visit rate by gender, ages 65 and older, United States, 2001–2020.

White people have disproportionately higher rates of falls and fall injuries compared with Non-Hispanic Blacks and Asian/Pacific Islanders.[11] By geography, older adults in rural counties also report a larger rate of falls when compared with their urban counterparts.[11]

Fear of falling and subsequent loss of independence are common concerns among older adults.[12] Falls are the most common cause of traumatic brain injuries (TBI) and around 90% of hip fractures among older adults occur due to falls.[13] Hip fracture-related hospitalizations are associated with lasting disability outcomes and considerably increase the likelihood of a long-term nursing home admission[14] thus creating either a temporary or permanent loss of independence.

A firm understanding of the risk factors for falls is required to reduce risk and prevent these outcomes.

128.2 RISK FACTORS

Falls and fall deaths increase with age. However, age-related physical and physiologic changes are only partially responsible for older adult falls. Chronic conditions, when in the presence of age-related changes, put an older adult at a higher risk.[15] Chronic conditions affect multiple systems in the body which can impair sensory and locomotor functions.[15] With age, the number of chronic conditions in an older adult increases,[16] and with every additional comorbidity, an older adult is more prone to a fall.[17] The following are some chronic conditions associated with older adult falls: stroke,[18] depression,[19] diabetes mellitus,[20] Parkinson's disease,[21] osteoarthritis in the knee,[22] and osteosarcopenia (defined as a combination of osteopenia/osteoporosis and sarcopenia).[15,23]

Multiple reviews have identified comorbidity and age-related changes as factors that increase fall risk.[13,15,17,24] For example, abnormal gait,[25,26] low muscle mass and strength,[27,28] impaired balance,[29] impaired cognition,[30] poor vision,[17,24] fear of falling,[17] and history of falls[17] are among the most common fall risk factors. Recent systematic reviews and meta-analyses have identified other risk factors such as orthostatic hypotension,[31] foot problems,[32] hearing loss,[33] chronic pain (e.g., in feet, knees, and back),[34] and acute or chronic multisite pain.[35]

Seppala et al. in a series of systematic reviews and meta-analyses identified specific medications including psychotropic drugs (e.g., anti-psychotics, tricyclic anti-depressants, selective serotonin reuptake inhibitors, benzodiazepines)[36] some cardiovascular drugs (e.g., loop diuretics),[37] and other drugs such as anti-epileptics and opioids[38] as increasing fall risk in an older adult. Polypharmacy, or the use of multiple medications is another risk factor.[38] Multiple medications could be associated with falls due to increased likelihood of using fall-risk-increasing drugs, or increased probability of drug-drug interactions.[38] In Seppala et al.'s review, most studies defined polypharmacy as using four or more medications concurrently.[38]

While falls can occur in any location, older adult falls occur more often indoors,[11,39] and in and around a person's home compared with public places.[10,11] Poor lighting, loose/frayed rugs, trailing electrical cords, unstable furniture, stray objects around the home, and snow/ice cover are common environmental hazards.[13,40,41] Common circumstances leading to a fall are tripping over objects (e.g., furniture, clutter),[13,42] using poorly designed stairs (e.g., those with high step height, low tread length, or absent handrails),[42,43] transferring (e.g., from a bed to chair),[44] getting in/out of something (e.g., bathtub),[45] and doing household chores (e.g., reaching for items in storage areas).[45,46]

Although many of the risk factors are independent predictors of falls, it is important to note that they often are interrelated (e.g., gait and cognition)[47] and interact with each other (e.g., mobility and environmental hazards).[46] And, as the number of risk factors increases so does an individual's risk for a fall.[13]

128.3 EVIDENCED-BASED STRATEGIES

Among older adults, there are many effective fall prevention interventions.[48,49] Some interventions focus on one specific risk factor and multifactorial interventions address multiple modifiable risk factors.[49,50] Implementation of these interventions, at the population level, is estimated to have the potential to prevent thousands of falls and avert millions in healthcare costs.[51]

128.3.1 Strength and Balance Programs

Exercise, particularly exercise that targets strength, gait, and balance, has been found to reduce fall risk, falls, injurious falls, and death, although the effect differs by duration, intensity, type, time for follow-up, and other factors.[50,52–55] A pooled analysis of 88 trials found that exercise reduced the rate of falls by 21% in community-dwelling older adults, with greater effects seen from exercise programs that challenged balance and involved more than three hours/week of exercise.[56] A systematic review by the US Preventive Services Task Force (USPSTF) found that exercise interventions reduced the number of older adults experiencing a fall by 11% and the number of fall injuries by 19%.[53] The most common exercise component in the trials reviewed by USPSTF was gait, balance, and functional training.[53] A review of 59 systematic reviews found exercise was consistently effective for community-dwelling older adults but not for those in care facilities.[55]

Multifactorial interventions that include exercise along with other intervention strategies (e.g., vision improvement, removal of home hazards) tend to be the most effective at reducing fall and fall injuries.[57,58] A 2017 systematic review and meta-analysis by Tricco et al. found that exercise plus vision assessment and treatment were among the most effective interventions to reduce injurious falls[58]. The American Geriatric Society/British Geriatric Society (AGS/BGS) Guideline recommends an exercise program that targets strength, gait, and balance with the highest-grade A recommendation (i.e., a strong recommendation

that physicians provide the intervention to eligible patients), and that exercise be included as a component of multifactorial interventions.[52]

There are a variety of effective fall prevention strategies to which providers can refer their patients. Burns et al. produced a compendium of effective randomized controlled trials that reduce the rate of falls or falling.[49] Included are 17 single and 16 multifactorial exercise interventions[49] The compendium also includes information on randomized controlled trials that have been translated into community-based programs.[49] In addition, two of these programs delivered in community settings have also been found to be cost-effective[59]—Stepping On: Moving for Better Balance[60] and tai chi.[61,62]

128.3.2 Home Modification

Hazards in the home are common and can be reduced by conducting home modifications. Home modifications led by an occupational therapist have been shown to reduce both the fall rate and number of older adults who fell.[50,52,55,63,64] In the critical review of two systematic reviews, Pighills et al. found that environmental assessment and modification reduced falls by 21% and the number of older adults who fell by 12%[64] Environmental assessment and modification were effective only with high-risk older adults and when delivered by occupational therapists[64] The AGS/BGS Guideline gives a grade A recommendation (i.e., a strong recommendation that physicians provide the intervention to eligible patients) for home environmentt assessment and intervention for older persons who have fallen or who have risk factors for falling, and for mitigation of identified home hazards, with evaluation and intervention to promote safe behavior.[52]

128.3.3 Medication Management

A recent systematic review and meta-analysis of 14 trials found that medication review (defined as a structured evaluation of a patient's medicines to optimize medicine use and improve health outcomes) was effective in preventing fall-related injuries, specifically fractures, in community-dwelling older adults.[65] Both a Cochrane systematic review and the review for the updated AGS/BGS Guidelines found that withdrawal or tapering of certain medications, including psychoactive medications, was an effective strategy as a single intervention or as a component of a multifactorial intervention.[50,52] The updated AGS/BGS Guideline recommends withdrawal or minimization of psychoactive medications with a B grade (i.e., a recommendation that clinicians provide this intervention to eligible patients).[52] Beyond the AGS/BGS Guideline, medications that cause dizziness, sedation, confusion, blurred vision, or orthostatic hypotension represent a modifiable risk factor for falls. Stopping these medications when possible, switching to safer alternatives, or reducing medications to their lowest effective dose may help prevent falls (www.cdc.gov/steadi).

128.3.4 Vision Improvement

Although vision impairment is an independent risk factor for falls among older adults, it is an underrepresented area of research.[66] A network meta-analysis of seven trials found that vision improvement in conjunction with strength and balance exercise, medication management, and home modification is most effective in reducing falls, followed by vision improvement and exercise.[67] Vision improvement included ophthalmologic examination, prescription glasses, and performing cataract surgery.[67] Harwood et al. found that first eye cataract surgery reduced fall rate and fracture risk among older women.[68] While additional research is needed to determine whether men would also benefit from cataract surgery, the AGS/BGS Guideline currently recommends expedited first eye cataract surgery with a B grade (i.e., clinicians provide this intervention to eligible patients) for older women in whom cataract surgery is indicated.[52]

128.3.5 Podiatric Care

Foot problems and footwear have been identified as risk factors for falls, but there are few studies that document the effectiveness of addressing these issues as a fall prevention strategy.[50,52,69] In a recent systematic review and meta-analysis of nine podiatry interventions, multifaceted podiatry interventions and multifactorial interventions that included a podiatry component were found to be effective over single component podiatry interventions.[69] While single component interventions included routine podiatry care and the use of balance-enhancing insoles or off-the-shelf footwear, multifaceted interventions had an additional component of foot and ankle exercises.[69] Multifactorial interventions assessed for and addressed other fall risk factors in addition to podiatry risk assessment and referral.[69] Multifaceted podiatry interventions reduced the rate of falls by 23% and multifactorial interventions by 27%.[69] With the effects of the two interventions being similar, Wylie et al. suggest that foot and ankle exercises might have a protective effect against falls.[69] Although the evidence is not strong enough for an AGS/BGS Guideline recommendation, footwear can affect balance, gait, and posture. Therefore, wearing shoes with a low heel height and shoes with slip-resistant soles is logical.[70]

128.3.6 Multifactorial Interventions

In a multifactorial intervention, an older adult's fall risk is assessed and interventions (such as exercise, home modification, and medication management) are administered based on the risk factor profile of the individual.[71] The 2018 USPSTF and 2018 Cochrane reviews found that multifactorial interventions reduced the rate of falls by 21% and 23%, respectively.[53,71] The most common types of interventions used in the reviewed trials were exercise and home modification, followed by medication management and psychological intervention (e.g., cognitive behavioral interventions,

referral to mental health services).[71] Although the USPSTF and Cochrane reviews did not find reductions in other fall-related outcomes, a more recent systematic review and meta-analysis found a 23% reduction in the number of older adults experiencing a fall, in addition to the reduction in fall rates in both high-risk and healthy individuals.[72] In the 2017 systematic review and meta-analysis of 283 trials designed to address older adult fall prevention, Tricco et al. found that exercise plus vision assessment and treatment; exercise plus vision assessment and treatment plus environmental assessment and modification (e.g., home modification); and clinic level quality improvement strategies (e.g., case management) plus multifactorial assessment and treatment, plus calcium supplementation, plus vitamin D supplementation were all associated with a reduced risk of injurious falls compared with usual care.[58] In addition, reductions in the number of fractures and the number of hip fractures were associated with a combined use of osteoporosis treatment plus calcium supplementation plus vitamin D supplementation.[58]

128.4 INTEGRATING EFFECTIVE FALL PREVENTION WITH CLINICAL CARE

Given many of the fall risk factors are clinical in nature (e.g., medication use, vision impairment), it is important for healthcare providers to implement a comprehensive fall prevention program that includes screening their older patients for fall risk, assessing their patient's modifiable risk factors, and intervening to reduce the identified risk using effective interventions. Such programs require a team-based approach in which all members of the team (e.g., physicians, nurses, medical assistants, administrative staff) play an integral role. The Center for Disease Control and Prevention's (CDC) STEADI initiative offers guidance to outpatient clinics on how to integrate a fall prevention program within the practice's existing workflow and electronic health records. Included is a step-by-step guide on how to assess practice readiness, obtain support, adapt electronic health records, train staff, and identify reimbursement and quality improvement opportunities. STEADI-based fall prevention programs have successfully been implemented in various health systems. After adopting a STEADI-based program, the Oregon Health and Science University was able to screen two-thirds of their older patients for fall risk, intervene, and treat 85% of older patients with gait impairment, 97% with orthostatic hypotension, 82% with vision impairment, 90% consuming inadequate vitamin D, 75% with foot issues, and 22% on high-risk medications. At United Health Services in New York, patients screened at risk for a fall who were given a STEADI-based fall prevention care plan to reduce their risk had fewer fall-related hospitalizations compared with older adults who were at risk but who did not receive a fall prevention care plan.[73]

Emory Healthcare in Atlanta, Georgia, implemented a telemedicine version of STEADI-based fall prevention. The healthcare system had incorporated STEADI-based fall prevention into their clinical workflow, modified their electronic health record, and trained providers to initiate telemedicine fall prevention in their outpatient clinics when the SARS-CoV-2 (COVID-19) pandemic started.[74] Nurses screened and assessed patients for fall risk factors via phone or video conference, and communicated findings and recommendations to providers to intervene based on identified risk factors. This adapation eliminated the need to travel to the appointment and showed promise for providing fall prevention to older adults who live in more rural areas with limited resources. The main disadvantage was that many older adults lacked either the technology needed or the ability to use it. Between 2011 and 2021, in the United States, the percentage of people aged 65 and older who reported using the Internet increased from 46% to 75%.[75] As more older adults obtain access to the internet and become more comfortable using the technology, this disadvantage will be lessened.

While most older adults seek medical care from outpatient practices, it is also important to consider other clinical settings. The risk of a fall among recently hospitalized older adults is substantially increased in the first 30 days after discharge.[76] Therefore, it is also important to reduce the risk of falls in hospitalized older adults during and after their hospital stay. The CDC STEADI: Best Practices for Developing an Inpatient Program to Prevent Older Adult Falls after Discharge, offers inpatient teams and healthcare systems a framework for promoting safe mobility and managing older patients' post-discharge fall risk.[77]

Pharmacists also play an integral role in fall prevention. As medication experts, pharmacists can identify older adults who may be at risk based on the type of medications filled (e.g., anti-depressants and opioids can increase fall risk) or the number of prescription medications filled.[78–80] They can then screen these older patients for fall risk, review their medications, and make suggestions to the patient and their health providers on ways to optimize their medications to improve health and reduce fall risk.[81]

Many older adults perceive falls as an inevitable part of aging. Therefore, successful fall prevention requires both buy-in from healthcare providers and older adults. The CDC's Still Going Strong awareness campaign (www.cdc.gov/stillgoingstrong) offers information for older adults and caregivers on how common injuries, like falls, can be prevented as we age. The campaign uses positive messaging to encourage older adults to remain healthy and independent by taking simple steps today to prevent future injuries from occurring.

128.5 CONCLUSIONS

In the United States, on average, an older adult falls every second of every day. With the number of older adults and fall death rates rising, the situation will worsen without active participation from all health sectors. Unlike other public health problems, we have considerable information on the burden, risk factors, and effective prevention

strategies to prevent falls and reduce their impact. Using this information, we can help older patients maintain their health and independence by screening them for fall risk, assessing their modifiable fall risk factors, and recommending effective interventions based on their identified risk.

CLINICAL APPLICATIONS

- Utilize annual Medicare Wellness visits or other clinical appointments to screen older patients for fall risk, or any time a patient presents with an acute fall.
- If not at risk, prevent future risk by recommending effective prevention strategies (e.g., refer to a community exercise program to maintain strength and balance, assess vitamin D intake).
- If at risk, assess the patient's modifiable risk factors (e.g., gait, strength, and balance, medications used, orthostatic blood pressure) and fall history.
- Intervene to reduce identified risk factors using effective strategies. This includes discussing patient and provider health goals and developing an individualized patient care plan.
- Query patients during regularly scheduled visits about any recent falls, near falls, or fall injuries.
- Maintain information on falls and fall risks in the electronic health record.
- Follow up with the patient in 30–90 days to discuss ways to improve patient receptiveness to the care plan and address barriers.
- Use available resources such as CDC's STEADI materials to implement a comprehensive fall prevention program into your existing clinical practice. Tools and resources are available for inpatient, outpatient, and pharmacy settings at www.cdc.gov/steadi.

129 Suicide Prevention: CDC's Approach to Prevention

Elizabeth M. Gaylor, MPH, Deborah M. Stone, ScD, MSW, MPH, and Alex E. Crosby, MD, MPH

KEY POINTS

- In 2020, suicide was in the top ten leading causes of death among age groups 5–9 through 55–64 and was the 12th leading cause of death overall.
- Suicide is just the tip of the iceberg. In 2020, there were 483,084 visits for self-harm to US hospital emergency departments with more than 180,000 hospitalizations.
- Suicide rates vary by race and ethnicity, with non-Hispanic American Indian/Alaska Natives (AI/AN) and non-Hispanic Whites having the highest rates.
- Veterans, people who live in rural areas, middle-aged adults, and older adult males are also disproportionately affected by suicide.
- A range of risk and protective factors for suicide exist at the individual, relationship, community, and societal levels.
- The Centers for Disease Control and Prevention (CDC) developed the "Suicide Prevention Resource for Action" that contains strategies and approaches with the best available evidence to prevent and respond to suicide risk, including those for healthcare providers.

