Lifestyle Medicine

FOURTH EDITION

Edited by

James M. Rippe, MD

CRC Press
Taylor & Francis Group

Lifestyle Medicine

The fourth edition of Dr. James Rippe's classic *Lifestyle Medicine* Textbook continues to lead and inform the rapidly growing field of lifestyle medicine. This is the discipline that focuses on the impact of daily habits and actions on both short- and long-term health and quality of life.

The first edition of this comprehensive work named the field of lifestyle medicine in the academic medical literature. The fourth edition continues to span and expand the field and offers extensive evidence-based literature in virtually every aspect of lifestyle medicine. This textbook, edited by cardiologist Dr. James Rippe, who is a leading lifestyle medicine researcher, represents the combined wisdom and recommendations of over 325 experts in virtually every aspect of lifestyle medicine. Chapter authors have been chosen because of their background as leaders in various aspects of lifestyle medicine.

Lifestyle Medicine, Fourth Edition contains extensive sections on the treatment and prevention of coronary heart disease, stroke, cancer, diabetes, obesity, substance abuse, dementia, and many other clinical conditions. Key lifestyle modalities such as physical activity, nutrition, weight management, sleep, stress reduction, and positive connections with other humans are supported by detailed discussion and state-of-the-art evidence. The expanded section on behavioral medicine provides an important framework for these discussions. Every chapter has been completely revised and many new topics added, such as lifestyle medicine for nursing, psychiatry, and preventive neurology.

The fourth edition of this classic text continues to serve as the leading, comprehensive textbook in lifestyle medicine. The original has been called the "indispensable bible" of lifestyle medicine, and the fourth edition of this work continues to justify this designation.

There is no longer any serious doubt that daily habits and actions have a significant impact on multiple aspects of health. The fourth edition of *Lifestyle Medicine* provides the scientific evidence to support this assertion and will serve as an invaluable reference and guide, not only to lifestyle medicine practitioners but to all primary care physicians, subspecialty physicians, nurses, and other healthcare practitioners.

This book contains information obtained from authentic and highly regarded sources. While all reasonable efforts have been made to publish reliable data and information, neither the author[s] nor the publisher can accept any legal responsibility or liability for any errors or omissions that may be made. The publishers wish to make clear that any views or opinions expressed in this book by individual editors, authors or contributors are personal to them and do not necessarily reflect the views/opinions of the publishers. The information or guidance contained in this book is intended for use by medical, scientific or health-care professionals and is provided strictly as a supplement to the medical or other professional's own judgement, their knowledge of the patient's medical history, relevant manufacturer's instructions and the appropriate best practice guidelines. Because of the rapid advances in medical science, any information or advice on dosages, procedures or diagnoses should be independently verified. The reader is strongly urged to consult the relevant national drug formulary and the drug companies' and device or material manufacturers' printed instructions, and their websites, before administering or utilizing any of the drugs, devices or materials mentioned in this book. This book does not indicate whether a particular treatment is appropriate or suitable for a particular individual. Ultimately it is the sole responsibility of the medical professional to make his or her own professional judgements, so as to advise and treat patients appropriately. The authors and publishers have also attempted to trace the copyright holders of all material reproduced in this publication and apologize to copyright holders if permission to publish in this form has not been obtained. If any copyright material has not been acknowledged please write and let us know so we may rectify in any future reprint.

Contents

Preface xviii
Serendipity and Important Milestones xxiv
About the Editor xxv
Contributors xxvi
Acknowledgments—*Lifestyle Medicine*, Fourth Edition xliii

PART I Lifestyle Management and Prevention of Cardiovascular Disease

Chapter 1 The Rationale for Intervention to Reduce the Risk of Cardiovascular Disease 3
James M. Rippe, MD

Chapter 2 Lifestyle Strategies for Risk Factor Reduction and Treatment of Cardiovascular Disease 23
James M. Rippe, MD

Chapter 3 Physical Activity and Fitness in the Prevention of Cardiovascular Disease 44
James M. Rippe, MD

Chapter 4 Clinical Strategies for Managing Dyslipidemias 62
Mary Hannan, PhD, APRN, AGACNP-BC, Thanakrit Jeamjitvibool, MSN, RN, and Ulf G. Bronas, PhD, ATC, FSVM, FAHA

Chapter 5 Lifestyle Management and Prevention of Hypertension 75
Mary Hannan, PhD, APRN, AGACNP-BC, Thanakrit Jeamjitvibool, MSN, RN, and Ulf G. Bronas, PhD, ATC, FSVM, FAHA

PART II Nutritional Aspects of Lifestyle Medicine

Chapter 6 Dietary Guidelines for Americans, 2020–2025: National Nutrition Guidance 89
Elizabeth B. Rahavi, RDN, Jean M. Altman, MS, Eve E. Stoody, PhD, and Monica K. Esquivel, PhD, RDN, CSSD

Chapter 7 Nutrition and Cardiovascular Disease 100
James M. Rippe, MD

Chapter 8 Optimal Nutrition Guidance for Older Adults 114
Alice H. Lichtenstein

Chapter 9 Effects of an Active Lifestyle on Water Balance and Water Requirements 123
Gethin H. Evans, Lewis J. James, Ronald J. Maughan, and Susan M. Shirreffs

Chapter 10 Culinary Medicine 133
Uma Naidoo, MD

Chapter 11 Nutrition, Lifestyle, and Environment 138
T. Colin Campbell, PhD

PART III Physical Activity

Chapter 12 The Health Benefits of Regular Physical Activity 147
James M. Rippe, MD

Chapter 13 Implementation of the Exercise Prescription 156
Rachele M. Pojednic, PhD, EdM, FACSM and Jennifer L. Trilk, PhD, FACSM, DipACLM

Chapter 14 The Role of Physicians in Promoting and Prescribing Increases in Physical Activity 163
James M. Rippe, MD

Chapter 15 Physical Fitness Evaluation 172
Peter Kokkinos, PhD and Jonathan Myers, PhD

Chapter 16 Exercise Prescription for Apparently Healthy Individuals and for Special Populations 187
Paul G. Davis, PhD, ACSM-CEP

Chapter 17 Physical Activity and Health: Key Findings from the Physical Activity Guidelines for Americans 2018 200
James M. Rippe, MD

Chapter 18 Overcoming Sedentary Behavior 209
James M. Rippe, MD

Chapter 19 Promoting Regular Physical Activity 213
James M. Rippe, MD

PART IV Behavioral Medicine

Chapter 20 Behavior Change 223
Elizabeth Pegg Frates and James E. Eubanks

Chapter 21 Applying Psychological Theories to Promote Healthy Lifestyles 229
Maryam Gholami, PhD, Cassandra Herman, MS, Cole Ainsworth, MPH, Dori Pekmezi, PhD, and Sarah Linke, PhD, MPH

Chapter 22 Motivational Interviewing and Lifestyle Change 240
Peter Fifield, EdD LCMHC, MLADC, Joji Suzuki, MD, Samantha Minski, PhD, and Jennifer Carty, PhD

Chapter 23 Transtheoretical Model 251
James O. Prochaska and Janice M. Prochaska

Chapter 24 The Impact of Positive Psychology on Behavioral Change and Healthy Lifestyle Choices 261
Shelley Carson, Andrea Cook, Stephanie Peabody, Sandra Scheinbaum, and Leslie Williamson

Chapter 25 The Intention–Behavior Gap 272
Mark D. Faries, PhD, Wesley C. Kephart, PhD, and Devin Graham, MS

Chapter 26 Cognitive-Behavioral Change Approaches to Enhancing Physical Activity Participation and Decreasing Sedentary Behavior in Adults 284
Barbara A. Stetson, PhD and Patricia M. Dubbert, PhD

Chapter 27 Enhancing the Nutrition Prescription Using Behavioral Approaches 297
Jonas Sokolof, DO, Margaret Loeper Vasquez, MS, RD, LDN, Jenny Sunghyun Lee, PhD, MPH, MA, DipIBLM/ACLM, FACLM, Elizabeth Pegg Frates, MD, FACLM, DipABLM, Sam Morley, MS, MPH, Daniel B. Clarke, MBA, and P. Michael Stone, MD, MS, IFMCP

Chapter 28 Behavioral Approaches to Manage Stress 309
Shirly Ramchandani, MD, Darshan Mehta, MD, MPH, Elise Loiselle, RN, MSN, FNP-C, and Jacqueline Proszynski BS

Chapter 29 Health Coaching and Behavior Change 329
Karen L. Lawson, Margaret Moore, Matthew M. Clark, Sara Link, Samantha Morley, MPH, MS, and Ruth Q. Wolever

PART V Lifestyle Medicine Approaches to Dysglycemia

Chapter 30 Overview: Dysglycemia-Based Chronic Disease—Exposing Lifestyle Medicine Targets 345
Michael A. Via, MD and Jeffrey I. Mechanick, MD

Chapter 31 Context: Impact of Dysglycemia and Lifestyle Medicine on Cardiometabolic-Based Chronic Disease .. 358
Waqas A. Malick, MD and Jeffrey I. Mechanick, MD

Chapter 32 Management: Lifestyle Medicine Approaches to Insulin Resistance, Prediabetes, Type 2 Diabetes, and Diabetes Complications 370
Reshmi Srinath, MD, Tracey Rosa, MD, Leena Shah, MD, and Jeffrey I. Mechanick, MD

Chapter 33 Implementation: Lifestyle Medicine Tactics to Optimize Dysglycemia Care 389
Ramfis Nieto-Martínez, MD, MSc, Diana De Oliveira-Gomes, MD, and Jeffrey I. Mechanick, MD

Chapter 34 Adiposity-Based Chronic Disease 411
Michael A. Via, MD and Jeffrey I. Mechanick, MD

PART VI Lifestyle Issues in the Prevention and Treatment of Cancer

Chapter 35 Exercise Oncology: The Role of Exercise across the Cancer Control Continuum 429
Maxime Caru, PhD and Kathryn H. Schmitz, MPH, PhD, FACSM, FTOS, FNAK

Chapter 36 The Health Consequences of Tobacco Use and Addiction: Assessment and Treatment 446
Jonathan Foulds, MAppSci, PhD

Chapter 37 The Role of Integrative Medicine in Cancer Prevention and Survivorship 458
Gabriel D. Moss, Stephanie R. Harris, and Richard T. Lee

Chapter 38 Cancer Prevention Vaccines 471
Melvin Berger, MD, PhD and Nathan A. Berger, MD

Chapter 39 Lifestyle Approaches To Obesity Management for Cancer Control 481
Debora S. Bruno, MD, MS and Nathan A. Berger, MD

Chapter 40 The Importance of Nutrition in Cancer Prevention 499
Elizabeth R. M. Zunica, PhD and L. Anne Gilmore, PhD, RD

PART VII Obesity and Weight Management

Chapter 41 Exercise Management for the Patient with Obesity 511
John M. Jakicic, PhD

Chapter 42 Dietary Management of Overweight and Obesity 523
Nina Crowley, PhD, RDN, LD and Katherine R. Arlinghaus PhD, RDN

Chapter 43 A Clinical Approach to Pharmacological Management of the Patient with Obesity 530
Magdalena Pasarica, MD, PhD

Chapter 44 Surgery for Severe Obesity 540
Robert F. Kushner, MD

PART VIII Immunology and Infectious Disease

Chapter 45 Chronic Exercise and Immunity 553
Melissa M. Markofski and Michael G. Flynn

Chapter 46 HIV and Exercise 561
Jason R. Jaggers and Gregory A. Hand

Chapter 47 Exercise, Aging, and Immunity 568
Brandt D. Pence, PhD, Jeffrey A. Woods, PhD, and Yi Sun, PhD

PART IX Pulmonary Medicine

Chapter 48 Respiratory Symptoms 577
Jeremy B. Richards, MD and Richard M. Schwartzstein, MD

Chapter 49 Asthma 595
Evan W. Jones and Stephen J. Krinzman

Chapter 50 Occupational and Environmental Lung Diseases 614
Shaun Toomey, Sunkaru Touray, Emil Tigas, and Nicholas A. Smyrnios

Chapter 51 Venous Thromboembolic Disease 624
Joseph Gallant, MD and Khabib Dgayli, MD

Chapter 52 Influenza 635
Lindsey E. Bazzone, MD, PhD

Chapter 53 Indoor Air Quality 647
Kyle T. Halligan and Anthony C. Campagna

Chapter 54 COVID-19 657
Monica Hinestroza Jordan, MD and Sandeep Singh Jubbal, MD

PART X Obstetrics, Gynecology, and Women's Health

Chapter 55 Preconception, Pregnancy, and Postpartum Care 669
Nancy L. Eriksen, MD, Dip ABLM and Kristi R. VanWinden, MD

Chapter 56 Menstrual Health and Menopause 689
Amanda McKinney, MD, FACOG, FACLM

Chapter 57 Female Breast and Gynecologic Cancer 693
Amber Orman, MD, Dip-ABLM, Gautam Krishna Koipallil, MD, MPH, Meghana Reddy, MD, Hari Krishna Koipallil, BS, Amy Comander, MD, DipABLM, and Michelle Tollefson, MD, Dip-ABLM

Chapter 58 Cardiovascular Disease, Diabetes, Obesity, and Lifestyle Medicine Considerations in Women 704
Neha Pathak MD, FACP, DipABLM

PART XI Cardiovascular Rehabilitation and Secondary Prevention

Chapter 59 Using Digital Health Technology to Promote Cardiovascular Disease Risk Reduction in Secondary Prevention 715
Neil F. Gordon, MD, PhD, MPH, FACC, Richard D. Salmon, DDS, MBA, Mandy K. Salmon, MD, and Prabakar Ponnusamy, MS

Chapter 60 Psychosocial Risk Factors as Modulators of Cardiovascular Outcomes in Secondary Prevention 725
Joel W. Hughes, PhD and David Ede, PhD

Chapter 61 Lipid Management in Secondary Prevention 735
Antonio B. Fernandez, MD and Stephanie J. Saucier, MD

Chapter 62 Counseling Coronary Heart Disease Patients about Their Body Weight: Implications Regarding the Obesity Paradox 740
Nadia Isabel Abelhad, MD, Peter G Pantlin, MD, Sergey Kachur, MD, and Carl J. Lavie, MD, Richard V Milani, MD

Chapter 63 Vitamins and Supplements: Evidence in the Prevention and Treatment of Cardiovascular Disease 750
Jenna M. Holzhausen, PharmD, BCPS and Aaron D. Berman, MD, FACC

PART XII Lifestyle Components of Pediatric Medicine

Chapter 64 Pediatric Preventive Medicine: An Introduction 765
Richard E. Boles, PhD, Jonathan R. Miller, PhD, and Stephen R. Daniels, MD, PhD

Chapter 65 Cardiovascular Risk and Physical Activity in Children 776
Peter T. Katzmarzyk, PhD

Chapter 66 Cardiovascular Risk and Diet in Children 786
Carly Faulkner, MS, RD, Sarah Couch, PhD, RD, and Jessica Hemingway, MS, RD

Chapter 67 Sleep and Obesity Prevention in Children and Adolescents 794
Jill L. Kaar, PhD and Stacey L. Simon, PhD

Chapter 68 Childhood Obesity 804
Jaime Moore, MD, MPH and Matthew Haemer, MD, MPH

Chapter 69 Identification and Management of Children with Dyslipidemia 817
Rachel J. Shustak, MD MSCE, Julie A. Brothers, MD, and Stephen R. Daniels, MD, PhD

Chapter 70 Diagnosis, Management, and Treatment of Systemic Hypertension in Youth 830
Carissa M. Baker-Smith, MD, MPH, MS and Samuel Gidding, MD

PART XIII Lifestyle Medicine and Nursing

Chapter 71 Lifestyle Nursing: Lifestyle Medicine and Nursing 843
Gia Merlo, MD, MBA, MEd and Carolyn Sweetapple, RN, PhD, MBA

Chapter 72 Code of Ethics, Self-Care, and Historical Changing Roles of Nurses 849
Deborah Chielli, MSN, APRN, AGNP-C, DipACLM and Janine Santora MSN, APRN, FNP-C, CNRN, SCRN

Chapter 73 Nursing Educators' Perspectives on Integrating Lifestyle Medicine into the Nursing Curriculum 857
Elizabeth R. Click, DNP, ND, RN, CWP and Gia Merlo, MD, MBA, MEd

Chapter 74 Staff Nurse Clinical Application of Lifestyle Medicine 864
Karen Laing, MSN, APRN, AGPCNP-BC, DipACLM, HWNC-BC, CHES

Chapter 75 Advanced Practice and Specialized Nursing Approaches to Lifestyle Medicine 871
Elizabeth Simkus, DNP, MSN, RN, FNP-C

PART XIV Mental Health and Psychiatry in Lifestyle Medicine

Chapter 76 Lifestyle Psychiatry: An Overview 879
Gia Merlo, MD, MBA, MEd, Steven G Sugden, MD, MPH, DipABLM, and Liana Abascal, PhD, MPH, DipACLM

Chapter 77 The Neuroscience of Brain Health 887
Sandra Bond Chapman, PhD, Ian H Robertson, PhD, Jennifer Zientz, MS, CCC/SLP, Harris Eyre, MD, PhD, Geoff Ling, MD, PhD, and Mark D'Esposito, MD

Chapter 78 Diet and Exercise Interventions in the Management of Psychiatric Disorders: Mechanism and Efficacy 896
Jonathan Burgess, MD, MPH, Patrick Ho, MD, Brigid Riedy, BA, and Douglas L. Noordsy, MD

Chapter 79 Risk and Protective Factors for Mental Health 904
Alyssa M Vela, PhD, Allison Young, MD, Samuel Kohlenberg, PhD, and April Hirschberg, MD

Chapter 80 Biopsychosocial Implications and the Prevention and Management of Chronic Illnesses 910
Christopher P. Fagundes, PhD and Jensine Paoletti, PhD

PART XV Preventive Neurology

Chapter 81 The Influence of Lifestyle on Parkinson's Disease Management 919
Mohadese Golsorkhi, MD, Ayesha Sherzai, MD, and Khashayar Dashtipour, MD, PhD

Chapter 82 Sleep and Lifestyle Medicine 925
Param Dedhia, MD, Farah Wahbeh, and Dean Sherzai, MD, PhD, MPH, MAS

Chapter 83 Headache and Lifestyle Medicine 935
Charn Grewal, MD, Dean Sherzai, MD, PhD, MPH, and Kasra Maasumi, MD, MS

Chapter 84 Stroke and Vascular Brain Diseases 943
Vikas Ravi, MD, Dean Sherzai, MD, PhD, MPH, MAS, and Ayesha Sherzai, MD

Chapter 85 Alzheimer's Disease: Pathophysiology and Prevention 954
Selene Jamall, DO, Sharanya Thiagarajan, MS-IV, and Dean Sherzai, MD, PhD, MPH, MAS

PART XVI The Practice of Lifestyle Medicine

Chapter 86 Definition of Lifestyle Medicine 967
George Guthrie, MD, MPH, CDCES, CNS, FAAFP, FACN

Chapter 87 Health Provider Core Competencies in Lifestyle Medicine 975
Liana Lianov, MD, MPH, FACPM, FACLM

Chapter 88 Lifestyle Medicine Clinical Processes 985
Jeni Shull Clayton, MD, MPH, DipABLM, FACLM and Ingrid Edshteyn, DO, MPH

Chapter 89 Emotional Health and Stress Management 1017
Neil Nedley, MD and Francisco E Ramirez, MD

Chapter 90 High-Intensity Therapeutic Lifestyle Change 1034
John Kelly, MD, MPH, FACLM

Chapter 91 Physician Health Practices and Lifestyle Medicine 1051
Erica Frank, MD, MPH, FACPM and Debora Holmes, MES

Chapter 92 Physician Burnout 1063
Gia Merlo, MD, MBA, MEd and James Rippe, MD

Chapter 93 Lifestyle Medicine Research 1071
Micaela Karlsen, PhD, MSPH and Kara Staffier, MPH

Chapter 94 Lifestyle Medicine around the World: The WHO Initiative to Combat Non-Communicable Diseases (NCDs) 1082
James M. Rippe, MD and Garry Egger, MD

PART XVII Substance Abuse and Addiction

Chapter 95 Addiction Section Introduction 1091
Joji Suzuki MD, Beth Frates MD, and Irena Matanovic

Chapter 96 History of Alcohol and Opioid Use and Treatment in the United States 1094
Sanchit Maruti, MD, MS and Steven A. Adelman, MD

Chapter 97 Behavioral Approaches to Enhancing Cigarette Smoking Cessation 1099
Joseph T. Ciccolo, PhD and Nicholas J. SantaBarbara, MS

Chapter 98 Alcohol Use Disorders: Diagnosis and Treatment 1110
Chwen-Yuen Angie Chen, MD and Sara C. Slatkin, MD

Chapter 99 Diagnosis and Treatment of Opioid Use Disorders 1125
Joseph R. Volpicelli, MD, PhD

Chapter 100 Cannabis Use Disorder and Treatment 1135
Julia M. Bujno, BS and Deborah Hasin, PhD

Chapter 101 Digital Health Technology for Behavior Change 1147
Bjorn Hansell, MD, Valerie Black, MBA, CWC, John Chan, MD, Christopher Dove, MD, PhD, Mindy Hong, PhD, MSPH, Patricia Zheng, MD, Courtenay Stewart, DO, Mark Berman, MD, FACLM, and Jeffrey Krauss, MD, DipABLM

Chapter 102 Psychosocial Interventions for the Treatment of Substance Use Disorders 1160
Saria El Haddad, MD, Miriam Chickering, RN, Monthe Kofos, DO, Kimberly Evans, MD, Diana Nguyen, DO, Leah A. Kofos, Esq., andErica Frank, MD, MPH, FACPM

Chapter 103 The Digital World and Addiction Treatment 1168
Mitika Kanabar MD MPH FASAM Dip ABLM, Miriam Chickering, RN, BSN, NE-BC, Monthe Kofos, DO, Leah A. Kofos, Esq., Roshan Bhad, MD DNB, and Erica Frank, MD, MPH, FACPM

PART XVIII Lifestyle Medicine in Geriatrics

Chapter 104 How Geriatrics Principles and Paradigms Can Inform Lifestyle Medicine Practice 1179
Jennifer D. Muniak, MD

Chapter 105 Addressing Physical Function, Sarcopenia, and Frailty through Lifestyle Medicine 1186
Hillary B Spangler, MD, David H. Lynch, MBBS, and John A Batsis, MD, AGSF

Chapter 106 Reducing Cognitive Decline through Lifestyle Medicine 1197
Mark Shehata, MD, MBA and Susan M. Friedman, MD, MPH

Chapter 107 Medication Management in Older Adults 1207
Rohit Moghe, PharmD, MSPH, DipACLM, CDCES

Chapter 108 What Matters: Geriatrics, Lifestyle Medicine, and Palliative Care 1218
Deborah Kempe Ames, MD, MPP, HMDC

Chapter 109 Healthy Aging: Impact of Loneliness and Social Isolation 1230
Paul Mulhausen, MD, MHS

Chapter 110 Caregivers: Bringing the Invisible Patient to the Forefront 1236
Kady Goldlist, MD

PART XIX Health Promotion

Chapter 111 Introduction to Health Promotion and Lifestyle Medicine 1245
Jane Ellery, PhD and Dee Edington, PhD

Chapter 112 Motivation as Medicine 1248
Jennifer S. Pitts, PhD and Alyssa B. Schultz, PhD

Chapter 113 Hybrid Health Promotion: Patient-Centric Digital Tools to Support Healthier Lifestyles 1251
Samantha Chown, BSc, MSc, Josée Thibodeau, RDN, and Anne Marie Kirby, CIS

Chapter 114 Community as a Catalyst for Healthier Lifestyles 1256
Jane Ellery, PhD and Peter Ellery, PhD

Chapter 115 International Health and Lifestyle 1262
Wayne N. Burton, MD, FACP, FACOEM

Chapter 116 Future Directions of Health Promotion: The Role of the Physician 1267
Alyssa B. Schultz, PhD

Chapter 117 "Responders" and "Non-Responders" in Exercise Studies 1270
Victor L. Katch, Professor Emeritus

Chapter 118 Health Promotion: History and Emerging Trends 1274
Michael D. Parkinson, MD, MPH, FACPM and Stephen T. Doyle, MS, MBA, RCEP

PART XX Exercise Psychology

Chapter 119 Mind/Body Interactions in the Exercise Domain: Stressing the Body to Improve Psychophysiological Functioning 1281
Allyson G. Box, PhD, Jonathan R. North, MS, and Steven J. Petruzzello, PhD

Chapter 120 Genetic Influences on Regular Exercise Behavior 1290
Eco J.C. de Geus, PhD and Matthijs D. van der Zee, MSc

Chapter 121 Influence of Physical Activity on Brain Aging and Cognition 1304
James M. Rippe, MD and Steven J. Petruzzello, PhD

Chapter 122 Physical Activity and Anxiety 1311
Katharina Gaudlitz, MSc, Brigitt-Leila von Lindenberger, MSc, Tim Aurich, and Andreas Ströhle, MD

Chapter 123 Physical Activity and Depression 1323
Chad D. Rethorst, PhD, Darragh O'Sullivan, BS, and Matthew P. Herring, PhD, FACSM

PART XXI Injury Prevention

Chapter 124 Injuries and Lifestyle Medicine 1339
David A. Sleet, PhD, Michael F. Ballesteros, PhD, and Judith R. Qualters, PhD

Chapter 125 Motor Vehicle Crashes, Injuries, and Deaths: Epidemiology and Prevention 1347
Merissa A. Yellman, MPH, Bethany West, MPH, and David A. Sleet, PhD

Chapter 126 Drowning Prevention 1362
Tessa Clemens, PhD and Briana Moreland, MPH

Chapter 127 Improving the Care of Children with Mild Traumatic Brain Injury: CDC's Evidence-Based Pediatric mTBI Guideline 1370
Kelly Sarmiento, MPH, Angela Lumba-Brown, MD, Matthew J Breiding, PhD, David Paulk, EdD, PA-C, Kenneth Vitale, MD, and David Sleet, PhD

Chapter 128 Older Adult Falls: Epidemiology and Effective Injury Prevention Strategies 1378
Robin Lee, PhD, Ramakrishna Kakara, MPH, and Gwen Bergen, PhD

Chapter 129 Suicide Prevention: CDC's Approach to Prevention 1386
Elizabeth M. Gaylor, MPH, Deborah M. Stone, ScD, MSW, MPH, and Alex E. Crosby, MD, MPH

PART XXII Public and Environmental Supports for Lifestyle Medicine

Chapter 130 Healthcare Reform and Lifestyle Medicine in the Post-COVID-19 Era: Moving Forward 1397

Gregory W. Heath, DHSc, MPH, FACSM, FAHA and Steven Fox, MD

Chapter 131 Policy and Environmental Supports for Physical Activity, Active Living, and Healthy Eating 1413

Elizabeth A. Dodson, PhD, MPH, Charlene Schmidt, PhD, RDN, LDN, Marissa McElrone, PhD, RDN, Nicholas Boer, PhD, MPH, Emily Maddux, MS-MPH, RD, LDN, ACE® CHC, Karissa Peyer, PhD, Steven Fox, MD, and Gregory W. Heath, DHSc, MPH, FACSM, FAHA

Index 1431

Preface

The field of lifestyle medicine continues to rapidly expand offering the potential for enormous health benefits around the world. I am proud that I named this field in the academic literature with the first edition of this textbook which was published in 1999. Now with the fourth edition of *Lifestyle Medicine,* we continue to see how the field has grown in stature and expanded in scope.

There is no longer any serious doubt that daily habits and actions profoundly impact both short and long-term health and quality of life. An overwhelming medical and scientific literature underscores these concepts. Literally thousands of studies provide evidence that regular physical activity, maintenance of a healthy body weight, not smoking cigarettes, following sound nutritional practices, reducing stress, getting healthy sleep and other health promoting practices all profoundly impact health. Recent studies have deepened our understanding in all of these areas.

Conversely, an inactive lifestyle, obesity, high levels of stress and cigarette smoking or exposure to cigarette smoke and other pollutants as well as poor nutritional habits all significantly and negatively impact on health.

Since the publication of the third edition of *Lifestyle Medicine* (CRC Press, 2019) the positive literature about lifestyle choices and health has continued to grow stronger, and the scientific basis has deepened and broadened. The field of lifestyle medicine has continued to expand around the globe and multiple new initiatives such as the World Health Organization initiative to combat non-communicable diseases emphasizing key lifestyle habits and practices have sprung up over the last few years.