129.1 INTRODUCTION

Suicide is a serious public health issue that affects people across the lifespan. Suicidal behavior can be fatal or non-fatal (planning or attempts). Suicide is death caused by injuring oneself with the intent to die. An attempt is when someone harms themselves with any intent to end their life but does not die due to their actions.[1] Suicide and suicide attempts cause serious physical, emotional, and economic impacts. People who attempt suicide and survive may experience serious physical and psychological injuries that can have long-term health effects. They may also experience depression and other mental health concerns.[2,3] More than 90% of people who attempt suicide and survive never go on to die by suicide.[4]

Suicide affects the health and well-being of surviving friends, loved ones, co-workers, and the community. These survivors of suicide loss may experience shock, anger, guilt, depression, or anxiety, and they may even experience thoughts of suicide themselves.[2, 3] Suicide also includes tremendous financial costs. Suicides and suicide attempts cost the nation an estimated $490 billion per year in medical, work loss, quality, and value of life.[5]

CDC's National Center for Injury Prevention and Control (NCIPC) uses the public health approach to systematically address suicide.[6] Data are used to define and describe the nature of the problem, study the factors that increase or decrease risk, and evaluate strategies and approaches with the best available evidence. This is followed by wide implementation and dissemination of what works.[7]

129.2 THE EPIDEMIOLOGY OF SUICIDE

Suicide rates increased 35% between 1999 and 2018 and then declined 5% between 2018 and 2020, yet nearly 46,000 lives were lost to suicide in 2020.[8,9] Suicide dropped below the top ten leading causes of death (LCD) in 2020 for the first time since 2008 due to the emergence of COVID-19 and increases in liver disease deaths.[9] However, suicide is still a major concern. While deaths in young children are not often classified as suicide due to the difficulty in ascertaining intent,[10] for the first time, in 2020, suicide was the tenth LCD among children five to nine years old (20 suicides). Suicide was the second LCD among people aged 10–14 and 25–34 years, third for those 15–24, fourth among people 35–44, seventh for those 45–54, and the ninth LCD among adults aged 55–64. By age and sex, suicide rates are greatest for males aged 85+ years (52/100,000 person-years). Rates are highest among females aged 50–54 (8.6/100,000). The most suicides (47.2%) occur among middle-aged adults 35 to 64 years.[8]

Suicides reflect only part of the problem. Among adults in 2020, 12.2 million seriously thought about suicide, 3.2 million made a plan, and 1.2 million attempted suicide.[11] Among high school youth during the COVID-19 pandemic, 20% thought about suicide, and 9% attempted suicide.[12] Further, 483,084 people visited hospital emergency departments (EDs) for self-harm in 2020, which included more than 182,000 hospitalizations.[8] Other research indicates that over half of persons with serious thoughts of suicide never seek health services.[13] Consequently, health records alone underestimate the true prevalence of suicidal behavior.

DOI: 10.1201/9781003227793-150

It was feared that the social isolation, economic decline, family stressors, new and worsening mental health symptoms, and disruptions to work and school related to public health mitigation measures for COVID-19 would lead to increases in suicides, but this did not occur. Suicide rates declined in 2019 and 2020, the first decline since 2005. However, rates increased among three subgroups, Hispanic males, non-Hispanic multiracial females, and persons aged 25–34 years. These groups may have been particularly hard hit during the pandemic.[14]

Some hypotheses for the overall decline include that people in close quarters at home may have noticed family member distress, leading to intervention, or people availed themselves of increased virtual resources during the pandemic, such as telehealth and digital tools.[15,16] Precedent for declines does exist, as rates declined during some past disasters only to increase after the disaster passed. For example, US suicide rates dropped 26% during the influenza pandemic of 1918 compared with the pre-pandemic period (1910–1917) and increased 10% in the post-pandemic period (1921–1928).[17] Finally, the famed sociologist, Emile Durkheim, theorized that major crises were associated with a decline in suicides because upheavals in society, such as wars, sharpen collective feelings and enhance connectedness by concentrating activities toward a single end, achieving greater societal integration, at least temporarily.[18] These potential explanations signal that suicide rates could increase once again as the pandemic begins to slow and its effects linger as people go back to their usual routines. Remaining vigilant to signs of suicide is critical.

Unlike suicides, ED visits for suspected suicide attempts increased early in the COVID-19 pandemic. Specifically, during February 21, 2021–March 20, 2021, ED visits for suspected suicide attempts were 50.6% higher among girls aged 12–17 years than in the same period in 2019; among boys, ED visits for suspected suicide attempts increased by 3.7%.[19] Among adults, 21% (2.5 million people) who had serious thoughts of suicide and 8.5% who made a plan in the past year, related these thoughts and actions to the COVID-19 pandemic.[11]

Suicide, non-fatal attempts, and/or ideation disproportionately affect certain populations. Suicide rates are higher among males (Figure 129.1), while suicidal thoughts and suicide attempts are greater among females[20] (Figure 129.2). Overall, suicide rates are highest among persons aged ≥85 years, followed by those aged 75–84 and 25–34 years.[14] However, rates of non-fatal self-harm are highest among adolescents and young adults.[8] Certain US populations such as non-Hispanic American Indian/Alaska Native (AI/AN), Asian/Pacific Islander (A/PI), Black, and Hispanic populations have their highest suicide rates among young adults (20–29 years), whereas non-Hispanic White populations have their highest rates among those 45–54 and ≥80 years old[8] (Figure 129.3).

Veterans, people who live in rural areas, and tribal populations are disproportionately affected by suicide.[21] Veterans have an adjusted suicide rate that is 52.3% greater than the non-veteran US adult population, and people who have previously served in the military account for 13.7% of suicides among adults.[22]

Groups at increased risk for non-fatal self-harm include sexual and gender minorities, youth, and females. Almost a quarter (23.4%) of high school students identifying as lesbian, gay, or bisexual reported attempting suicide in the prior 12 months versus 6.4% for heterosexual peers.[3,20]

Use of a firearm is the leading method of suicide in the United States followed by suffocation and drug poisoning. Poisoning is the means most used in non-fatal self-harm cases.[14]

129.3 RISK AND PROTECTIVE FACTORS

129.3.1 Risk Factors

No single cause for suicide exists. It is influenced by many factors acting at multiple levels—individual, relationship,

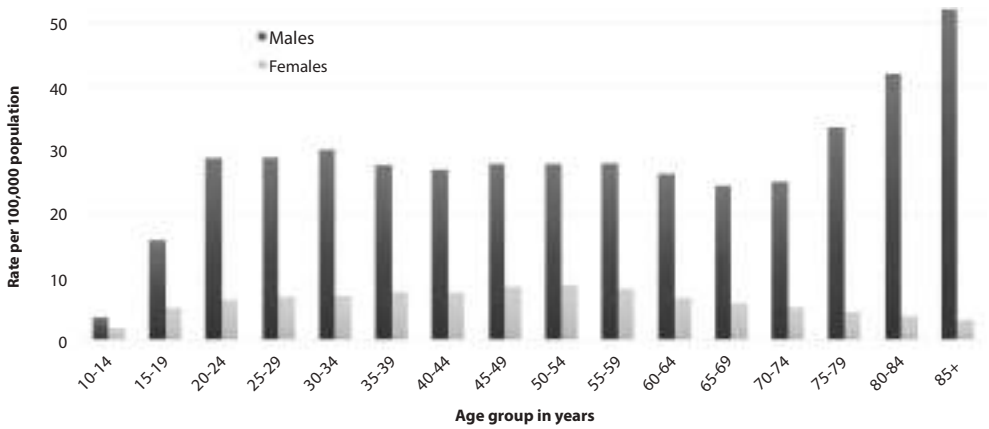

FIGURE 129.1 Suicide rates among all persons by age and sex—United States, 2020; *suicide was defined by ICD-10 codes X60–X84, Y87.0, U03. community, and societal—over time.[21] Individual-level risk factors include previous suicide attempts; mental illness (such as depression); social isolation; criminal, legal, and/or financial problems; job problems or loss; impulsive or aggressive tendencies; serious physical illness; and substance use disorder.[23] Risk factors at the relationship level include adverse childhood experiences, such as child abuse and neglect; bullying; family history of suicide; relationship problems such as a break-up, violence, or other loss; and victimization from sexual violence. Community-level risk factors are barriers or lack of access to health or mental health care; cultural and religious beliefs that suicide is acceptable (e.g., suicide is a noble resolution of a personal problem); and a suicide cluster in the community. Societal-level risk factors include stigma associated with mental illness or help-seeking; easy access to lethal means among people at risk (e.g., firearms, medications); and unsafe media portrayals of suicide. Some risk factors vary by age, gender, and culture, while others are universal.[23]

129.3.2 Risk Factors among Children/Pre-Adolescents

Suicide among children, particularly prior to puberty, is a rare event. This may be due to the two most common risk factors—depression and exposure to drugs and alcohol—which do not typically occur until adolescence.[24] In addition, determining suicidal intent in young children is difficult.[10] However, some young children die by suicide and may understand the implications of the behavior.[25] Some research suggests that a lack of fear of physical pain and death may enable the behavior.[24]

129.3.3 Risk Factors among Adolescents and Young Adults

Adolescence is a time of transition and growth characterized by biological, psychological, and social changes. It often includes risk-taking and pushing boundaries to

achieve greater independence. Successfully navigating adolescence impacts the transition into young adulthood when new job and family responsibilities take precedence.[26] Risk factors for suicide during adolescence and young adulthood may include the onset of mental illness/substance use, prior suicide attempts, hopelessness, family history of suicidal behavior, parental divorce, child maltreatment, school problems, bullying, a peer's suicide, poor problem-solving, easy access to lethal means among young people at risk, conduct disorder among males, troubled relationships with parents and peers, and peer victimization.[26,27]

129.3.4 Risk Factors among Middle-Aged Adults

Middle adulthood challenges may include changes in marriage, job, health status (onset of chronic illness, disability), children leaving home, and caring for an aging parent.[28] Less is known about the unique suicide-related risk factors in this age group because much of the research on suicidal behavior has focused on youth and older adults.[29] However, some risk factors include mental health conditions, alcohol and/or substance use, relationship problems (e.g., lack of connectedness, divorce, adverse childhood experiences, criminal/legal difficulties, and job/financial problems.[30] On a population level, research finds, for example, that suicide rates among working-age adults 25–64 years tend to increase during recessions and fall during times of economic expansion.[31]

129.3.5 Risk Factors among Older Adults

Older adulthood may be characterized as a time of more predictable and stable emotions, but both social roles and networks change, as does physical functioning.[32] Based on post-mortem psychological autopsy studies, research shows that between 71% and 95% of older adult suicides involved a mental health condition, most notably, depression.[33] More recent research, based on medical examiner/coroner and law enforcement reports and death certificates in 41 states/jurisdictions, indicates 33% of older adult suicides in 2019 had *known* mental health conditions, as reported by next of kin.[30] While certain physical conditions have been associated with suicide, including cancer and heart disease, a more important factor may be the presence of multiple conditions and not the specific illnesses themselves.[34] Still, other studies indicate that it is not the physical health condition that matters but rather one's activity limitation.[35] Additionally, a study in one health system found that 67% of older adults who died by suicide had visited a healthcare provider in the month prior to death,[36] offering an opportunity for prevention. Other risk factors in older age include, loss of a spouse, a lack of social connectedness to family, friends, and community, access to lethal means among people at risk, and a greater intent to die.[37]

Finally, looking across age groups, research has shown that suicide and violence (e.g., intimate partner and sexual violence, child maltreatment, and elder abuse and neglect) are interconnected and share many underlying factors.[38] Understanding the overlapping causes of suicide and violence and what can protect people and communities is important. For example, suicide and violence are shaped by structural factors, such as racism and sexism, resulting in inequities in outcomes.[21]

129.3.6 Protective Factors

Protective factors buffer or reduce suicide risk. Like risk factors, they occur across the individual, relationship, community, and societal levels. Protective factors at the individual-level include coping and problem-solving skills to build resilience; reasons for living (family, friends, pets, etc.); cultural and religious beliefs that discourage suicide; and sense of self-worth.[23] At the relationship level, they include connections to individuals, family, community, societal institutions, and supportive relationships with healthcare providers. Research shows that connectedness to family, in particular, is effective at reducing suicide risk among youth.[39] Community-level protective factors are safe and supportive school, work, and community environments, and sources of continued care after psychiatric hospitalization. Protective factors at the societal-level include the availability and accessibility of physical and mental healthcare and reduced access to lethal means (e.g., firearms, pesticides, medications) among people at risk. Unfortunately, less research is conducted on protective factors in comparison with risk factors.

129.3.7 Prevention Strategies

In 2017, CDC released "Preventing Suicide: A Technical Package of Policy, Programs, and Practices", which was updated to the "Suicide Prevention Resource for Action" in 2022 (Prevention Resource)[3,40] This report documents a collection of strategies that represent the best available evidence. Communities and states can use the Prevention Resource to sharpen their focus on strategies and approaches with the greatest potential to prevent suicide. A strategy is defined as the preventive direction or action to achieve the goal of preventing suicide. Approaches are specific ways to advance the strategy, such as through policies, programs, or practices. Communities and states can use the resource for selecting prevention strategies and approaches based on the local suicide problem, existing patterns in the data (e.g., populations disproportionately impacted by suicide), and available resources for responding. Adopting multiple strategies and approaches can lead to a substantial and potentially synergistic effect and improve outcomes. This resource targets suicide risk and protective factors at the individual, relationship, community, and societal levels. The seven strategies and their corresponding approaches shown below start with those that will most likely impact the population as a whole, followed by those focused more narrowly on individuals.

Suicide Prevention Resource for Action

Strategy	Approach
1) Strengthen economic supports	• Improve household financial security • Stabilize housing
2) Create protective environments	• Reduce access to lethal means among persons at risk of suicide • Create healthy organizational policies and culture • Reduce substance use through community-based policies and practices
3) Improve access and delivery of suicide care	• Cover mental health conditions in health insurance policies • Increase provider availability in underserved areas • Provide rapid and remote access to help • Create safer suicide care through systems change
4) Promote healthy connections	• Promote healthy peer norms • Engage community members in shared activities
5) Teach coping and problem-solving skills	• Support social-emotional learning programs • Teach parenting skills to improve family relationships • Support resilience through education programs
6) Identify and support people at risk	• Train gatekeepers • Respond to crises • Plan for safety and follow-up after an attempt • Provide therapeutic approaches
7) Lessen harms and prevent future risk	• Intervene after a suicide (postvention) • Report and message about suicide safely

Brief information about each strategy and the rationale for its inclusion in CDC's Prevention Resource is provided below. Consult www.cdc.gov/suicide/prevention/index.html for additional details.