As the field of lifestyle medicine has grown and expanded, so has the *Lifestyle Medicine* text in order to serve the needs of an increasing number of individuals who are incorporating lifestyle medicine practices in various components of health care. The fields impacted by lifestyle medicine include not only practicing physicians but also public health officials and physicians in virtually every branch of medicine. Serving these diverse audiences remains the goal of the fourth edition of *Lifestyle Medicine.*

The devastating impact of COVID-19 has further underscored why lifestyle medicine modalities are so important. Individuals who have high blood pressure, who are obese, who smoke cigarettes, or who have significant risk factors for heart disease, all disproportionately suffered morbidity and mortality from COVID-19. This pandemic also underscored the vital importance of continuing to work to achieve health equity. Disadvantaged populations, particularly in minority populations such as Hispanics and Blacks suffered three to four times the mortality of Caucasians from COVID-19 in the United States. These underserved populations often do not have access to adequate medical care and often live in crowded inner-city environments. Major health organizations such as the American Heart Association, the American College of Physicians and the American College of Lifestyle Medicine have all articulated important initiatives to address and improve health equity.

The fourth edition of *Lifestyle Medicine* has been thoroughly rewritten and updated and also incorporates a number of new sections and chapters which address the needs and concerns of lifestyle medicine practitioners as well as a wide variety of other healthcare providers and physicians throughout the world.

As always, the fourth edition of *Lifestyle Medicine* focuses on the evidence-base for lifestyle medicine procedures and practices. This has been the goal since the first edition of this textbook. The enormous strength and literature are underscored by the incorporation of lifestyle recommendations in virtually all evidence-based guidelines addressing the prevention and treatment of metabolic diseases. For example, the following guidelines and consensus statements from various prestigious medical organizations all provide an emphasis on lifestyle medicine principles and practices as key components of the prevention and treatment of disease.

- JNC VIII Guidelines for Hypertension, Prevention and Treatment
- ACC/AHA Guidelines for the Prevention, Detection, Evaluation and Treatment of High Blood Pressure 2018
- NCEP (ATP IV) Guidelines for Blood Cholesterol
- Institute of Medicine Guidelines for Obesity Treatment
- ACC/AHA Scientific Consensus Statement on the Treatment for Blood Cholesterol
- Guidelines from the American Diabetes Association for the Management of Diabetes
- Dietary Guidelines for Americans 2020–2025
- American Heart Association Nutrition Implementation Guidelines
- Guidelines from the American Academy of Pediatrics for the Prevention and Treatment of Childhood Obesity
- Guidelines from the American Academy of Pediatrics for the Treatment of Pediatric Blood Pressure
- Guidelines from the American Academy of Pediatrics for the Treatment of Lipids
- Guidelines from the American Heart Association and the American Academy of Pediatrics for the Prevention and Treatment of the Metabolic Syndrome
- American Heart Association Strategic Plan for 2020

- Joint Statement from the American Heart Association and American Cancer Society for the Prevention of Heart Disease and Cancer
- Presidential Advisory from the AHA and American Stroke Association
- AHA/ACC/TOS Guideline for the Management of Overweight and Obesity in Adults
- ACS/ADA/AHA Scientific Statement on Preventing Cancer, Cardiovascular Disease and Diabetes
- Physical Activity Guidelines Advisory Committee Report of 2018
- The AHA/ACC Guidelines for the Management of Blood Cholesterol
- Adult Treatment Panel from the Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adult
- 2013 AHA/ACC Guideline on Lifestyle Management to Reduce Cardiovascular Risk
- Recommendations for Cardiovascular Health and Disease Surveillance for 2030 and Beyond: A Policy Statement from the American Heart Association
- 2021 American Heart Association (AHA) Scientific Statement on Dietary Guidance to improve Cardiovascular Health
- The AHA Guidelines for Detection, Evaluation, and Treatment of High Blood Pressure
- World Health Organization Executive Summary for Non-Communicable Disease Initiative

Unfortunately, despite the widespread recognition of these evidence-based guidelines and consensus statements about the important role of lifestyle measures and practices in the prevention and treatment of metabolic diseases, progress in these areas has been frustratingly slow in populations around the world. In the United States, for example, consider the following:

- Cardiovascular disease remains the leading killer of both men and women in the United States, resulting in over 37% of all mortality every year and has multiple lifestyle factors as underlying risk factors.
- Over 75% of the adult population in the United States does not achieve enough physical activity to result in health benefits.
- Over 72% of the adult population in the United States is either overweight or obese
- The prevalence of pediatric obesity has tripled over the last 20 years.
- Only 12% of the adult population in the United States consume adequate levels of fruits and only 7% consume the recommended amount of vegetables.
- 15% of individuals still smoke cigarettes.
- Over 40% of the adult population in the United States has high blood pressure.

The difficulty of achieving healthy lifestyle habits and practices is a worldwide problem. The World Health Organization estimates that 71% of worldwide mortality comes from non-communicable diseases and most of the risk of these diseases comes from lifestyle habits and practices.

An enormous body of scientific evidence demonstrates that positive lifestyle factors dramatically lower risk factors for chronic disease. One good example involves the Nurses' Health Study, where it was reported that 80% of all heart disease and over 91% of all diabetes in women, could be eliminated if they adopted a cluster of positive lifestyle practices including maintenance of a healthy body weight (body mass index of 19–25 kg/m^2), regular physical activity (30 minutes or more on most days), not smoking cigarettes, and following a few simple nutritional practices such as increasing whole grains and consuming more fruits and vegetables. The same was true for men. The US Health Professionals Study showed similar dramatic reductions of risk in men from those with positive lifestyle factors. Even if individuals adopted only one of these positive factors, their risk of developing coronary artery disease and diabetes would be cut in half. Unfortunately, numerous studies have shown that fewer than 5% of adults in the United States follow most or all of these health promoting practices.

Large, randomized trials have also shown the power of daily habits and practices. For example, the Diabetes Prevention Program followed individuals with baseline glucose intolerance who increased their physical activity and lost 5% of their body weight. These individuals reduced their risk of developing diabetes by 58%.

In the LOOK AHEAD Trial, individuals who lost 7% of their body weight significantly reduced risk factors for heart disease and diabetes. In both of these large, randomized controlled trials, over 90% of initial weight loss was maintained over four years for individuals who continued to follow the program and received periodic follow up from health professionals.

The literature relating lifestyle practices and habits and their impact on health continues to grow deeper and more complex. This presents a challenge for physicians and other health care professionals trying to keep up to date on this ever-expanding field and incorporating these findings into modern medical practice. The literature is also complicated because it is spread over a wide variety of disciplines. This provides the rationale for why the need for a comprehensive, evidence-based textbook spanning the field of lifestyle medicine has become even more evident in the last four years since the publication of the third edition of this textbook which, is a major goal for the fourth edition of *Lifestyle Medicine*.

In the first edition of *Lifestyle Medicine* in 1999 we coined the term "lifestyle medicine" and summarized key findings across multiple disciplines that existed in the late 1990's. Since the publication of this first edition of *Lifestyle Medicine* a number of other initiatives have taken place, including the launch of a peer reviewed academic journal

in lifestyle medicine (the *American Journal of Lifestyle Medicine*; SAGE Publications). Consensus statements about the core principles of lifestyle medicine have also been published in the *Journal of the American Medicine Association* as well as in the *American Journal of Lifestyle Medicine*.

In addition, an academic medical society in lifestyle medicine, the American College of Lifestyle Medicine (ACLM), has been established for physicians and other health care workers. This organization currently has more than 11,000 members and is the most rapidly growing health care organization within academic medicine. ACLM has also launched numerous important initiatives in education and the practice of lifestyle medicine.

In addition to ACLM, other medical and professional groups have increasingly embraced the concept of lifestyle medicine. These include the American Heart Association which now has a changed the name of its council from the "Nutrition, Physical Activity and Metabolic Council" to the "Council on Lifestyle and Cardiometabolic Health." The American Academy of Family Practice and the American College of Preventive Medicine now also offer education tracks for individuals interested in adding lifestyle medicine as a key component of their medical practices.

The field of lifestyle medicine has now spread around the world. Over 40 countries have now established lifestyle medicine programs. These programs reflect the enormous interest and potential of lifestyle medicine to exert a positive impact on global healthcare. For example, I was pleased to give the opening keynote address for the third annual China Healthy Lifestyle Medicine conference held in 2023 in Shenzhen, China sponsored by the Fuwai Hospital in Beijing in conjunction with its newly established Center for Lifestyle Medicine. The interest in lifestyle medicine in China is staggering. Over 2.5 million individuals participated virtually in the plenary session and viewed my keynote address.

The international growth of lifestyle medicine coincides with the major initiative announced by the World Health Organization to combat non-communicable diseases (NCDs). As already indicated, the WHO states that over 71% of all mortality each year is caused by NCDs. The recommended modalities to ameliorate this worldwide pandemic involve multiple lifestyle medicine modalities such as increased physical activity, weight management, avoidance of cigarette smoking and reduction in excessive use of alcohol. It is clear that lifestyle medicine has now become a worldwide initiative with the potential to improve the health of every country on earth.

All of these advances are welcome and will enhance the likelihood of formal adoption of lifestyle medicine practices within the medical community. Unfortunately, at the current time, less than 40% of physicians routinely counsel their patients on such important habits and actions such as weight management, physical activity, and proper nutrition. This is a squandered opportunity since more than 75% of adults see their primary care physician at least once per year. This gap between evidence and application represents an enormous mandate and opportunity to underscore the links between lifestyle habits and practices and health outcomes.

So, what is "lifestyle medicine?" In the first edition of this textbook, I defined it as "the integration of lifestyle practices into the modern practice of medicine both to lower the risk factors for chronic disease and/or, if disease is already present, serve as an adjunct in its therapy. Lifestyle medicine brings together sound, scientific evidence in diverse health related fields to assist the clinician in the process of not only treating disease, but also promoting good health." This definition, while over two decades old, has largely stood the test of time. Other organizations that have entered the area of lifestyle medicine have offered very similar definitions of lifestyle medicine and these definitions serve as the defining principle behind the fourth edition of *Lifestyle Medicine*.

The fourth edition of *Lifestyle Medicine* is divided into 22 sections related to lifestyle medicine. Each section has been edited by a leader of that particular discipline and chapters have been rewritten by recognized leaders within the discipline. All chapters have been fundamentally rewritten or substantially revised and brought up to date with current evidence and understanding of practices. There are also many new chapters and three new sections which have been added to reflect modern understandings in particular areas that have emerged which are critically important to lifestyle medicine.

The fourth edition of *Lifestyle Medicine* opens with Part I on *Lifestyle Management and Prevention of Cardiovascular Disease*. This was chosen as the initial section for several reasons. First, I am a cardiologist and my initial interest in lifestyle medicine came through issues related to lowering the risk of cardiovascular disease. Secondly, the area of cardiovascular medicine has been one of the leaders in recommending positive lifestyle habits and practices to reduce the risk of disease. These concepts are articulated both in the AHA Strategic Goals for the Year 2020 and for the AHA Impact Goals for 2030. The council that I sit on within the AHA has changed its name from the "Council on Nutrition, Physical Activity and Metabolism" to the "Council on Lifestyle and Cardiometabolic Health." This represents a welcome recognition of the key role that lifestyle plays in the prevention and treatment of heart disease. In addition, the most recently developed practice guidelines for cardiologists as well as the evidence-based recommendations for lipid management and high blood pressure management all start with the strong recommendation to focus on lifestyle as the foundational recommendation to lower the risk of heart disease. The 2021 nutritional guidance from the American Heart Association furthers this cause.

Part II is on *Nutritional Aspects of Lifestyle Medicine.* Nutrition plays a very prominent role in healthy lifestyle habits and actions. This section has been entirely updated and includes such new chapters on the Dietary Guidelines for Americans 2020-2025 as well as important chapters on

nutrition for elderly individuals and an important chapter on nutrition and hydration.

Part III is an expanded section on *Physical Activity.* This section focuses on state-of-the-art chapters on exercise prescription for various populations emphasizing what physicians should know about prescribing exercise and physical activity. I hope that this section will encourage physicians to play a more active role in this area. Physical activity remains one of the most powerful tools we have to lower the risk of chronic disease. The Physical Activity Guidelines for 2018 Advisory Committee report documented an expanded list of health benefits of physical activity throughout every stage of life ranging from the age of two to older adults. A recent emphasis on the health risks of an inactive lifestyle is also the focus of a new chapter in this section.

Part IV is an expanded and updated section on *Behavioral Medicine*. Understandings of how to change behaviors are foundational for virtually every aspect of lifestyle medicine. This section includes chapters outlining theoretical frameworks for how to apply psychological theories to promote healthy lifestyles and also contains chapters on Motivational Interviewing, and the Transtheoretical Model of Change and Positive Psychology. An important chapter is also included on the "Intention- Behavior Gap" which offers suggestions of how to bridge the gap between what individuals know they should do and what they, in fact, are actually doing. The chapter on coaching remains an important aspect of this area.

Part V contains a fundamentally reworked chapter on Approaches to Dysglycemia. This section includes recommendations for prevention and treatment of diabetes but puts them in a broader context of an emerging framework of Dysglycemia Based Chronic Disease which emphasizes how lifestyle factors can play a key role in all stages of Dysglycemia. In the chapter on Adiposity-Based Chronic Disease, the authors argue that this framework is a much more action-oriented approach to weight gain and obesity than previous concepts in this area.

Part VI is an expanded section on *Lifestyle Issues in the Prevention and Treatment of Cancer.* This includes not only chapters on physical activity and nutrition and cancer, but also tobacco, vaccines and weight control. Cancer is the second leading cause of morbidity and mortality in the United States and lifestyle measures can a play critically important role at all stages of life to lower risk factors or serve as an adjunct to therapy. This section was admirably edited by Dr. Nathan Berger. I am sad to report that Dr. Berger suddenly passed away just prior to the publication of this book. He will be missed.

Part VII is a detailed section on *Obesity and Weight Management* which provides modern understandings, not only on the epidemiology of weight gain and obesity, but also important chapters on pharmaceutical and surgical treatments in addition to both exercise and nutrition.

Part VIII explores issues related to *Lifestyle and Immunology and Infectious Disease*. It has been well known that regular physical activity can improve immunity and this section documents the theories of why this occurs.

Part IX on *Pulmonary Medicine* contains updated and expanded chapters on such critically important topics as Asthma, Influenza, and Indoor Air Quality. The chapter on Lifestyle Measures and their Impact on COVID-19 represents a new and important addition to this section.

Part X represents a combined section on *Obstetrics, Gynecology and Women's Health* dealing with these important issues throughout the lifespan.

Part XI contains important new chapters on *Cardiac Rehabilitation and Secondary Prevention* and is updated to include recent advances in digital health as well as lipid management and the pros and cons of various supplements and vitamins in the prevention and treatment of cardiovascular disease.

Part XII on *Lifestyle Components of Pediatric Medicine* is written by recognized experts in this area. This section spells out in detail the importance of lifestyle measures at every stage of life, even prior to birth. Chapters in this section provide guidance for lifestyle medicine practitioners to help families explore, and if necessary, treat issues of childhood obesity and potential complications such as high blood pressure and dyslipidemia in children. This comes at an important time since the prevalence of obesity in children has tripled in the last 20 years.

Part XIII represents a fundamentally new and important section in lifestyle medicine on *Lifestyle Medicine and Nursing.* Nurses are often the front line healthcare professionals who interact with individuals while making recommendations about lifestyle habits and practices. There are over four million registered nurses in the United States, which makes nursing the largest healthcare profession within the United States. For all of these reasons, the expansion of lifestyle medicine as a component of nursing practice is an important expansion of the purview for the fourth edition of *Lifestyle Medicine.*

Part XIV also represents a new section and emphasis in lifestyle medicine entitled *Mental Health and Psychiatry Issues in Lifestyle Medicine*. A significant overlap exists between psychiatric issues and metabolic issues so a section in this area is highly welcomed and an important expansion of the field of lifestyle medicine. Included in this section are important chapters on the treatment of various psychiatric issues such as anxiety and depression. An important chapter on lifestyle and brain health emphasizes that many of the factors which have been incorporated into cardiovascular medicine are also of great importance in the area of maintaining a healthy brain throughout life.

Part XV also represents a new section in the fourth edition entitled *Preventive Neurology.* Multiple chapters in this section elucidate how lifestyle medicine habits and practices impact not only on the likelihood of developing Alzheimer's Disease and other dementias but also on stroke and Parkinson's Disease. The chapter on Sleep and Lifestyle Medicine in this section emphasizes that sleep carries multiple health related implications. It is particularly important to have a comprehensive chapter on sleep since it is clear that sleep also plays very significant roles in cardiovascular medicine and other aspects of lifestyle medicine.

An increasing number of individuals have begun to make lifestyle medicine a cornerstone of their medical practice. For this reason, we have greatly expanded the section on *The Practice of Lifestyle Medicine* (Part XVI) to provide guidance for principles and practices of lifestyle medicine, both for individuals who want to have this area be part of their practice and also those who want to make it the cornerstone of their practice. There is now an emerging trend in lifestyle medicine involving individuals who want to obtain advanced understandings of the field. An important chapter on high intensity lifestyle medicine has been included in this section.

Part XVII on *Substance Abuse and Addiction* reflects the fact that lifestyle medicine practitioners often end up treating individuals with these issues in the course of their regular practice. There is abundant information in this section about how lifestyle habits and practices impact on both the likelihood of abusing substances and how to treat addiction.

Positive lifestyle habits and actions are critically important at every stage of life. This is particularly important for individuals over the age of 65 who represent the fastest growing portion of the United States population. Individuals who reach the age of 65 have an 80% chance of reaching the age of 80. Individuals who reach the age of 80 live an average of 8-10 years longer. For all these reasons, it is important to emphasize the role of lifestyle medicine in geriatrics. This is core motivating principle behind the

greatly expanded section on "*Lifestyle Medicine in Geriatrics"* (Part XVIII). In addition to lifestyle issues related to the geriatric population valuable chapters include how to manage the stresses and strains of caregivers which are often underestimated. Issues related to loneliness, which is an increasing problem in the geriatric population, is also a focus of this section as well as the role of lifestyle medicine practices and habits to lower the risk of polypharmacy which occurs commonly in the geriatric population. All of these factors impact on the emerging concept of "successful aging" which underscores lifestyle and health benefits for individuals over the age of 65.

Part XIX on *Health Promotion* is an important and historically prominent component of lifestyle medicine. This section in the third edition of *Lifestyle Medicine* was under the able direction of Dr. Dee Edington, a pioneer in health promotion. Sadly, Dr. Edington passed away in the midst of editing this section and it was admirably completed by his colleague Dr. Jane Ellery. Diverse topics of health promotion and their role in both corporate America and for individuals are elucidated in chapters in this section.

The multiple psychological benefits of regular physical activity are well known. In fact, in one survey of regular exercisers 75% indicated that the major reason why they exercise is for stress reduction. I can say in my own life that while as a cardiologist I am very well aware of how my daily exercise sessions lower my risk of heart disease and helps me maintain a healthy body weight. I also view daily exercise as a powerful health promotion tool. Part XX on *Exercise Psychology* describes in detail the interactions between mind and body. In fact, in this section, the authors start with the conviction that the separation between mind and body is artificial and that we ought to be thinking of a unified whole. Important chapters on regular physical activity and its powerful effect on anxiety and depression are important. Perhaps most attractive about this section is the concept of cognitive reserve. Regular exercisers seem to delay the likelihood of dementia and increase regular cognitive performance through their long-term exercise habits.

Injuries are the leading cause of morbidity and mortality for individuals under the age of 40. Part XXI written largely by experts from the CDC provides detailed evidence on how to prevent or treat this common occurrence.

Lifestyle changes do not occur in isolation; thus, public policy issues play an important role either in the environment or policies which can support or undercut individuals' ability to improve their health through lifestyle measures. The final part of this book, Part XXII on *Public Policy and Environmental Supports for Lifestyle Medicine* makes critical linkages between how public health and environmental conditions can play an important role in supporting individuals' efforts to improve their life and health through regular habits and actions.

The daunting task of generating this comprehensive and up to date volume of *Lifestyle Medicine* involves the hard work, talent and expertise of 24 section editors who have devoted enormous energy and talent to the difficult tasks of organizing and editing each section of the fourth edition of *Lifestyle Medicine* to ensure that each chapter is scientifically accurate, up to date and clinically useful. These section editors have recruited and interacted with over 325 distinguished contributors to a textbook which I hope and believe is not only evidence-based but clinically useful and motivational for clinicians and other healthcare professionals at all levels of training. We have also sought to make the book practical by providing state of the art summaries and practical applications of modern science and medical understandings in each chapter.

We have further emphasized clinical utility in the fourth edition of *Lifestyle Medicine* by asking each author to list "key points" at the beginning of each chapter and "Clinical Applications" at the end of each chapter. These additions, I hope, will help introduce key concepts in each chapter and guide readers through practical applications of information with the hope that this will enhance its applicability in the daily practice of medicine. The overarching goal, of course, remains to help all of our patients lead happier, healthier, and more productive lives, while also lowering their risk of chronic diseases and enhancing their quality of life.

Over the two and a half decades since the publication of the first edition of *Lifestyle Medicine*, important and extensive new information has been developed to provide scientific links between daily habits and actions and their critical impact on short and long-term health and quality of life. What started out as an aspirational idea has now grown into a worldwide movement.

As always, a key consideration for those of us in the healthcare community remains applying these understandings to the modern practice of healthcare in general and medicine in particular. Making a positive impact on lifestyle habits and actions which are the cornerstone of lifestyle medicine is, in my view, the single, greatest opportunity that we have to improve health outcomes and lower cost. This is absolutely essential to underscore and advance the value proposition in the practice of medicine. Enhancing health continues to be the challenge and enormous opportunity for all of us who are entrusted and blessed as gatekeepers for the health of our patients of our country. I hope that the fourth edition of *Lifestyle Medicine* will continue to support the magnificent efforts of all who strive to enhance the health for themselves and their patients.

Serendipity and Important Milestones

With the publication of the fourth edition of *Lifestyle Medicine*, we celebrate the 25th anniversary of the publication of the first edition of this textbook. This is also serendipitous since, also this year, we celebrate the 20th anniversary of the establishment of the American College of Lifestyle Medicine which was founded and inspired by the first edition of this textbook.

About the Editor

James M. Rippe, M.D., is a graduate of Harvard College and Harvard Medical School with postgraduate training at Massachusetts General Hospital and the University of Massachusetts Medical School. He is currently the Founder and Director of the Rippe Lifestyle Institute and Professor of Medicine at the UMass Chan Medical School.

Over the past 30 years, Dr. Rippe has established and run the largest research organization in the world exploring how daily habits and actions impact short- and long-term health and quality of life. This organization, Rippe Lifestyle Institute, has published hundreds of papers that form the scientific basis for the fields of lifestyle medicine, risk factor reduction, and high performance health. Rippe Lifestyle Institute also conducts numerous studies every year on physical activity, nutrition, and healthy weight management. Dr. Rippe has written over 500 academic papers and abstracts and written or edited 60 books, including 37 for health care professionals and 23 for the general public.

A lifelong and avid athlete, Dr. Rippe maintains his personal fitness with a regular walk, jog, swimming, and weight training program. He holds a black belt in karate and is an avid wind surfer, skier, and tennis player. He lives outside Boston with his wife, television news anchor Stephanie Hart, and their four children, Hart, Jaelin, Devon, and Jamie.

Acknowledgments—*Lifestyle Medicine*, Fourth Edition

Textbook writing and editing are truly collaborative efforts involving the hard work, skills, knowledge, and passion of numerous contributors. Many individuals have stimulated my thinking about the interaction between lifestyle and health for many years. These individuals are too numerous to acknowledge each by name, but I would like to particularly thank a few individuals who have made vital contributions to the fourth edition of *Lifestyle Medicine*.

First, my long-term Editorial Director, Beth Grady, who plays a critically important role in all the major writing and editing projects that emerge from my research organization. Beth deserves special thanks. The fourth edition of *Lifestyle Medicine* is one of over 60 books which have been generated through our organization that Beth has managed. In addition to the current textbook, Beth provides editorial direction to two academic journals which I edit, as well as a major intensive care textbook (*Irwin and Rippe's Intensive Care Medicine*, ninth edition, Wolters Kluwer, 2023). She also helps to coordinate numerous other academic endeavors and regularly interacts with hundreds of contributors to our various publications. Beth possesses superb editorial skills and puts in enormous effort with unfailing good humor to make these complicated and difficult projects possible.

I would also like to extend gratitude to the 24 section editors who contributed hard work, expertise, and exceptional editorial skills to ensure scientific accuracy and clinical relevance for each of the sections of this book. Special thanks go to the more than 325 scientists and healthcare professionals and clinicians who have contributed chapters to this textbook. These individuals, who are internationally known experts in key fields related to lifestyle medicine, have made invaluable contributions to the field and for this textbook while assembling and explaining enormous amounts of data in this rapidly emerging discipline.

I would also like to express my appreciation to my office support staff, including my Executive Assistant, Carol Moreau, who seamlessly coordinates my schedule and travel plans to free up the time necessary for such large writing and publishing projects. Our Office Assistant, Deb Adamonis, assists all of us in the multiple daily tasks required to expedite diverse projects in our office, while our Chief Financial Officers, Connie Martell and Wendy Graves, make sure that financial processes are in place for all of our projects to move forward smoothly. The research team at Rippe Lifestyle Institute has also contributed enormous insight over many years to clarify my thinking about numerous aspects of lifestyle medicine.

I would also like to thank the outstanding Editorial Team at Taylor and Francis/CRC Press. Included in this group are Randy Brehm, Senior Editor, who has been an early and key ongoing supporter of our textbooks; Tom Connelly, Editorial Assistant, who coordinated all aspects of the publication process and provided important day-to-day leadership and invaluable assistance on multiple issues related to manuscripts; Marsha Hecht, the Project Editor at Taylor and Francis Group/CRC Press who managed every step of the production process with expertise, patience, and knowledge; as well as Bryan Moloney, Project Manager at Deanta Global, who managed the editing, design, and typesetting of the book with great skill.

Finally, I am grateful to my family, including my loving wife, Stephanie Hart Rippe, and our four beautiful daughters, Hart, Jaelin, Devon, and Jamie, who continue to love and support me through the arduous process of writing and editing many major textbooks and journals and the other diverse professional responsibilities that I juggle along with my family life.

If there are errors or omissions in *Lifestyle Medicine*, the responsibility is mine. If there is credit due for this project, it belongs to the numerous people who have made substantial contributions along the way.

1 The Rationale for Intervention to Reduce the Risk of Cardiovascular Disease

James M. Rippe, MD

KEY POINTS

- Cardiovascular disease (CVD) remains the leading cause of death and disability in the United States and worldwide.
- Multiple risk factors increase the risk of CVD. Many of these risk factors have a significant lifestyle component.
- There has been a significant decrease in CVD mortality over the past four decades. Half of this decrease is due to lower risk factors. Increases in several risk factors, however, including obesity and diabetes, threaten to wipe out gains in all other risk factors.
- If individuals followed the four positive daily lifestyle measures—maintain proper weight, do not smoke cigarettes, engage in regular physical activity, and follow sound nutritional patterns (more fruits and vegetables, whole grains and fish), the prevalence of CVD could be decreased over 80%, and the prevalence of diabetes could be decreased over 90%.
- The American Heart Association (AHA) has recommended an emphasis on "primordial prevention," which is lowering the likelihood of developing risk factors in the first place.
- Physician visits are an ideal opportunity to stress the importance of lifestyle habits and practices to reduce the risk of CVD.

1.1 INTRODUCTION

Cardiovascular disease (CVD) remains the leading cause of death for both men and women in the United States each year[1]. Over 37% of all mortality in the United States comes from CVD.[1] Although knowledge of many factors contributing to CVD is incomplete, it is clear that many risk factors contribute in significant ways to the ongoing epidemic of CVD.

CVD is truly a pandemic and represents the most important cause of death worldwide. In 2020, CVD resulted in an estimated 17.9 million deaths and 293 million disability-adjusted life-years (DALYs) lost.[2] These represent approximately 32% of all deaths worldwide and 13% of all DALYs lost that year. The World Health Organization (WHO) lists CVD as the leading cause of death worldwide. This disease not only impacts high income countries but has become increasingly prevalent in both low and middle income countries, which have seen an alarming increase in CVD rates.