- Strengthen economic supports:
  Research indicates that suicides increase during economic downturns (and decrease during expansions).[31] The financial strain associated with job loss, long periods of unemployment, eviction/foreclosure, and other consequences of unanticipated financial stress can exacerbate suicide rates, both directly and indirectly, through worsening physical and mental health concerns. Expanding unemployment benefits, providing temporary financial assistance, and implementing housing policies that allow people to stay in their homes can help buffer the negative effects of financial strain, and thereby promote suicide prevention.
- Create protective environments:

  Creating environments that address risk and protective factors where people live, work, and play can help prevent suicide.[41] For example, the burden of suicide is highest among middle-aged adults,[8] certain occupational groups,[42] and people in detention facilities,[43] such as jail or prison. Therefore, implementing programs, practices, and policies in these settings can buffer against suicide risk. This may involve reducing access to lethal means (e.g., safe storage practices);[44] creating healthy organizational policies and culture in the workplace;[45] and developing community-based policies and practices to reduce substance misuse.[46, 47]
- Improve access and delivery of suicide care:

  Research suggests that services are improved when health and behavioral healthcare systems are integrated and set up to effectively and efficiently deliver care.[48] Identifying ways to improve access to care that is timely, affordable, and high quality is critical. Such approaches include implementing mental health parity laws;[49] implementing policies and practices to increase provider availability, especially in underserved areas;[50] and creating safer suicide care through systems change.[51,52]
- Promote healthy connections:

  Connectedness is the degree to which an individual or group is socially close, interrelated, or shares resources with each other. It typically refers to connectedness to family, friends, or others. However, it may also convey connectedness to school, church, or other organizations. Connectedness may protect against suicide by decreasing isolation, encouraging adaptive coping behaviors, and increasing access to helping services, belongingness, self-worth, and resilience.[53] Two evidence-based approaches for enhancing connectedness include programs that 1) normalize help-seeking and 2) community engagement activities that may buffer against suicide risk by

decreasing isolation and increasing knowledge of mental and physical health services.[26]

- Teach coping and problem-solving skills:

  Managing problems, conflicts, stress, and emotions are critical life skills for dealing with daily challenges such as occupational, school, relationship, and health concerns that may increase suicide risk. School-based social-emotional learning programs can help youth resolve relationship conflicts, communicate more effectively about their needs, and avoid negative influences (e.g., drugs and alcohol). Parenting and family relationship programs also offer skill-building and problem-solving. These programs support caregivers, promote positive parent-child interactions, and improve children's behavioral and emotional skills and abilities.[54] They are effective in reducing suicide-related thoughts and behaviors.[55]

- Identify and support people at risk:

  Approaches that ensure people at risk are identified and connected to services are critical. For example, training community members and others who interact with populations at increased risk so they know the warning signs of suicide and how to respond, called gatekeeper training, can be effective. Additionally, crisis intervention services (e.g., hotlines) and various treatment modalities (e.g., collaborative care, cognitive behavior therapy, brief interventions in EDs) have been shown to prevent suicide attempts and re-attempts.[40]

- Lessen harms and prevent future risk:

  Harm can be direct, such as the death of a loved one or close friend to suicide, or indirect, such as exposure to unsafe media reporting about suicide. Whether direct or indirect, such harms are known to increase the risk of suicide. Programs that support the bereaved (i.e., survivors of suicide loss)—for example, using face-to-face outreach and telephone support can reduce psychological distress and risk of suicide ideation and attempts.[56] Responsible media reporting (e.g., not using sensational headlines or pictures of the suicide decedent, not mentioning the method of suicide, not reducing suicide to one cause, and providing protective factor information and helping resources) can decrease suicides and suicide contagion.[57]

129.4 ROLE OF LIFESTYLE MEDICINE PRACTITIONERS

Lifestyle medicine practitioners look at systemic and population-based interventions to improve the health of people.[58] This basic tenet of lifestyle medicine lends itself to a public health approach.[7,59] and for practitioners to serve several roles in preventing suicide. These roles include clinical responsibilities and support for patients and communities, research, and education.[60]

As a clinician, the lifestyle medicine practitioner may have clinical responsibilities from both the patient and population-based perspectives. Those who work in primary care settings, schools, community centers, homeless shelters, and other related locations have the access and opportunity to play a pivotal role in suicide prevention. Awareness of specialty organization policy statements and guidelines on suicide prevention can help direct practitioners' decision-making and assessment of suicidal ideation, depression, and other risk factors.[61] Evidence-based assessment tools and best-practice models are available.

Some lifestyle medicine practitioners who work in community-based organizations, local or state health departments, or federal health agencies can impact suicide prevention through the public health approach.[7,59] A focus on community health needs related to suicide is also warranted, as is support for comprehensive prevention policies.[62,63] Championing the implementation of evidence-based research can assist effective decision-making about suicide prevention policies and programs.

Practitioners can also serve as compelling advocates for suicide prevention in their communities because of their unique training and practical experience. A clinician's obligation to advocacy is grounded in their professional experience, expertise, and duty to patients.[64] Several physician organizations recognize the role of clinicians in public policy, and some believe activism is a medical responsibility that requires skilled training for effectiveness.[65]

Prevention practitioners have a broad array of expertise in various areas; however, many have little training, experience, or proficiency in suicide prevention, specifically. In these cases, they could seek opportunities to gain knowledge, including information about suicide risk and protective factors, and the latest evidence for screening, treatment, and prevention modalities. Formal learning options include professional development and continuing education conferences. Practitioners may also discover community resources for patients and population-based activities. In addition, sensitivity to the unique characteristics of the population with whom they interact is encouraged. Understanding these cultural differences is critical for communicating with people from diverse geographic, ethnic, racial, cultural, economic, sexual orientation, spiritual, or social backgrounds.[66]

129.5 CONCLUSION

Suicide is an urgent public health crisis in the United States. The COVID-19 pandemic has brought renewed attention to suicide prevention, mental health promotion, and health equity as individuals, families, and communities have struggled under the weight of the pandemic and its effects

on social, physical, and emotional well-being. As the United States and the world continue to bear the consequences of the COVID-19 pandemic, vigilance is needed, both in implementing prevention and identifying and supporting populations disproportionately impacted by COVID-19 and suicide.

A comprehensive public health approach is needed to address the range of risk and protective factors associated with suicide. The comprehensive approach includes both upstream strategies, such as those from CDC's Prevention Resource that aim to prevent suicide risk in the first place, as well as downstream prevention efforts (lifestyle medicine practitioner perspective), which aim to respond to people at immediate risk and prevent re-attempts. These efforts include knowing the risk and protective factors and warning signs for suicide, providing direct clinical care, counseling on access to lethal means for people at risk, discussing cultural and/or behavioral determinants that contribute to suicide, assuring smooth transitions between levels of care, ongoing professional development, and engaging in research, education, and policy.

Lifestyle medicine practitioners care for patients and address conditions in the environment that cause disease and injury. They are trained to approach health concerns and understand the broad scope of an entire community and the context of the patient. This combined perspective is essential in addressing population-based, subgroup, and individual issues that play such a prominent role in suicide and its prevention.

CLINICAL APPLICATIONS

- Physicians can help identify early signs of suicidal thoughts and behaviors.
- Practitioners can seek evidence-based assessment tools and employ best-practice models, such as those from the National Action Alliance for Suicide Prevention (https://theactionalliance.org/healthcare) the "Assessment of suicide risk" from the American Psychiatric Association (APA) Practice Guidelines for the Psychiatric Evaluation of Adults (https://psychiatryonline.org/doi/epdf/10.1176/appi.books.9780890426760), and other APA resources.
- Practitioners can address research gaps by contributing rigorous, evidence-based models for screening interventions. The National Institute of Mental Health (NIMH) conducts ongoing research to address suicidal behavior. See www.nimh.nih.gov/health/topics/suicide-prevention/index.shtml.
- The American Psychological Association (APA) has psychological research, effective treatments, and educational materials for various audiences (decision-makers, researchers, and the public). See www.apa.org/news/apa/2018/suicide-prevention-month.
- Lifestyle medicine practitioners can support suicide prevention policies and programs in their communities and through formal advocacy training through seminars or conference sessions at professional meetings or fellowships.
- Many medical groups and associations (e.g., American Medical Association, APA, American College of Preventive Medicine) have additional resources for clinical practice.

130 Healthcare Reform and Lifestyle Medicine in the Post-COVID-19 Era: Moving Forward

Gregory W. Heath, DHSc, MPH, FACSM, FAHA and Steven Fox, MD

KEY POINTS

- The COVID-19 pandemic has demonstrated an exacerbation of previously existing health disparities linked to lifestyle diseases and conditions due much in part to the widening gap between private healthcare organizations and public health agencies with misconstrued functions for each in addressing population health.
- The COVID-19 pandemic in the United States and globally can therefore be considered a *syndemic*, where there is an adverse interaction between diseases and social determinants of health (e.g., poverty, education, housing, employment, racism, access to healthcare), in this case, the high prevalence of chronic diseases and their antecedent risk factors among the US population and a highly infectious agent, SARS-CoV-2 and its variants.
- The Affordable Care Act (ACA), having been in place for over 12 years, continues to provide considerable improvement in the number of people with health insurance coverage, however, with the cancelation of the individual mandate, many segments of the population representing diverse race/ethnic groups and people of lower socioeconomic status have seen a downturn in the proportion of those insured.
- The focus on primary care for the delivery of preventive care and lifestyle medicine services is critical for the success of any type of healthcare reform going forward.
- The ACA has demonstrated that significant numbers of US residents have benefitted from increased access to care and coverage of clinical preventive services without cost-sharing.
- The ACA legislation contains elements that could further advance lifestyle medicine and primary prevention, but this opportunity is dependent on the approval of the American electorate to expand the government's role in the regulation of the healthcare delivery system.
- Traditional fee-for-service reimbursement creates an incentive for providers to supply a high volume of expensive services if the payment exceeds the cost of the service delivery.
- Modification of patient health behaviors is central to the practice of lifestyle medicine and primary prevention; however, this requires a combination of the healthcare teams' lifestyle medicine skills, patient responsibility, and community-based supportive policies and environments (cultural, physical, social, etc.) to ensure that lifestyle changes are both initiated and sustained. Currently, this approach is quite variable and only emphasized by employer-sponsored health plans.
- The American healthcare system faces three interrelated challenges: cost, quality, and access to services.
- Support for lifestyle medicine was evident in the CMS recognition of obesity as a disease in 2014, thereby creating the potential for Medicare coverage of obesity-related treatments.
- Policies and evidence-based environmental interventions outlined in this chapter identify primary prevention strategies that hold significant promise for the alleviation of premature suffering from disease, the maintenance of functional health, and the prevention of early death.

130.1 INTRODUCTION

The COVID-19 pandemic at the time of this writing has continued for over 30 months across the globe.[1] The impact in the United States of America (US) has been devastating with an excess of over 80 million cases, 4.5 million hospital admissions, and 977,000 deaths[1] (Figure 130.1 and Figure 130.2).

To say the least, the pandemic has overwhelmed and stretched the healthcare and public health systems of the US well beyond their capacity to keep pace with the COVID-19 outbreak.[2] Healthcare providers have become exhausted, frustrated, and mentally/emotionally challenged throughout the pandemic.[3] During the early weeks of the pandemic in the US, a pattern emerged among cases and deaths that revealed that those most vulnerable to a severe and/or critical course of COVID-19, often requiring hospitalization,

DOI: 10.1201/9781003227793-152

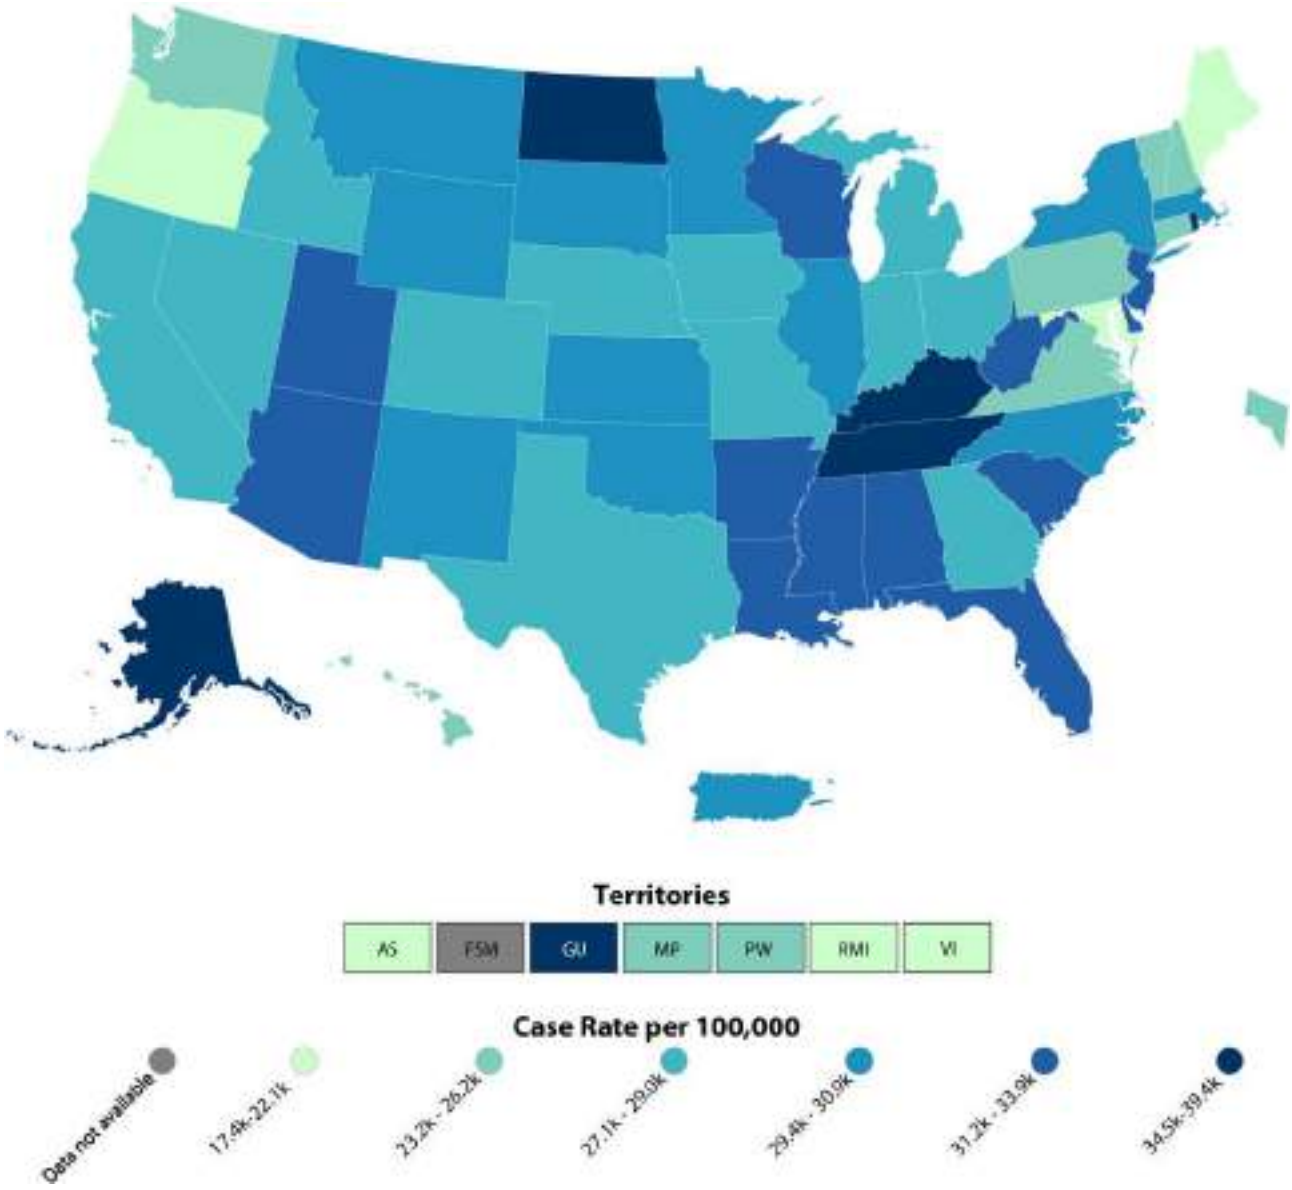

FIGURE 130.1 COVID-19 cases by state (2020–2022) per 100,000 (source: https://covid.cdc.gov/covid-data-tracker/#cases_newcaserateper100k).

suffered from pre-existing conditions and comorbidities that predisposed them to such outcomes.[4,5] These "underlying conditions" most often included lifestyle diseases such as hypertension, type 2 diabetes, chronic respiratory diseases, and chronic kidney disease.[6] Other independent lifestyle risk factors for COVID-19 cases, hospitalizations, and deaths also emerged, including overweight, obesity, and a history of physical inactivity.[7–9] Another pattern emerged during the pandemic that identified a disparate burden for COVID-19 outcomes among African American/Black, Hispanic/Latino, and persons representing lower socioeconomic status.[10–12] These marked disparities reflected pre-existing disparities driven by the social determinants of poverty, lack of access to regular healthcare including preventive/lifestyle medicine, and historical systemic racism.[13] In general, the US population's health status was inadequate to fend off the onslaught of SARS-CoV-2 and its variants, especially among disparate populations, establishing the pandemic as a *syndemic*, i.e., the interaction of the social determinants of health with COVID-19.[14] The high prevalence of non-communicable diseases (NCD) and the lifestyles of poor diet, cigarette smoking, physical inactivity, and obesity among the US population as a whole provided for the "perfect storm" for such a syndemic as can be seen through these series of maps[15] (Figures 130.3–130.9).

Since the Patient Protection and Affordable Care Act, often referred to as the Affordable Care Act (ACA), was signed into law on March 23, 2010, healthcare reform has been on the minds of patients, politicians, and providers alike. The impact of the ACA was much like the impact

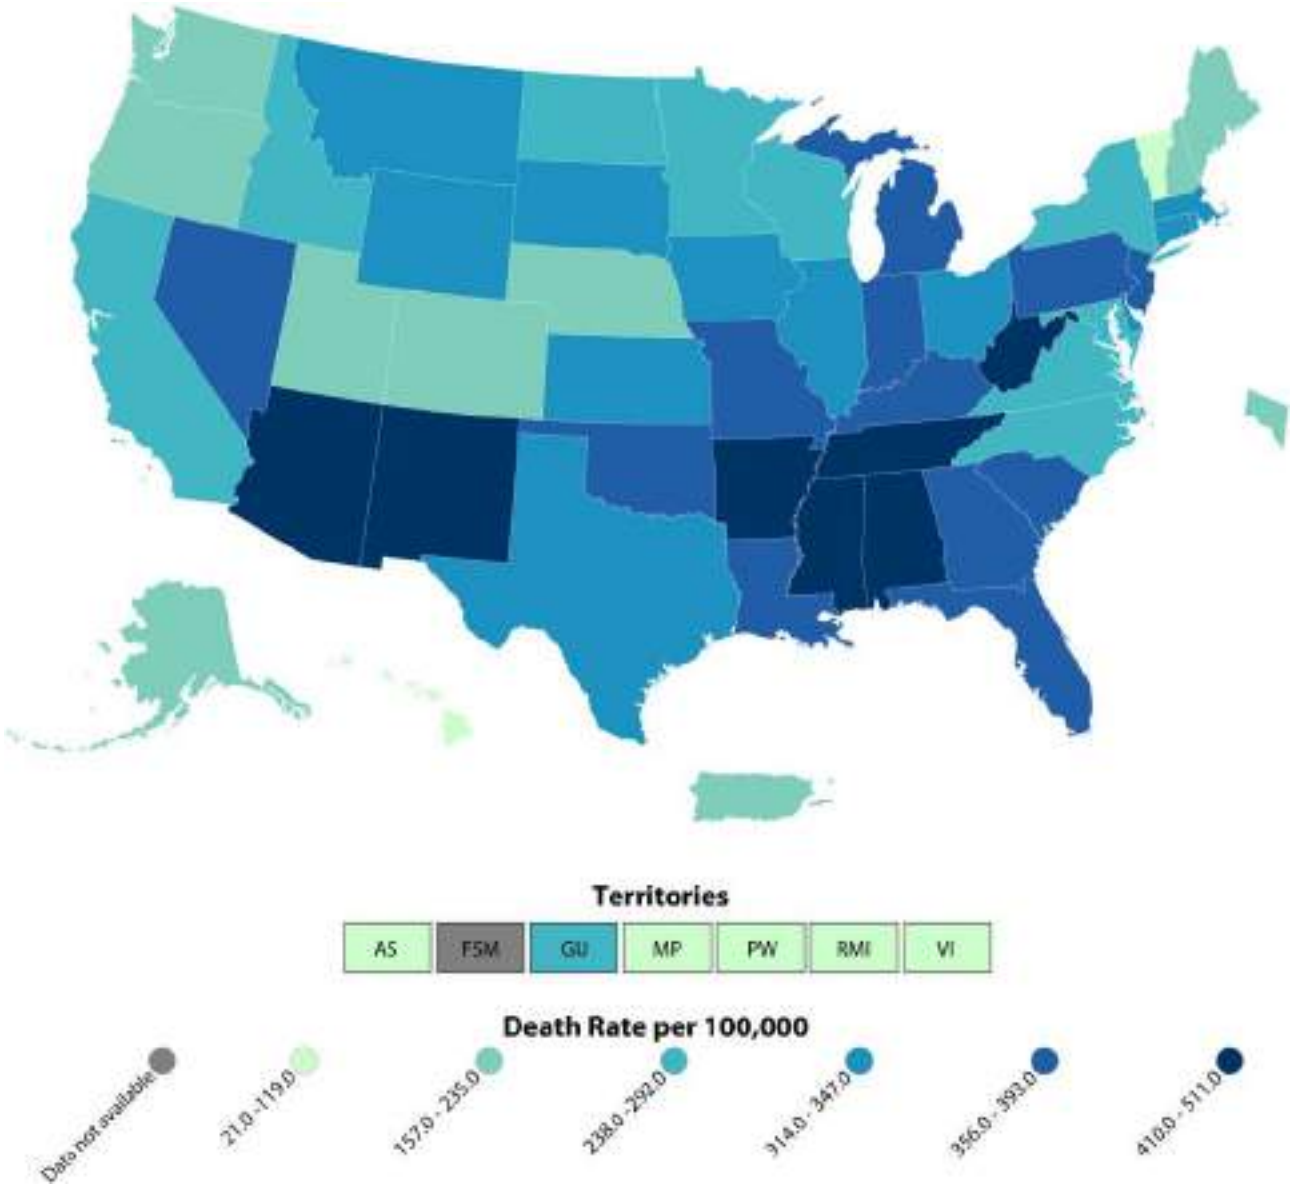

FIGURE 130.2 COVID-19 deaths, by state, USA (2020–2022) per 100,000 (source: https://covid.cdc.gov/covid-data-tracker/#cases_newdeathrateper100k).

of the creation of Medicare and Health Maintenance Organizations, and the law was an attempt to transform healthcare delivery in the US. Over the past 12 years, numerous regulations, and policies, many of which are still in the process of being implemented, have affected the healthcare delivery system. In many cases, planned changes are being modified in response to court decisions and debates in Congress, state legislatures, and communities. The discussion is certain to continue, as government-sponsored programs are estimated to account for 47% of all healthcare spending by 2025, with total expenditures estimated to represent 20.1% of the total US economy.[16]

With the start of ACA in 2014, 20.4 million uninsured individuals obtained coverage, with 43.9% enrolled in Medicaid, 31.8% enrolled in private non-group insurance (mostly through ACA exchanges), and the remaining 24.3% enrolled through employer-sponsored insurance. During the first half of 2020, according to newly released estimates from the National Health Interview Survey (NHIS), 30 million US residents lacked health insurance.[17]

This number indicates a steep decline in the number of uninsured Americans since 2010, before the implementation of the large coverage expansions under the ACA. The ACA produced particularly large coverage gains for Blacks, Latinos, Asian Americans, and Native Americans, as well as for lower-income families. However, the uninsured rate has increased since 2016, even prior to the COVID-19 pandemic. From 2017–2019, the uninsured rate rose by 1.7%, most likely due to new policy changes to coverage options available under the ACA and Medicaid. Estimates from the NHIS show no significant change in uninsured rates during the early months of the COVID-19 pandemic. However, the

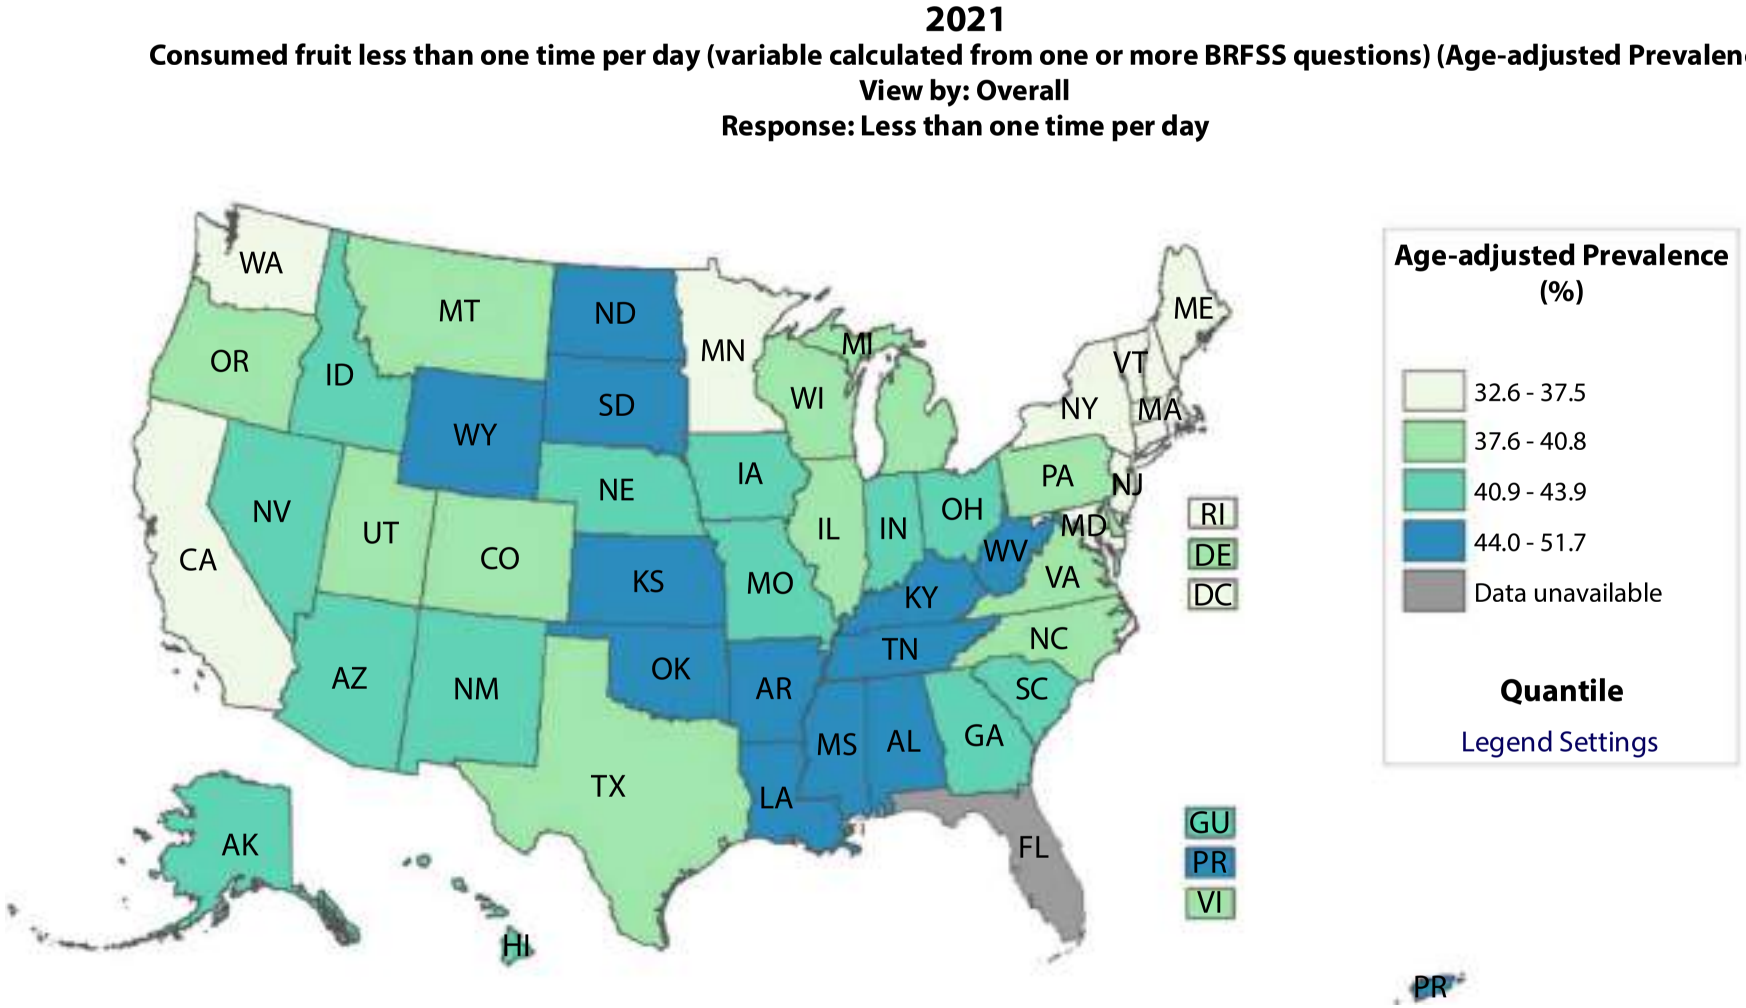

FIGURE 130.9 State-specific consumption of fruits among adults 18 years and older, United States, 2021 (source: https://www.cdc.gov/brfss/brfssprevalence/index.html).

pandemic itself created challenges in conducting the survey that may affect estimates of the uninsured, due to reduced response rates and a temporary shift from an in-person survey to a telephone survey. Compared with other Americans, the uninsured disproportionately represent Black or Latino populations; younger adults; those with low incomes; or live in states that have not expanded Medicaid.[17]

A primary ACA objective is the development of alternative payment models. Currently, there are more than 20 ongoing value-based payment programs that often overlap with one another.[18,19] This has created a challenging environment, especially for healthcare organizations to make decisions about participation, care redesign, and investments.[18] This environment also limits the rigor of model testing. Isolating the effect of a model might be nearly impossible, leading to a situation in which singular models are not deemed successful despite contributing to system-level improvements in quality and cost.[20] As has been stated by Navathe et al.,[20] "Some of these programs have evolved from early CMS projects and ACA provisions, like the Accountable Care Organization (ACO) and bundled payment programs, but the sheer breadth of such programs can be perplexing for providers". Hence, even though there have been several financial incentives, or penalties, these have apparently had little documented effect on healthcare delivery itself but have created healthcare provider exasperation and disappointment.[21]

The most impactful programs for lifestyle medicine probably relate to Primary Care Transformation, episodic care models, and initiatives focused on the Medicare and Medicaid populations. The ACA has substantially increased access to care and coverage of preventive services without cost-sharing for millions of Americans.[22] Many preventive services including vaccinations, well-child visits, screening for HIV and sexually transmitted infections, HIV pre-exposure prophylaxis, contraception, and cancer screening are required to be covered by most group and individual health plans and for many Medicaid beneficiaries without cost-sharing. Such expanded access to recommended preventive services has increased the number of people covered through both private health insurance and Medicaid expansion under the ACA.[22]

The analyses of recent CMS data indicate that more than 150 million people with private insurance (58 million women and 37 million children) currently are able to receive preventive care services without cost-sharing under the ACA.[22] Additionally, approximately 20 million Medicaid adult expansion enrollees and 61 million Medicare beneficiaries can potentially benefit from the ACA's preventive care services provisions.[22] As a result of these non-cost-sharing benefits, evidence from impact studies of the ACA has revealed an increase in colon cancer screening, vaccinations, use of contraception, and chronic disease screening inclusive of opportunities to identify the lifestyle contribution to these diseases/conditions.[22]

The potential success of the integration of lifestyle medicine into the fabric of healthcare in the US hinges on the following important steps: 1) lifestyle healthcare providers need to identify opportunities and incentives to attract previously uninsured Medicaid enrollees as well as privately insured patients to better prevent and manage chronic diseases/conditions; 2) lifestyle healthcare providers need to be better equipped to deliver lifestyle medicine services to their patients; 3) lifestyle healthcare providers need to partner and successfully refer their patients to existing community-based programs and services designed to reinforce behavioral and lifestyle changes among their patients; and 4) lifestyle health providers and their associates should be equipped to assist patients with navigation of the healthcare delivery system with a goal to improve access to the correct care when needed.