So prominent has been the role of certain lifestyle factors that it has been argued that the world is entering into a new epidemiologic transition. In the past four epidemiologic transitions, the predominant causes of death have been identified, starting with pestilence and famine, then receding pandemics, followed by degenerative and man-made diseases, and finally, delayed degenerative diseases. It has been argued that the modern world may be entering a fifth epidemiologic phase highlighted by inactivity and obesity/diabetes, both of which contribute in significant ways to CVD.[3]

Lifestyle habits and practices constitute a significant contributor to this ongoing epidemic. While progress has been made in some of these areas (e.g., hypertension, total cholesterol, smoking cessation, physical activity), unfortunately, regression has occurred in such areas as obesity and diabetes.[4,5] The increasing prevalence of these latter two conditions has the potential to wipe out progress made on all the other lifestyle related risk factors for CVD.[3]

In addition to its human cost, CVD also represents an enormous financial drain in the United States. It has been estimated that over $219 billion per year is spent on direct medical expenses and other associated costs related to CVD.[6,7]

Lifestyle factors play a particularly prominent role in the development and pathogenesis of CVD. Indeed, five of the major risk factors for developing CVD relate to lifestyle practices, including the following: the choice of whether or not to use tobacco products, level of physical activity, control of lipids, diabetes, and obesity.[8]

This chapter will focus on the rationale for intervening to reduce risk factors for CVD. The next chapter will discuss applications of lifestyle interventions in clinical practice to reduce the risk of CVD.

Deaths from CVD and stroke have been declining in the United States for the past four decades. For example,

DOI: 10.1201/9781003227793-2

between 1963 and 1990, the mortality of coronary heart disease fell by more than 50%.[9] Nonetheless, CVD and stroke remain the leading causes of morbidity and mortality in the United States and in most other industrialized countries. The decline in CVD and stroke is a result of not only reduced prevalence of risk factors but also advances in treatment and therapies. Nonetheless, the increased prevalence of diabetes, obesity, and an aging population work against reductions in CVD and stroke prevalence and require expanded efforts to reduce lifestyle related risk factors in order to continue reducing the burden of CVD.

Between1980 and 2000, the decline in age related death for coronary heart disease (CHD) led to an estimated decrease of 341,745 deaths.[4] About half of this decline resulted from improvements and advances in treatment, while approximately 44% related to risk factor reduction. An estimated 149,635 fewer deaths from CVD came from improved treatment[4] of some of its risk factors, while an estimated 59,370 increase in deaths occurred from the higher rates of obesity and diabetes.[4] The increasing prevalence of obesity and diabetes has the potential to completely wipe out the advances in the reduction of other risk factors if the trends of these two lifestyle risk factors are not reversed.

Despite advances in reducing certain lifestyle related risk factors for CVD, these factors remain extremely common. For example, the prevalence of hypertension in the United States has continued to increase, with recent data suggesting that more than one-third of American adults have high blood pressure, as defined by systolic BP >140 and diastolic BP >90 mmHg or taking antihypertensive medicines.[9,10] The Surgeon General's Report on Physical Activity and Health documented that over 70% of the adult population in the United States fail to get enough regular physical activity to lower their risk of CVD,[11] despite the fact that the 2018 Physical Activity Guidelines for Americans demonstrate multiple health benefits for virtually every population group.[12] Overweight and obesity have continued to rise in the United States, with over 73% of the population showing one of these two conditions.[13]

The epidemic of diabetes (T2DM) in the United States continues to rise, with approximately 9% of the adult population currently suffering from this chronic condition—almost double the rate of 20 years ago.[14] After several decades of encouraging declines in cigarette smoking, progress unfortunately appears to have leveled off in this area, with about 15% of the overall adult population in the United States still smoking. Thus, some progress in reducing risk factors has occurred, but enormous challenges and opportunities remain for applying lifestyle measures, often in conjunction with pharmaceutical therapy, to reduce the risk of CVD.

1.2 THE PATHOPHYSIOLOGY OF ATHEROSCLEROSIS

As knowledge of the pathophysiology of atherosclerosis has advanced, new understandings have provided crucial linkages to the role of various lifestyle interventions in reduction of the risk of CVD. For example, poor diet (e.g., elevated consumption of saturated fats and calories, etc.) and diminished physical activity have been known for years to contribute to atherogenesis.[16,17] However, only in the past decade has the significant role of inflammation as an initiating event in the process of atherosclerosis begun to be elucidated. Since multiple related entities such as CHD, obesity, diabetes, glucose intolerance, and the metabolic syndrome have significant overlap, it may indeed be a component of systemic inflammation that unites all of these processes.

Fundamental to the understanding of the interplay between lifestyle and atherosclerosis is the evolving concept of the role of various structures and the interaction of components of both normal and diseased arteries (e.g., endothelium, smooth muscle, and intima) as well as how various cells in these structures function both in health and in disease.[16,18]

The evolving understanding of the biology of atherosclerosis is beyond the scope of the current chapter. The reader is referred to several recent excellent reviews that discuss current understandings of the atherosclerotic process in detail.[19–21]

1.3 UNDERSTANDING RISK FACTORS

1.3.1 The Concept of Risk Factors

The concept of risk factors is relatively new in the history of medicine. In fact, until the initial findings from the Framingham study were published in the 1960s, the concept of risk factors for CVD did not formally exist.[22] Framingham data showed that factors such as diabetes,[23–26] dyslipidemia,[27–31] high blood pressure,[32–35] and cigarette smoking[36–39] each independently and significantly increased the risk of CVD. The concept of CVD risk factors has been expanded to include physical inactivity[40] and obesity.[41] Other emerging risk factors where lifestyle habits and practices may play a role are under active investigation.

Framingham data also demonstrated that risk factors act synergistically and tend to cluster with each other.[42] Thus, in the presence of two risk factors, an individual quadruples their chance of developing CVD compared with individuals having no risk factors. Individuals with three risk factors increase their risk of developing CHC between 8- and 20-fold compared with individuals having no risk factors.[43]

In addition to the lifestyle related risk factors identified by the Framingham study and other observational and interventional studies, other risk factors have been determined, including age, gender, family history of CVD, elevated C-reactive protein (CRP), hemostatic factors, excessive alcohol consumption, hypertriglyceridemia, elevated homocysteine levels, and perhaps stress and other psychological factors such as depression.

Numerous studies have demonstrated that reducing risk factors for CVD can significantly decrease its likelihood.[44–46] Lifestyle measures are a particularly powerful and effective way of lowering risk factors, since these

measures are low risk and many of them simultaneously affect multiple risk factors.

1.3.2 Evidence Based Alternatives to "Risk Based" Approaches to the Prevention of Cardiovascular Disease

With the widespread use of statin medications, the "risk based" approach to prevention has now been challenged by many cardiologists in the area of primary prevention. Since the data on safety for statins are now prevalent, even for individuals at the lower end of absolute vascular risk as determined by currently available risk profiles such as the Framingham Heart Risk Score, preventive cardiologists have recently focused more attention on establishing risk profiles based on what works and in whom as a more evidence based and simpler approach to the complex model of previously existing risk factor scales. Cardiologists in the United States, Canada, and Europe have suggested five recommendations for simple and easily understood guidelines for the use of statin therapy in the prevention of CVD. The recommended five components of guidelines for the use of statin therapy are as follows:

1. On the basis of a quality, randomized clinical trial data (RCT), statin therapy should be used as an adjunct to diet, exercise, and smoking cessation for secondary prevention in individuals with a previous history of myocardial infarction (MI), stroke, or clinically apparent atherosclerosis.
2. High quality RCTs support the use of statin therapy as an adjunct to diet, exercise, and smoking cessation as a component of primary prevention for individuals over the age of 50 with diabetes, elevated low density lipoprotein (LDL) cholesterol, low high density lipoprotein (HDL) cholesterol or elevated high sensitive C-reactive protein (hs-CRP), or multiple risk factors.
3. On the basis of high quality RCTs, in prescribing statin therapy, physicians should seek to maximize the intensity of the regimen and then focus efforts on compliance and long-term adherence.
4. On the basis of high quality RCTs, the use of non-statin lipid lowering agents for mono-therapy or in combination with a statin should be limited while awaiting evidence that such an approach further reduces cardiovascular event rates in specific patient groups.
5. Guidelines based on trial evidence (to determine what works) and on trial entry criteria (to ascertain in whom) are simple, practical, and consistent with evidence based principles and should, therefore, result in broad clinical acceptance.

This fundamentally different approach based on evidence based alternatives from RCTs, particularly as they relate to the use of statins, has been widely accepted now in the preventive cardiology community.

It has been argued that this approach will be more effective in providing appropriate statin therapy for individuals at lower to middle risk from previous risk assessments such as the Framingham Risk, the Reynold's Risk, or the European System Coronary Risk Evaluation (SCORE). Previously available scores have typically been more effective in targeting lifestyle interventions for individuals at the highest risk. New, evidence based guidelines are thought to be more effective in recognizing individuals at lower or intermediate risk and reserving aggressive, pharmacologic interventions to those with "higher" risk profiles. It should be noted that in this new approach to cardiovascular prevention, lifestyle therapies are still a key component in all of the recommendations.

1.3.3 Relative Risk versus Absolute Risk

It is important to differentiate between "relative" and "absolute" risk, since this distinction underlies treatment strategies for risk factor reduction in CVD. *Relative risk* is a comparison between different risk levels. This estimates the likelihood that an individual who possesses a specific risk factor will develop CVD in comparison to an individual without that risk factor. *Absolute risk* represents the likelihood of developing CVD over a specified period of time. Framingham risk scores, for example, typically assess the absolute risk of developing CVD over a ten year period.

The difference between relative and absolute risk is a critical factor in clinical decision making. For example, a young individual with abnormal lipids would be treated differently than an older individual with a similar lipid profile, all other things being equal, since while their increased relative risk may be the same, their absolute risk may be quite different.[47–49]

One way of viewing relative risk may be that it provides an indication of how rapidly an individual may move to absolute risk. Thus, a young individual with high relative risk would be at greater risk of ultimately developing high absolute risk, motivating the clinician to devise strategies for lowering risk as a means of slowing the early stages of developing CVD. Interventions such as lifestyle measures, which carry multiple benefits and relatively little risk and expense, are attractive means for lowering both relative and absolute risk of CVD.

1.3.4 Primary versus Secondary Prevention

It is also important to distinguish between "primary" and "secondary" prevention when approaching risk factor reduction. Primary prevention is based on the goal of preventing or delaying the development of CVD, while secondary prevention focuses on interventions designed to reduce the likelihood of repeat cardiovascular events and/or mortality in individuals who already have established CVD. More aggressive measures for risk factor reduction

are typically indicated in individuals when they are used in secondary prevention.

Guidelines for risk factor reduction in primary prevention are available from a variety of sources. The most widely used is still the Framingham Risk Scoring system.[50]. Guidelines for interventions for secondary prevention have also been published by the AHA and are discussed in detail in **Chapters 60 and 61** later in this book.

1.4 PRIMORDIAL PREVENTION AND "IDEAL" CARDIOVASCULAR HEALTH

In 2010, the AHA issued a strategic plan through the year 2020 and beyond.[51] New to this plan was a concept of "primordial" prevention. The goal of primordial prevention as articulated by the AHA is "by 2020 to improve the cardiovascular health of Americans by 20% while reducing deaths from cardiovascular and stroke by 20%." In issuing this statement, the AHA recognized and declared that "[h]ealth is a broader, more positive construct than just the absence of clinically evident disease." It defined "primordial" prevention as a process to avoid adverse levels of risk factors in the first place rather than trying to reduce risk factors when they are already present or treating already established disease. This broader risk factor reduction strategy is completely consistent with the goals and vision of lifestyle medicine and will require careful attention to daily lifestyle habits and actions and their impact on risk factors and overall health.

The AHA Strategic Plan[51] also defined a construct of "ideal" cardiovascular health, which was defined as the following:

> The simultaneous presence of four favorable health behaviors: absence of smoking within the last year, physical activity at goal, consumption of a "heart healthy" dietary pattern and an ideal body mass index (BMI).
>
> "Ideal" cardiovascular health included as well as four favorable health factors: untreated cholesterol less than 200 mg/dL, untreated blood pressure less than <120/<80 mm Hg, and the abstinence of diabetes mellitus, absence of clinical cardiovascular disease (including CVD, stroke, heart failure, etc.).

Clearly, this very welcome framework will result in an increased emphasis on physicians treating, and patients following, positive lifestyle behaviors to improve their cardiovascular health.

1.5 IMPLEMENTING RISK FACTOR REDUCTION GUIDELINES

Another welcome trend in the area of risk factor reduction comes from the Dietary Guidelines for Americans 2020–2025,[52] Physical Activity Guidelines for Americans 2018,[12] and American Heart Association Scientific Statement on Implementing Pediatric and Adult Nutrition Guidelines.[53] All three of these guidelines have emphasized real world, practical implementation of guidelines. This is an important and new emphasis from these three widely read and influential documents.

1.6 THE SCIENTIFIC BASIS FOR RISK FACTOR REDUCTION

Multiple observational and interventional studies, including the Framingham Study,[54] the Nurses Health Trial,[55] the US Male Professional Health Trial, and the Women's Health Initiative,[56] have all demonstrated the link between risk factors and developing CVD as well as the power of reducing risk factors to reduce the likelihood of developing CVD. Results from these and other studies form the basis for recommendations in the following sections of this chapter on specific risk factors.

1.7 EVIDENCE-BASED VERSUS RISK-BASED STRATEGIES FOR PREVENTION OF CARDIOVASCULAR DISEASE

As already indicated, as new evidence has become available over the last decade from large randomized trials, some have advocated that guidelines for strategies to prevent cardiovascular disease should be based on clinical trial evidence rather than epidemiologic evidence.[57,58] This has been particularly useful when thinking about when to use statin medications for prevention of cardiovascular disease. Preventive cardiologists in the United States, Canada, and Europe have combined a list of recommendations on clinical trial data concerning when to use statins in the prevention of cardiovascular disease.[59,60] This strategy has been memorized as "what works" and "in whom." These recommendations will be handled in more detail in Chapter 2.

1.8 MODIFIABLE RISK FACTORS

This section will focus on risk factor reduction for those risk factors that can be modified, while the next section will focus on those risk factors that cannot be modified. The modifiable risk factors represent a particularly important area for clinical intervention. Numerous studies have demonstrated that the use of lifestyle measures for reducing modifiable risk factors is an effective strategy for reducing the risk of developing CVD.

1.8.1 Tobacco Use

Cigarette smoking is the leading preventable cause of death from all causes in the United States and the single most prevalent modifiable risk factor for the development of CVD.[61] CVD causes 35–40% of smoking related deaths, and an additional 8% of deaths have been attributed to second hand smoke exposure.[62–64]

Unfortunately, following many years of decline in cigarette smoking prevalence in the United States, the percentage of adults who smoke has recently stabilized at about 15%.[15] Rates of tobacco use are actually increasing among adolescents, young adults, and women.[15]

The link between cigarette smoking and increased risk of CVD has been established in multiple studies. Individuals who consume 20 or more cigarettes per day have a two- to threefold increase in CVD. Framingham study data demonstrated that cardiovascular mortality increases by 31% in women and 18% in men for each ten cigarettes smoked per day.[65] Multiple observational studies have also shown that smokeless tobacco and low tar cigarettes do not reduce the risk of CVD.

Numerous studies have demonstrated that smoking cessation improves longevity and reduces the risk of CVD.[66] Thus, stopping cigarette smoking remains the single most important intervention in preventive cardiology and lifestyle medicine. Smoking cessation yields significant benefits in a relatively short period of time.[67] In one study comparing 1,282 cigarette smokers with 2,068 controls, the risk of developing CVD amongst those individuals stopping cigarette smoking approached the level of never smokers within three years.[66] In addition to contributing greatly to the risk of CVD, cigarette smoking also significantly increases the likelihood of developing lung cancer and chronic obstructive pulmonary disease.

Despite the important and powerful health benefits of cigarette smoking cessation, the medical community has not been active enough in this area. The Centers for Disease Control and Prevention (CDC) estimates that only slightly more than half of smokers who had at least one physician visit in the previous year reported they were advised to quit smoking cigarettes.[67,68] The impact of spouse, friends, and families on cigarette smoking cessation is also significant. Recent studies suggest that smoking cessation by a spouse decreases an individual's chance of smoking by 67%, while smoking cessation by a co-worker, sibling, or friend contributes to a decrease of 25–36% in a person's likelihood of smoking.[69]

1.8.2 Dyslipidemias

Numerous trials have demonstrated that a variety of dyslipidemias or a combination of dyslipidemias increase the risk of CVD.[45,70–80]

1.8.3 Elevated Low Density Lipoprotein Cholesterol and Hyperlipidemia

Hypercholesterolemia has been clearly associated with increased risk of CVD. In particular, increased plasma levels of LDL have been associated with increased incidence of CVD. Based on these data, the Nutrition Cholesterol Education Program Adult Treatment Panel Guidelines (ATP III) established LDL as the primary target for intervention.[74] Numerous observational trials, including the Framingham study, MRFIT, the Nurses' Health Study, and the US Male Health Professional follow up study, have all demonstrated an association between elevated blood cholesterol and increased risk of CVD. Numerous interventional studies have also established that elevated blood cholesterol and in particular, elevated LDL is associated with increased incidence of CVD.[70–80] Several lines of evidence have suggested that what are regarded as "normal" cholesterol levels in Western society are higher than is necessary for good health. Furthermore, cholesterol levels measured early in life influence long-term cardiovascular risk, suggesting that cholesterol should be routinely measured in children. These studies have become particularly robust since the development of hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins). These agents lower LDL cholesterol much more efficiently than previously available drugs. Numerous, large clinical trials where statins have been utilized to lower LDH cholesterol by 20–60% reduced coronary events by up to one third over a five-year period without evidence of increased non-vascular mortality.[44]

1.8.4 Low Levels of HDL Cholesterol

A number of prospective cohort studies have also demonstrated an inverse relationship between HDL cholesterol and risk of CVD. Conversely, low HDL increases the risk of CVD.[44] Each increase in HDL cholesterol by 1 mg/dL is associated with a 2–3% decrease in risk of total cardiovascular disease.[44,80] Low HDL cholesterol has been defined as an HDL lower than 40 mg/dL. Levels lower than this are defined as an independent risk factor for CVD in the National Cholesterol Education Program (NCEP) Guidelines. Moreover, the NCEP Adult Treatment Panel (ATP III) Guidelines support an HDL level of >60 mg/dL as a negative risk factor for CVD.[81] It should be noted that several recent trials of novel pharmaceutical agents designed to raise HDL have been somewhat disappointing and have resulted in untoward side effects such as hypertension. Trials such as the "AIM-HIGH" study, which randomly allocated high risk patients to niacin supplementation, increased HDL cholesterol and reduced triglycerides, yet did not yield reductions in clinical events.[82] Furthermore, in the Investigation of Lipid Level Management to Understand its Impact on Atherosclerotic Events (ILLUMINATE), individuals at higher vascular risk who were given the Cholesterylester Transfer Protein (CETP) inhibitor torcetrapib actually showed an unanticipated increase in all-cause mortality.[83] Despite these negative results, HDL cholesterol level as a "negative risk factor" for CVD is strongly supported by both cross-sectional and prospective studies, which support its continued use in guidelines worldwide.

1.8.5 Hypertriglyceridemia

Triglycerides tend to vary inversely with HDL. An association between elevated triglyceride levels and cardiovascular

disease has been known for many years.[84,85] However, the evidence supporting a direct linkage is less robust than that for elevated LDL or low HDL and CVD. Recent attention has been focused on elevated triglycerides as a risk for heart disease, given its association with obesity, insulin resistance, and diabetes. Statements from the AHA on Childhood and Adolescent Obesity and on Triglycerides and Cardiovascular Health emphasize the importance of lowering triglycerides through lifestyle measures as a means of lowering risk of CVD.[86] Current designations for triglyceride levels are as follows: 150–199 mg/dL borderline high, 200–499 mg/dL high, and >500 mg/dL very high. Overall, 31% of the adult population in the United States has a triglyceride level ≥150 mg/dL.[84,85]

1.8.6 Hypertension

High blood pressure constitutes a significant increased risk of CVD. The prevalence of hypertension has increased steadily in the United States over the past ten years.[87] According to the report of the Joint National Committee on Prevention, Evaluation and Treatment of High Blood Pressure (JNC VII), more than one out of every three adults suffers from high blood pressure.[87] This means that more than 50 million individuals have high blood pressure.[87] A subsequent report based on data from a recent National Health and Nutrition Evaluation Survey (NHANES III) places the number even higher at 38% of the population (65 million individuals).[88] Even individuals who have normal blood pressure at the age of 55 have a 90% risk of developing hypertension during their lifetime, according to data from the Framingham Heart Study.[89]

The relationship between blood pressure and the risk of CVD events is independent of other risk factors for CVD. For every 10 mmHg rise in diastolic blood pressure or 20 mmHg rise in systolic blood pressure above 115/75 mm Hg, the increase in risk of CVD doubles.[87]

The JNC VII guidelines create a lower than previously established guideline for normal blood pressure (below 120/80 mmHg) and created a new category of "prehypertension" to replace the old category of "high normal." The JNC VII classification for blood pressure in adults is found in Table 1.1.[87]

High blood pressure is also frequently found co-existing with other risk factors for CVD.[88,89] For example, individuals with high blood pressure have a greater than 40% chance of having elevated blood cholesterol.[90–92] This is particularly important, since over half of heart disease occurs in individuals with two or more risk factors. JNC VII guidelines recommend a six month trial of lifestyle related measures such as weight loss, smoking cessation, regular exercise, and improved nutrition for individuals with Stage 1 hypertension before starting pharmacologic therapy.[87]

It should be noted that a commission was established to formulate JNC VIII guidelines and made somewhat different recommendations.[93] The JNC VIII guidelines contain the following statement:

> There is strong evidence to support treating hypertensive individuals aged 60 or older to a BP goal of less than 150/90 mmHg and hypertensive patients 30–59 years of age to a diastolic goal of less than 90 mmHg; however there is insufficient evidence in hypertensive persons younger than 60 years for a systolic goal or for those younger than 30 years for a diastolic goal. So the panel recommends a BP of less than 140/90 mmHg for those groups based on expert panel.

The attempt from the JNC VIII guidelines was to make the blood pressure control recommendations based on

TABLE 1.1
Classification of Management of Blood Pressure for Adults 18 Years or Older

BP classification	Systolic BP, mm Hg*		Diastolic BP, mm Hg*	Management*		
				Lifestyle modification	Initial drug therapy	
					Without compelling indication	With compelling indications
Normal	<120	and	<80	Encourage		
Prehypertension	120–139	or	80–89	Yes	No antihypertensive drug indicated	Drug(s) for the compelling indications†
Stage 1 hypertension	140–159	or	90–99	Yes	Thiazide-type diuretics for most; may consider ACE inhibitor, ARB, β-blocker, CCB, or combination	Drug(s) for the compelling indications; other antihypertensive drugs (diuretics, ACE inhibitor, ARB, β-blocker, CCB) as needed
Stage 2 hypertension	≥160	or	≥100	Yes	2-Drug combination for most (usually thiazide-type diuretic and ACE inhibitor or ARB or β-blocker or CCB)‡	Drug(s) for the compelling indications; other antihypertensive drugs (diuretics, ACE inhibitor, ARB, β-blocker, CCB) as needed

Abbreviations: ACE, angiotensin-converting enzyme; ARB, angiotensin-receptor blocker; BP, blood pressure; CCB, calcium channel blocker.
*Treatment determined by highest BP category.
†Treat patients with chronic kidney disease or diabetes to BP goal of less than 130/80 mm Hg.
‡Initial combined therapy should be used cautiously in those at risk for orthostatic hypotension.

evidence from randomized control trials. However, these recommendations have not been widely adopted. The JNC VIII guidelines emphasize that while these targets have been articulated, people's judgement should still prevail in hypertensive therapy.[93] Of note, both JNC VII and JNC VIII recommend lifestyle interventions such as regular aerobic exercise, eliminating salt intake, maintenance of proper healthy weight, and not smoking cigarettes as the cornerstone of any antihypertensive regimen. The 2017 report from the AHA and American College of Cardiology (ACC) presents guidelines roughly similar to JNC VIII and will be discussed in the next chapter.[94]

1.8.7 Diabetes and Glucose Intolerance

The incidence of type 2 diabetes, which represents a major risk factor for CVD, has increased dramatically in both men and women in the United States over the past 30 years. Diabetes now affects over 9% of adults.[14] Perhaps of even greater importance is that an estimated 35–40% of adults have impaired glucose tolerance or impaired fasting glucose levels.[95] In one study, the prevalence of glucose intolerance in individuals over the age of 75 years was 80%. Diabetes is also one of the most common chronic diseases in the world, affecting an estimated 285 million adults in 2010 (6.4% of the global adult population).[95] It is estimated that the prevalence of diabetes will grow to more than 430 million individuals (7.7% of the global adult population) by the year 2030.[14] Diabetes represents a significant risk factor for CVD. Individuals with diabetes have between two and eight times higher rates of cardiovascular events compared with nondiabetic controls.[91] This risk factor is particularly potent in women with diabetes, who increase their risk of developing CVD three- to sevenfold compared with a two- to threefold increased risk in men. The increase in diabetes parallels the increase of obesity in the United States.[92] It has been estimated that individuals born in the United States in the year 2000 will have a 36% chance of developing diabetes in their lifetime.[95]

For all of these reasons, prevention, early detection, and treatment of diabetes assume great importance as a modality for reducing the risk of CVD. Typical treatment involves multiple components of lifestyle measures such as weight loss for individuals who are overweight or obese, proper diet using medical nutrition therapy, and regular physical activity.

1.8.8 Obesity

The prevalence of overweight and obesity has increased significantly in the United States and other developed countries over the past 30 years. It is estimated that over 73% of the adult population in the United States is now overweight or obese.[13] Increases have been particularly prominent in the area of Stage 1 obesity and severe obesity. Between 1980 and 2004, the prevalence of obesity amongst adults in the United States doubled. In 2018, it was estimated that 38% women and 35% of men in the United States were obese.[13] Numerous studies have demonstrated that obesity constitutes a strong and independent risk factor for CVD in addition to its association with other risk factors such as dyslipidemia, diabetes, and hypertension. The AHA classifies obesity as a major risk factor for CVD because of these associations.

The most practical and recognized way of assessing obesity in clinical practice is to determine an individual's BMI. BMI has also been shown in numerous studies to correlate with health risk. BMI classifications, according to the Institute of Medicine,[96] are listed in Table 1.2.

The linkages between obesity and CVD are not completely understood, although they are probably mediated

TABLE 1.2
Classification of Overweight and Obesity as Recommended by the National Heart, Lung, and Blood Institute Guidelines

	Disease risk[a] relative to normal weight and waist circumference			
			Waist circumference	
	BMI (kg/m²)	Obesity class	<102 cm (men)<88 cm (women)	>102 cm (men)>88 cm (women)
Underweight	<18.5		–	–
Normal[b]	18.5–24.9		–	–
Overweight	25.0–29.9		Increased	High
Obesity	30.0–34.9	1	High	Very high
	35.0–39.9	2	Very high	Very high
Extreme obesity	≥40.0	3	Extremely high	Extremely high

[a]Disease risk for type 2 diabetes, hypertension, and cardiovascular disease.
[b]Increased waist can also be a marker for increased risk in normal weight individuals.
BMI, body mass index.

not only by direct effects on the cardiovascular system (a hyperdynamic state and increased blood flow) but also through systemic inflammation. Adipocytes used to be considered relatively inactive storage depots; however, recent studies have shown that in fact, adipocytes are very metabolically active and generate a variety of inflammatory markers such as interleukin-6 (IL-6), tumor necrosis factor alpha (TNF),[100] and C-reactive protein (CRP).[96–99] Excess weight is also associated with a variety of novel risk factors, including an atherogenic dyslipidemia (low HDL-C, elevated triglycerides, elevated apoprotein B, and elevated LDL). In addition, obesity is associated with elevations in thrombotic factors such as Plasminogen Activator Inhibitor I and increased levels of fibrinogen.[101,102]

The distribution of body fat is also strongly and independently associated with CVD over and above increased body weight. In particular, increased abdominal obesity has been demonstrated to increase the risk of CVD.[103–105] A practical way of estimating abdominal obesity is to measure waist circumference. A waist circumference of ≥40 inches in men and ≥35 inches in women confers a significantly increased risk of CVD compared with lower levels of abdominal fat.

Adult weight gain also confers additional risk of CVD. According to the Nurses' Health Study[106] and US Men's Health Professional Study,[10] individuals who gained 20 lbs or more during their adult life significantly increased their risk of type 2 diabetes and CVD.[108]

1.8.9 Inactive Lifestyle

Physical activity carries multiple health benefits.[12] Unfortunately, the population in the United States (both children and adults) has become increasingly inactive. Numerous studies have demonstrated that an inactive lifestyle significantly increases the risk of CVD. In one study, fitness level was more strongly associated with heart disease than any other risk factor, including cigarette smoking and hypertension.[109] The Physical Activity Guidelines for Americans 2018 (PAGA 2018) lists multiple significant benefits for increased physical activity,[12] as demonstrated in Table 1.3.