Several CMS programs have been implemented to expand the use of preventive medicine to promote health and wellness. The most visible of those programs has increased Medicare payments for some preventive services up to 100% of the actual charge or fee schedule rate (e.g., obesity prevention services).[23] In 2017, the Comprehensive Primary Care Program was designated as the Comprehensive Primary Care Plus (CPC+) program for regionally based multi-payer reform.[24] The CPC + program created a payment structure that includes a care management fee as well as a performance-based incentive beyond fee-for-service payments. This structure continues the fee-for-service payment model while providing funding to expand care management resources that are expected to improve the quality of care provided through the performance-based incentive.

The focus on primary care for the delivery of preventive services is critical to the success of healthcare reform.[25,26] The ACA takes important, but modest, steps to address critical primary care needs: payment reform, workforce training, transformation of practice, and expansion of the primary care safety net. ACA provisions included the establishment of a National Health Care Workforce Commission, increased support for workforce training (Title VII and the Prevention and Public Health Fund), cultural competency training, enhanced payments, expansion of community health centers, and piloting of new care models. ACA provisions have also provided Medicare bonus payments to primary care physicians and eliminated differences in payments between Medicaid and Medicare for primary care services. It further provides Medicare bonuses to primary care physicians who work in shortage areas, thereby helping to minimize geographical disparities in resources available to patient populations with social disadvantage. These reforms could also conceivably reduce de facto segregation by insurance type within healthcare systems that receive federal funding, but regulations prohibiting intra-institutional segregation of care may be needed. Modest increases in payments alone will not be sufficient to address the current geographical distribution of primary care physicians, much less avert a primary care shortage.[27]

The ACA legislation took several steps to promote the quality of healthcare service delivery. A key component of that was the establishment of the Patient-Centered

Outcomes Research Institute (PCORI). This non-governmental entity has been charged with setting research priorities and promoting research that provides a clinical evidence base to help providers and patients make informed healthcare decisions; to assist healthcare delivery systems in providing evidence-based, efficient, and safe healthcare; to ensure that evidence is dependent on and applied to racially and ethnically diverse and geographically distributed communities; and to develop broad prevention and screening strategies that promote health across such diverse populations. Much reporting about the PCORI research agenda has focused on the term "comparative effectiveness research" (CER). Although the foundational basis for effectiveness research has existed for over half a century, the legislation envisioned a far more expansive and inclusive role for CER. In addition to comparing therapeutic treatments, CER has been conceptualized as the rigorous application of science to evaluate and compare health outcomes, clinical effectiveness, and risks and benefits of a much broader set of interventions—from new healthcare delivery methods to medical procedures and devices to drugs and biologicals, and to integrative health practice strategies, as well as prevention strategies. Moreover, the legislation directed that CER must include broad participation across the nation to create a representative evidence base that could help identify and address health disparities and inform decisions by patients in special population groups. Comparative effectiveness research is expected to extend beyond academic health centers (AHCs) and teaching hospitals to include research in partnership with community-based care settings and practice-based networks as well as with community-engaged research, which provides for engagement with communities as partners in research.[28] Such a focus on CER and similar methods that embody rigorous science to determine what interventions/treatments work best for whom, in what settings, and under what circumstances supports lifestyle medicine by translating preventive care and disease management evidence into changes in practice and behavior at the level of individuals, populations, and healthcare delivery systems.[29]

Understanding the role of employers is central to understanding the US healthcare system. At present, almost two-thirds of American citizens under the age of 65 are covered by an employer-sponsored health plan. Some thought that the employer penalty could result in the sudden disappearance of employer-sponsored health insurance,[30] but there has not been an erosion of employer-sponsored coverage since ACA was implemented.[31] The historic linkage of health insurance to employment for over 80 years has presented a problem of access to affordable healthcare services for unemployed individuals, but the private sector system does promote innovation and value through its influences on competing providers.[32,33] Furthermore, the availability and generosity of healthcare coverage for Americans ultimately depends on the economic fortunes of private companies. Government-sponsored health insurance relies on individual and corporate taxes, which are directly linked to employment and economic growth. The less tax revenue collected by the federal and state governments, the greater will be the necessity to ration care among the population that relies upon a government-sponsored program.[30]

Value-based purchasing and pay-for-performance represent employer-initiated innovations that Medicare used on an experimental basis.[34] The Medicare Physician Group Practice (PGP) Demonstration introduced "shared savings" as a mechanism to reduce costs and improve the quality of care provided to its beneficiaries. Participating physician group practices received regular fee-for-service reimbursements but were also eligible to receive an additional performance payment if a CMS-specified cost target was achieved (i.e., an 80% share of the difference between the actual cost of services provided and a risk-adjusted spending trend for treatment of the given condition in each market). The Medicare PGP Demonstration served as the model for a provision of the ACA legislation that established the ACO as a mechanism for providers to become eligible for participation in the Medicare Shared Savings Program.[35,36]

Although the ACA legislation intended to reduce the cost and improve the quality of healthcare for all Americans, CMS payment policies have historically resulted in cost-shifting to private payers. An analysis of the PGP Demonstration suggested that most provider groups would experience a financial loss because of participation in a similar shared savings program, which poses a risk to the entire value-based purchasing movement initiated by employers.[37] The creation of ACOs by dominant providers through mergers and acquisitions could drive up costs for private payers. Market consolidation can also have an adverse effect on the ability of private payers to obtain the service quality data that are essential to value-based purchasing.[35] Although the inclusion of a hospital in an ACO is needed for optimal coordination of healthcare services, a potentially serious conflict of financial interests exists between physician groups and hospitals about the necessity for hospitalization of many patients. Some experts believe that hospital-centric provider organizations adversely affect the potential for physician groups to benefit from a shared savings program[36] and that they will not serve the best interests of the country.[38]

Modification of patient behaviors is central to the practice of lifestyle medicine and primary prevention, but the patient's responsibility to ensure that a high degree of value is derived from clinical medical services has only been emphasized by employer-sponsored health plans. Patient consumerism is promoted by high-deductible health plans that are combined with health savings accounts to incentivize healthy behaviors, and through employer-sponsored worksite health management programs. Because impaired glucose metabolism is the primary underlying cause of numerous high-cost conditions, regular physical activity and healthful dietary behaviors can profoundly influence employers' self-insured health plan costs.[39,40] Because poor employee health decreases corporate profitability through high health plan costs, work absenteeism, and suboptimal

productivity, employers have a strong interest in promoting personal responsibility for healthy lifestyle choices and informed utilization of healthcare services. Unless commercial insurance and government-sponsored health plans incentivize healthy behaviors and healthcare consumerism, no type of provider-payment model alone is likely to produce long-term control of cost escalation. Rather, a conscientious effort to identify key policies and environmental supports for healthy lifestyles that are community-based and accessible to all Americans needs to coincide with provider-based training and incentives to integrate the practice of lifestyle medicine into healthcare with an overall result in improved population health.[41]

Years of fee-for-service reimbursement have produced a provider-centered and process-oriented system for the delivery of clinical services that is highly resistant to change. Both CMS and commercial insurance pay-for-performance initiatives have defined quality of care based on process-of-care measurements (e.g., provider adherence to clinical practice guidelines) rather than patient outcomes.[34,42] Value should be defined as the outcomes achieved per dollar spent. Measuring the total costs over a patient's entire care cycle and relating them to the outcomes realized from the collective set of services could lead to future reallocation of spending among the various types of services. For example, greater frequency of physical activity among obese individuals has been documented to produce greater claims costs related to the treatment of musculoskeletal disorders.[43] Primary and preventive care of obese patients might provide greater value (i.e., better long-term outcomes at lower cost) through substantial involvement of a clinician who possesses expertise in exercise prescription for the avoidance of musculoskeletal disorders or the prudent referral of patients to community programming and/or fitness specialists. Different patient populations (e.g., obese children, healthy adults, patients with multiple chronic conditions) will need different bundles of services, which require different types of outcome measurement. Condition-specific outcome measurement instruments are needed, and no single outcome can fully capture the results of care.[42] The outcomes that are most important to the patient should provide the numerator for the value equation, and the denominator should be the total cost of all services that jointly determine success in meeting the patient's needs.[42]

Although the term "patient-centered care" is widely used, the existing provider-centered and disease-oriented healthcare system often fails to devote sufficient attention to the needs, concerns, and preferences of patients. Patient-centered care involves efforts to inform, educate, and communicate with individual patients, shared decision-making, and continuous advocacy of injury and disease prevention in the context of understanding the patients' living, learning, working, and playing environments. Clinical care is delivered to one patient at a time, but a "population health" perspective is essential for the improvement of the quality of care that is provided to individual patients. Identification of the needs of specific patient populations can be achieved through systematic collection and analysis of patient-centered outcomes data, but it is difficult to accomplish without the utilization of appropriately designed health information technology (HIT). Unfortunately, the current organizational structure of the healthcare system and prevailing financial incentives have focused HIT development on systems for the documentation of billable events rather than the collection of data to support continuous quality improvement.[44] The Health Information Technology for Economic and Clinical Health (HITECH) Act clearly supports the development of a mechanism for the secure exchange of electronic data between providers, but such a platform is not likely to facilitate meaningful improvements in healthcare value without financial incentives that reward patient-centered care.

Support for lifestyle medicine has been evident in the CMS recognition of obesity as a disease in 2014, thereby creating the potential for Medicare coverage of obesity-related treatments.[45] Despite Medicaid being a state-administered program, the CMS decision influenced several states that extended their Medicaid coverage to include both prevention and treatment of obesity. West Virginia[46] and Tennessee[47] offer both full and partial reimbursement for Weight Watchers© programs. Another set of policy supports for lifestyle medicine was initiated in early 2006 through the National Committee for Quality Assurance (NCQA), which approved Healthcare Effectiveness Data and Information Set (HEDIS) measures of health plan performance regarding the measurement of physical activity and BMI as "vital signs" among adults, children, and adolescents. In addition, nutrition and physical activity assessment and counseling for adults, children, and adolescents were also recommended. However, even with the broad implementation of such assessment and counseling interventions, it is clear from recent studies that this alone is not sufficient to facilitate effective and sustained health behavior change among most patients.[48] Most US health plans use HEDIS measures to monitor provider performance that is reported to purchasers of healthcare plans and consumers.[49] The new chronic disease prevention and obesity-related measures target improvements in providers' practice behaviors related to chronic disease and obesity prevention, care, and treatment. Chronic disease and obesity-related HEDIS measures demonstrate the role that a policy intervention can have on preventive care practice behaviors among providers.[49] The ACA expansion of Medicaid appears to have created an improvement in the care for chronic disease care. The states with expanded Medicaid enrollment have found improved adherence to medication use among patients with chronic conditions, increased communication with physicians, and improved health status.[50]

Current policies and practices relating to the delivery of healthcare do not provide adequate incentives, monetary or otherwise, for providers to integrate lifestyle medicine and preventive care into their existing practices.[50,51] Preventive care advocates emphasize the potential cost savings that the US healthcare delivery system could realize but the likely impact has been questioned by many within the medical

community.[51,52] However, critics of preventive care expansion often confuse early detection and treatment with primary prevention and public health efforts, with the latter appearing to provide the best mechanisms for cost savings and prevention of premature morbidity and mortality.[53,54]

As with any governmental legislation, questions about the impact on the public are critical for determining the success or failure of its implementation. The true impact of the ACA will not be known for years to come, but there is substantial data to support the arguments of both its advocates and its critics. For low-income adults, access to primary care, affordability of care, preventive visits, screening tests, and self-reported health have all improved because of the ACA.[50] The reduction of patient cost-sharing for many preventive services has also had mixed results. Research has documented a modest increase in the use of some preventive services.[51–53] However, the early results for critical preventive screening services such as colonoscopy and mammography have been less positive.[54] Administrative barriers, such as a lack of accurate coding for a preventive service, patients' unawareness of policy changes, and insufficient cost-sharing, may be responsible for a lack of increase in preventive service utilization.[54]

With the advent of the 12th anniversary of the ACA, traditional fee-for-service reimbursements to individual providers are unlikely to continue. Should an optimal balance be achieved between government-mandated initiatives and private-sector influences on the US healthcare delivery system, perhaps the cost, quality, and access problems can be collectively resolved. In any case, physicians and other healthcare practitioners who are committed to the delivery of patient-centered clinical care should welcome payment reform that rewards excellence and facilitates the realization of optimal patient outcomes. The transition from fee-for-service to pay-for-performance offers the potential to expand healthcare equity by rewarding providers for high-quality care.[55] However, a reversal in the expansion of healthcare access that the ACA has created, especially among current Medicaid enrollees, would likely have an adverse effect on healthcare equity.[56]

Policies and evidence-based interventions and environmental supports outlined in this chapter identify primary prevention strategies that hold significant promise for the prevention of premature suffering from disease and early death. In addition, the outlined practices can greatly benefit the patient with an existing chronic condition by effectively using lifestyle medicine to manage chronic disease/conditions such as obesity, coronary heart disease, type 2 diabetes, hypertension, and stroke.[57] The future of this field will evolve with payment reforms that will drive care transformation and greater community engagement on the part of the healthcare system. Lifestyle medicine providers need to embrace these opportunities as they develop to align patient needs with the availability of financial resources for payment of clinical services and linkages to community resources that will optimize health for all.

CLINICAL APPLICATIONS

Action	Tools	Comments
1. Engage primary care providers in changing their practice patterns.	Practice in teams; implement and follow professional medical guidelines.	Engaging patients in primary care and lifestyle medicine for the prevention and management of chronic conditions requires clinicians to work in interprofessional teams and implement team-based care.
2. Encourage patients to take an active role in their care through shared decision-making and communication about self-management, medications, and lifestyle changes.	Implement and train all providers in the use of the electronic medical/health record (EHR).	Patients can contribute to the design of the practice and share their experiences of medical visits and access to lifestyle education.
3. Connect EHRs across organizations and spread the implementation.	Clinical care coordinators/navigators; health education videos/presentations in waiting rooms and designated office space.	Hire ongoing health information technology support staff to maintain the functionality of an EHR system, including changing and upgrading the software and incorporating new information on patient management.
	ACOs can help practices adapt EHRs to connect with hospitals and other providers in the ACO that may not be on the same platform.	
4. Standardize lifestyle vital signs within EHR.	ACLM/ACPM guidelines. ACSM/AMA EIM solution.	Training and CME in lifestyle medicine vital signs, patterns of referral to community resources.

131 Policy and Environmental Supports for Physical Activity, Active Living, and Healthy Eating

Elizabeth A. Dodson, PhD, MPH, Charlene Schmidt, PhD, RDN, LDN, Marissa McElrone, PhD, RDN, Nicholas Boer, PhD, MPH, Emily Maddux, MS-MPH, RD, LDN, ACE® CHC, Karissa Peyer, PhD, Steven Fox, MD, and Gregory W. Heath, DHSc, MPH, FACSM, FAHA

KEY POINTS

- Physical inactivity and unhealthy eating are significant, independent risk factors for the major chronic diseases responsible for premature morbidity, disability, and death in the United States and globally.
- Evidence from community-wide and multifaceted approaches targeting the reduction of unhealthy behaviors and the promotion of healthy behaviors is necessary to improve population health.
- Interventions that increase physical activity are a critical component in the prevention and management of chronic diseases and include social and behavioral approaches; informational approaches and community-wide campaigns; and policy and environmental approaches.
- Environmental supports, such as improved access to healthful foods, access to transportation, online grocery shopping, healthful vending, and behavioral economics are promising strategies for promoting healthy eating.
- Policy and environmental approaches to promoting physical activity and healthy eating have been demonstrated to be effective and significant reinforcers for physicians and other healthcare providers who counsel and advise their patients to be more physically active and to eat more healthfully.
- School settings have been shown to provide effective opportunities to increase physical activity and healthy eating among children and youth.
- Worksites have repeatedly been shown as places where physical activity and healthy eating can be successfully promoted among employees.
- Community organizations can often provide physical activity facilities and programming.
- Public recreational facilities and parks provide places to be physically active and often offer programming for a broad cross-section of participants.
- Environmental infrastructure, both built and natural, provides opportunities for people to participate in active transport, active sports, and recreation.
- Food and nutrition security are critical in promoting healthy eating.
- Individuals and communities experiencing food insecurity may adopt unhealthful coping strategies that, over time, can lead to poor physical and mental health outcomes, such as obesity, diabetes, and cardiovascular disease.
- African American/Black, Indigenous, and people of color experience food insecurity at disproportionately higher rates, making it more difficult for these individuals to consistently exhibit healthful food behaviors.
- Federal nutrition policy (e.g., menu and food labeling) and the *Dietary Guidelines for Americans* provide useful guides for healthy eating patterns.
- Lifestyle medicine clinicians have a key role to play in strategic alliances to promote healthy behaviors and environments, and there is growing recognition that involvement in these types of efforts is a professional responsibility.
- To create policy, systems, and environmental changes that address social determinants of health, it is important to utilize approaches that build on community strengths and acknowledge the interdependence of individuals, their social networks, and the community structures, norms, cultures, histories, and values.