There is strong evidence that regular physical activity lowers the risk of high blood pressure, adverse lipid profiles, type 2 diabetes, the metabolic syndrome, and weight gain. In addition, regular physical activity also lowers the overall risk for CVD, risk for stroke, and all-cause mortality.

The Healthy People 2010 Initiative recommended the goal that at least 30% of the population over the age of six should engage in light to moderate physical activity of at least 30 minutes per day. This goal has been repeated in the Healthy People 2020 guidelines[110] and the 2030 guidelines.[111] Clearly, we are falling far short of these goals. The Surgeon General's Report on Physical Activity documented that 24% of individuals report no recent physical activity, 54% are active but fall short of the recommendations from Healthy People 2020, while only 22% of adults achieve this level of activity.[110]

It should be emphasized that even very small amounts of physical activity substantially reduced the risk of both all-cause mortality and heart disease. As depicted in Figure 1.1, steep decreases in the risk of overall mortality in cardiovascular mortality occur for individuals who engage in physical activity at even the level of 30 minutes per week.

Further reductions occur up to the recommended 150 minutes of moderate physical activity per week, while even further reductions in risk occur beyond this recommended level in the PAGA 2018. However, the benefits of substantial increases beyond 150 minutes per week are much smaller than those of the first 150 minutes per week. (These benefits are depicted graphically in Figure 1.1.)

According to the PAGA 2018, over half of all adults do not obtain enough physical activity, and almost 32% of adults are classed as "inactive." The levels of physical activity for adults are found in Figure 1.2.

Numerous guidelines, including those from the AHA, the American College of Sports Medicine (ACSM),[109] the Centers for Disease Control (CDC), and the PAGA 2018,[12] all consistently recommend that adults accumulate at least 30 minutes of moderate intensity physical activity on most, if not all, days. The Physical Activity Guidelines for Americans 2018 provides an alternative of 75 minutes per week of vigorous intensity physical activity.[12] Definitions of low, medium and high physical activity are found in Table 1.4.

Recently, a corollary to the physical activity issue has been raised, with studies suggesting that excessive time spent sitting, particularly watching television or screen time, correlates with increased risk of CVD. A meta-analysis of prospective cohort studies estimated that if every adult in the United States decreased sitting time to less than three hours per day, the life expectancy of the population would increase by 2.0 years. In addition, if every adult reduced television viewing time to less than two hours a day, life expectancy would increase by 1.4 years.[112]

Numerous studies have shown that physician recommendation is a powerful motivator to change lifestyle habits, including level of physical activity. Moreover, several studies support the finding that if the physician him- or herself is physically active, they are more likely to recommended physical activity to their patients.[113,114] The most common form of physical activity recommended by physicians (first choice of over 90% of physicians) is walking.[114]

1.8.10 Poor Nutritional Habits

A large body of research supports a linkage between nutritional habits and risk of CVD. The AHA Guidelines for Pediatric and Adult Nutrition,[115] the Dietary Guidelines for Americans 2020–2025,[52] and the AHA's Strategic Impact Goal Plan through 2020 and Beyond all recommend nutrition intervention to lower the risk of CVD. These guidelines are consistent in recommending lower fat, higher fiber, increased consumption of fruits and vegetables, and control of calories to maintain a healthy body weight.[115]

TABLE 1.3

Physical Activity-Related Health Benefits for the General Population and Selected Populations Documented by the 2018 Physical Activity Guidelines Advisory Committee

Children	
3 to <6 years of age	**Improved bone health and weight status**
6 to 17 years of age	**Improved cognitive function (ages 6 to 13 years)**
	Improved cardiorespiratory and muscular fitness
	Improved bone health
	Improved cardiovascular risk factor status
	Improved weight status or adiposity
	Fewer symptoms of depression
Adults, all ages	
All-cause mortality	Lower risk
Cardiometabolic conditions	Lower cardiovascular incidence and mortality (including heart disease and stroke)
	Lower incidence of hypertension
	Lower incidence of type 2 diabetes
Cancer	Lower incidence of **bladder**, breast, colon, **endometrium, esophagus, kidney, stomach, and lung cancers**
Brain health	**Reduced risk of dementia**
	Improved cognitive function
	Improved cognitive function following bouts of aerobic activity
	Improved quality of life
	Improved sleep
	Reduced feelings of anxiety and depression in healthy people and in people with existing clinical syndromes
	Reduced incidence of depression
Weight status	**Reduced risk of excessive weight gain**
	Weight loss and the prevention of weight regain following initial weight loss when a sufficient dose of moderate-to-vigorous physical activity is attained
	An additive effect on weight loss when combined with moderate dietary restriction
Older adults	
Falls	Reduced incidence of falls
	Reduced incidence of fall-related injuries
Physical function	**Improved physical function in older adults with and without frailty**
Women who are pregnant or postpartum	
During pregnancy	**Reduced risk of excessive weight gain**
	Reduced risk of gestational diabetes
	No risk to fetus from moderate-intensity physical activity
During postpartum	**Reduced risk of postpartum depression**
Individuals with pre-existing medical conditions	
Breast cancer	**Reduced risk of all-cause and breast cancer mortality**
Colorectal cancer	**Reduced risk of all-cause and colorectal cancer mortality**
Prostate cancer	**Reduced risk of prostate cancer mortality**
Osteoarthritis	**Decreased pain**
	Improved function and quality of life
Hypertension	**Reduced risk of progression of cardiovascular disease**
	Reduced risk of increased blood pressure over time
Type 2 diabetes	**Reduced risk of cardiovascular mortality**
	Reduced progression of disease indicators: hemoglobin A1c, blood pressure, blood lipids, and body mass index
Multiple sclerosis	**Improved walking**
	Improved physical fitness
Dementia	**Improved cognition**
Some conditions with impaired executive function (attention deficit hyperactivity disorder, schizophrenia, multiple sclerosis, Parkinson's disease, and stroke)	**Improved cognition**

Benefits in **bold** font are those added in 2018; benefits in normal font are those noted in the 2008 Scientific Report. Only outcomes with strong or moderate evidence of effect are included in the table.

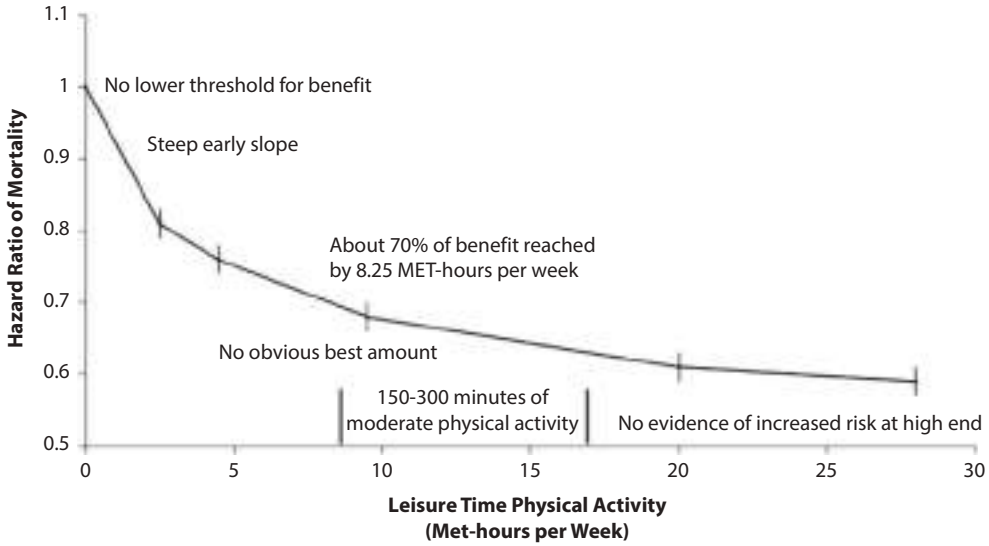

FIGURE 1.1 Relationship of moderate to vigorous physical activity to all-cause mortality with highlighted characteristics common to studies of this type. (From All-Cause Mortality. Cardiovascular Mortality and Incident Cardiovascular Disease. Part F. Chapter 6 in 2018 Physical Activity Guidelines Advisory Committee. 2018 Physical Activity Committee Scientific Report. Washington, DC, U.S. Department of Health and Human Services, 2018.)

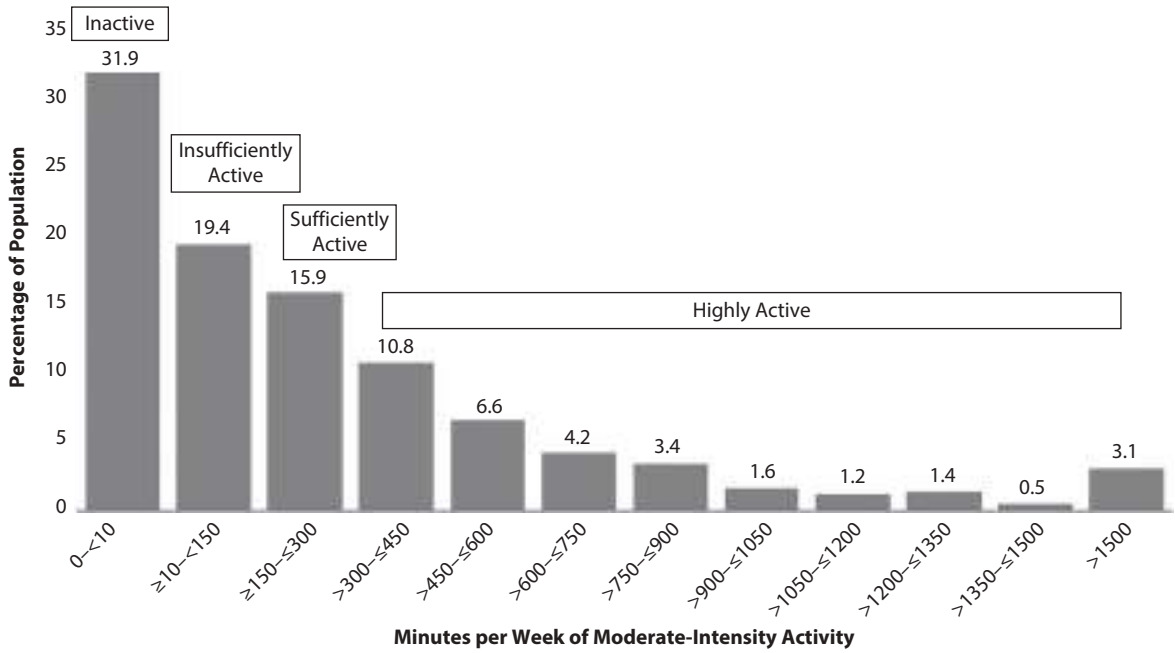

FIGURE 1.2 Distribution of self-reported volume of moderate-to-vigorous physical activity, 150 minutes per week increments, U.S. adults, 2015. (2018 Physical Activity Guidelines Advisory Committee. 2018 Physical Activity Guidelines Advisory Committee Scientific Report. Washington DC: U.S. Department of Health and Human Services, 2018. Adapted from the data found in the National Health Interview Survey, 2015.)

The AHA Strategic Plan for 2020[51] establishes the following metric for nutrition goals to lower the risk of CVD and states:

> in the context of diet that is appropriate in energy balance pursing an overall dietary pattern that is consistent with a DASH (Dietary approaches to Systolic Hypertension) type eating plan including, but not limited to:
>
> - Fruits and vegetables: ≥ 5 cups per day
> - Fish: ≥ two 3.5 servings per week (preferably oily fish)

TABLE 1.4
Classification of Levels of Physical Activity

Classification of Total Weekly Amounts of Aerobic Physical Activity Into Four Categories (Levels of Physical Activity)	Range of Moderate-Intensity (Minutes a Week)	Summary of Overall Health Benefits	Comment
Inactive	No activity beyond baseline	None	Being inactive is unhealthy.
Low	Activity beyond baseline but fewer than 150 minutes a week	Some	Low levels of activity are clearly preferable to an inactive lifestyle.
Medium	150 minutes to 300 minutes a week	Substantial	Activity at the high end of this range has additional and more extensive health benefits than activity at the low end.
High	More than 300 minutes a week	Additional	Current science does not allow researchers to identify an upper limit of activity above which there are no additional health benefits.

- Fiber rich whole grains: ≥ 1.1 g of fiber per 10 g of carbohydrate (≥ three one oz equivalent servings per day)
- Sodium: < 1,500 mg per day
- Sugar sweetened beverages: ≤ 450 kcal (36 oz) per week

While these recommendations do not cover all aspects of a heart healthy diet, they represent a good starting point for physicians counseling patients about improved nutritional practices to lower the risk of CVD. These recommendations have been expanded upon in recent reviews.[116,117] Some recent evidence has suggested that diets adhering to the principles of a Mediterranean style diet supplemented with extra virgin olive oil or nuts reduced the incidence of major cardiovascular events in individuals with high cardiovascular risk.[118] Evidence based guidelines for overall dietary health are summarized in the Dietary Guidelines for 2020–2025 report.[52]

1.9 NONMODIFIABLE RISK FACTORS

The risk factors described in the previous section can all be reduced through appropriate lifestyle practices and habits in patients' daily lives. There are also a number of nonmodifiable risk factors for CVD, which will be discussed in this section.

Although this second group of risk factors cannot be altered through lifestyle habits, they play an important role as part of the overall patient risk factor profile. Specifically, individuals who have significant nonmodifiable risk factors should be even more strongly counseled to make appropriate lifestyle changes to alter those risk factors that are modifiable.

1.9.1 Age

Strong and consistent evidence associates increased age with increased risk of CVD. Approximately 80% of all fatal myocardial infarctions occur in individuals over the age of 65.[119] Thus, in the elderly population, control of modifiable risk factors assumes increasing importance. Regular physical activity, weight management, and control of lipids and blood pressure are all important areas for physicians to counsel patients over the age of 65.

1.9.2 Gender

More women than men die each year of heart disease, although CVD typically occurs at a younger age in men than in women.[120] Framingham study data demonstrate that men typically display the onset of symptoms of CVD ten years younger than women.[120] It is important to note that symptoms of CVD may present differently in women than in men. The AHA "Wear Red" program has provided an important emphasis on reducing risk factors for heart disease in women.[121]

1.9.3 Family History

A positive family history of CVD before the age of 65 in a first degree relative constitutes an independent risk factor for CVD.[119] Why CVD tends to aggregate in some families is not completely understood, although it may be mediated through genetics or through risk factors that relate to lifestyle components, such as levels of physical activity, nutritional habits, dyslipidemias, or weight.

1.10 THE METABOLIC SYNDROME AND THE CONCEPT OF MULTIPLE RISK FACTORS

Framingham data clearly support that clustering of risk factors is common.[40] One type of clustering of risk factors has been referred to as the "metabolic syndrome." While there is ongoing debate about the criteria for the metabolic syndrome,[122] and numerous different definitions exist, the

one most commonly employed (such as in the National Cholesterol Education Program ATP III Guidelines) includes the following criteria:

- Waist circumference >40 inches
- Blood pressure >135/85 mmHg
- Fasting blood glucose >110 mg/dL
- HDL cholesterol <40 mg/dL
- Fasting triglycerides >150 mg/dL

According to the ATP III Guidelines, if an individual has three or more of these five criteria, he or she is considered to have the metabolic syndrome.

Individuals with metabolic syndrome are at significantly higher risk for both CHD and diabetes than the general population. The ATP III Guidelines recommend that an individual with the metabolic syndrome should be treated as though they already have CVD. Data from the Framingham study demonstrate that 60% of CVD is found in individuals who possess two or more risk factors.

Debate is ongoing about the exact mechanism through which metabolic syndrome increases the risk of CVD. Some investigators maintain that the mechanism is through insulin resistance.[123] Others have emphasized underlying inflammatory processes as part of the metabolic syndrome that link to increased risk of CVD.[124] While the metabolic syndrome and obesity are not synonymous, they are strongly linked to each other. According to Framingham study data, obese individuals have approximately a 50% chance of having at least two other risk factors for CHD.[43]

The increased prevalence of obesity in children has drawn attention to its linkage to the increasing prevalence of both diabetes and the metabolic syndrome in children.[125] While considerable controversy exists about the criteria for the metabolic syndrome in children, the AHA has recommended careful exploration for other risk factors for CVD in children who are obese.

It should also be noted that recent data support that metabolic syndrome also results in a pro-inflammatory state. This is recognized by the most recent definition of the metabolic syndrome by the National Heart, Lung and Blood Institute.[125] This observation is important, since a pro-inflammatory state also occurs in diabetes, hypertension and obesity.

1.10.1 Low Dose Aspirin Therapy

Low dose aspirin therapy has been demonstrated to clearly and consistently provide substantial net benefits for persons at high risk for subsequent events secondary to existing CVD.[126] Thus, for secondary prevention, anti-platelet therapy with aspirin yields substantial net benefits, and the use of low dose aspirin is recommended, unless there are major contraindications. The use of other anti-platelet agents with demonstrated efficacies, such as clopidogrel, should be limited to patients who have aspirin allergy or intolerance.

For the primary prevention of CVD, however, the role of aspirin is not straightforward.[127] This is because individuals without established CVD have a lower absolute risk of cardiovascular events and thus, less absolute benefit, despite the fact that the risk of major adverse effects, such as bleeding, remains the same. In 2016, the United States Preventative Services Task Force (USPSTF) supported a statistically significant 22% reduction in non-fatal MI and a borderline significant 6% benefit in total mortality, a non-significant 5% benefit for non-fatal stroke, and a 6% benefit for cardiovascular mortality with low dose aspirin therapy.[128] Bleeding is the major known liability of aspirin use and an important consideration in assessing the likely risk to benefit ratio of aspirin in primary prevention. Thus, the benefit of low dose aspirin in secondary prevention in individuals for CVD is established, and use of low dose aspirin for primary prevention remains in debate. Several large studies are addressing this concern.

1.11 EMERGING RISK FACTORS

Recent research has identified a variety of other risk factors that are associated to a greater or lesser degree with CVD. These risk factors are discussed in this section.

1.11.1 High Sensitivity C-Reactive Protein (hs-CRP)

Inflammation has been identified as a key component of atherosclerothrombosis and provides an important link between plaque formation and acute rupture.[129] CRP, which is a marker of inflammation, has been identified as a significant cardiovascular CVD risk marker.[130] Numerous prospective studies have demonstrated that hs-CRP independently predicts the risk of CVD.[131–136] These data also apply not only to individuals with existing CVD but also to healthy individuals, including both men and women at all age levels. Elevated hs-CRP is not only associated with obesity and diabetes but also found in increased prevalence in individuals who lead sedentary lifestyles or are cigarette smokers.[130] These findings carry significant practical implications for counseling individuals concerning a variety of lifestyle measures. Comprehensive meta-analyses of the hazard associated with CVD associated with hs-CRP have demonstrated that it may exceed the risks associated with either elevated blood pressure or cholesterol.[137] The Emerging Risk Factor Collaboration study showed that hs-CRP is as accurate as total HDL cholesterol in predicting future CHD events.[138] Individuals with elevated hs-CRP and low levels of LDL cholesterol have higher absolute risk of vascular disease than those with low levels of hs-CRP and elevated levels of LDL. For all these reasons, it appears clinically wise to include hs-CRP measurement along with lipid evaluation as a strategy for lowering the risk of CVD.[139]

Several of the statin medications have been demonstrated to lower CRP in additional to lowering LDL cholesterol, which carries significant implications for combining pharmaceutical therapies along with lifestyle measures.[140,141]

1.11.2 Other Markers of Inflammation

The relationship between CVD and inflammation is an area of active research. A variety of other markers of inflammation in addition to CRP have emerged as potential risk factors for CVD. Most prominently TNF-α and Interleukin-6 (IL-6) have been associated with increased risk of CVD, but the data supporting these relationships are not as advanced as with CRP.[44]

1.11.3 Hemostatic Factors

Factors that may contribute to thrombogenesis have also been associated with increased risk of CVD. Factors currently under investigation that may contribute to thrombogenesis include Plasminogen Activator Inhibitor I (PAI-1), fibrinogen,[141–143] and coagulation Factor VII.

1.11.4 Homocysteine

Elevated levels of homocysteine, an amino acid derived from the degradation of methionine, have been associated with increased risk of CVD. Although the epidemiologic evidence is somewhat diverse, on average a 25% lower homocysteine level appears to be associated with approximately 11% lower risk of CHD in the general population. Homocysteine elevations are typically found in diets that are low in folate. In countries such as the United States where folate supplementation occurs, the prevalence of elevated homocysteine is significantly reduced. While laboratory tests are available to assess homocysteine, studies attempting to reduce the risk of CVD by reducing homocysteine levels have not yielded promising results.[144,145] Thus, homocysteine is not currently included as part of a risk factor profile.

1.11.5 LDL Subclasses and Particle Size

Laboratory tests are available to determine the amount of cholesterol carried by individual lipoprotein particles, which are characterized by their particle size. Some studies have suggested that small, dense LDL particles may be more atherogenic than larger LDL particles.[146,147] Of note, small, dense LDL particles have been associated more frequently with obese individuals and individuals with abdominal obesity than normal weight individuals. The data have not established the association between LDL particle size and CVD risk at a level that is useful for risk factor reduction strategies.

1.11.5.1 Lipoprotein (a)

Lipoprotein (a) is an LDL particle linked to a protein by a disulfide bridge. A number of studies have supported the role of LP(a) as a determinant of vascular risk.[148] However, it remains uncertain that LP(a) contributes further sensitivity or specificity to standard risk factor reduction strategies.[149]

1.12 OTHER RISK FACTORS

A variety of other risk factors for CVD have been either identified or postulated to potentially influence the likelihood of its development.

1.12.1 Levels of Antioxidants

Initial observational studies including the Health Professional Follow-up Study[150] and the Nurses' Health Trial[151] showed an association between high levels of vitamin E and other antioxidants and reduced risk of CVD. Subsequent interventional trials, however, have not corroborated these findings.[152] The AHA does not currently advocate antioxidant supplementation as a means of reducing CVD risk.

1.12.2 Alcohol

Alcohol consumption exerts a variety of effects on the overall cardiovascular system. A number of studies have demonstrated that moderate alcohol consumption reduces the overall risk of CVD.[153] "Moderate" alcohol consumption is typically defined as no more than one to two beers, one to two glasses of wine, or one to two "shots" of distilled spirits daily. Men are typically able to drink higher amounts of alcohol within the moderate range than women because of higher levels of alcohol dehydrogenase—the enzyme in the liver that breaks down alcohol. The mechanism by which moderate alcohol consumption may reduce the risk of CHD is attributed to either increasing HDL or decreasing platelet aggregation.[154] In contrast, alcohol consumption of three alcoholic drinks per day or more has been associated with increased risk of hypertension, overall risk of heart disease, congestive heart failure, a variety of gastrointestinal cancers, and motor vehicle accidents. Thus, a U-Shaped Curve[155] relationship exists relating the risk of CVD and alcohol consumption. Any individual or population wide recommendation for levels of alcohol consumption must consider the complexity of this relationship.[156]

1.12.3 Stress and Type A Personality

Some studies have supported the concept that personality type may contribute to the risk of CVD; however, these data remain controversial and inconclusive.[157,158] In particular, the anger element of Type A personality (a Type A personality is often found in individuals who are highly competitive and ambitious and perceive a constant struggle with their environment) may increase the risk of CVD. The mechanism by which stress may lead to increased risk of vascular disease is not completely understood but is possibly related to platelet and endothelial dysfunction as well as the induction of ventricular arrhythmias.

1.12.4 Depression

Depression has been demonstrated in a number of studies to predict CVD.[159,160] This association appears to be an independent one, although depression is also associated with lack of physical activity, hypertension, and smoking.[159,160] The mechanism through which depression may increase the risk of CVD includes elevated levels of hs-CRP, increased platelet activation, and decreased heart rate variability. Depression occurs in one out of three patients with heart failure and one out of five patients with CHD. Whether therapy for depression lowers the risk for CVD is uncertain.

1.13 FUTURE TRENDS IN RISK FACTOR ASSESSMENT

Some technologic enhancements, in both imaging techniques and genomics, have provided opportunities that may yield more precise and individualized characterizations of atherosclerotic plaque and risk of CVD.

1.13.1 Direct Plaque Imaging

High speed computed tomography (CT scanning) of the coronary arteries has been demonstrated in several studies to detect pre-clinical atherosclerosis.[161] Advances such as volume CT scanning (VCT) may further enhance the precision and predictive value of these technologies. At the current time, these technologies remain investigational. Concern has also been raised about the potential to overinterpret predictive values from imaging techniques such as coronary calcium scoring. In one study, 41% of all future vascular events occurred in individuals with a coronary calcium score lower than 100, and 17% occurred with a coronary calcium score of zero.[162] In this study, individuals with high risk scores by Framingham criteria, but low coronary calcium scores, still remained at high risk of CVD. Another imaging test that has been employed to attempt to assess the risk of CVD is ultrasound measurement of the common carotid intima-media thickness (CIMT). With regard to CIMT, a meta-analysis of 14 population based cohorts reported a consistent and strategically significant 9% increase of future vascular risk for each 0.1 mm increase in CIMT thickness.[163] This same analysis, however, found that CIMT measurement did not improve clinical accuracy once risk estimates and re-classification were utilized to adjust for usual risk factors.[164] In addition, Framingham investigators have reported limited usefulness for CIMT in this prediction.[165]

1.13.2 Genomic Approaches

Heritability accounts for up to one half of susceptibility to CHD. However, genetic risk factors have proven difficult to quantify. Advances continue to be made in genetic determinants of atherothrombosis. Although this field remains in its early stages of development, progress continues to be made.[166–168] Challenges exist because of multiple gene–environment interactions. Although this remains an area of active research, no genetic markers for atherothrombosis have yet achieved clinical utility. A recent study involving over 55,000 individuals, including 7,814 participants in the Atherosclerosis Risk in Community (ARIC) study, 21,222 in the Women's Genome Health Study (WGHS), 22,389 in the Malmö Diet and Cancer Study (MDCS), and 4,260 participants in the cross-sectional BioImage, assessed the risk of pulmonary events in individuals who had high genetic risk (top quintile of polygenic scores) compared with low risk (bottom quintile of polygenic scores). Coronary events were 91% higher in the high genetic risk group. Importantly, among participants in the high genetic risk profile, a favorable lifestyle (defined by no current smoking, no obesity, regular physical activity, and a healthy diet) resulted in a 46% lower relative risk of coronary events than those who had an unfavorable lifestyle. While this type of research[169] is in its infancy, it suggests that healthy lifestyle practices play an important role in individuals who are at high genetic risk of CVD.

1.13.3 New Risk Factor Scoring Systems

The Framingham Risk Scoring System has contributed in substantial ways to the ability to predict the risk of CVD; however, it is limited by not incorporating such risk factors as level of physical activity and obesity. One particularly attractive system has emerged from the New Zealand Guidelines Group, which provides useful information on the five- and ten-year risk of atherosclerosis. This area remains one of active research. Another attractive scoring system is the Reynolds Risk Score (www.reynoldsriskscore.com), which has the advantage of including both hs-CRP and family history as part of global risk assessment.[170]

1.13.4 Implementation of Risk Factor Reduction Strategies

One encouraging trend in risk factor reduction is an increased emphasis on more sophisticated and comprehensive approaches to the implementation of currently existing risk factor reduction guidelines.[52,54,114] Both the Dietary Guidelines for Americans 2020–2025[52] and the Nutrition Guidelines from the American Heart Association[54] make a substantial effort to focus on strategies for implementing existing guidelines.

1.14 CONCLUSIONS

The identification of risk factors for CHD continues to evolve and is an area of great practical relevance to clinicians. Particularly given the high level of modifiable risk factors for CVD, an enormous opportunity exists for physicians and other healthcare workers to counsel patients on lifestyle medicine concepts to lower their risk of CVD. Specific concepts for how to integrate lifestyle measures into clinical practice will be the topic of the next chapter.

CLINICAL APPLICATIONS

Action	Available Tools	Comment
Determine risk of CVD in all patients	Multiple risk factor scoring systems are available	See Chapter 2 for more details
Determine "vital signs" of positive lifestyle	Include body mass index (BMI), level of physical activity, nutritional practices, and smoking status in all initial assessments	These are key determinants of lifestyle CVD risk
Discuss smoking cessation with all smokers	Multiple tools available from many sources	Over one third of smokers are never counseled about cigarette smoking
Counsel all patients on weight management	Obtain weight and BMI on all patients	Forty percent of overweight and obese patients are never counseled on weight management
Counsel all patients on physical activity	U.S. Physical Activity for Americans Guidelines, 2018	Become familiar with these guidelines, utilize them, and counsel
Counsel all patients on nutrition	Dietary Guidelines for Americans 2020–2025, also multiple materials from the American Heart Association	Improved nutrition is a key in reducing the CVD risk

2 Lifestyle Strategies for Risk Factor Reduction and Treatment of Cardiovascular Disease

James M. Rippe, MD

KEY POINTS

- Lifestyle strategies play a significant role in reducing risk factors for cardiovascular disease (CVD).
- Lifestyle interventions are key components of the American Heart Association (AHA)'s strategic plan for 2020 to lower the burden of cardiovascular disease in the United States and the 2030 AHA impact goals.
- Lifestyle strategies are a key component for both the prevention and treatment of metabolic diseases and are recognized as such by virtually every major national, evidence based guideline in metabolic diseases.
- In addition to annual fasting lipid profile, high sensitive C-reactive protein (hs-CRP) should be obtained, since levels of hs-CRP are the equivalent risk of lower density lipoprotein (LDL) cholesterol.
- Assessment and counseling for factors for CVD should be a part of every healthcare visit.

2.1 INTRODUCTION

Cardiovascular disease (CVD) remains the leading killer of men and women in the United States.[1] CVD also represents one of the quintessential lifestyle related diseases, since many of the risk factors for it, including cigarette smoking,[2] elevated cholesterol,[3] high blood pressure,[4] obesity,[5] and an inactive lifestyle[6] have significant lifestyle related components.

Lifestyle strategies can play a significant role in the reduction of risk factors for CVD as well as its prevention and effective treatment. In Chapter 1, we focused on the rationale for employing lifestyle strategies for risk factor reduction. The current chapter provides practical strategies for employing these modalities in clinical practice for the prevention and treatment of CVD.

Lifestyle interventions also represent an important strategy for physicians and other healthcare workers to assist patients in lowering their risk factors as well as preventing CVD and treating individuals with established CVD. These lifestyle related strategies are particularly valuable since they carry very little risk and may simultaneously reduce multiple risk factors for CVD. Furthermore, the AHA has articulated a vision to pursue "primordial" risk factors, meaning the prevention of risk factors in the first place. Lifestyle measures will be key components of this strategy.[7]

The AHA Impact Goal for 2030 articulates the goal of expanding health associated life expectancy while increasing lifespan, wellbeing, and health equity by Year 2030. The concept of Health Adjusted Life Expectancy (HALE) is defined as the number of years in good health, for years lived with disease or disability, for years lost to premature death. As articulated by the AHA, HALE can be increased by improving health and wellbeing, preventing or delaying the onset and manifestations of disease, and increasing life expectancy. All of these represent concepts that are very familiar to practitioners of lifestyle medicine.

The concept of wellbeing broadens the AHA vision from simply health to additionally encompassing mental status and aspects of life such as "security, prosperity, sense of connection and purpose." This broadens the mission of both CVD specialists and lifestyle specialists into the areas of neurobiological, behavioral, emotional, socioeconomic, and cultural wellbeing. Good data are available showing that how people feel about their overall life satisfaction strongly predicts how healthy they are, how long they will live, and their future healthcare needs *per se*.

The AHA 2030 Impact Goal continues the evolution from the AHA to incorporate lifestyle into the practice of cardiovascular medicine.[8] The AHA further articulated the importance of lifestyle in cardiovascular disease with the AHA/Adult Treatment Panel (ATP) Guidelines for Lifestyle Management to Reduce Cardiovascular Risk, published in 2014.[9]

Lifestyle measures are already incorporated as key recommended early intervention steps in most of the major, evidence based guidelines either prior to or in conjunction with pharmaceutical therapy to help patients lower the risk of CVD.[3,4,8–17] Unfortunately, many healthcare workers still do not properly emphasize these measures in their daily clinical practices. In addition, reimbursement models currently provide disincentives for using these strategies, since lifestyle interventions are typically not covered by health insurance plans. Aspects of the Health Care Reform Act,[18]

DOI: 10.1201/9781003227793-3

particularly the Accountable Care Organizations provision, provide financial models to encourage these low cost, potentially high yield lifestyle measures. The challenge for healthcare professionals will be to understand and utilize these models to aggressively incorporate lifestyle measures into the prevention and treatment of CVD and other lifestyle related disease.

In addition to the financial disincentives, lack of time may represent another hurdle. Delivery of those measures related to prevention of CVD recommended by the U.S. Preventive Health Services Task Force has been estimated to take the typical clinician a minimum of 1.5 hours per day in non-reimbursable time.[19] Thus, it will be important in clinical practice to find ways to deliver proven lifestyle interventions with efficient strategies that are time sensitive.

A representative listing of national guidelines that incorporate lifestyle medicine emphasis in the treatment of CVD or as a strategy for lowering risk factors for related metabolic conditions is found in Table 2.1.

Healthcare professionals can be enormously influential in helping patients take positive lifestyle actions to lower their risk of CVD. Healthcare providers' recommendations to make changes in behaviors, such as cigarette smoking cessation, weight loss, or improved nutrition, have all been demonstrated to play important roles in lowering risk factors for CVD. Numerous studies have shown that the public perceives medical professionals as a reliable and credible source of information concerning health related behaviors.[20–27] Often, however, healthcare workers underestimate how powerful their role as health counselors can be. For example, fewer than 50% of smokers report receiving advice to quit from their physician,[22] and fewer than 40% of obese individuals report receiving advice about weight loss.[28] This is unfortunate, since the average adult in the United States visits a physician's office more than five times per year, and it has been estimated that physicians come in contact with over 75% of adults in the United States in any given year.[29] In addition to physicians, nutritionists, nurses with an interest and background in preventive cardiology or diabetes education, and other healthcare professionals can play critically important roles in counseling patients on positive lifestyle behaviors to lower their risk of coronary heart disease (CHD).

It should also be noted that the majority of patients who make lifestyle behavior changes do this without formal participation in an organized program. For example, over 90% of individuals who have stopped smoking have done this without formal smoking cessation programs.[30] Furthermore, the majority of patients who lose weight also do this on their own. Nonetheless, healthcare professional recommendations and support can be very valuable to motivate patients to start and maintain the process of behavioral change.

It is particularly important that physicians play a proactive role in this area. At the current time, physician office visits represent a missed opportunity to promote behavioral changes. It is hoped that the advent of such organizations as the American College of Lifestyle Medicine[31] and the lifestyle medicine track of the American College of Preventive Medicine[32] will help physicians build the knowledge, basic skills, and confidence needed to make these recommendations. A "blue ribbon" panel of physicians representing most major medical organizations has urged physicians to become involved in lifestyle medicine and outlined a series of competencies in this area.[33] The American College of Lifestyle Medicine, a professional organization dedicated to advancing the field of lifestyle medicine, has doubled its membership each year for the past five years. Since 2003, membership in this organization has increased over 1,200%, making it the fastest growing medical specialty in the United States.[34] In 2016, this organization outlined a series of topics and offered certification for those interested in deepening their knowledge of lifestyle medicine and incorporating it into their clinical practices.[35]

Increasingly, medical organizations in various subspecialties are understanding the power of daily lifestyle habits and practices in both the prevention and treatment of various disease, including CVD. For example, in 2013, the AHA and the American College of Cardiology (ACC)[36] jointly issued guidelines for lifestyle management to reduce

TABLE 2.1

Evidence-Based Guidelines that Employ Lifestyle Measures to Reduce the Risk of CHD and Other Metabolic Conditions

- American Heart Association Nutrition Implementation Guidelines
- Guidelines from the American Academy of Pediatrics for the Prevention and Treatment of Childhood Obesity
- Guidelines from the American Academy of Pediatrics for Heart Disease Risk Factor Reduction in Children
- Guidelines from the American Heart Association and American Academy of Pediatrics for the Prevention and Treatment of Metabolic Syndrome
- Joint statement from the American Heart Association and American Cancer Society on the prevention of heart disease and cancer

cardiovascular risk. In conjunction with this initiative, the study group within the AHA, which had previously been called "The Council on Nutrition, Physical Activity and Metabolism," changed its name to "The Council on Lifestyle and Cardiometabolic Health."[37] Along with these changes, a series of articles was published by the AHA in the journal *Circulation* entitled "Recent Advances in Preventive Cardiology and Lifestyle Medicine."[38] Furthermore, the Health Care Reform Act[16] including the Accountable Care Provision mandated that physicians become more active in this area.

The case for aggressive employment of lifestyle measures in clinical medicine has continued to grow. Multifactorial risk factor reduction programs have been clearly demonstrated to reduce each of these risk factors individually and in groups of risk factors treated together. Epidemiologic studies have shown that positive lifestyle measures, such as not smoking; engaging in at least 30 minutes of physical activity per day; consuming a diet of more fruits, whole grains, fish, and vegetables; and maintaining a healthy weight, can reduce the incidence of CVD by over 80% and diabetes by over 90%.[39,40] Of note, incorporating just one of these health promoting practices reduces the risk of developing CVD and diabetes by over 50%.[39,40]

2.2 PREDICTING RISK

A key first step prior to using lifestyle measures to lower risk factors for CVD involves predicting risk. Risk prediction involves understanding the type and strength of evidence underlying risk factor assessment strategies as well as clearly understanding the difference between relative risk and absolute risk (see Chapter 1).

Most currently employed, evidence based frameworks for lowering risk factors for CHD involve assessing absolute risk. For example, lowering absolute risk underlies the strategies for the National Cholesterol Education Program ATP III Guidelines[41] and ATP IV Guidelines,[3] the American Diabetes Association Guide of Managing Diabetes,[11] and The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7)[42] as well as the 2018 AHA/ACC 2018 Practice Guidelines.[3]

2.3 ASSESSING RISK

Multiple frameworks are available for assessing the risk of CVD. The most widely used one is the framework developed by the Framingham Heart Study investigators. This framework is found in Figure 2.1 and Figure 2.2. Figure 2.1 is used to assess risk for men, and Figure 2.2 is used to assess risk for women. The Framingham framework is based on estimating an individual's ten-year risk of developing CVD.[43] The higher the ten-year risk, the more intensity of intervention is warranted.

It should be noted that there are alternatives to the Framingham score. For example, the Reynolds Risk Score provides a variation to the Framingham score by incorporating whether a parent suffered a myocardial infarction (MI) before the age of 60 years as well as high sensitivity CRP (hs-CRP) level.[44,45] The Reynolds Score appears to be a better predictor of individuals in the middle risk category and is comparable to the Framingham Risk Score for individuals with low or high risk.

Other available risk scores include Systematic Coronary Risk Evaluation Project (SCORE), developed by the European Joint Task Force utilizing studies in 12 European countries involving 250,000 individuals.[46] A more recent set of guidelines was developed by the New Zealand Guidelines Committee, which assesses absolute cardiovascular risk during five years instead of ten.[47]

In 2013, the American College of Cardiology (ACC) and the AHA released new Guidelines for the Treatment of High Blood Cholesterol.[48] These guidelines were designed to update the previous Adult Treatment Panel III (ATP III) Report of the National Cholesterol Education Program.[41] These guidelines also followed a new paradigm for cholesterol management. The guideline process for this panel followed the "Rules" for Guideline Development published by the Committee for the Institute of Medicine (IOM).[49] The IOM report emphasized the necessity for "evidence based medicine" in guideline development, which basically outlines that recommendation should be made mainly on evidence obtained from randomized clinical trials (RCTs). Since other types of evidence, such as epidemiologic evidence, were no longer utilized, guidelines left many clinicians in the position of having to use their own clinical judgement to arrive at many clinical decisions, instead of having science based guidance to inform these clinical choices. It should be emphasized that both ATP III and the ACC/AHA Guidelines emphasize the value of lifestyle medicine. This emphasis, despite the fact that the ACC/AHA Guidelines, did not provide RCT evidence.

While ATP III identified LDL as a major cause for atherosclerotic coronary vascular disease (CVD), the ACC/AHA Guidelines *do not* make LDL the centerpiece of the guidelines. While they note that lowering LDL would be beneficial, by adhering to the ACC/AHA paradigm, LDL is basically irrelevant to guideline development. Instead, statin therapy became the lynchpin for recommendations. Thus, the ACC/AHA Guidelines (also called ATP IV) make cholesterol management different from the ATP III.

The ATP III Guidelines set a goal for LDL-C as less than 100 mg/dL for high risk patients, especially those with established atherosclerotic cardiovascular disease (ASCVD), and patients with a diabetes risk of >20% were further counted as high risk patients. Those considered at very high risk (i.e. established ASCVD), plus multiple risk factors, resulted in ATP III guidance of lowering cholesterol to <70 mg/dL. This LDL-C goal of <70 mg/dL is also based on RCTs outlined in ATP IV. In ATP III, if a patient at very high risk did not achieve an LDL-C of <70 mg/dL, the addition of a second LDL lowering drug was allowed to attain greater reduction of LDL-C. The ATP IV

Step 1

Age		
Years	LDL Pts	Chol Pts
30–34	–1	[–1]
35–39	0	[0]
40–44	1	[1]
45–49	2	[2]
50–54	3	[3]
55–59	4	[4]
60–64	5	[5]
65–69	6	[6]
70–74	7	[7]

Step 2

LDL-C		
(mg/dl)	(mmol/L)	LDL Pts
< 100	< 2.59	–3
100–129	2.60–3.36	0
130–159	3.37–4.14	0
160–190	4.15–4.92	1
≥ 190	≥ 4.92	2

Cholesterol		
(mg/dl)	(mmol/L)	Chol Pts
< 160	< 4.14	[–3]
160–199	4.15–5.17	[0]
200–239	5.18–6.21	[1]
240–279	6.22–7.24	[2]
≥ 280	≥ 7.25	[3]

Step 3

HDL-C			
(mg/dl)	(mmol/L)	LDL Pts	Chol Pts
< 35	< 0.90	2	[2]
35–44	0.91–1.16	1	[1]
45–49	1.17–1.29	0	[0]
50–59	1.30–1.55	0	[0]
≥ 60	≥ 1.56	–1	[–2]

Step 4

Blood Pressure					
Systolic (mm Hg)	Diastolic (mm Hg) < 80	80–84	85–89	90–99	≥ 100
< 120	0 [0] pts	0 [0] pts	1 [1] pts	2 [2] pts	3 [3] pts
120–129					
130–139					
140–159					
≥ 160					

Note: When systolic and diastolic pressures provide different estimates for point scores, use the higher number

Step 5

Diabetes		
	LDL Pts	Chol Pts
No	0	[0]
Yes	2	[2]

Step 6

Smoker		
	LDL Pts	Chol Pts
No	0	[0]
Yes	2	[2]

Step 7 (sum from steps 1–6)

Adding up the point	
Age	_____
LDL-C or Chol	_____
HDL-C	_____
Blood Pressure	_____
Diabeles	_____
Smoker	_____
Point Total	_____

Step 8 (determine CHD risk from point total)

CHD Risk			
LDL Pts Total	10-Yr CHD Risk	Chol Pts Total	10-Yr CHD Risk
< –3	1%		
–2	2%		
–1	2%	[< –1]	[2%]
0	3%	[0]	[3%]
1	4%	[1]	[3%]
2	4%	[2]	[4%]
3	6%	[3]	[5%]
4	7%	[4]	[7%]
5	9%	[5]	[8%]
6	11%	[6]	[10%]
7	14%	[7]	[13%]
8	18%	[8]	[16%]
9	22%	[9]	[20%]

13	47%	[13]	[45%]
≥ 14	≥ 56%	[≥ 14]	[≥ 53%]

Step 9 (compare to average person your age)

Comparative Risk			
Age (years)	Average 10-Yr CHD Risk	Average 10-Yr Hard* CHD Risk	Low† 10-Yr CHD Risk
30–34	3%	1%	2%
35–39	5%	4%	3%
40–44	7%	4%	4%
45–49	11%	8%	4%
50–54	14%	10%	6%
55–59	16%	13%	7%
60–64	21%	20%	9%
65–69	25%	22%	11%
70–74	30%	25%	14%

Relative Risk
- Very low
- Low
- Moderate
- High
- Very High

* Hard CHD events exclude angina pectoris

† Low risk was calculated for a person the same age, optimal blood pressure, LDL-C 100–129 mg/dl or cholesterol 160-199 mg/dl, HDL-C 45 mg/dl for men or 55 mg/dl for women, nonsmoker, no diabetes

Risk estimates were derived from the experience of the Framingham Heart Study, a predominantly Caucasian population in Massachusetts, USA

FIGURE 2.1 Coronary heart disease (CHD) score sheet for calculating 10-year CHD risk according to age, total cholesterol (TC) (or low- density lipoprotein cholesterol [LDL-C]), high-density lipoprotein cholesterol (HDL-C), blood pressure, diabetes, and smoking. Score sheet for men based on the Framingham experience in men 30 to 74 years at baseline. Average risk estimates are based on typical Framingham subjects, and estimates of idealized risk are based on optimal blood pressure, TC of 160 to 199 (or LDL-C of 100 to 129 mg/dL), no diabetes, and no smoking.

Step 1

Age		
Years	LDL Pts	Chol Pts
30–34	–9	[–9]
35–39	–4	[–4]
40–44	0	[0]
45–49	3	[3]
50–54	6	[6]
55–59	7	[7]
60–64	8	[8]
65–69	8	[8]
70–74	8	[8]

Step 2

LDL-C		
(mg/dl)	(mmol/L)	LDL Pts
< 100	< 2.59	–2
100–129	2.60–3.36	0
130–159	3.37–4.14	0
160–190	4.15–4.92	2
≥ 190	≥ 4.92	2

Cholesterol		
(mg/dl)	(mmol/L)	Chol Pts
< 160	< 4.14	[–2]
160–199	4.15–5.17	[0]
200–239	5.18–6.21	[1]
240–279	6.22–7.24	[1]
≥ 280	≥ 7.25	[3]

Step 3

HDL-C			
(mg/dl)	(mmol/L)	LDL Pts	Chol Pts
< 35	< 0.90	5	[5]
35–44	0.91–1.16	2	[2]
45–49	1.17–1.29	1	[1]
50–59	1.30–1.55	0	[0]
≥ 60	≥ 1.56	–2	[–3]

Step 4

Blood Pressure					
Systolic (mm Hg)	Diastolic (mm Hg) < 80	80–84	85–89	90–99	≥ 100
< 120	–3 [–3] pts	0 [0] pts			
120–129			0 [0] pts		
130–139				2 [2] pts	
140–159					3 [3] pts
≥ 160					

Note: When systolic and diastolic pressures provide different estimates for point scores, use the higher number

Step 5

Diabetes		
	LDL Pts	Chol Pts
No	0	[0]
Yes	4	[4]

Step 6

Smoker		
	LDL Pts	Chol Pts
No	0	[0]
Yes	2	[2]

Step 7 (sum from steps 1–6)

Adding up the point	
Age	_____
LDL-C or Chol	_____
HDL-C	_____
Blood Pressure	_____
Diabeles	_____
Smoker	_____
Point Total	_____

Step 8 (determine CHD risk from point total)

CHD Risk			
LDL Pts Total	10-Yr CHD Risk	Chol Pts Total	10-Yr CHD Risk
< –2	1%	[≤ –2]	[1%]
–1	2%	[–1]	[2%]
0	2%	[0]	[2%]
1	2%	[1]	[2%]
2	3%	[2]	[3%]
3	3%	[3]	[3%]
4	4%	[4]	[4%]
5	5%	[5]	[4%]
6	6%	[6]	[5%]
7	7%	[7]	[6%]
8	8%	[8]	[7%]
9	9%	[9]	[8%]
10	11%	[10]	[10%]
11	13%	[11]	[11%]
12	15%	[12]	[13%]
13	17%	[13]	[15%]
14	20%	[14]	[18%]
15	24%	[15]	[20%]
16	27%	[16]	[24%]
≥ 17	≥ 32%	[≥ 17]	[≥ 27%]

Step 9 (compare to average person your age)

Comparative Risk			
Age (years)	Average 10-Yr CHD Risk	Average 10-Yr Hard* CHD Risk	Low† 10-Yr CHD Risk
30–34	< 1%	< 1%	< 1%
35–39	< 1%	< 1%	< 1%
40–44	2%	1%	2%
45–49	5%	2%	3%
50–54	8%	3%	5%
55–59	12%	7%	7%
60–64	12%	8%	8%
65–69	13%	8%	8%
70–74	14%	11%	8%

Relative Risk
- Very low
- Low
- Moderate
- High
- Very High

* Hard CHD events exclude angina pectoris

† Low risk was calculated for a person the same age, optimal blood pressure, LDL-C 100–129 mg/dl or cholesterol 160-199 mg/dl, HDL-C 45 mg/dl for men or 55 mg/dl for women, nonsmoker, no diabetes

Risk estimates were derived from the experience of the Framingham Heart Study, a predominantly Caucasian population in Massachusetts, USA

FIGURE 2.2 Score sheet for women based on Framingham experience in women 20 to 74 years of age at baseline. Average risk estimates are based on typical Framingham subjects, and estimates of Idealized risk are based on optimal blood pressure, total cholesterol (TC) of 160 to 199 mg/dL (or low-density lipoprotein cholesterol [LDL-C of 100 to 129 mg/dL), high-density lipoprotein cholesterol (HDL-C) of 55 mg.' dL. no diabetes, and no smoking. Use of the LDL-C categories is appropriate when fast ng LDL-C measurements are available. Pts. points. (From Wilson PW: D' Agostino RD, Levy D, et al. Predication of coronary heart disease using risk factor categories. *Circulation.* 1998;97:1837–1847.)

Guidelines also recommended that individuals with ≥5% risk could also receive statin therapy. ATP III allowed statin therapy for patients with 10% risk and an LDL >100 mg/dL, whereas ACC/AHA allowed statin at an LDL-C >70 mg/dL. This value is justified by the recent results from the JUPITER Trial,[50] which showed efficacy in patients with LDL-C <100 mg/dL. Controversy has arisen about whether or not to use the ATP III criteria or the ATP IV criteria. At the time of this writing, this controversy remains unresolved.

Since the risk of ASCVD increases with age, in the ATP IV Guidelines, there will be an increased number of people over the age of 65 who are eligible for statin therapy. This would include most men in their 60s and more women in their 70s. This increased use of statin medicine is also controversial, and the debate concerning this has not been resolved as of this writing.

For middle aged persons, the ACC/AHA Guidelines are similar to each other, although lower risk and lower LDL-C qualify for statin therapy in the ATP IV (ACC/AHA guidelines). With regard to young adults, the ACC/AHA Guidelines make no recommendations in this area, whereas the ATP III Guidelines recommended testing for lipoproteins every five years, starting at age 20. Other risk factors, likewise, should be measured in young adults. Risk factors clearly associate with the development of atherosclerosis in the age range of 20–39 years.[51] The ATP III Guidelines stress the importance of early intervention and risk factors, while the ACC/AHA Guidelines do not. It is important to emphasize that in both the ATP III and the ATP IV Guidelines, lifestyle modalities play essential roles.

2.4 CLASSIFYING INTERVENTIONS FOR MODIFIABLE RISK FACTORS

As outlined in Chapter 1, risk factors for CHD can be conveniently divided into "modifiable" and "non-modifiable." This framework also carries practical implications and is a commonly employed classification strategy.[52] In addition, classifications employed by the ACC and the AHA divide intervention to reduce risk factors into four categories based on the level of evidence that modifying a particular risk factor will result in lower risk of CHD. The following four classifications are typically employed:

- Class 1 Interventions: These interventions involve risk factor reduction strategies that have been proven to reduce risk when used.
- Class 2 Interventions: This classification includes risk factors where interventions are likely to lower the incidence of events but proof is less strong than Class 1 interventions.
- Class 3 Interventions: This classification includes risk factors that have been clearly associated with increased risk of CHD and which, if modified, might lower the likelihood of a coronary event.
- Class 4 Interventions: This classification includes risk factors that have been associated with increased risk of CHD and which, if modified, are not likely to decrease the risk of CHD or cannot be modified.

This framework for classifications is summarized in Table 2.2.

TABLE 2.2
Framework for Risk Factor Reduction Interventions

Class 1 Interventions
- Cigarette smoking cessation
- Management of dyslipidemias
- Management of hypertension
- Pharmaceutical measures for cardiac protection

Class 2 Interventions
- Obesity prevention and management
- Diabetes/glucose intolerance management
- Physical inactivity

Class 3 Interventions
- Nutritional counseling
- Psychological risk factors/counseling
- No alcohol consumption

Class 4
- Age
- Male gender
- Low socioeconomic status
- Family history of early onset CVD

See text for details.

2.5 CLASS 1 INTERVENTIONS

2.5.1 Lifestyle Approach to Cigarette Smoking Cessation

Cigarette smoking is the leading cause of preventable death in the United States each year, resulting in an estimated 480,000 deaths.[53] More than 32% of deaths from cigarette smoking result from CVD.[53] It has been estimated that over 49,000 of the smoking related deaths are the result of secondhand smoke exposure. Smoking also has an enormous economic impact on the United States economy.[54] It has been estimated that the United States incurs $96 billion in direct medical expenses and $97 billion in lost productivity annually as a result of cigarette smoking. Smokers lose at least one decade of life expectancy compared with never-smokers. The risk of death from cigarette smoking has continued to increase among women,[55] and the increased risks are now identical between men and women.[56] The 2004 Surgeon General's Report showed that smoking doubles the risk of CVD and increases CVD mortality by 50%.[54] Both of these risks increase with age and the number of cigarettes smoked. Worldwide, more than one million more deaths were attributable to tobacco in the year 2000 than in 1990.[56] Tobacco use is estimated to be responsible for five

million deaths worldwide per year.[57] In the United States, cigarette smoking peaked in 1955, when 55% of men were smokers. The peak for women came ten years later, with more than 33% smoking. Since that time, cigarette smoking has substantially declined; however, the rate of decline has slowed substantially in the past decade.

Currently, in the United States, 15.5% of adults smoke.[53] Slightly more of these individuals are men than women. Approximately 13.5% of women over the age of 18, and approximately 17.5% of men over the age of 18, smoke.[53] If individuals do not smoke cigarettes by the time they graduate from high school, it is highly unlikely that they will adopt this habit as adults. Smoking rates among high school seniors are slightly above 30%, with a slightly higher number of female smokers than males.[57] Smoking also tracks with socioeconomic status. Thirty-two percent of individuals living below the federal poverty line are smokers.[58]

The U.S. Public Health Service has published clinical practice guidelines classifying tobacco dependency as a chronic condition requiring repeated intervention.[56] These guidelines recommend that healthcare professionals ask every patient about tobacco use at every clinic visit.[59] Counseling and behavior therapies are based on the following:

1. securing social support
2. providing problem solving skills
3. social support outside treatment

According to the U.S. Public Health Service guidelines, which support a combination of counseling and pharmaceutical therapy, seven pharmacotherapies reliably increase long-term smoking abstinence, including bupropion hydrochloride,[60] Varenicline, and five nicotine replacement therapies (nasal spray, gum, patch, inhaler, and lozenges).[61] The efficacy of smoking cessation programs, in terms of success for one year, ranges from 6% with physician counseling alone to 18% with self-help programs and 20–40% with counseling plus pharmacologic intervention.[62] All individuals who smoke should, of course, be counseled to cease this potentially deadly habit. A particularly appropriate time to encourage patients to make this effort is after a cardiac event or discovery of existing CVD.

The Healthy People 2020 Initiative has established a goal of the United States reducing the national prevalence of cigarette smoking among adults to under 12%. Achieving this ambitious goal will require extensive implementation of evidence based tobacco control interventions. Some advances in tobacco control have occurred recently in the United States, including implementation of the 2009 Family Smoking Prevention and Tobacco Control Act, which granted the U.S. Food & Drug Administration (FDA) authority to regulate the manufacture, distribution, and marketing of tobacco products.[63] Other laws include the Children's Health Insurance Reauthorization Act, the Prevent All Cigarette Trafficking Act, and the Patient Protection and Affordable Care Act. These laws grant various federal agencies both authority and funding to regulate tobacco products and decrease access to tobacco among youth. In 2010, the U.S. Department of Health & Human Services entered a National Strategic Plan for Tobacco Control, including 21 Action Steps to accomplish this goal.

2.5.2 Lifestyle Approach to Management of Dyslipidemias

Average cholesterol levels among adult men and women in the United States have decreased to some degree since the 1960s but are still considered higher than good health requires. Agrarian societies have very low rates of CVD and exhibit total and LDL cholesterol levels well below those accepted as normal in Western societies.

Currently, approximately 45% of all American adults still have cholesterol levels greater than 200 mg/dL, and 16% have levels higher than 240 mg/dL.[64] In addition, both depressed high density lipoprotein (HDL) cholesterol levels and elevated triglyceride levels often occur together and result from different metabolic pathways than are typically involved in elevated LDL. These latter two lipid abnormalities are particularly associated with the metabolic syndrome.