131.1 INTRODUCTION

The burden of chronic disease in the United States is overwhelming. To address this burden, researchers and practitioners are paying increasing attention to environmental and policy interventions.[1,2] Of particular interest are interventions to increase physical activity, a critical component in the prevention of chronic disease. Community-based approaches to promoting physical activity were initially assessed systematically for effectiveness by Kahn et al.[3] and

DOI: 10.1201/9781003227793-153

TABLE 131.1
Community Interventions to Promote Physical Activity

Informational approaches

- **Community-wide campaigns:** These large-scale, highly visible, multicomponent campaigns direct their messages to large audiences using a variety of approaches, including television, radio, newspapers, movie theaters, billboards, and mailings. ***Recommended with strong evidence***

Behavioral and social approaches

- **Individually-adapted health behavior change programs:** These programs are tailored to a person's specific interests or readiness to make a change in physical activity habits. Teaching behavioral skills such as goal setting, building social support, self-rewards, problem solving, and relapse prevention, the programs help people learn to incorporate physical activity into their daily routines. ***Recommended with strong evidence***
- **School-based physical education (PE):** This approach seeks to modify school curricula and policies, to increase the amount of time students spend in moderate-to-vigorous activity while in PE class. Schools can accomplish this either by increasing the amount of time spent in PE class or by increasing students' activity levels during PE classes. ***Recommended with strong evidence***
- **Social support interventions in community contexts:** The goal of this approach is to increase physical activity by creating or strengthening social networks. Examples include exercise buddies, exercise contracts, and walking groups. ***Recommended with strong evidence***

Environmental and policy approaches

- **Creating or improving access to places for physical activity combined with informational outreach:** Examples include building walking/biking trails or making it possible for people to use exercise facilities in community centers or in the workplace. Informational outreach includes activities such as training on equipment, seminars, counseling, risk screening, and health workshops. ***Recommended with strong evidence***
- **Point-of-decision prompts to encourage stair use:** These signs are placed by elevators and escalators and encourage people to use nearby stairs instead. ***Recommended with sufficient evidence***
- **Community-scale urban design land use policies and practices:** Examples involve the efforts of planners, architects, engineers, developers, and public health professionals to change the physical environment of urban areas consistening of several square miles or more to support physical activity. ***Recommended with sufficient evidence***
- **Street-scale urban design and land use policies:** Examples involve the efforts of planners, architects, engineers, developers, and public health professionals to change the physical environment of small geographic areas to support physical activity. ***Recommended with sufficient evidence***
- **Built environment approaches combining transportation system interventions with land use and environmental design:** Examples include combining policies improving street connectivity, sidewalk and bicycle infrastructure, and public transit access with policies or designs enhancing access to parks and recreational facilities. ***Recommended with sufficient evidence***

Heath et al.[4] Within these systematic reviews, the authors identified three major domains of community-based physical activity interventions. These domains include behavioral/social, informational/community-wide campaigns, and policy/environmental approaches to promoting physical activity in community settings (Table 131.1).[3–5]

In addition to physical inactivity's contribution to the burden of chronic disease in the United States and throughout the world is the role of unhealthy eating, which can take the form of overnutrition or undernutrition.[6] Consuming food is a matter of survival for all human beings and consuming nutritious foods is more complicated than one might imagine. Disparities in both healthy eating and nutrition-related chronic diseases (e.g., obesity, diabetes, cardiovascular disease) are often influenced by various socioecological factors (e.g., food security) outside of an individual's direct control.[7] Food environments should promote healthful eating behaviors via supportive policies, which will improve health outcomes, especially among populations disproportionately affected by chronic diseases.[8]

Successful and sustainable changes have been demonstrated at local and even national levels.[9] The North Karelia Project, for example, demonstrated that relentless campaigning and partnering with local community and social influencers can reduce smoking, cholesterol, blood pressure, and cardiac death outcomes by changing health behaviors over the course of the last 50 years.[9] This model of broad-scope intervention is currently being implemented by organizations like the Blue Zones Project in the United States to help communities align community residents, organizations, institutions, and agencies to impact policies, places, and people using evidence-based interventions, media campaigns, and data tracking to promote health and wellness in the context of local culture.[10]

The current chapter seeks to identify for the lifestyle medicine practitioner evidence-based interventions that address policy and environmental supports for promoting physical activity and healthy eating that can reinforce a healthy lifestyle through active living and healthful eating assessment, counseling, and referral.

131.2 COMMUNITY-BASED APPROACHES TO PROMOTING PHYSICAL ACTIVITY

Adults in developed countries report many barriers to participation in regular physical activity. One commonly cited factor is a lack of access to facilities or safe places for physical activity.[11] Healthcare practitioners can encourage and even prescribe physical activity for their patients, but unless individuals have a place in which to be active, they are often unable to follow such recommendations. Creating or enhancing access to places for physical activity is an example of a policy or environmental intervention.[3,12] Such interventions include creating/enhancing existing walking/biking trails or exercise facilities and increasing access to existing facilities by reducing barriers to their use (e.g.,

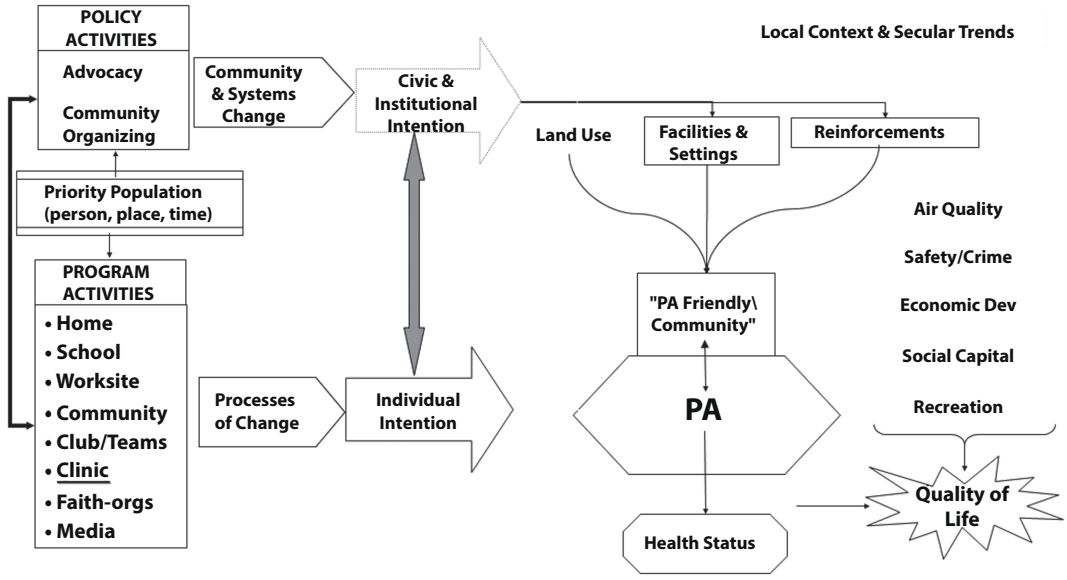

FIGURE 131.1 Community-based physical activity promotion logic model (Dodson EA and Heath GW. Policy and environmental supports for physical activity and active living. In: *Lifestyle Medicine*, 3rd Edition, pp 1367, Figure 123.1 [Rippe JM, editor]. CRC Press, Taylor & Francis Group, LLC, 2019).

increasing safety or enhancing affordability). These efforts often include personnel and/or participant training, social support, and further integration of these structures, facilities, and programs into participants' communities. Policy and environmental approaches for promoting physical activity are predicated on the basis of establishing a foundation on which the concept of a "physical activity-friendly" community/space is created, whereby intersectoral efforts of physical activity programming, promotion, and civic action can yield greater success among community residents.[13] Figure 131.1 provides a detailed logic model illustrating the key intersectoral steps and components of a comprehensive approach to promoting physical activity within the context of a local community. Although such things as civic and individual intent may vary across communities/settings, the principles of social support and intentional linkages between the clinical setting and community support for physical activity appear to be necessary to bring about improvements in a population's level of physical activity.[12,13] An exemplary intervention that embodies such a model, albeit on a smaller scale, is described by Linenger et al.[14] It included new infrastructure (i.e., bike paths), access to facilities (e.g., expanded hours of operation, lighted and integrated paths), and improved programming on a residential US Navy base.[12] More recently, a systematic review of adult physical activity behaviors and their relation to green spaces found that the presence of outdoor fitness equipment promotes physical activity.[15] Multiple studies have documented that developing or installing such infrastructure is reasonable from a cost perspective.[16–18]

Another effective strategy within the domain of policy and environmental approaches has been successfully implemented in Latin America.[19–22] This strategy consists of community-wide policies and planning that place physical activity within the public policy agendas of communities, emphasize the promotion of physical activity guidelines, provide organizational incentives, address institutional and environmental barriers, and use media effectively.[23] Two examples of this promising intervention approach are described by Ribeiro et al.[23] and Reis et al.,[19] who report on the effects of community physical activity programs in Recife, Brazil, and Curitiba, Brazil, respectively. These programs, created in response to the burden of chronic diseases among local populations, involve the dissemination of information about physical activity, assessments of current lifestyle choices, and physical examinations. Concurrent with these interventions, weekly radio programs are broadcast, physical activity classes are offered, strength training equipment is made available, and various races, games, and dance events are sponsored to provide incentives for physical activity.[19–23]

Policy- and environmental-based interventions that are designed to create or provide access to places where people can be physically active often involve the combined efforts of worksites, schools, coalitions, government agencies, and community members.[3] These interventions are characterized by providing improved access to existing exercise facilities, such as fitness centers (both proprietary and non-profit), community centers, and walking/bicycle trails, and by providing access to school grounds.[3,4] In addition to promoting access, many of these interventions incorporate components such as supervision of equipment use, health behavior education and counseling, risk factor screening, referrals to health services, buddy systems, transportation system interventions, and promotion of facility use.[24,25]

A more detailed discussion of each of these areas of intervention follows.

131.3 PLACES THAT MAY PROMOTE REGULAR PHYSICAL ACTIVITY

131.3.1 Schools

Schools present an excellent site for interventions to increase physical activity in children and adolescents. In particular, the Community Preventive Services Task Force (CPSTF) has recently found sufficient evidence to recommend two new types of interventions. Classroom-based physical activity breaks allow teachers to integrate short bursts (lasting four to ten minutes) of moderate-to-vigorous physical activity into daily classroom activities several times per day. Such breaks have been shown to increase student daily physical activity and educational outcomes. Similarly, classroom-based, physically active lesson interventions are recommended to increase time spent engaging in daily physical activity for school-aged children. These lessons allow teachers to incorporate physical activity directly into lessons taught. They may be conducted inside or outside and typically last 10–30 minutes.[26]

School physical education and health education curricula now provide methods of promoting youth physical activity, and many of these strategies have been shown to be effective.[27–29] In particular, systematic reviews have resulted in the recommendation of enhanced school-based physical education, wherein curricula are modified to ensure the engagement of K–12 students in longer periods of moderate- or vigorous-intensity physical activity during physical education classes. These redesigned classes may be combined with other interventions at the school or community levels, including those encouraging family involvement, education about physical activity, and increased opportunities for physical activity through community partnerships.[30]

However, currently, within the United States, a paradox exists in many schools. Although school buildings and grounds may be the most widely available public resources for physical activity within the community, they are often underutilized. Studies of students' engagement in physical activity during leisure time at school (e.g., during lunch, before or after school) reveal that few students use this time to be physically active.[31,32] Many studies have examined associations between physical activity and school physical and social environments. A recent review of these studies highlights several factors associated with increased physical activity in schools: the presence of dedicated spaces for physical activity (e.g., sports fields, gyms); access to sports equipment (although these associations were present only for boys); safe, interesting, and newer playgrounds; and sufficient space for physical activity.[33]

Most schools have policies in place that restrict access to school grounds by students and community members outside of school hours. Thus, these abundant public resources are underutilized; further, these policies may have the most negative impact on low-income communities, which commonly lack other places for safe physical activity. There are several community advocacy groups around the country seeking solutions to this problem. Among them is the Denver Learning Landscapes Alliance.[34] This group seeks to transform school playgrounds and surrounding neighborhoods by designing multidimensional school playgrounds that offer elements of public parks and focus on low-income communities.[32] The addition of more pleasing landscapes encourages participation and park use and has the potential to improve physical, mental, and social well-being.[35,36]

Another approach to increasing the usability of existing spaces for physical activity by community members involves the creation of shared or joint use agreements. These agreements describe costs and risks associated with community use of spaces owned or managed by schools, universities, community centers, faith-based organizations, and so on, and define the terms for their shared use. Such agreements have been implemented in multiple states and may be a way to improve access to places for physical activity, especially among communities with low incomes.[37]

Active transport by walking and cycling to and from school can provide substantial physical activity for children and youth.[38] This has been illustrated by a recent evaluation of the Safe Routes to School program.[39] In 2016**,** advocacy efforts by the Safe Routes to School National Partnership resulted in a revision of transportation performance measures by the US Department of Transportation dictating that performance will be measured by the safety of individuals rather than the speed at which cars travel.[40] As part of its mission, the Safe Routes to School program leverages available federal dollars set aside to promote cycling and pedestrian activities in communities through assistance from state departments of transportation. For example, the California Department of Transportation provided $66 million in funding over three years for Safe Routes to Schools grants to 270 schools.[40] Such funding was used to make physical improvements, such as sidewalk and bike lane construction or enhancements, traffic calming, and street crossing improvements around schools. Some schools added promotional and educational programs to encourage people to use the improved streets. In Marin County, CA, walking to school increased by 64% and biking increased by 114% after a combined intervention.[41] A statewide evaluation of ten schools found that students who passed by the improvements on their way to school increased walking and biking by 15% compared with 4% for those who did not pass the improvements.[42]

131.3.2 Worksites

Many employed adults spend at least half of their waking hours at work, where the pressures of work may contribute to poor activity behaviors; thus, worksites are natural places for physical activity promotion.[43,44] Further, while the number of employees working in sedentary jobs has increased, those in physically active jobs have decreased over time.[44] Meanwhile, sedentary behavior is an independent risk factor for chronic disease and mortality.[45–47] This new reality

highlights the importance of utilizing the worksite as an intervention site for physical activity promotion. A particularly promising type of worksite health promotion strategy involves environmental and policy changes that may assist employees in making healthful choices at work. Research indicates that the presence of worksite supports for physical activity (e.g., on-site exercise facilities, showers, subsidized health club memberships, time or breaks for physical activity during the workday) can increase the likelihood that employees will engage in physical activity and meet national physical activity recommendations.[1,2,43,48,49]

Across worksites, there is wide variation in the types of work performed and the settings in which employees conduct their work. Thus, worksite physical activity interventions that increase physical activity in those employed in manufacturing may not be most effective for those in healthcare or finance. One recent study examined which worksite supports for physical activity were available in various industries and occupations, and which combinations of these supports were associated with the likelihood that employees would meet physical activity recommendations.[50] As part of a large, multi-city study in Missouri, adult participants employed more than 20 hours per week outside the home were surveyed about their occupation and activity behaviors.[51,52] Researchers asked about 16 different worksite supports for physical activity, including the presence of bike storage, availability of showers, incentives to walk/bike to work, and flexible time during the workday for physical activity. Results indicated a wide variety in the availability of worksite supports for physical activity, depending on the type of industry or occupation, suggesting great disparity in access to physical activity supports at worksites. Further, where the availability of one support for physical activity did not always increase the likelihood that employees would meet physical activity recommendations, the combination of certain pairs of support did. For example, when employees have incentives to bike and a place to safely store their bikes, they may be more likely to bike to work. If employees have flexible time during the workday for physical activity combined with exercise facilities, maps suggesting walking routes around the worksite, or showers, they may have reduced barriers to incorporating physical activity into the workday. Of note is the fact that many of the worksite supports examined were of low or no cost to implement (e.g., flexible time for exercise, maps of worksite-adjacent walk/bike routes), hopefully removing one perceived barrier (cost) from employers seeking to encourage physical activity in employees.