Various organizations have listed somewhat different recommendations for cholesterol screenings. There is wide agreement that all patients with currently existing CVD should be periodically screened for serum cholesterol levels. The National Cholesterol Education Program (NCEP) ATP III Guidelines recommend that all adults older than 20 years should be routinely screened for serum cholesterol,[41] while the ATP IV Guidelines are silent on this issue. The American College of Physicians (ACP) provides less aggressive screening recommendations with advice that men between the ages of 35 and 65 and women between the ages of 45 and 65 be screened.[64] The U.S. Preventive Services Task Force advocates screening women over the age of 45 and men over the age of 35.[59]

It is important to understand that all of the above referenced guidelines advocate treatment based on assessment of the patient's overall risk. The ATP III Guidelines not only utilize LDL level but also recommend calculations based on the Framingham Risk Score (see Figure 2.1 and Figure 2.2). A guideline algorithm presented by the ATP III Guidelines is shown in Figure 2.3.

A variety of lifestyle recommendations are incorporated as first line treatment in the NCEP ATP III Guidelines. Nutritional intervention is recommended, including maintaining calories from fat between 25% and 35%, saturated fat counting for less than 7%, with cholesterol level intake limited to less than 200 mg/day. Complex carbohydrates are recommended at 50–60% of calories and protein at 15%. NCEP ATP III Guidelines recommend consumption of 20–30 grams of dietary fiber daily—an amount far more than the average American adult currently consumes.[41]

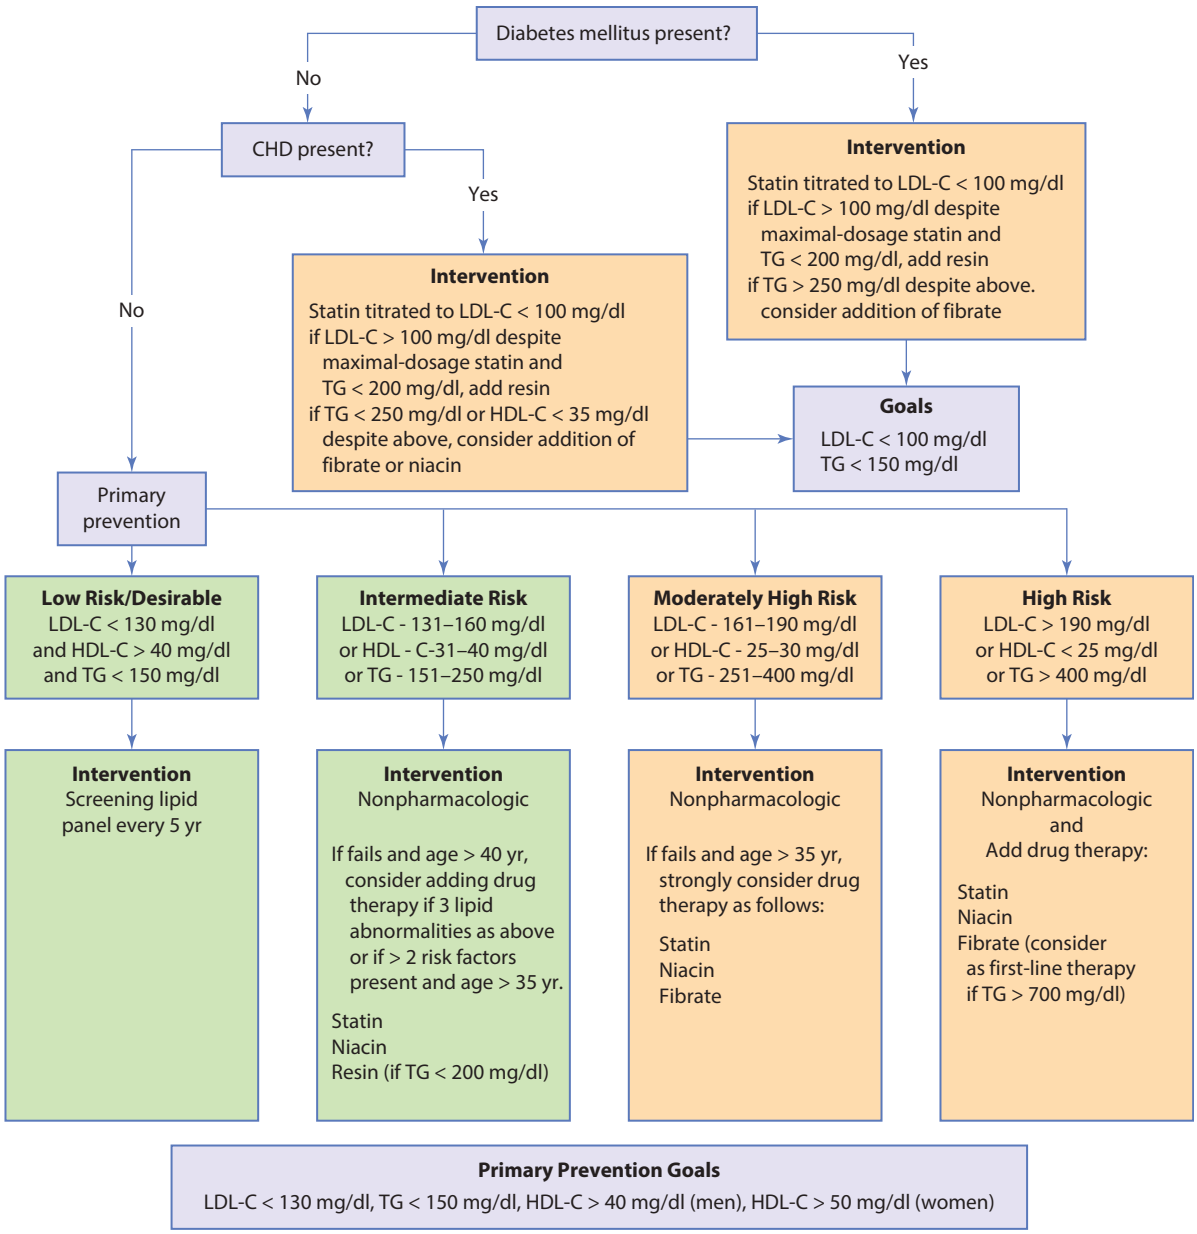

FIGURE 2.3 Algorithm for lipid-lowering therapy based on findings from intervention trials. CHD, coronary heart disease; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol; TG, triglycerides. (From the Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults [Adult Treatment Panel III]: final report. *Circulation*. 2002;106:3143– 3421.)

In 2006, ACC and AHA updated their secondary prevention guidelines for lipid management, including most of the provisions in the NCEP guidelines but also strengthening them for individuals with established CHD. The AHA/ACC Guidelines extend the option of levels of less than 70 mg/dL for LDL for all patients with CHD, not just those at very high risk.[65] The guidelines also recommend that patients with triglyceride levels of 200–499 mg/dL should have non-HDL cholesterol level of less than 130 mg/dL and potentially further reduction to less than 100 mg/dL. Also in 2006, the AHA listed its nutritional and lifestyle recommendations.[66] A summary of these recommendations and their lifestyle interventions is found in Table 2.3. Within a clinical setting, it may be valuable for patients to receive the services of a registered dietitian to help them adhere to nutritional guidelines recommended by the AHA and NCEP ATP III.

In 2013, the ACC and AHA issued "Guidelines for the Treatment of Blood Cholesterol to Reduce Atherosclerotic Cardiovascular Disease in Adults." These Guidelines recommend increased use of statin medications to reduce ASCVD events in secondary and primary prevention and also recommend discontinuation of use of specific LDL and HDL treatment targets.[67] The four major statin benefit

TABLE 2.3

AHA 2008 Diet and Lifestyle Recommendations for Cardiovascular Disease Risk Reduction

1. Balance caloric intake and physical activity to achieve or maintain a healthy body weight
2. Eat a diet rich in vegetables and fruits
3. Choose and prepare foods with little or no salt
4. Minimize your intake of beverages and foods with added sugars
5. Consume oily fish at least twice a week
6. Limit your intake of saturated fat to <7% of energy, trans fat to <1% of energy, and cholesterol to <300 mg per day by choosing lean meats and vegetable alternatives; selecting fat free (skim), 1% fat and low fat dairy products and minimizing intake of partially hydrogenated fats
7. Choose whole grain, high fiber foods in your diet
8. If you consume alcohol, consume in moderation
9. When you eat food that is prepared outside of your home, follow the AHA Diet and Lifestyle Recommendations

Adapted from Lichtenstein AH, Appel LJ, Brands M, Carnethon M, et al. Diet and Lifestyle Recommendations Revision 2006. A Scientific Statement From the American Heart Association Nutrition Committee. *Circulation*, 114, 82–96, 2006.

groups where the use of statin medicines, according to this report, were indicated to reduce ASCVD risk were the following: Individuals 1) with clinical ASCVD, 2) primary elevations of LDL-C>190 mg/dL, 3) diabetics aged 40 to 75 years with LDL-C 70 to 189 mg/dL and without clinical ASCVD, and 4) individuals without *clinical* ASCVD or diabetes with LDL-C 70 to 189 mg/dL who had a ten-year ASCVD risk >7.5%. These Guidelines were immediately criticized for recommending excessive use of statins, particularly in individuals with risk of >7.5%.[68,69] This controversy persists as of this writing.

A variety of pharmaceutical agents have been demonstrated to lower both total and LDL cholesterol as well as reduce morbidity and mortality from CHD. Most prominent amongst these medicines are the statins. While statins vary according to potency, they appear to be equally efficacious. Adherence is the key issue.

A recent approach to use of statins based on evidence from clinical trials has been suggested by preventive cardiologists in the United States, Canada, and Europe[68, 69]. It is based on the following five guidelines:

- Statin therapy should be used as an adjunct to diet, exercise, and smoking cessation for secondary prevention in patients with previous history of MI, stroke, or clinically apparent atherosclerosis.
- Statin therapy can be considered as an adjunct to diet, exercise, and smoking cessation as a component of primary prevention in those age 50 or over with either diabetes related lower HDL cholesterol or elevated hs-CRP.
- When prescribing statin therapy, physicians should seek to maximize the intensities of therapies and focus efforts on compliance and long-term adherence.
- The use of non-statins for lowering cholesterol agents for monotherapy or in combination with a statin should be limited until evidence is available that such an approach further reduces cardiovascular event rates in specific patient groups.
- A guideline based on prior evidence and on prior entry criteria must be simple, practical, and consistent with evidence based principles and should, therefore, result in broad clinical acceptance. New advances in prevention should be incorporated into these guidelines as quickly as possible.

It should be noted that these guidelines underscore the importance of lifestyle medicine principles of incorporating diet, exercise, and smoking cessation into the regimens that may also employ statin medicines.

Other agents available include niacin, fibrates, bile acid sequestrants, and cholesterol absorption inhibitors. A complete review of pharmaceutical therapies for the management of dyslipidemia is beyond the scope of this chapter and has been well treated in a variety of other publications. All the major cholesterol management guidelines advocate that lifestyle measures be combined if pharmaceutical agents are employed to produce the most favorable outcome (see also Chapter 4 on Clinical Strategies for Managing Dyslipidemias).

2.5.3 Lifestyle Management of Hypertension

According to the Joint National Committee (JNC) 7 Report, one out of every three American adults has high blood pressure, which represents more than 50 million Americans.[42] Another 25% fall into the "pre-hypertensive" category, which represents another 45 million Americans. The JNC 7 blood pressure classification is found is in Chapter 1.

A Commission was established to formulate JNC 8 Guidelines. However, the report of this Commission was never issued as formal guidelines. The intent was to change the approach to guidelines to a more evidence based rather than epidemiologic based approach.[70] The Commission issued a report that, as already indicated in Chapter 1, contained the following statement:

> There is strong evidence to support treating hypertensive patients age 60 or older to a BP goal of <150/90 mmHg and hypertensive patients 30-59 years of age to a diastolic goal of <90 mmHg. However, there is insufficient evidence in hypertensive persons under the age of 60 years for a systolic goal or in those under the age of 30 years for a diastolic goal, so the panel recommends a BP of <140/90 mmHg for those groups based on expert opinion.

As a practical matter, it should be noted that most organizations, including the AHA in their Clinical Guidelines for Establishing Goals for 2020, continue to use the cutoffs articulated in the JNC VII Guidelines.[42]

According to data from the Framingham Heart Study, individuals who have a normal blood pressure at the age of 55 still have a 90% chance of developing hypertension in their lifetime.[71] Control of high blood pressure in the United States remains abysmally low, with over two-thirds of individuals with hypertension not adequately controlled.[72]

A number of lifestyle measures are recommended by JNC 7 and can play significant roles in either reducing the likelihood of developing hypertension or treating it if it currently exists. These lifestyle measures include weight management, regular physical activity, proper nutrition, cessation of cigarette smoking, and moderation of alcohol—all of which represent first line lifestyle related measures in the treatment of high blood pressure within the JNC 7 framework.[42]

Increased body weight has clearly been associated with increased risk of high blood pressure.[73] Conversely, weight reduction in overweight or obese individuals represents a highly reliable way of lowering blood pressure. In most studies, individuals who are overweight or obese can anticipate reducing both systolic and diastolic blood pressure by 1 mmHg for every 2 lbs of weight loss.[74] The mechanism of blood pressure lowering resulting from weight loss is not completely understood. It may represent a decrease in blood volume, an initial diuresis, or reduction in systemic vascular resistance.[75]

Proper nutrition can also play a significant role in blood pressure control. Both the JNC VII Guidelines[42] and the AHA Nutrition Guidelines[66] recommend that individuals with hypertension should consume a diet with no more than 2,300 mg of sodium per day. Recently released Dietary Guidelines for Americans 2020–2025[76] recommends an even lower sodium consumption of 1,500 mg per day for individuals at increased risk for cardiovascular disease and all individuals over the age of 50.

Practical ways to lower salt consumption include removing the salt shaker from the table, reduction of salt in cooking, careful label reading of processed foods (a significant and often under-recognized source of sodium), and increased consumption of whole grains and fruits and vegetables. The Dietary Approaches to Stop Hypertension (DASH) diet, which emphasizes whole grains, fruits and vegetables, and low fat dairy products, has been shown to reliably lower high blood pressure.[77] An addition of further sodium restriction to the DASH diet results in further reduction in blood pressure.[78] Unfortunately, fewer than 20% of individuals with established high blood pressure are following a DASH type diet.[79]

Regular physical activity also helps prevent high blood pressure and lowers blood pressure in individuals with currently existing hypertension. Physically active individuals reduce their risk of hypertension by between 20% and 50%.[73] Individuals with established hypertension who start a physical activity program (emphasizing aerobic activities such as walking) may lower both systolic and diastolic blood pressure by 5-10 mmHg by participating in such moderate intensity physical activity.[80–82]

Excessive alcohol consumption is a risk factor for hypertension.[83] Moderation of this habit also can contribute significantly to controlling blood pressure. Cigarette smoking and use of other tobacco products has been repeatedly shown to raise blood pressure.[84,85] Cessation of this deadly habit should be recommended for multiple reasons.

Some evidence supports stress reduction as playing a role in lowering blood pressure, although this effect seems to be less prominent than the other lifestyle measures already discussed.[86] A beneficial aspect of lifestyle measures in relationship to blood pressure control is that they often act synergistically with each other. It should be noted that positive lifestyle measures when practiced simultaneously appear to have additive benefits. The PREMIER trial showed that a combination of weight loss, sodium restriction, increased physical activity, and limited alcohol consumption when practiced together resulted in substantial blood pressure reductions in individuals with above optimal blood pressure, including Stage 1 hypertension (140–159 mmHg systolic and 90–95 mmHg diastolic), and who were not taking antihypertensive medications.[87] Further benefits were achieved by individuals who implemented a DASH diet in addition to these other lifestyle modifications.

Some controversy has continued to exist related to whether or not lowering blood pressure to 140/90 mmHg is the optimum recommendation. The recently completed SPRINT (Systolic Blood Pressure Intervention Trial)[88] showed a benefit from reduced risk of kidney disease and heart failure in individuals who were at elevated risk for these conditions from lowering systolic blood pressure to 120 mmHg as compared with 140 mmHg. One negative aspect of this study is that it required an average of three pharmaceutical agents to obtain these further reductions. This would argue for a combination of fewer pharmaceutical agents plus lifestyle measures, which are likely to be synergistic with pharmaceutical therapy.

In late 2017, the ACC and the AHA issued new guidelines recommending more stringent control of blood pressure.[4] These guidelines lowered the definition of high blood pressure to any level higher than 120/80 mm Hg. These guidelines are intended to account for an increased risk of cardiovascular complications above these numbers.

As a practical matter, the new definition of high blood pressure resulted in nearly half of the United States population (46%) being categorized as having high blood pressure.

The greatest impact occurred in younger people. The prevalence of high blood pressure was expected to triple in men under the age of 45 and double among women under the age of 45 according to the new guidelines.

The ACC/AHA guidelines also recommended that high blood pressure should be treated earlier with lifestyle changes and in some instances with medication to reach levels of 130/80 mm Hg rather than 140/90 mm Hg in young, asymptomatic individuals. Abundant research suggests that increased physical activity and proper nutrition (including lower amounts of salt and fats in the diet and weight loss if necessary) can significantly lower blood pressure and act synergistically with each other and also with medications.

Categories in the new blood pressure guidelines are:

- Normal (less than 120/80 mmHg)
- Elevated: systolic between 120 and 129 and diastolic less than 80 mmHg
- Stage 1: Systolic between 130 and 139 or diastolic between 80 and 89 mmHg
- Stage 2: Systolic ≥140 or diastolic ≥90 mmHg

Hypertensive crisis was defined as systolic over 180 mmHg and/or diastolic over 120 mmHg. These patients need prompt changes in medication if there are no other indications of problems or need hospitalization if there are signs of organ damage. The guidelines also stressed the importance of using proper technique for measuring blood pressure and the use of home blood pressure monitoring using validated devices.[4] (See also Chapter 5.)

2.5.4 Pharmaceutical Measures for Cardiac Protection

A detailed review of pharmacologic interventions to lower the risk of heart disease is beyond the scope of this chapter. However, it is important to recognize that certain pharmacologic interventions have been demonstrated to be effective in either primary or secondary prevention of cardiovascular disease.

Aspirin has been demonstrated to lower the risk of subsequent events in individuals with existing CHD, where aspirin reduces the risk of subsequent events by 25%.[80] The AHA/ACC lowered the recommended prophylactic dose of aspirin in individuals with existing CHD from 75 to 325 mg/day to 75 to 162 mg/day, since anti-platelet trials had showed no difference in the reduction benefit and reduced risk of bleeding at this lower dosage range.[89] Other anti-platelet agents do not offer significant benefit over aspirin. These agents, such as Clopidogrel, should be limited to patients with aspirin allergy or intolerance.[90]

The picture of aspirin usage in primary prevention is less clear.[91] The AHA guidelines issued in 2007 for women recommend aspirin for high risk women whose ten-year risk of a coronary event, based on Framingham criteria, exceeds 20% and for all women over the age of 65 in whom blood pressure is controlled and the potential benefit for preventing MI or ischemic stroke outweighs the risk of bleeding or hemorrhagic stroke. The United States Preventive Health Services Task Force recommends aspirin for men 45–79 years of age and women 55–79 years of age for benefit in reduction of risk of MI in men and ischemic stroke in women if these benefits outweigh the risk of gastrointestinal bleeding.[92] It should be emphasized that most of the data on the use of aspirin in primary prevention predate concomitant use of statin therapy. Thus, many cardiologists consider utilizing statins as an adjunct to diet, exercise, and smoking cessation rather than aspirin in primary prevention.

Other potentially beneficial pharmaceutical agents include statins, beta adrenergic receptor blockers after MI, and angiotensin converting enzyme inhibitors in individuals at high risk for CHD events. Extensive reviews of all these medications may be found elsewhere.

2.6 CLASS 2 INTERVENTIONS

2.6.1 Obesity Prevention and Management

Obesity,[93] adult weight gain,[94] and increased abdominal fat[95] are all independently associated with increased risk for coronary heart disease.[95–99] Obesity also contributes to a variety of other risk factors for CHD, including hypertension, Type 2 diabetes (T2DM), and dyslipidemia. The AHA recognizes obesity as an independent risk factor over and above its association with other risk factors for CHD.[100]

Over the last 40 years, the percentage of the United States population considered to be overweight (body mass index [BMI] ≥25 ≤29.9) and obese (BMI ≥30.0) has risen steadily and substantially. As depicted in Figure 2.4, over 73% of the adult population in the United States are now considered overweight or obese.[101] The prevalence of obesity has risen particularly sharply, with the most dramatic increases in individuals who are extremely obese (BMI ≥40.0).[102]

The same trends have occurred in children,[103] as depicted in Figure 2.5. The prevalence of overweight has more than tripled amongst children in the United States in the past 40 years. ("Overweight" in children is defined by Centers for Disease Control [CDC] criteria as ≥95th percentile weight for height based on CDC 2000 tables).[104,105] Some criteria, such as those from the American Medical Association, also include a description of ≥85th percentile weight for height as "overweight" and ≥95th percentile of weight for height as an appropriate definition for "obese" in children.

Obese individuals are particularly likely to demonstrate clustering of risk factors.[96,106] Framingham data have demonstrated that over two-thirds of CHD is found in individuals with two or more risk factors.[96] Moreover, obesity is the major driver of the metabolic syndrome, which afflicts 25–35% of the adult population in the United States and represents a potent risk factor for both CHD and diabetes.[107]

Although the association between obesity and increased risk of CHD is well established, no large scale, randomized

FIGURE 2.5 Trends in childhood overweight. (From National Center for Health Statistics. www.cdc.gov/nchs/data/hestat/obesity-child1516/obesitychild1516.pdf)

trials of weight reduction as an intervention to lower the risk of CHD are available to estimate the benefits of weight loss. A number of trials, however, have shown that weight loss in obese individuals reduces risk factors for CHD and a variety of other chronic conditions. For example, in the Diabetes Prevention Program, individuals who were overweight and who lost 5–7% of their body weight and adopted a program of regular physical activity reduced their risk of

developing diabetes by 58%.[108] Nutritional strategies, with a particular emphasis on matching calorie intake to calorie output, have demonstrated effectiveness for weight loss. The Dietary Guidelines for Americans 2020–2025[76] list overconsumption of calories and overweight/obesity as the leading nutritional problems in the United States.

In addition, regular physical activity in conjunction with attention to caloric consumption has been found in numerous studies to help in the maintenance of long-term weight loss.[109–111] The preferred form of physical activity for most overweight or obese individuals is walking. Some studies have recommended 30–60 minutes of moderate intensity walking per day as a reasonable goal for individuals as a component of an effective and safe weight loss program.[110] The Dietary Guidelines for Americans 2020–2025 recommend 60 minutes or more of moderate physical activity as a component of weight management.[76]

Behavioral strategies and social support are also important as components of an overall strategy for long-term weight loss.[112] Support from an individual's family and friends or from groups (e.g. from an organization such as Weight Watchers International) has been demonstrated to be helpful in long-term maintenance of weight loss.[113]

A number of pharmaceutical therapies are currently available to assist in weight loss. These include Phentermine, the combination of topiramate/phentermine Qsymia, Supreza (phentermine), Lorcaserin, Orlistat (prescription), Orlistat (over-the-counter), Naltrexone, Bupropion, and Liraglutide. A description of the dosages and actions of these medications is beyond the scope of this chapter; they have been extensively reviewed elsewhere.[104] It should be noted that all of these medicines should be utilized in conjunction with positive lifestyle measures such as proper nutrition and regular physical activity.

It has been regularly shown that physician involvement in recommendations for weight loss represents an important predictor of both initial weight loss and maintenance of weight loss. A detailed description of available programs and therapies for weight loss is beyond the scope of the current chapter. The author has co-edited several textbooks on this topic, and the reader is referred to these textbooks for more detailed information in this area.[114,115]

2.6.2 Diabetes/Glucose Intolerance

The prevalence of diabetes in the United States has grown significantly over the past decade, which appears to reflect corresponding increases in the prevalence of overweight and obesity.[116] Currently, approximately 9% of the adult population in the United States—nearly 24 million people—have diabetes mellitus. The vast majority of these individuals (more than 90%) have T2DM.[117] Unfortunately, approximately one-quarter of individuals with diabetes are not aware they have this condition. Another significant problem is the recent increase in T2DM in children. It is now estimated that more new cases of T2DM than Type 1 diabetes are found in children each year.[118]

Diabetes represents a significant risk factor for CVD, which is the leading cause of death for both men and women with diabetes, resulting in 75% of all mortality.[116,117] A variety of lifestyle measures, such as weight loss in overweight or obese individuals and regular physical activity, play important roles in the management of diabetes.[119–121] These modalities are particularly important for blood sugar control in individuals with T2DM.

Because patients with diabetes often have other risk factors for CVD, aggressive treatment of these other risk factors is imperative. For example, guidelines from the American Diabetes Association for treating high blood pressure in individuals with diabetes recommend a target of BP at ≤130/80 mmHg for individuals with diabetes.[122,123] NCEP ATP III Guidelines treat diabetes as a CVD equivalent and recommend reduction of LDL cholesterol in diabetic individuals to a goal of less than 100 mg/dL[41].

Impaired glucose tolerance often proceeds overt diabetes and is particularly common in obese individuals. CDC data indicate that 35–40% of the adult population in the United States have glucose intolerance.[124] Recent studies have shown that overweight individuals with impaired glucose tolerance who lose weight, reduce total fat intake, and increase physical activity significantly decrease their risk of developing diabetes.[108,125] Thus, lifestyle measures are highly appropriate in both diabetic and pre-diabetic patients.

Few data are available to address appropriate strategies for long-term reduction in CVD mortality amongst patients with T2DM. To date, interventions to improve fitness and achieve weight loss as methods to reduce CVD morbidity and mortality have been disappointing. The Look AHEAD Trial randomized patients either to intensive lifestyle intervention, which promoted weight loss through increased physical activity and decreased caloric intake, or to a diabetes support and education program. The intent of the lifestyle intervention focused on weight loss but did not reduce the rate of cardiovascular events in this group during a median follow up period of almost ten years, despite the fact that beneficial effects occurred on levels of several biomarkers.[126] Thus, while this trial did not demonstrate a reduction in the risk of cardiovascular morbidity and mortality, it is important to note that patients in the intervention group had meaningful clinical improvement in multiple areas, including hemoglobin A1C, weight, physical fitness, and all other measured cardiovascular risk factors, except for LDL cholesterol levels. In addition, benefits to individuals in the intervention group included reduction in urinary incontinence, sleep apnea, and depression and improvements in quality of life, physical functioning, and mobility. All of these were accomplished with a high level of acceptance in the intervention group and low side effects. Thus, this trial suggests that the high intensity lifestyle intervention approach can be safely conducted and result in significant weight loss in diabetic patients. Application of these findings will depend on clinical judgement and individual patient characteristics for those physicians treating diabetes.

2.6.3 Physical Inactivity

The United States population has become increasingly sedentary.[81] Both the U.S. Surgeon General's Report on Physical Activity and Health[127] and data from the Behavior Risk Factor Surveillance System (BRFSS)[128] have suggested that more than 70% of the adult population in the United States do not achieve 30 minutes of moderate intensity physical activity on most, if not all, days. Multiple studies have demonstrated that an active lifestyle substantially decreases the risk of CVD. The AHA has listed the lack of physical activity as a major risk factor for CVD.[129]

The Physical Activity Guidelines for Americans 2018 provides a listing of known or anticipated health benefits from increased physical activity.[81] A listing of these known benefits and the strength of the evidence supporting these relationships are found in Table 2.4. As can be seen from this table, many of the known benefits from physical activity involve reduction of the risk of CHD.