Watanabe and colleagues described a recent randomized trial in which the effects of a multi-component worksite intervention were tested in three worksites.[53] Intervention worksites were allowed to select from a variety of intervention programs in which they participated for three months. Intervention options included stair-use prompts, on-site exercise programs, and individual competitions, among others. Control worksites (N = 5) were offered feedback and usual care occupational health services. Physical activity, the primary outcome, was measured at baseline, three months, and six months. The overall physical activity level of employees in the intervention sites increased compared with those of employees at control sites. The proportion of employees achieving a high level of physical activity (defined by levels of physical activity intensity and frequency) increased from 13% at baseline to 21.5% at six months.[53] This flexible intervention showed a positive effect on physical activity among participants and is likely feasible for broad application to other, similar worksites.

131.3.3 Public Recreation Facilities and the Built Environment

Public parks and recreation facilities are widely used, with about 80% of the population making some use of municipal facilities and a smaller but substantial percentage using park programs and services.[54] A major national study of neighborhood parks was conducted in 2016, wherein a representative sample of 114 parks in major US cities was observed and park administrators interviewed.[55] Walking loops and gymnasia were especially well utilized. Parks in low-income neighborhoods were utilized less than those in high-income neighborhoods, where more programs and supervised activities were available.[54] Another recent review of park characteristics, use, and physical activity found that more males than females used parks, older adults were less likely to use parks, and youth were generally more active in parks than adults.[49]

The evidence is strong that the contribution of public recreation facilities and programs to physical activity could be enhanced by optimizing the design of facilities to support physical activity for various population groups and promoting the use of the facilities.[54–56] The potential impact of improved park design was indicated by an Australian study that found adults with very good access to large and attractive public open spaces were 50% more likely to be regular walkers than those without such access.[57]

The research is strong that the presence of parks may enhance physical activity;[58] further, there is some evidence that park and recreation professionals are enthusiastic about participating more in promoting physical activity. A survey of 44 recreation center directors in San Diego County found that most center directors wanted to provide more physical activity programs to youth, 75% were willing to partner with health professionals to train staff in physical activity leadership, and 59% wanted to improve the marketing of their programs.[59] The most frequently cited barriers to offering more physical activity programs for youth were inadequate staff and training, departmental support, and funding.[59] Increased collaboration between public health and recreation professionals to maximize the use of public recreation facilities for physical activity is indicated.[60]

In addition to parks, the design of the built environment (e.g., the presence and condition of sidewalks, location and condition of green space, and availability of

public transportation) has immense potential to impact participation in physical activity. A large body of evidence documents the positive relationship between the built environment and physical activity.[60–62] A recent analysis of urban environments, conducted in 14 cities in ten countries around the world,[63] found that residential, intersection, and public transport density, as well as the number of parks, were significantly and linearly related to physical activity. Further, participants living in the most activity-friendly neighborhoods sampled reported 68–89 more minutes of physical activity per week compared with those living in the least activity-friendly neighborhoods.[64]

Additionally, after a recent review, the CPSTF now includes, among its recommendations for increasing physical activity, built environment strategies combining one or more interventions designed to improve pedestrian or bicycle transportation with one or more land and environmental design interventions.[24] For example, transportation system interventions could include policies aiming to improve sidewalk, bicycle, and trail infrastructure or street connectivity. When combined with a land use intervention, such as a policy or project that enhances access to parks and public or private recreational facilities, there is sufficient evidence that the combination of these interventions can increase physical activity. These new recommendations offer opportunities for community leaders to apply evidence-based interventions to increase physical activity among community residents.

131.3.4 Community Organizations

Many community organizations provide physical activity facilities and programs or have the potential to do so. In the private sector, health clubs, dance studios, martial arts organizations, swimming clubs, and sports leagues are familiar examples. Non-profit organizations include YMCAs/YWCAs and Boys' and Girls' Clubs as well as sports leagues. Faith-based organizations often have physical activity facilities and programs for their members, which could be made available to others in the community. Private and public housing developments often have recreational and fitness facilities. Thus, many resources throughout communities can be used for recreational physical activity, and with improved promotion can become better utilized. However, there do not appear to be any well-designed systematic studies of how the facilities and programs within these community organizations contribute to the physical activity levels of individuals in surrounding communities. Although there are undoubtedly many exemplary programs in these organizations, there currently are no programs that have been systematically evaluated regarding changes in physical activity behaviors due to policy and environmental supports to promote physical activity. A historical systematic review conducted by Kahn et al. identified a strong body of evidence under the category of community-wide campaigns that identified successful collaboration across multiple community sectors, which included many of the community organizations mentioned above.[3,25,65] A conclusion from this work suggests that the public health impact of such facilities and programs can be maximized by increasing the number of participants, increasing the frequency and duration of activity sessions, and sponsoring year-round programs (especially sports organizations). Making resources available to the general community and having reduced fees for low-income participants could help contribute to reduced disparities in physical activity.

131.4 PROMOTING THE USE OF ECONOMICS IN PLACES TO BE PHYSICALLY ACTIVE

Through the systematic evidence reviews by the CPSTF, there has emerged substantial evidence that policies combined with improved infrastructure that supports active transport and active recreation (e.g., walking, biking, and running) results in increased physical activity among children, youth, adults, older adults, and persons with disabilities.[66,67]

King et al. suggested that, where possible, an environmental and policy intervention should be chosen based on likely potency and cost-effectiveness.[68] While evidence supporting the cost-effectiveness of some policy and environmental interventions is still growing, research indicates that such interventions can be cost-effective in schools, worksites, and community settings.

131.4.1 Costs/Benefits and Funding

During the past decade, there has been an emergence of studies supporting the cost-benefit/effectiveness of several community-based interventions to promote physical activity and healthy eating. Earlier efforts focused on school-aged children and the effects of a comprehensive school-based intervention among overweight children.[69] The results of this controlled study demonstrated the cost-effectiveness of preventing weight gain and facilitating weight loss among these students.[69]

Roux and colleagues[70] conducted an econometric simulation based on the systematic reviews of the CPSTF using the effectiveness results for each of the categories of physical activity promotion, behavioral/social, informational/campaigns, and policy and environmental approaches and reported the projected positive cost-benefit and cost-effectiveness of these intervention strategies. Further, Abildso and colleagues recently demonstrated the cost-effectiveness of community rail-trail conversions on the successful promotion of physical activity among community residents.[71]

The most recent findings from the CPSTF addressed interventions to increase active travel to school and found that there were substantial economic benefits associated with the provision of walking/biking infrastructure and the promotion of active transport to school among children and youth.[72,73]

The strategy of combining both physical activity promotion and healthy eating interventions targeting youth and

school-aged children has been recently reported by the CPSTF.[74,75] The use of digital health intervention strategies among overweight and obese youth has resulted in the prevention of further weight gain as well as weight loss.[74] Whereas the combination of healthy snacks (e.g., fruits and vegetables, water) and increased physical activity during school hours (in addition to physical education) have resulted in the prevention of weight gain and a decrease in BMI trends among school-aged elementary students.[75]

Undoubtedly, policy and environmental approaches are essential for sustaining improvements in physical activity behaviors within communities. By creating connections across disciplines, including land use planning, transportation, public health, and economic development, substantial policy changes may be gained. Improving policy and engaging community members may be the important formula for enhancing success.

131.5 FOOD SECURITY AND HEALTHY EATING

Eating behaviors of individuals, families, and communities are influenced, in part, by various socioecological factors outside of their direct control, including food security. Food security, defined by the United States Department of Agriculture (USDA), is "access by all people at all times to enough food for an active, healthy life".[76] Achieving a food-secure home requires adequate quantity, quality, and diversity of foods to meet the health needs of everyone in the household. Closely linked to this concept of food security is the emerging topic of nutrition security. Nutrition security encompasses a variety of additional factors including availability, affordability, access, acquisition, consumption, and education related to foods that promote well-being and prevent disease.[75] As the prevalence of nutrition-related chronic diseases continues to increase, shifts in environmental and policy priorities beyond caloric sufficiency and food quantity to a more health-promoting, nutrition-secure focus are necessary to encourage the adoption of healthful eating behaviors among individuals from diverse communities.[77]

131.5.1 Disparities in Food Security

Food insecurity affects every community in the United States. In the most current 2020 report, the USDA estimated that approximately 10.5% of households were experiencing food insecurity, which equates to over 38 million people.[74] While rates of food insecurity have decreased in the United States from a high of 14.9% in 2011, it is projected that the COVID-19 pandemic has erased much of this progress.[78] Moreover, these rates represent national averages. Although this steady decrease in pre-pandemic food insecurity rates has been noted, a significant gap among rates in different populations persists, making it more difficult for these communities to consistently exhibit healthful food behaviors.[76]

One type of disparity in food insecurity exists among different racial and ethnic groups. On average, both White, non-Hispanic/Latinx and Other, non-Hispanic/Latinx households have low food insecurity rates compared with the national averages.[76] However, there is a significant difference in the food insecurity experiences of Black, Indigenous, and people of color (BIPOC) households. Additionally, other disparities in food insecurity can be seen among different household types, areas of residence, and geographic regions. The 2020 USDA data revealed that households with children had a substantially higher rate of food insecurity (14.8%) than those without children (8.8%), with the highest rates existing among households headed by single mothers (27.7%). The prevalence of food insecurity was higher for households located in principal cities of urban areas (12.7%) and rural areas (11.6%) compared with those located in suburban and other urban areas outside principal cities (8.8%). Regionally, the 2020 food insecurity rate was highest in the South (12.3%) compared with the Northeast (9.3%), and Midwest and West (both 9.5%) US geographic regions.[76]

131.5.2 The Relationship between Food Security and Chronic Disease

The rapid and sustained rise of nutrition-related chronic diseases (e.g., obesity, diabetes, cardiovascular diseases) over the last three decades is a major public health concern in the United States. While these nutrition-related conditions touch all communities across the country, they disproportionately impact lower-income BIPOC communities often experiencing food insecurity.[79] These nutrition-related health disparities stem, in part, from a complex array of health inequities. The interplay between various social determinants of health, including poverty and low food security, and the incidence and prevalence of chronic diseases is well documented.[6–8,80,81]

The relationship between food insecurity and chronic disease development is cyclic in nature.[81] Often, food-insecure households alternate between adequate food supply and scarcity throughout the month and/or year. In response to this inconsistency, households may adopt unhealthful behaviors to cope with times of food insecurity. For example, adults who anticipate future food scarcity may overconsume during times of adequate food supply, which can lead to physiologic changes such as binge eating, efficient energy storage (i.e., fat accumulation), and peripheral insulin resistance. Over time, these unhealthful coping strategies can lead to poor physical and mental health outcomes. With the onset of chronic conditions, healthcare costs may rise (e.g., increased medication and physician visits), household income may decrease (e.g., missing or losing employment due to illness), and spending tradeoffs may be used to cope. When individuals and families are forced to choose between selecting healthful food and paying electric bills, the food insecurity cycle continues.[81]

Although it appears counterintuitive, the high rates of overweight and obesity among food-insecure and

low-income individuals are associated with obesogenic factors experienced by the general American public (e.g., increased portion sizes and sedentary behavior). However, this population faces additional unique challenges in adopting and maintaining healthful eating behaviors, which make them particularly vulnerable to obesity. Factors such as limited resources, limited access to affordable, healthful foods, and greater exposure to the marketing of unhealthy foods and beverages can all lead to poor eating behaviors.[82] Improvements in these factors may promote more healthful eating among all populations, including those experiencing food insecurity (Table 131.2).

131.6 PROMOTING HEALTHY EATING THROUGH ENVIRONMENTAL AND POLICY APPROACHES

Food security, its relationship to nutrition-related chronic disease, and healthful food choices are complex, interrelated issues requiring multifaceted approaches. Story and colleagues propose a socioecological framework illustrating the myriad influences on food choices individuals make.[83] Mounting evidence leads experts to suggest policy and environmental interventions to increase healthy eating[1,83] (Table 131.3).

131.6.1 Environmental and Policy Supports for Healthy Eating

Food deserts and food choices. Adequacy of the food supply, such as certain types of restaurants or fresh produce, impacts the types of foods that are available to individuals and families. Food deserts, or places lacking access to foods that are nutritious, such as fruits and vegetables, whole grains, low-fat dairy products, and others exist in the United States.[84] The body of literature is growing about food deserts in the United States and their impact on health.[85]

As defined by the USDA, a food desert contains several key components: low-access community, number of individuals impacted, and distance an individual lives from a supermarket or grocery store that is not considered a convenience store or quick mart.[82] A "low-access community" must consist of 1000–8000 people and averages around 4000 people; furthermore, at least 33% of the census tract's

TABLE 131.2
Policy and Environmental Interventions for Obesity Prevention and Control

Action	Tools	Comments
The first step in building a strategic alliance is to show consistency, authenticity, and transparency when advocating for a healthier environment with the community within one's own clinic or practice.	Institutionalized policies (i.e., modifying policies to remove soft drinks from the waiting room). Materials are readily available, highlighting the importance of physical activity and eating healthier food. Community partners can help! They include but are not limited to schools, neighborhood associations, clinics, the local health agency, and non-profit organizations.	When committing to healthier communities, physicians and clinicians should first assess the immediate environment of the clinic or practice.
Physicians and clinicians should address the social and environmental determinants of health within the community they serve so to increase their influence on both population and patient health. As an individual citizen, a clinician can be an active community member.	Ask clients where they shop for fruits and vegetables, where their children play, and how they get to work. Walk the neighborhoods and communities to experience the environments firsthand. Public meetings. Testimonials before policymakers. Refer patients to community resources or programs.	Physicians are unlikely to have a full understanding of the specific nature of the community they serve. Community engagement is an important component of the work for multidisciplinary partnerships.
Screen for food insecurity in healthcare settings	Electronic medical record (EMR) embedded Healthy Eating Vital Sign (see reference [120]).	Healthcare providers are increasingly screening for food insecurity in the clinical setting. Individuals who positively screen for food insecurity should be referred to local resources (e.g., food pantries) and nutrition assistance programs (e.g., SNAP) (https://hungerandhealth.feedingamerica.org/explore-our-work/community-health-care-partnerships/addressing-food-insecurity-in-health-care-settings/).

population must live in excess of one mile from a supermarket or large grocery store. An additional quantifier is added for rural individuals, such that the distance must be greater than ten miles from the supermarket. Food deserts also contain larger numbers of quick marts and convenience stores that offer mostly sugar- and fat-laden processed foods, which are associated with obesity.[86] While interventions, such as implementing farmers' markets in food deserts, have had some success, access to these healthful food options alone is not always enough to change eating behaviors.[87–89] Additional approaches addressing the knowledge, skills, and behavior related to the preparation and consumption of healthful foods are needed.