The Physical Activity Guidelines for Americans 2018 recommend that individuals try to accumulate 150 minutes of moderate intensity activity or 75 minutes of vigorous activity on a weekly basis. Moderate intensity activities include such forms of physical activity as walking, jogging, cycling, or swimming at moderate intensity. A listing of physical activity guidelines is beyond the scope of this chapter. The reader is referred to the Physical Activity Guidelines for Americans 2018 for an excellent compendium of literature in this area.[81]

2.6.4 Moderate Alcohol Consumption

A number of studies have demonstrated that moderate alcohol consumption decreases the risk of vascular diseases such as heart attack, peripheral vascular disease, and sudden cardiac death.[83] It should be noted that these studies have also demonstrated that excessive alcohol consumption increases both all-cause mortality and cardiovascular disease mortality.[130,131] Moderate alcohol consumption has been defined as one drink per day for women and up to two drinks per day for men. The higher level allowed for men is a result of enhanced ability to metabolize alcohol due to more robust activity of the enzyme alcohol dehydrogenase in the liver in men. These levels of alcohol consumption have consistently corresponded to reduction of the risk for cardiovascular disease of approximately 20–40%. The most reasonable course in a clinical setting is to assess the

TABLE 2.4
Health Benefits Associated with Regular Physical Activity

Children and Adolescents

- Improved bone health (ages 3 through 17 years)
- Improved weight status (ages 3 through 17 years)
- Improved cardiorespiratory and muscular fitness (ages 6 through 17 years)
- Improved cardiometabolic health (ages 6 through 17 years)
- Improved cognition (ages 6 to 13 years)
- Reduced risk of depression (ages 6 to 13 years)

Adults and Older Adults

- Lower risk of all-cause mortality
- Lower risk of cardiovascular disease mortality
- Lower risk of cardiovascular disease (including heart disease and stroke)
- Lower risk of hypertension
- Lower risk of type 2 diabetes
- Lower risk of adverse blood lipid profile
- Lower risk of cancers of the bladder, breast, colon, endometrium, esophagus, kidney, lung, and stomach
- Improved cognition
- Reduced risk of dementia (including Alzheimer's disease)
- Improved quality of life
- Reduced anxiety
- Reduced risk of depression
- Improved sleep
- Slowed or reduced weight gain
- Weight loss, particularly when combined with reduced calorie intake
- Prevention of weight regain following initial weight loss
- Improved bone health
- Improved physical function
- Lower risk of falls (older adults)
- Lower risk of fall-related injuries (older adults)

Source: 2018 Physical Activity Guidelines for Americans. https://health.gov/our-work/nutrition-physical-activity/physical-activity-guidelines (page 32: Table 2-1. Health Benefits Associated with Regular Physical Activity). Accessed April 25, 2023.

risks and benefits of alcohol consumption on a case by case basis with each patient.

2.7 CLASS 3 INTERVENTIONS

2.7.1 Nutritional Counseling

Numerous studies have demonstrated that diet has an impact on CHD risk.[132–136] The U.S. Preventive Services Task Force listed nutritional counseling as having "moderate" evidence supporting its role in lowering the risk of CVD. Recent Scientific Statements from the AHA[59] as well as the Dietary Guidelines for Americans 2020–2025[76] both emphasize the important role of nutritional counseling to lower the risk of CVD. In particular, improved nutritional practices may help improve blood lipids, and strategies such as the DASH Diet[77,78] have been demonstrated to help control high blood pressure.

Numerous guidelines and resource materials are available in this area from the American Heart Association[137] as well as the American Dietetic Association[138] and the Preventive Cardiology Nurses Association[139] to assist patients in making nutritional choices to lower their risk of CVD. Additional guidelines are available from various professional societies providing key components of overall health and nutritional patterns. The guidelines are all very consistent with each other, so the individual healthcare professional is able to choose whichever one fits most conveniently into his/her practice.[140]

The complexity of recommending an optimal diet for cardiovascular health reduction has been recognized in all of these guidelines. Most recently, with this caveat in place, the 2020 Strategic Plan from the American Heart Association defined dietary goals as:

> in the context of a diet that is appropriate in energy balance, pursuing an overall dietary plan that is consistent with DASH including, but not limited to:
>
> - Fruits and vegetables ≥ 4.5 cups per day,
> - Fish ≥ 3.5 ounce servings per week (preferably oily fish),
> - Fiber rich whole grain (≥ 1.1g of fiber per 10g of carbohydrate: 3 one ounce equivalent servings per day),
> - Sodium <1500 milligrams per day,
> - Sugar sweetened beverages ≤ 450 kcals (36 ounce) per week.

These recommendations seem reasonable and have been expanded upon in recent reviews.[141,142] Some recent evidence has suggested that diets adhering to the principles of the Mediterranean style diet, which has been supplemented with extra virgin olive oil or nuts, can reduce the incidence of major cardiovascular effects amongst individuals with high cardiovascular risk. The Dietary Guidelines for Americans 2015 and 2020–2025 incorporate and expand upon these principles.[76]

2.7.2 Psychological Risk Factors/Counseling

A number of psychological factors, including depression, chronic hostility, social isolation, and lack of social support, have been linked to increased risk of CHD.[143] Some studies have suggested that improved psychological support systems may improve outcome following MI. For example, 1 meta-analysis of 37 smaller studies showed that stress management and health education in individuals with CHD reduced recurrent MI by 29% and cardiac mortality by 34%.[143] Office visits following MI clearly represent an excellent opportunity to assess levels of depression and social isolation in individuals who have suffered recent cardiac events.

2.8 POST MENOPAUSAL ESTROGEN THERAPY

It is well established that the risk of CVD in women increases significantly following menopause. Relatively few women experience CVD at younger than 45 years of age in the United States.[144] However, by the age of 60, CVD is the leading cause of death among women.

Multiple factors may explain the increased risk of CVD after menopause. For many years, the increase in CVD after menopause was attributed to the decline in endogenous estrogen that accompanies menopause. However, the Women's Health Initiative findings did not support this concept.[145–147] For this reason, hormone therapy is no longer recommended as an approach to prevention of CVD by the United States Preventive Services Task Force (USPSTF), the American Heart Association, or other scientific organizations.[146]

2.9 DETERMINANTS OF BEHAVIOR CHANGE

The belief that it is possible to change patient behavior provides the fundamental underpinnings to the concept of utilizing lifestyle measures to help patients adopt positive lifestyle behaviors to lower the risk of CHD or as an adjunct to the treatment of established CHD. A detailed review of the literature in this area is beyond the scope of the current chapter. However, this literature has been very well summarized in a variety of other publications.[148–150]

A variety of theoretical constructs provide the foundation for behavioral therapy.[148–150] These include:

- cognitive behavioral therapy (which assumes that behavior is learned and can, therefore, be unlearned through cognitive and behavioral strategies)
- social cognitive theory (this is based on the assumption that behavior is the result of interaction of personal and behavior factors as well as environmental influences)

- transtheoretical theory (stages of change; based on accurately placing an individual along the path of various stages of change)[149]

Familiarity with these theoretical constructs as well as the technique of motivational interviewing provides useful underpinnings and a practical framework for incorporating lifestyle change messages in clinical practice.

2.10 ESTABLISHING A LIFESTYLE MEDICINE EMPHASIS IN CLINICAL PRACTICE

As already indicated, physicians can play a particularly powerful role by recommending and monitoring lifestyle related changes for reduction in the risk of CVD. While challenges remain, including lack of time, inadequate reimbursement models, etc., it is clear that healthcare professionals need to move in this direction. Recent publications have suggested ways that interested physicians can incorporate more lifestyle medicine strategies into their daily practice of medicine.[150–154]

The evidence supporting lifestyle therapies for reduction of the risk of CVD is diverse and powerful. Moreover, an emphasis on the linkages between daily lifestyle habits and practices and the risk of CVD is incorporated in virtually all of the evidence based guidelines for treating CVD and its risk factors as well as reducing the risk of other metabolic diseases.[3–15] The AHA has also included positive lifestyle measures as a fundamental component of its strategic plan for 2020 for improving the cardiovascular health of the nation[7] as well as its Impact Goal for 2030[155] and its recommendations for Cardiovascular Health and Disease Surveillance 2030 and Beyond.[156] Finally, the Accountable Care Organization provision of the recent Affordable Health Care Act outlines that healthcare organizations and individual providers are mandated to increase involvement in this area.[142] The Guidelines for Physical Activity 2008[81,117] as well as the Dietary Guidelines for Americans 2015 and 2020–2025[69] provide fundamental, evidence based approaches to lifestyle related issues and should be the foundation for every healthcare worker's increasing emphasis on these strategies in their daily practice.

There has been a recent impetus toward incorporating models of Intensive Therapeutic Lifestyle Change (ITLC) into the practice of medicine. Several recent publications have provided guidance into the rationale for employing these strategies as well as methods for including them and potential outcomes.[157,158]

2.11 SUMMARY

An extensive body of scientific literature supports the concept that positive lifestyle measures are highly effective in lowering multiple risk factors for CHD as well as serving as components of therapy for individuals who already have established CHD. These interventions carry the substantial advantages of being low cost, carrying virtually no adverse side effects, and often simultaneously ameliorating multiple risk factors for CHD. The key imperative for physicians and other healthcare workers is to commit to learning how to incorporate counseling concerning these lifestyle measures in clinical practice and establishing strategies to bring this valuable body of information to their patients.

CLINICAL APPLICATIONS

Actions	Available Tools	Comments
Assess risk of CVD in all patients	Framingham Risk Scores or the equivalent are available for this purpose	Other risk scores including the Reynolds Risk Score are alternatives to the Framingham Risk Scores
Assess and counsel all patients who smoke on the importance of smoking cessation	Multiple tools are available from the American Heart Association, American Lung Association, etc.	Second hand smoke also poses danger and should be discussed with all patients
Assess and counsel related to dyslipidemias	Use the National Cholesterol Education Program (NCEP) criteria and tools or the equivalent	Lifestyle strategies including proper nutrition, weight management, and physical activity are a key component of managing dyslipidemias
Assess and counsel all patients related to blood pressure	Use JNC VII criteria to help individuals understand not only high blood pressure but also high normal and normal blood pressure and what can be done to treat them	Lifestyle strategies are a key component for individuals to maintain healthy blood pressure or lower blood pressure if they are in the pre-hypertension or hypertension categories
Assess and counsel all patients on obesity prevention and management	Obtain weight, body mass index (BMI), and waist circumference on all patients	Both BMI and waist circumference independently predict the risk of CVD
Assess and counsel all patients on physical activity	Utilize criteria from the U.S. Physical Activity Guidelines	These are very useful guidelines for all age groups, from children up to senior citizens

3 Physical Activity and Fitness in the Prevention of Cardiovascular Disease

James M. Rippe, MD

KEY POINTS

- Cardiovascular disease (CVD), including coronary heart disease (CHD), stroke, hypertension, and heart failure, is the leading cause of morbidity and mortality in the United States and around the world.
- Increased cardiovascular fitness and physical activity have both been shown to lower the risk of CVD and serve as an adjunct to its treatment.
- An inactive lifestyle, in contrast, increases the risk of CVD, particularly sedentary activities such as television watching and other forms of screen time.
- Assessment of physical activity and fitness should be a component of all physician visits.

3.1 INTRODUCTION

CVD, as defined by the Centers for Disease Control and Prevention (CDC), encompasses CHD, stroke, hypertension, and heart failure.[1] CVD accounts for nearly one in three deaths in the United States. Approximately 2,150 Americans die from some manifestation of CVD every day; roughly one every 40 seconds.[1] CVD has been the leading cause of death since 1900 and remains so despite a decades-long decline in CVD mortality.[1]

It's predicted that over 650,000 Americans will experience a first myocardial infarction (MI) this year, and approximately 300,000 will be the victim of a reinfarction.[1] It's estimated that another 155,000 infarctions will be "silent," with no symptoms or symptoms other than angina, which are missed or ignored.[1] Collectively, this means that an American experiences a coronary event every 34 seconds. Compared with those who are very physically active, the risk of CHD in sedentary individuals is 150–240% higher.[1] Unfortunately, only about a quarter of all Americans engage in enough exercise to meet the minimum standards of the Centers for Disease Control and Prevention (CDC): at least 150 minutes per week of moderate-intensity aerobic exercise or at least 75 minutes of vigorous exercise and muscle-strengthening activities at least 2 days per week.[2] Given that the greatest reduction in risk for CHD appears to be for those engaging in even modest amounts of physical activity compared with the most physically inactive,[3] even relatively small increases in physical activity could potentially result in a significant decrease in CHD for a large portion of the American population. For example, epidemiological data suggest that the estimated 2.3% decline in physical inactivity between 1980 and 2000 prevented or at least postponed 17,445 deaths due to CHD in the United States.[4]

In spite of the overwhelming evidence implicating physical inactivity as an important and significant risk factor for CHD, fewer than half of adults meet even the minimum recommendation for aerobic exercise.[5] Statistics for young people are even more alarming, with fewer than 20% of adolescents performing the recommended 60 minutes or more of daily physical activity.[6]

Despite the documented lack of physical activity in the United States, and the well-established benefits of regular exercise, many physicians are not encouraging their patients to exercise and lose weight.[7–9] Of equal importance, they do not appear to be adequately prepared to provide recommendations for exercise and physical activity. For example, a survey of 175 primary care physicians revealed that only 12% were aware of the recommendations of the American College of Sports Medicine (ACSM) for physical activity.[9] An evaluation of 51 internal medicine residents reported that while 88% were confident in their knowledge of the benefits of exercise, only about 25% demonstrated adequate knowledge useful for patient counseling.[10]

Healthcare professionals need to promote physical activity with all of their patients. In that regard, an understanding of the health benefits associated with physical fitness and regular physical activity is fundamental. This chapter reviews the evidence linking greater physical activity and fitness with primary prevention of cardiovascular and metabolic disease through effective risk factor management. Recommendations for exercise are also provided both in general terms and for specific conditions.

3.2 PHYSICAL FITNESS VERSUS PHYSICAL ACTIVITY

Physical fitness, specifically cardiorespiratory fitness, is defined here as the ability to deliver and utilize oxygen during sustained activity and typically quantified as maximal oxygen uptake (VO_{2max}). When respiratory gases are measured with a metabolic cart during a maximal graded exercise test, VO_{2max} is valid and reliable. However, submaximal tests or those relying on indirect measures such as time to

DOI: 10.1201/9781003227793-4

exhaustion are subject to considerable error. Measures of physical activity, on the other hand, usually rely on retrospective self-reported data (i.e., physical activity questionnaires). Non-vocational or leisure-time physical activity (LTPA) is most commonly assessed. Vocational physical activity, household chores, and biking or walking to work are also sometimes quantified, but less often. The definitions of physical activity vary greatly from study to study, and the components of physical activity or exercise, such as intensity, duration, and frequency, are often not reported or inadequately assessed.

The categorization of physical activity (i.e., low, moderate, or high) also varies from study to study. Many studies use different criteria for moderate- and vigorous-intensity exercise or activity. The ACSM defines moderate physical activity as any activity requiring 50–70% of VO_{2max} or maximal heart rate.[11] Vigorous physical activity is anything greater than 70% VO_{2max} or maximal heart rate.[11] Walking or brisk walking is generally recommended as the type of exercise that meets the criteria for moderate physical activity. However, it is important to understand that the intensity of walking, or any exercise for that matter, is relative to an individual's age, physical condition, and fitness level. For example, based on the ACSM Guidelines for Exercise Testing and Prescription,[11] even brisk walking may not be of sufficient intensity to meet the minimum criteria for moderate physical activity in a normal, healthy individual of college age. Conversely, brisk walking might be considered vigorous activity for someone over the age of 65. As such, any exercise recommendations should be applied relative to the individual's capabilities and limitations.

Surprisingly, physical fitness has been shown to be only modestly correlated with physical activity, with correlations ranging from 0.09[12] to 0.60.[13] In a meta-analysis of 7 physical fitness and 16 physical activity cohorts cited in the 1996 Surgeon General's Report,[14] Williams[5] found that the risk of CHD or CVD decreased linearly with increasing percentiles of physical activity. He also found that the reduction in risk for CHD or CVD associated with increasing percentiles of physical fitness demonstrated a precipitous decrease occurring just before the 25th percentile of the physical fitness distribution. Further, at all percentiles ≥25th, the reduction in risk for CHD and CVD was significantly greater for physical fitness compared with physical activity, as illustrated in Figure 3.1.

These findings are supported in a more recent comparison of fitness versus physical activity in predicting all-cause mortality in a cohort of 842 men referred for exercise testing.[12] While both physical activity and fitness were strong predictors of all-cause mortality, physical fitness was a stronger predictor of mortality than activity level. A 1,000 kcal per week increase in physical activity was found to be similar to a 1 MET (metabolic equivalent; oxygen uptake of 3.5 $ml \cdot kg^{-1} \cdot min^{-1}$) improvement in fitness, with both conferring a 15–20% reduction in mortality. Of equal, if not greater, interest, these data also demonstrated that 40% of the reduction in mortality occurred between the least active or fit and the next least fit or active groups, suggesting that even modest increases in physical activity or fitness, especially in those who are inactive, may result in a significant reduction in mortality.

It is important to emphasize that while the reduction in risk of CVD is greater when comparing levels of fitness with levels of physical activity, both the Physical Activity Guidelines for Americans 2018 (PAGA 2018) and the ACSM emphasize that in the area of physical activity, "some is better than none." It is also essential to note that it is often misunderstood that even a very small amount of physical activity substantially lowers the risk of mortality, in general, and from CVD, in particular. As illustrated in Figure 3.2, the highest part of the risk comes from individuals who were previously sedentary and begin to engage in physical activity for even as little as 30 minutes per week.

As evidenced from this graph taken from the PAGA 2018, there is no lower threshold for benefits. Increasing benefits occur for individuals who engage in approximately 150 minutes of regular physical activity, although meaningful benefits occur in individuals who engage in physical

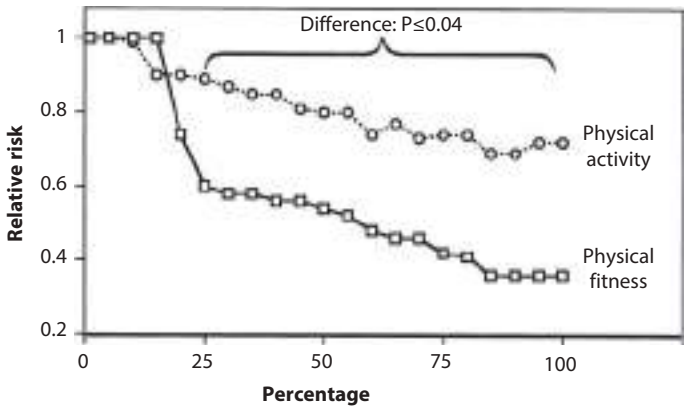

FIGURE 3.1 Estimated dose–response curve for the relative risk of either CHD or CVD by sample percentages of fitness and physical activity. Studies weighted by person-years of experience. activity even substantially more than this. As illustrated in this figure, 70% of the benefit is achieved by individuals who engage in moderate physical activity, such as walking 30 minutes five times a week. However, 20% of the benefit comes for individuals who accumulate only 30 minutes per week!

While only approximately 25% of individuals achieve the chief guideline of 150 minutes of moderate-intensity physical activity on a weekly basis, according to the PAGA 2018 Guidelines, fewer than half of adults meet even minimum recommendations for physical activity, as illustrated in Figure 3.3.

3.3 GENERAL RECOMMENDATIONS FOR PHYSICAL ACTIVITY

In 1996, the Surgeon General's Report on Physical Activity and Health recommended:

people of all ages to include a minimum of 30 minutes of physical activity of moderate intensity (such as brisk walking) on most, if not all, days of the week. It is also acknowledged that for most people, greater health benefits can be obtained by engaging in physical activity of more vigorous intensity or of longer duration.[14]

More recently, the 2018 Physical Activity Guidelines for Americans[15] provide updated and more specific recommendations for different age groups and some clinical populations. The following is a very brief summary of their recommendations.

3.3.1 Adults

- All adults should avoid inactivity. Some physical activity is better than none, and adults who participate in any amount of physical activity gain some health benefits.
- For substantial health benefits, adults should do at least 150 minutes a week of moderate-intensity, or 75 minutes a week of vigorous-intensity aerobic physical activity, or an equivalent combination of moderate- and vigorous-intensity aerobic activity.
- Adults should also do muscle-strengthening activities that are moderate or high intensity and involve all major muscle groups on two or more days a week, as these activities provide additional health benefits.

3.3.2 Children and Adolescents

- Children and adolescents should do 60 minutes (one hour) or more of physical activity daily.
- Aerobic: Most of the 60 or more minutes a day should be either moderate- or vigorous-intensity aerobic physical activity, and should include vigorous-intensity physical activity at least three days a week.
- It is important to encourage young people to participate in physical activities that are appropriate for their age, that are enjoyable, and that offer variety.

3.3.3 Older Adults

- When older adults cannot do 150 minutes of moderate-intensity aerobic activity a week because of chronic conditions, they should be as physically active as their abilities and conditions allow.
- Older adults should do exercises that maintain or improve balance if they are at risk of falling.
- Older adults should determine their level of effort for physical activity relative to their level of fitness.
- Older adults with chronic conditions should understand whether and how their conditions affect their ability to do regular physical activity safely.

The updated Physical Activity Guidelines for Americans are scheduled to be released in late 2018 and are likely to carry similar recommendations. They may be accessed at https://health.gov/news/blog-bayw/2018/03/2018-physical-activity-guidelines-advisory-committee-submits-scientific-report/.

3.4 WOMEN AND CHD

One in three women have some form of CVD; 6.6 million have been diagnosed with CHD.[1] In 2013 alone, 398,086 women died from CVD; about one death every 80 seconds.[1] Just over 40% of these deaths were attributable to CHD, including 50,742 from MI.[1] On average, new and recurrent MI as well as fatal CHD impact 405,000 women each year.[1] Because women typically have heart attacks at older ages than men do, they're more likely to die from them within a few weeks.[1]

Despite these overwhelming statistics, surveys indicate that some 44% of women still do not know that CHD is by far the number one killer of women in the United States.[1] And while regular physical activity has been demonstrated to significantly reduce the risk of CVD in women, they are on average less physically active than men, with only 46.1% of women compared with 54.2% of men engaging in moderate to vigorous activity on three or more days per week.[5]

Although a greater exercise volume and/or intensity appears to produce greater health benefits for most people, the literature examining the relationship between exercise intensity and risk for CHD is not unequivocal.[3] A meta-analysis of 16 gender-specific physical activity cohorts found that the risk for CHD decreased linearly with increasing percentiles of physical activity, but examination of the individual cohorts revealed considerable variation in the outcomes.[3] Specifically, there is evidence to suggest that the dose–response relationship between exercise intensity and risk for CHD or mortality may differ between men and women.[16–20] For example, based on data from the Nurses' Health Study, a cohort of 72,488 female nurses 40 to 65 years old, Manson et al.[17] concluded that "the reduction in risk for CHD for women who walked at a brisk pace three or more hours per week was similar to those women who engaged in regular vigorous ($\geq$ 6 MET) exercise." In 2001, data from the Women's Health Study[16] showed that walking 1 to 1.5 hours per week was associated with a 51% reduction in risk for CHD but walking $\geq$2 hours per week conferred no greater reduction in risk. More vigorous activity was not associated with a lower risk for CHD, comparing highest with lowest. Similarly, the relationship between walking pace and risk for CHD did not demonstrate a linear trend.

Other studies have not demonstrated an association between physical activity/inactivity and CHD and/or mortality in women, with 1 review reporting no relationship between physical inactivity and CHD in 10 of 14 studies.[18] More recently, Blair et al.[19] found that all-cause mortality rates in women did not differ across the range of physical activity levels. The Framingham Study also found no association

between physical activity level and mortality in women.[20] In contrast, a 2004 meta-analysis of 30 longitudinal studies examining the impact of physical activity on the risk for CVD in women showed a dose–response relationship, with a 20% to 40% reduction in risk for CVD in the most active women compared with those who were sedentary.[21]

This inconsistency in findings has been observed elsewhere[17] and may be the result of real gender differences or may reflect differences in study participants and/or design. For example, in the 16 studies he examined, Williams[3] found that the intervals (tertiles, quartiles, etc.) reported differed greatly, with 9 studies using 3 levels, 6 using 4 levels, and 1 study using 6 levels. In particular, the apparent gender differences in the response to physical activity may also be mediated by the physical activity levels of the study participants. As an example, in 2001, the most active 20% of women in the Women's Health Study expended ≥ 1,500 kcal per week in LTPA, whereas men in the highest quintile of physical activity in the Harvard Alumni Health Study reported expending ≥ 3,129 kcal per week in LTPA.[3] Interestingly, very recent physical activity data acquired by accelerometer from over 17,000 older women in the Women's Health Study showed a clear dose–response relationship with time engaged in "moderate to vigorous" physical activity.[22] Those women who exercised just over an hour per day at this intensity had mortality rates almost 65% lower than women who were sedentary.

The limited data on the relation between physical fitness and risk for CVD and/or mortality in women suggest a greater similarity with studies of men when compared with studies of physical activity. A relatively recent review of the literature revealed that low exercise capacity and slow recovery heart rate predicted CVD and mortality in both men and women.[23] Data from the St. James Women Take Heart Project demonstrated a 17% reduction in mortality in women for every 1 MET increase in exercise capacity.[21] As such, it would appear that women who engage in exercise vigorous enough to improve aerobic fitness gain health benefits comparable to those of their male counterparts.

3.5 STROKE

While the incidence of stroke and associated mortality rate has been declining since at least 2001, it is estimated that 795,000 people in the United States experience a new (~610,000) or recurrent (~185,000) stroke each year.[1] Of these, the large majority are ischemic (~87%) with the remainder being hemorrhagic in nature.[1] The risk of a stroke for African-Americans is nearly double that for Caucasians, and it tends to occur at a younger age.[1] Hispanics, particularly Mexican-Americans, have significantly higher rates of ischemic stroke and at a younger age.[1] Annually, 55,000 more women than men have a stroke, with the incidence in women aged 45 to 54 years being especially high.[1]

Some 200,000 to 500,000 transient ischemic attacks (TIAs) are estimated to occur in the United States each year, and the incidence is higher in men and in African- and Mexican-Americans.[1] The occurrence of a TIA increases the risk of a stroke in both the short term and the long term.[1] Approximately 15% of all strokes are preceded by a TIA, and about 12–13% of individuals will die within a year of a TIA.[1]

The most important risk factors for stroke include history of TIA, pre-existing CHD, age, hypertension, diabetes mellitus, cigarette smoking, and atrial fibrillation.[1] Physical inactivity has also been shown to increase the risk of a stroke and stroke mortality, but its relationship to cerebral events is less well understood than its relationship to CHD.[1] Meta-analyses have shown that the reduction in risk for stroke associated with aerobic exercise/activity ranges between 20% and 40% depending on the type of stroke and the study design.[22,23] The benefit for women is less clear and may not be as great as that for men.[22] It remains unresolved whether or not a dose–response relationship exists between level of physical activity and stroke risk. While those studies that looked at different levels of physical activity generally found a greater benefit for higher levels of physical activity, there was a real lack of consistency in their findings.[22] In addition, the criteria for different levels of physical activity are not uniform, varying from study to study and often poorly quantified. As such, an exercise prescription to optimize the reduction in risk for stroke remains undetermined. Currently, the American Heart Association recommends moderately intense aerobic physical activity for *at least* 30 minutes per day to reduce the risk of ischemic stroke.[24] While there is evidence that greater muscular strength in youth is associated with a modestly reduced risk (~5–10%) for stroke later in life,[25] the relationship between muscular strength, strength training, and stroke risk remains virtually unexplored.

3.6 HYPERTENSION

Based on data from the National Health and Nutrition Examination Survey (NHANES), it's estimated that some 80 million adults or almost 1 in 3 American adults suffer from hypertension (systolic blood pressure [SBP] ≥140 mmHg and/or diastolic blood pressure [DBP] ≥90 mmHg).[1] The prevalence in African-American adults is amongst the highest in the world. Looking at all Americans with hypertension, 82.7% were aware of it, 76.5% were being treated, and only 54.1% had it under control. A meta-analysis of 61 studies involving more than 1 million individuals demonstrated that mortality associated with both ischemic heart disease (IHD) and stroke increases linearly from levels as low as 115 mmHg SBP and 75 mmHg DBP.[26] For every 20 mmHg systolic or 10 mmHg diastolic increase in blood pressure, there is a doubling of mortality from both IHD and stroke.[26] Those with hypertension have a shorter life expectancy and a shorter life expectancy free of CVD, and can expect to live more years with CVD compared with those who are normotensive.[1]

Regular physical activity has been shown to be an effective way to lower blood pressure in 75% of persons with

hypertension.[27,28] Compared with sedentary adults, those who are physically active have a lower incidence of hypertension,[29–31] with blood pressures that average 5 mmHg lower.[32] Higher levels of occupational and/or leisure-time physical activity are associated with lower blood pressure.[27,31,33] These data have led to recommendations for regular physical activity as lifestyle therapy for the prevention and management of hypertension.

The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VII)[34] recommends regular aerobic physical activity such as brisk walking at least 30 minutes per day, most days of the week, for the prevention and management of hypertension. In a meta-analysis of 44 trials of at least 4 weeks' duration and after controlling for other factors, increased physical activity was associated with a small but significant decrease of 3/2 mmHg in normotensive subjects and 7/6 mmHg in hypertensive subjects.[35] The training intensity in these studies averaged 65% of heart rate or VO_2 reserve. However, the characteristics of the training programs (intensity, duration, and frequency) explained less than 5% of the variance in blood pressure response. Weekly energy expenditure was not significantly related to the changes in SBP or DBP. Vigorous exercise was not found to be different from moderate-intensity exercise in its ability to reduce blood pressure, with some studies showing that exercise at 40% of VO_2 reserve produced a greater reduction in SBP than exercise at 65–75% of VO_2 reserve.[35,36] As such, and per JNC VII, regular moderate-intensity exercise is recommended for the prevention and management of hypertension.