Accessibility to full-service grocery stores. Increased consumption of fruits and vegetables has been reported by those who shopped at a supermarket compared with those who did not. Adequate fruit and vegetable consumption has been associated with a more nutritious diet and more improved health outcomes.[90] However, access to nutritious foods is also affected by a lack of transportation and long distances between households and supermarkets or grocery stores. Not surprisingly, residents are at risk for food insecurity and chronic disease in neighborhoods where transportation options are limited, the travel distance to stores is greater, and there are fewer supermarkets. Lack of access to public transportation or personal vehicle limits access not only to food itself but, importantly, to nutritious food.[91] Additionally, some people live in a "food mirage", where individuals reside near grocery stores or supermarkets, but cannot afford the foods sold there. In these cases, individuals must still find transportation to more affordable options.[92]

Shopping patterns, including food purchasing, dramatically shifted to online purchasing during the COVID-19 pandemic. Shoppers can now choose curb-side pick-up and grocery delivery which, according to recent Nielsen research about measuring and understanding the shopper "shift", will likely remain options.[93] Online grocery shopping may improve access to healthful options for some individuals and has the potential to reduce less healthful impulse food purchases. However, elements of online grocery shopping like consumers' reluctance to buy fresh produce online may have a negative impact on food purchases.[94]

Behavioral economics. When behavioral economics (i.e., how individuals are influenced to make choices) is applied to the food environment setting, choice architecture is a key factor in decision-making about nutritious and non-nutritious foods.[95] Choice architecture is a concept in behavioral economics that adjusts the appeal or availability of choices in an individual's mind to encourage one specific choice over another. Choice architecture may preserve freedom of choice while making unhealthy options less convenient or more healthful choices immediately visible to the consumer. Behavioral economics may lead to poor food choices and decision-making and is present in supermarkets, convenience stores, and food pantries. Something as simple as the placement of food at eye level, on or at the front of the shelf can influence a choice for the consumer that may be undesirable, in terms of the nutritional quality of a food item. While more healthful items may be available, they may not be located within immediate view; thus, the attractive packaging, flashy signage, and eye-level placement of food products impact selection by the consumer. By contrast, simply placing healthful foods in prominent locations in stores may encourage individuals to select them. Behavioral economics recognizes that even though consumers may have the required information, skills, and decision bias about a food product, they may still choose a food that is not as nutritious as another due to placement in a store or other elements that are responding to choice architecture.[96] Behavioral economics presents a low-cost, feasible approach to improving food choices but does not address other barriers such as access, transportation, time, or energy required to prepare foods.[95]

Healthy school vending. Although non-nutritious foods in school vending machines are being banned in many states across the nation, schools may be substituting other sugar-sweetened beverages, such as sports and energy drinks. Both the USDA and the CDC support new regulations that determine what may be provided in the vending

machines throughout the school day.[96,97] According to the Food and Drug Administration (FDA), there are now limits on fat, sugar, sodium, and total calories in the food products stocked in school vending machines. According to the Smart Snacks in Schools guidelines,[98,99,100] such snacks must:

- Be a grain product that contains 50% or more whole grains by weight (have a whole grain as the first ingredient); or
- Have as the first ingredient a fruit, vegetable, dairy product, or protein food; or
- Be a combination food that contains at least a quarter cup of fruit and/or vegetable; and
- The food must meet the nutrient standards for calories, sodium, sugar, and fats.

The nutrient standards for smart snacks are:

- Calories: 200 or less
- Sodium: 200 mg or less
- Total fat: 35% of calories or less
- Saturated fat: less than 10% of calories
- Trans fat: 0
- Sugar: 35% by weight or less

Thus, changing the food environment by ensuring that healthful foods are available and affordable, and utilizing choice architecture to make it easier and more appealing to select healthful foods may be effective means of addressing food choices contributing to chronic disease.

Federal Nutrition Policy and Dietary Guidelines for Americans. Federal Nutrition Policy and Dietary Guidelines are useful guides for healthy eating patterns. Every five years, the USDA publishes updated recommendations for Americans through the Dietary Guidelines. The 2020–2025 Dietary Guidelines deliver new key messages with a recently incorporated theme of "make every bite count" and include recommendations for every life stage, beginning with pregnancy and lactation.[90] The recommendations note that:

- At every life stage, meeting food group recommendations, even with nutrient-dense choices, requires most of an individual's daily calorie needs and sodium limits.
- Nutrient-dense food and beverage choices are customizable and should reflect individual and cultural preferences, and budgetary needs.
- A small amount of added sugars, saturated fat, or sodium can be added to nutrient-dense foods and beverages to help meet food group recommendations, but foods and beverages high in these components should be limited.
- Foods and beverages higher in added sugars, saturated fat, and sodium, as well as alcoholic beverages, should be limited.

The contribution of dietetic professionals. The Academy of Nutrition and Dietetics (AND) also plays a role in advocating for federal nutrition policy that supports healthy eating. The Academy is "committed to improving the nation's health and advancing the profession of dietetics through research, education and advocacy".[101] Registered dietitian nutritionists (RDNs) play a key role in chronic disease prevention and treatment, helping to shape food choices of consumers, and improving the overall nutrition status of people. RDNs can translate science into practical recommendations for those they work with. These professionals also work with policy leaders at all levels of government "to promote health and reduce the burden of chronic disease through nutrition services and interventions".[101]

Worksite supports for healthy eating. Because many adults employed full time spend so many hours at work, worksites are excellent places to assist employees in making healthful food choices. Research shows that increasing the selection of fruits, vegetables, and salad, while reducing the prices of these items, increases purchases.[102] Recommended strategies for creating healthy worksite food environments include ensuring access to clean water, providing healthful food in on-site cafeterias and vending machines, and reducing prices for fruits and vegetables.[103,104] In a study designed to examine the associations among worksite environmental and policy influences and physical activity and healthy eating, researchers found that employees reporting the availability of a cafeteria, snack bar, or food services at the worksite were more likely to consume fruits and vegetables more than twice per day and less likely to consume fast food more than twice per week.[105] Further, they found that employees reporting that their worksite cafeteria, snack bar, or food services provided daily fresh fruits and vegetables were also less likely to consume fast food more than twice per week. These results suggest that access to healthful and affordable foods at worksites may improve employee food choices.[105]

131.6.2 Role of Food Labels

The potential of FDA-required food labels to promote healthy eating is limited without expanded and improved consumer education. In 2018, the FDA published the updated and redesigned Nutrition Food Label (see Figure 131.2). Changes were made to make it easier for individuals to make informed decisions about the foods that they eat. This is important because many foods that contribute to chronic disease include pre-packaged, convenience food items. All manufacturers were required to update their product labels by July 1, 2021. The purpose of these updates is to help consumers be better educated about food choices.[106] Specific changes include the following:

- Serving sizes have been changed to reflect what people actually consume, rather than what is recommended. Also, if a package is intended to be

FIGURE 131.2 New nutrition labeling (www.FDA.gov/NewNutritionFactsLabel).

eaten in one or two sittings, the manufacturer must list the entire container as one serving.

- Calorie-count font size is larger and bolder for easier reading.
- The calories from fat information were eliminated as research has illustrated that type of fat consumed matters more than amount.
- "Added sugars" are now listed in grams and as a percent daily value to help people reach the Dietary Guidelines goal of consuming "less than 10% of calories per day from added sugars".
- Vitamin D and potassium have been added to the food label since these are typically nutrients that Americans typically under-consume; vitamins A and C have been removed since deficiencies in these are uncommon.
- A footnote has been updated to help the consumer better understand what the product provides. This is given as a percentage in relation to total daily consumption.

It is recommended that saturated and trans fats be limited to less than 10% of kilocalories per day, added sugars to less than 10% of kilocalories per day, and sodium to less than 2300 mg per day. Alcohol, if consumed, should be in moderation, up to one drink per day for women and two drinks per day for men, and only by adults over the legal drinking age. A standard drink is anything that contains one-half ounce of pure ethanol. Some examples include 5 ounces of wine, 10 ounces of wine cooler, 12 ounces of beer, and 1.5 ounces of 80-proof whiskey, scotch, rum, or vodka[90] (see Figure 131.3). These guidelines are often confusing to consumers who do not have the knowledge or energy to calculate these amounts of sugars in their diets or read food labels to determine a food's sodium content.[107]

131.6.3 Restaurant Menu Labeling

Menu labeling in restaurants is a promising strategy for promoting healthful food choices. Americans are busy and convenience food options are abundant.[106] In addition, more consumers are eating out at restaurants more frequently, and consuming about one-third of their calories from foods that they do not prepare themselves. Therefore, the FDA has established the Menu Labeling Rule for all restaurants and similar retail food establishments covered under this rule. This includes any restaurant establishment that has 20 or more locations. The standard menu items will have the calories listed beside the name or the price of the item (food or beverage). At facilities where there are salad bars, buffets, and so on, the calories will be available to consumers on signs that are near the foods. However, calories will not be required for "condiments, daily specials, custom orders, or temporary/seasonal menu items".

FIGURE 131.3 Standard drink of alcohol (www.niaaa.nih.gov/alcohols-effects-health/overview-alcohol-consumption/what-standard-drink; accessed 4/15/2022).

Restaurants will also be required to provide written nutrition information, which will provide the full nutrition facts of the menu items.[107] When fully implemented, this Menu Labeling Rule will provide additional opportunities for consumers to be aware of the nutritional content of food choices.[108]

131.7 BUILDING STRATEGIC ALLIANCES TO PROMOTE HEALTHY EATING AND ACTIVE LIVING

To create environmental and policy changes that address social determinants of health, it is important to utilize approaches that build on community strengths and acknowledge the interdependence of individuals, their social networks, and the community structures, norms, cultures, histories, and values.[109–111] Because of the importance of these more multilevel, multisector, interdisciplinary changes, many federal, state, and nongovernmental agencies are calling for the development of strategic alliances (i.e., partnerships, coalitions, asset-based community building) to promote healthy eating and active living.

Lifestyle medicine clinicians have a key role to play in strategic alliances to promote healthy behaviors and environments, and there is a growing recognition that involvement in these types of efforts is a professional responsibility. Within the clinical setting, most physicians focus their time and energy on individual- and social- or family-level factors to enhance the health of their patients. This may involve testing, counseling, and referrals to other clinicians and clinical resources (nutritionists, physical therapists, etc.). While these traditional clinical roles are absolutely critical to patient care, many physicians have found that they want to have a role in addressing the other factors that impact the health of their patients. These include but are not limited to employment status, literacy levels, food insecurity, adequate housing, and access to healthcare and transportation. At the same time, professional expectations and spheres of influence are changing to reflect the important responsibility physicians have in advocating for health outside the bounds of the typical patient encounter or the walls of the clinic (Figure 131.4).[112,113]

Bringing organizations and community members together from a range of disciplines, sectors of society, and diverse backgrounds is necessary when striving to enhance healthy eating and active living in a community. The resultant groups have been called strategic alliances, coalitions, or multidimensional partnerships. Each group may go through various stages of development,

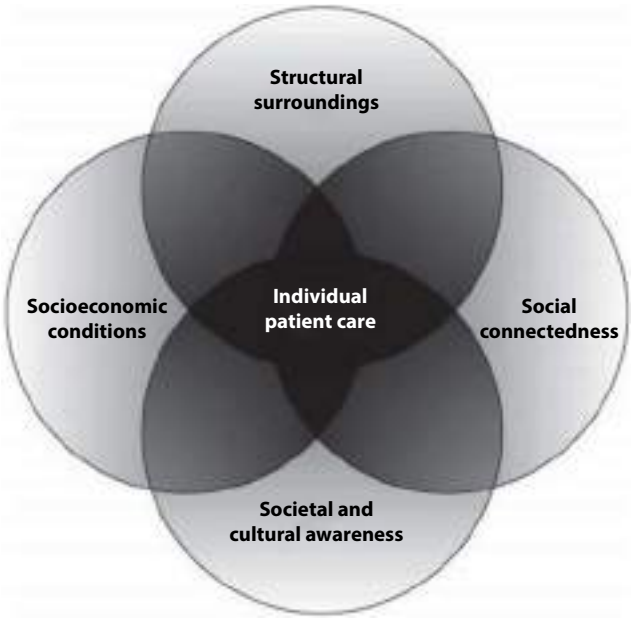

FIGURE 131.4 Assessing community engagement (source: Organizing Committee for Assessing Meaningful Community Engagement in Health and Health Care Programs and Policies. 2022. Assessing Meaningful Community Engagement: A Conceptual Model to Advance Health Equity through Transformed Systems for Health. NAM Perspectives. Commentary, National Academy of Medicine, Washington, DC. https://doi.org/10.31478/202202c.).

progressing from initial conversations, regular meetings, development of an organizational structure, development of partnership capacity, development of a mission and vision, action planning, implementation, evaluation, and eventually to sustainability and maintenance. With time, trust can be developed within a group, and, in turn, the level of collaboration strengthens and becomes more productive. The first level of collaboration might include sharing information and referrals (e.g., between clinics and community programs). The next level might be to jointly define a goal with each partner acting individually toward this shared goal (e.g., sending letters to encourage healthy choices at school events). A third level might be to contribute or exchange resources (i.e., money, space, equipment, or personnel) for a common goal. The last and often most difficult level is collaborating on planning, funding, implementing, and evaluating policy, systems, and environmental (PSE) change activities.[114,115] The benefits of these multidimensional partnerships are wide-ranging. Partnering with community members (schoolteachers, retired nurses, parents of children, etc.) can ensure that goals and activities are culturally relevant and feasible within the community. Also, having a variety of partners from different sectors (transportation, elected officials, schools, businesses, land use planning, etc.) can help a group navigate unique systems and processes and translate professional jargon. As an ongoing process, partners should work together to respond to the demands of the project as well as demands for increased information, resources, communication, community input, and utilization of services to improve outcomes.[116–118]

131.8 SUMMARY

In the practice of lifestyle medicine, healthcare professionals cannot rely solely on effective assessment and counseling of their patients to adopt and maintain a more physically active and healthy eating lifestyle. Indeed, health behaviors are seldom changed or adopted within the confines of the clinical setting. However, the astute lifestyle medicine practitioner committed to promoting physical activity and healthy eating among her/his patients will proactively identify existing physical activity and healthy eating resources and supports within the patient's community and neighborhood as essential in achieving individual health-related levels of physical activity and healthy eating. Such resources and supports are conveyed through programming, policies, and infrastructure in communities, worksites, schools, parks, community organizations, and transportation systems. By linking clinic to community, lifestyle medicine practitioners are thus assured of maximizing the likelihood of their patients adopting and sustaining a healthier eating and physically active lifestyle.

The obesity and overweight epidemic is growing in proportions faster than healthcare professionals or public policy influence can offset, despite research-based recommendations about guidelines for healthy eating. Continued attention and research need to be focused on how the environment, in multiple ways and facets, plays a role in individual choices. Better access to nutritious foods along with perceptions about the quality of food that is available and a focus on the prevention of overeating of non-nutritious and processed foods needs to be an ongoing effort. Food deserts, transportation issues, and affordability in low-income and BIPOC neighborhoods must be remedied in the way of policy change and environmental supports for eating behaviors to ultimately produce reduced chronic disease risk and improved health outcomes.

Physicians and other healthcare professionals can play a key role with strategic alliances in creating sustainable environmental and policy changes that are critical for the health and well-being of their patients and the community. Furthermore, there is growing recognition that this involvement is a professional responsibility and that work to develop community-integrated health systems also clearly advances the "quadruple bottom line" goals of a healthcare system that is rapidly undergoing a number of transformations. Participation can be achieved through a variety of roles and levels of involvement. Regardless of the role, it is helpful to be aware of how alliances can be structured to be most effective in accomplishing their goals. The support of physicians (through participation and/or leadership) can greatly enhance the success of strategic alliances, and their community-based work can also extend the physician's ability to advocate for the health of their patient population

and increase the effectiveness of a physician's counseling for healthy behaviors.

CLINICAL APPLICATIONS

Action	Tools	Comments
Assess physical activity of all patients.	Electronic medical record embedded Physical Activity or Exercise Vital Sign (PAVS/EVS) - Available through Exercise is Medicine (www.exerciseismedicine.org)	Unfortunately, <35% of individuals are routinely assessed for physical activity levels in primary care settings.
Counsel inactive patients or individuals not meeting the current Physical Activity Guidelines for Americans level of physical activity strategies.[119]	Multiple materials are available from the NIH, ACP, AAFM, AAP, CDC, and others.	Effective strategies to promote physical activity involve understanding the patient's living/community situation, personal preferences, and health status.
Refer patients and work with public health, parks/recreation, and other community-based organizations to provide resources and guidance for patients to be more physically active.	EMR-generated referrals to community resources, which offer places and programs for physical activity promotion.	Physical activity promotion requires both a public health approach and an individual approach to increase physical activity with policy and environmental (physical, social, cultural) supports holding the greatest promise.