The JNC VIII Guidelines made the same recommendations. Some significant changes were made in the 2017 American College of Cardiology (ACC)/American Heart Association (AHA) Guidelines for the Prevention, Detection, Evaluation and Management of High Blood Pressure in Adults.[37] The 2017 ACC/AHA Guidelines established classification and treatment thresholds, found in Table 3.1. These guidelines also recommend a variety of non-pharmacologic interventions, prominently featuring physical activity consisting of 120–150 minutes per week of aerobic physical activity and 90–120 minutes per week of dynamic resistance exercise.

The guidelines for blood pressure in the 2017 ACC/AHA recommendations were significantly lower than previous recommendations and were based on the findings of the Systolic Blood Pressure Intervention Trial (SPRINT).[38] This study was conducted on over 9,000 individuals with a mean age of 67.9 years and a SBP of 130–180 mmHg who were at increased risk for cardiovascular events. Researchers compared targets of SBP <120 mmHg with standard targets of SBP <140 mmHg. The SPRINT Trial showed a 30% decrease in the composite outcome of MI, acute coronary syndrome, stroke, and heart failure or death compared with the standard target group. Unfortunately, in order to achieve these lower levels of blood pressure, three antihypertensive medicines were required in many participants, which may make it impractical in a normal clinical setting. It should be emphasized that many of the lifestyle modalities, such as weight management, weight loss, increased physical activity, and proper nutrition, can also significantly lower blood pressure, which may make these lower thresholds more achievable.

3.6.1 Resistance Exercise Training and Blood Pressure

Resistance training is generally recommended as an adjunct to aerobic activity. On average, studies have reported 3 mmHg reductions in resting SBP and DBP following progressive weight lifting programs.[30,37–39] Although this decrease may seem small, a 3 mmHg reduction lowers the risk of CHD, stroke, and all-cause mortality.[30] Two to three days per week of total body resistance training is generally recommended.[16,40–42] However, as with aerobic exercise, the "optimal" exercise prescription for strength training is not known. More specifically, low- to moderate-intensity strength training (30–40% of a 1 repetition maximum (1RM) for upper body exercises, and 50–60% 1RM for lower body exercises) is currently recommended by some for the prevention and management of high blood pressure.[27,42] Cornelissen et al.[43] showed that single bouts of either high- or low-intensity resistance exercise lowered SBP, but only low-intensity training lowered DBP. Other studies reported that high-intensity resistance training reduced neither SBP nor DBP, and actually raised SBP in some individuals.[44]

TABLE 3.1
Categories of Blood Pressure in Adults

BP classification	SBP (mmHg)	DBP (mmHg)	Lifestyle habits	Drug treatment
Normal BP	<120	<80	Promote	None
Elevated BP	120–129	<80	Yes	None
Stage 1 hypertension	130–139	80–89	Yes	May be indicated[a]
Stage 2 hypertension	≥140	≥90	Yes	Indicated[b]

Adapted from 2017ACC/AHA Categories of BP in Adults.
[a]Initiate pharmacological treatment if clinical atherosclerotic CVD or estimated ten-year CVD risk >10%.
[b]Consideration of two medications from two different classes.

The currently recommended strength training program to optimize blood pressure reduction is 1–3 sets of 10–15 repetitions for each of the major muscle groups (thighs [hamstrings and quadriceps], hips, back, chest, arms, and abdominals), on two to three days per week.[30,42,45–49]

3.7 HEART FAILURE

It's estimated that some 5.7 million Americans suffer from heart failure (HF, also known as congestive heart failure).[1] The risk of developing HF increases with age; by the age of 40, both men and women have a 1 in 5 risk of developing HF at some time in their lives.[1] Both the incidence and prevalence of HF are particularly high in minorities, especially African-Americans.[1] HF occurs earlier and mortality is higher in African-Americans compared with Caucasians.[1]

Surprisingly few studies have examined the relationship between physical activity and primary prevention of HF. Two large longitudinal studies exploring this association found that compared with sedentary individuals, those who engaged in regular vigorous exercise had a 15–35% lower risk for developing HF.[50,51] Vigorous activity was defined as activities "vigorous enough to work up a sweat,"[45] such as running, jogging, swimming, heavy gardening, or competitive sports.[50,51] The reduction in risk was correlated with the frequency of vigorous exercise in a dose–response manner.[45] Activity of a moderate intensity, defined as > four hours/week of walking, cycling, or light gardening, was associated with ~15% reduction in risk. Pooled data from three large cohort studies showed a strong and negative dose–response relationship between LTPA and risk for HF. Those individuals whose LTPA exceeded 1,000 MET/min/week had a risk for HF that was 19% lower than that of their sedentary counterparts.[52,53]

3.8 DIABETES

The latest available data from NHANES estimate that 12.8% of Americans over the age of 19 have diabetes mellitus (DM), of which >90% are classified as Type II (T2DM).[1] Insulin resistance often precedes the onset of T2DM and is prevalent in the pre-diabetic states of impaired fasting glucose (IFG) and impaired glucose tolerance (IGT). Over 35% of Americans are classified as pre-diabetic with IFG and/or IGT.[1] This means that more than 47% of all adults have some degree of abnormal glycoregulation![1] The prevalence of CHD has been estimated to be as high as 55% in adult diabetics, and T2DM is an independent risk factor for myocardial infarction and CVD in both men and women.[53] T2DM is a predictor of ischemic stroke and HF, and DM increases the overall CV risk in patients with pre-existing HF.[54,55] Compared with non-diabetics, mortality from CHD has been reported to be twice as great in diabetic men and four to five times greater in diabetic women.[52] CVD is responsible for at least two-thirds of deaths in adults with DM.[52]

3.8.1 The Metabolic Syndrome, CVD, and T2DM

The clustering of risk factors known as the metabolic syndrome (see following section for definition and more information) is predictive of both T2DM and CVD. It is associated with a twofold increase in the risk for cardiovascular events.[53] Abdominal obesity in particular is an independent risk factor for insulin resistance[54,55] and T2DM.[56] Much of the increased risk of CHD and CVD associated with T2DM can be attributed to the presence of the metabolic syndrome.[57] One study reported ten-year cardiovascular mortality to be 3.55 times greater in men with metabolic syndrome than in those without the condition.[58]

Numerous studies have demonstrated an inverse relationship between physical activity and/or fitness and the risk for developing T2DM.[59–6]. Men of low fitness have a two to three times greater risk of developing T2DM compared with those in the higher fitness categories.[59,60] Similarly, physical activity shares an inverse relationship with the risk for T2DM in a dose–response manner. Even just daily walking for more than 30 minutes has been shown to reduce the risk of developing T2DM by 20–45%.[66,69–72,69–7]. Brisk/faster walking was associated with a lower risk independent of time spent walking.[63,66,67] In an interventional trial involving 18 previously sedentary middle-aged men and women, six months of walking (minimum of three days per week for 30 minutes) resulted in improved insulin sensitivity.[70] Sedentary behaviors such as excessive television watching have been demonstrated to increase the risk for T2DM even after controlling for diet and physical activity levels. It has been estimated that 43% of new cases of diabetes could be prevented by watching TV for less than ten hours per week and engaging in brisk walking for 30 minutes or more per day.[68] Modest improvements in diet and exercise habits have been shown to reduce the incidence of T2DM even in those at highest risk for developing it—those with IFG and/or IGT.[71–73]

3.8.2 Glycemic Control

Studies of aerobic exercise training have shown significant but modest reductions in glycosylated hemoglobin (HbA_{1c}, long-term index of glycemic control) of about 8% from baseline.[79,80] The exercise intensity in these studies accounted for almost 83% of the differences in post-intervention HbA_{1c} compared with 21% determined by exercise volume. Those interventions with an intensity >65% of VO_{2max} demonstrated the greatest improvement in HbA_{1c}. As such, exercise interventions for glycemic control should include some vigorous exercise.[79]

3.8.3 Strength Training

Resistance training, especially in combination with aerobic exercise training, can significantly improve HbA_{1C} levels, fasting blood glucose, and insulin sensitivity.[80] Additionally, other risk factors, such as blood pressure, have been shown

to be significantly reduced in diabetics with a program combining strength and aerobic training compared with either aerobic or resistance training alone.[77] As such, The American Diabetes Association now recommends strength training, in addition to aerobic exercise training, as part of a program to prevent or manage T2DM.[81] Weight training has been found to be safe in persons with CVD, ST depression, myocardial ischemia, ventricular dysrhythmias, and other cardiovascular complications.[78] The myocardial demands of high-intensity weight training are comparable to activities such as stair-climbing, walking uphill, or carrying 20–30 lbs of groceries.[81]

The following are some of the specific recommendations from the American Diabetes Association Consensus Statement on Physical Activity/Exercise and Type II Diabetes:[81]

- People with IGT should begin and continue a program of weight control, including at least 150 minutes per week of moderate to vigorous physical activity and a healthful diet with modest energy restriction.
- To improve glycemic control, assist with weight maintenance, and reduce risk for CVD, the panel recommends 150 minutes per week or more of moderate-intensity aerobic physical activity, and/or 90 minutes per week or more of vigorous aerobic exercise. The physical activity should be distributed over at least 3 days per week, with no more than 2 consecutive days without physical activity.
- Compared with lower volumes of activity, performing at least 4 hours per week of moderate to vigorous aerobic and/or resistance exercise is associated with greater CVD risk reduction.
- For long-term maintenance of major weight loss (≥13.6 kg or 30 lbs), larger volumes of exercise (7 hours per week of moderate or vigorous aerobic physical activity) may be helpful.
- Unless contraindicated, people with type 2 diabetes should be encouraged to perform resistance exercise 3 times per week, targeting all major muscle groups. This should progress to 3 sets of 8 to 10 repetitions at a weight that cannot be lifted more than 8 to 10 times. Initial supervision and periodic reassessments by a qualified exercise specialist are recommended to ensure that resistance exercises are performed correctly, to maximize health benefits, and to minimize the risk of injury.

3.9 OBESITY

Based on the most recent data from the NHANES, and using body mass index (BMI, body weight in kg/height in meters^2) as the criterion measure, the prevalence of overweight and obesity in the United States has decreased among those of higher socioeconomic status but increased among those of lower socioeconomic status.[1] The overall prevalence of extreme obesity in U.S. youth continues to increase, especially among adolescent boys. In adults, overweight is defined as a BMI of 25–29.9 kg/m^2. Obesity is defined as a BMI ≥30; extreme (formerly morbid) obesity is defined as a BMI ≥40. Overall, 73% of U.S. adults were overweight or obese according to recent NHANES data.[82] Among men, non-Hispanic blacks were less likely to be overweight or obese (69%) compared with Hispanics (80%) and non-Hispanic whites (73%). In women, non-Hispanic blacks (82%) and Hispanics (76%) were much more likely to be overweight or obese compared with non-Hispanic whites (61%). Among all U.S. adults, 35% were obese (34% of men vs. 36% of women). Hispanic and non-Hispanic black males (38%) were more likely to be obese than non-Hispanic white men (34%). Among women, non-Hispanic blacks (58%) and Hispanics (43%) were more likely to be obese than non-Hispanic whites (33%).

Over the last two decades, it has become increasingly apparent that abdominal adipose tissue has unique metabolic properties and may be more predictive of CVD, the metabolic syndrome, and diabetes than BMI or measures of overall adiposity.[83–93] Abdominal or central obesity is most commonly assessed by measuring waist circumference or waist-to-hip ratio (WHR). From 1988–1994 to 1999–2000 (most recent data available), the mean waist circumference of adult Americans increased from 95.3 cm to 98.6 cm in males and from 88.7 cm to 92.2 cm in females.[85]

Despite these rather alarming trends, only 40.3% of obese patients were advised to lose weight by their family physician in 2004, down from 42.3% in 1994.[86] An evaluation of an academic pediatric hospital found that only a few more than half (53%) of the children who met the NHANES criteria for overweight (≥95th percentile for BMI) were identified as such by their primary care physician.[87] Interestingly, while a majority (69%) of the children's charts contained an "adequate" dietary history, only 15% included information regarding physical activity and/or television watching.

3.9.1 Central Adiposity, Inflammation, and CVD

Atherosclerosis has now come to be understood as an inflammatory disease.[94–98] A growing body of evidence further demonstrates that greater adipose tissue mass, especially visceral adipose tissue, directly contributes to systemic inflammation.[92–94] The pro-inflammatory state associated with abdominal obesity has been proposed as a common underlying condition linking CVD, insulin resistance/T2DM, and the metabolic syndrome.[95–97] While a complete discussion of the complex physiology and mechanisms of adipose-related inflammation is beyond the scope of this chapter, it is increasingly evident that visceral adipose tissue secretes a veritable host of pro-inflammatory cytokines. Greater levels of central adiposity have been shown to be associated with higher circulating levels of these pro-inflammatory proteins, such as interleukin-6 (IL-6), tumor necrosis factor–alpha (TNF-alpha), and C-reactive protein (CRP).[98–100]

A published review of lifestyle interventions and systemic inflammation observed that 9 of the 12 studies reviewed demonstrated an inverse relationship between physical activity or fitness and markers of inflammation, after controlling for BMI or other measures of adiposity.[101] For example, in a 20-year follow-up of 4,252 elderly men (aged 40–59 at baseline), Wisse et al.[102] found that physical activity level was inversely associated with levels of CRP and other inflammatory markers, even after adjusting for BMI and other covariates. In those men who went from "at least lightly active" to inactive, the levels of these markers were similar to those men who had been inactive throughout the follow-up period. Those who were inactive at baseline but increased their level of activity had levels similar to those men who had remained continuously active.

The HERITAGE Family Study examined the effects of 20 weeks of exercise training on CRP levels in 652 sedentary, but healthy, adults.[103] The training program was performed on cycle ergometers three days per week, progressing to 50 minutes at 75% of baseline VO_{2max}. This protocol resulted in a substantial (17.8%) increase in VO_{2max}. However, reduction in CRP levels only occurred in the individuals with high baseline levels of CRP. The positive relationship between baseline CRP levels and exercise-induced changes has been observed elsewhere[104] and may explain, at least in part, why some studies have not found that an exercise intervention reduces levels of inflammatory markers.[105–110]

3.9.2 The "Fitness vs. Fatness" Debate

While it is well established that both increased body fat and low levels of physical activity and/or fitness are associated with increased mortality, T2DM, and CVD, it is not precisely clear as to their relative importance or how they interact. An extensive review of the literature addressing the fitness vs. fatness debate as it pertains to CHD and/or CVD concluded: "physically active lifestyle and/or a moderately high fitness level (i.e., not in the bottom 20% of the population) reduces the risk of CVD/CHD in overweight or obese persons."[111] While they suggest that overweight or obese individuals who are physically fit or active have levels of risk that approach those associated with those of lean, unfit persons, they also concede that their risk is still greater than for those who are fit/active and of normal weight. The authors further observed that the risk reduction associated with increased fitness or activity is greater in those who are overweight or obese compared with those of normal weight. Finally, they recommend that physical activity should be encouraged regardless of whether or not that activity induces weight loss. This recommendation is supported by the majority of the studies reviewed that found physical activity/fitness to be independent risk factors for CHD/CVD.

Addressing obesity begins with the understanding that weight gain is caused by a cumulative positive energy balance where energy intake exceeds energy expenditure. As such, weight loss can *only* occur in the presence of a negative energy balance. Maintenance of body weight, therefore, requires that energy intake matches energy expenditure. While the concept of energy balance or imbalance is conceptually simple, the respective roles of diet and exercise in weight loss and management are less clear. There follows a brief summary of recent and relevant investigations of the role of physical activity in 1) preventing weight gain, 2) weight loss, and 3) weight loss maintenance.

3.9.3 Preventing Weight Gain

In 2003, the International Association for the Study of Obesity (IASO) released the following statement regarding physical activity and prevention of unhealthy weight gain:

> The current physical activity guideline for adults of 30 minutes of moderate intensity activity daily, preferably all days of the week, is of importance for limiting health risks for a number of chronic diseases including CHD and diabetes. However for preventing weight gain or regain this guideline is likely to be insufficient for many individuals in the current environment. There is compelling evidence that prevention of weight regain in formerly obese individuals requires 60–90 minutes of moderate intensity activity or lesser amounts of vigorous intensity activity … For children, even more activity time is recommended. A good approach for many individuals to obtain the recommended level of physical activity is to reduce sedentary behaviour by incorporating more incidental and leisure-time activity into the daily routine.[112]

3.9.4 Physical Activity and Sustained Weight Loss

Unfortunately, most studies do not support increasing physical activity, either alone or in combination with a calorie restrictive diet, to be an effective means to produce short-term weight loss.[116–118] However, physical activity appears to play a major role in long-term maintenance of weight loss.[113–116] An extensive review of the role of exercise in promoting weight loss combined data sets and used weighted mean differences (WMD) to explore the efficacy of exercise interventions.[116] The randomized clinical trials (RCTs) in this review only included studies that incorporated a follow-up of at least 12 months' duration to assess long-term maintenance of weight loss. A summary of their findings follows:

- Compared with diet alone, diet plus exercise produced significantly greater weight loss at 12 months (WMD = −1.95 kg),18 months (WMD = −7.83 kg), and 36 months (WMD = −8.22 kg). In addition, there were small but significantly greater differences/improvements in high-density lipoprotein (HDL) and triglycerides at 12 months. At 18 months, diet plus exercise demonstrated large and significantly greater reductions in SBP (WMD = −8.90 mmHg) and DBP (WMD = −12.10 mmHg).

- A separate analysis in this review compared diet plus behavior therapy with diet plus behavior therapy and exercise. The addition of exercise produced significantly greater weight loss at 12 months (WMD = −3.02 kg) and at 24 months (WMD = −2.16 kg). There were no significant differences between groups for cholesterol, blood pressure, or glucose.

These data suggest that regular physical activity is advantageous for sustained weight loss.

3.9.5 How Much Physical Activity Is Required for Sustained Weight Loss?

There is a general consensus that 2,500–2,800 kcal per week (60–90 minutes per day of moderate-intensity physical activity) is required for long-term weight loss, as reflected in the recommendations and consensus statements of the U.S. Department of Health,[117] ACSM, and IASO.[118] These recommendations are supported by data from the National Weight Control Registry (NWCR), a database of approximately 5,000 individuals who have minimally lost 30 lbs. for at least one year (average weight loss is about 30 kg for an average of 5.5 years).[119] Data collected on these "successful losers" indicate that more than 90% of participants expended ~2,800 kcal per week in physical activity.

3.9.6 Resistance Training and Weight Loss

Despite claims in the popular literature, strength training is not recommended as the primary mode of exercise for weight loss.[118] While strength/resistance training has been shown to preserve fat-free mass when coupled with a calorie-restrictive diet, it has not been shown to enhance weight loss either alone or in combination with a dietary intervention.[113,115,116,118] Despite the apparent ability of resistance training to maintain muscle mass in the presence of calorie deficit, it does not appear to be able to prevent the decrease in resting energy expenditure associated with weight loss.[118,120] In the absence of a dietary intervention, some studies have shown that high-intensity resistance training can significantly increase resting energy expenditure for 16 hours or more.[121–125] However, these findings are based on a very small number of subjects and are not supported by the results of other investigations.[126–128] As such, in the absence of stronger evidence, resistance training is not recommended as the primary form of exercise to promote or enhance weight loss.[118] However, weight training may provide an advantage in maintaining fat-free mass and enhancing body composition with a weight loss intervention.[120,129–131]

3.10 LIPIDS

The role of blood lipids in the pathology of atherosclerosis is well established, and dyslipidemia is understood to be an important contributing factor for CHD.[132] Dyslipidemia includes elevations in total cholesterol (TC), low-density lipoprotein cholesterol (LDL-C), and triglycerides (TG) and low levels of high-density lipoprotein cholesterol (HDL-C).[132] In addition, newer lipid and lipoprotein measures such as lipoprotein particle size and number, apolipoproteins, and triglyceride-rich lipoproteins (TRL) are emerging as risk factors that may also increase CVD risk.[133] The National Cholesterol Education Program Adult Treatment Panel III has published guidelines establishing lipid and lipoprotein modification goals for both primary and secondary prevention.[132] However, data from NHANES indicate that many Americans have not achieved recommended levels for all lipids and lipoproteins.[134]

One of the proposed mechanisms by which regular physical activity reduces the risk for CHD is its effect on blood lipids, especially the increase in HDL-C and reduction in TG levels.[132–134] Cross-sectional studies have consistently shown a positive association between the volume and intensity of aerobic activities and HDL-C levels and a negative association with TG levels.[135] However, reviews of the literature reveal a surprisingly inconsistent response of other blood lipids to regular aerobic exercise.[135,136] These findings may be further confounded by concurrent changes in body weight or composition. In studies without a dietary intervention, the most commonly reported change in lipids was an increase in HDL averaging 4.6%, ranging from a decrease of 5.8% to an increase of 25%. Simultaneous reductions in TG (3.7%), LDL-C (5.0%), but not TC, were also observed.[135] Changes in TC and LDL-C are much less frequently reported, are modest when they do occur, and may be more attributable to weight loss than the exercise intervention per se. As such, regular exercise alone cannot be recommended as an effective strategy to lower TC or LDL-C.[134]

Relatively few studies have attempted to evaluate the effect of the exercise prescription (intensity, volume, etc.) on blood lipids, and as such, there is no consensus on the optimal exercise regime for improving cholesterol profile. In most of the studies reviewed, the exercise intervention was performed at moderate to high intensity, three to five times per week, for at least 30 minutes per session. Total caloric expenditure, as opposed to exercise intensity, has been proposed to be of greatest importance for blood lipids, and a threshold of between 1,200 and 2,500 kcal per week has been proposed.[137]

A meta-analysis of studies that explored the effect of strength training on blood lipids, dating back to 1955, found that strength training resulted in modest but significant improvements in blood lipid profiles (but not HDL-C).[138] However, while earlier studies generally demonstrated an improvement in blood lipid profile with resistance training, at least some suffered from design flaws, including no or poor dietary control,[139–142] no control group,[139–141] or no control for fat loss.[140–143] Better designed and/or more recent studies have not found an improvement in lipoprotein profiles with resistance/strength training.[144–148]

3.11 METABOLIC SYNDROME

The clustering of established risk factors for CVD and T2DM has been recognized for decades.[149–165] In 1988, Gerald Reaven drew immense attention to risk factor clustering and CVD in his now famous "Banting Lecture" at the annual meeting of the American Diabetes Association.[153] He described a constellation of risk factors leading to the development of T2DM and CVD, which he termed *Syndrome X*. Reaven postulated the etiology and clinical course of three major related diseases—T2DM, CVD, and hypertension—all having a common foundation of insulin resistance and hyperinsulinemia. However, at that time, adiposity was not considered a major etiological factor.

The metabolic syndrome has been recognized as a global public health problem that is strongly linked as a seminal cause of CVD and T2DM, both of which are responsible for premature mortality and morbidity worldwide.[166–169] The metabolic syndrome is characterized by the clustering of specific cardiovascular risk factors including insulin resistance (IR), central obesity, hypertension, and atherogenic dyslipidemia (specifically, elevated TG and low levels of HDL-C.[170–174] Also, depending on the medical society definition applied, microalbuminuria may also be considered another risk factor.[174]

3.11.1 Different Medical Society Definitions of the Metabolic Syndrome

In establishing an *official diagnosis* for the metabolic syndrome, the American Association of Clinical Endocrinologists (AACE) championed the creation of the International Classification of Disease 9th revision (ICD-9) Code 277.7 for the metabolic syndrome.[171] Currently, there are five working medical society definitions proposed for the diagnosis of the metabolic syndrome.[175,176] Table 3.2 summarizes the various definitions published by the following medical societies: 1) World Health Organization (WHO),[177] 2) European Group for the study of Insulin Resistance (EGIR),[173] 3) AHA and the National Heart, Lung and Blood Institute (NHLBI) definition,[178] which refers to the updated National Cholesterol Education Program (NCEP) 2001 definition, 4) the American College of Endocrinology (ACE) and AACE consensus definition for epidemiological research,[174] and 5) the International Diabetes Federation (IDF).[175]

The majority of the recent research focusing on the metabolic syndrome involved the use of the NCEP definition because of its clinical utility (see Table 3.2). The NCEP definition requires that three of the following five criteria be present for a diagnosis of the metabolic syndrome: IFG,

TABLE 3.2
Metabolic Syndrome Definitions Issued by Various Medical Societies

	WHO 1999	EGIR 1999	ACE/AACE 2003	IDF 2005	AHA/NHLBI 2005
Requisite Criteria	IGT,IFG, type 2 diabetes, insulin in top quartile of population	Insulin in top quartile of population	High risk[a] BMI >25 kg/m^2 or WC >102 cm(men) or >88 cm (women)	WC ≥94 cm (men) and ≥80 cm (women), and population specific for ethnic groups[b]	N/A
Other Criteria	Plus ≥2 of:	Plus ≥2 of:	Plus ≥2 of:	Plus ≥2 of:	Plus ≥2 of:
Glucose	N/A	≥100 mg/dL, 2-hour post OGTT ≥140 mg/dL but not diabetes	≥100 mg/dL, 2-hour post OGTT ≥140 mg/dL but not diabetes	≥100 mg/dL, diabetes	≥100 mg/dL, diabetes or Rx
Obesity	W:H ratio >0.9 (men) or >0.85 (women); BMI >30 kg/m^2	WC ≥94 cm (men) or ≥80 cm (women)	N/A	N/A	WC ≥102 cm (men) or ≥88 cm (women)
Lipids	TG ≥150 mg/dL and/or HDL-C <35 mg/dL (men) or <39 mg/dL (women)	TG >180 mg/dL and/or HDL-C <39 mg/dL in men or women or Rx	TG >150 mg/dL or HDL-C <40 mg/dL (men) or <50 mg/dL (women)	TG ≥150 mg/dL or Rx or HDL-C <40 mg/dL (men) or <50 mg/dL (women) or Rx	TG ≥150 mg/dL or HDL-C <40 mg/dL (men) or <50 mg/dL (women) or Rx
Hypertension	≥140/90 mmHg or Rx	≥140/90 mmHg or Rx	>130/85 mmHg or Rx	≥130/85 mmHg or Rx	≥130/85 mmHg or Rx
Other	Microalbuminuria ACR ≥30 mg/g				

WC, waist circumference; W:H, waist hip; TG, triglycerides; OGTT, oral glucose tolerance test; Rx, medication; ACR, albumin: creatinine ratio; others designated in text. WHO = World Health Organization; EGIR = European Group for the study of Insulin Resistance; AHA/NHLBI = American Heart Association/National Heart, Lung, and Blood Institute; ACE/AACE = American College of Endocrinology/American Association of Clinical Endocrinologists; IDF = International Diabetes Federation.

[a]Family history of type II or gestational diabetes, known CVD, polycystic ovary syndrome, physically inactive lifestyle, >40 years of age, and ethnic populations at high risk for type II diabetes.

[b]In this analysis, Mexican-American men were classified using a WC cut-off value of ≥90 cm and Mexican-American women ≥80 cm.[9]

represented by a fasting blood sugar ≥110 milligrams per deciliter (mg/dL), including T2DM; HDL-C <40 mg/dL in men and <50 mg/dL in women; triglycerides ≥150 mg/dL; an augmented waist circumference (WC) of ≥102 centimeters (cm) in men and ≥88 cm in women; or a blood pressure value of ≥130/85 millimeters of mercury (mmHg).

3.11.2 Current Prevalence Estimates

It is estimated that close to one billion people worldwide have the metabolic syndrome.[179] Global prevalence estimates of the metabolic syndrome vary considerably, depending on the population under study, definition applied, and study design utilized. Using the NCEP definition, the age-adjusted prevalence for the metabolic syndrome in the United States is estimated to be 34.6%. These data also showed a 10% increase in the prevalence of the metabolic syndrome in U.S. adults from 1988–2002. With the metabolic syndrome becoming more common in Westernized societies,[179] the prevalence and incidence are anticipated to increase in line with the prevalence and incidence of obesity[177] and T2DM.[178]

3.11.3 Physical Activity and Prevalence of the Metabolic Syndrome

The association between physical activity or inactivity and prevalence of the metabolic syndrome is not clear, at least based on cross-sectional studies.[179–188] In most studies, the initial analysis often shows a negative relationship between physical activity level and the prevalence or risk of metabolic syndrome, but this association typically disappears after controlling for other factors such as gender, age, education, and socioeconomic status or other risk factors (i.e., smoking).

Several longitudinal studies showed that increased levels of physical activity, especially of vigorous intensity, were associated with significantly and dramatically reduced risk for developing the metabolic syndrome in a dose–response manner. Interventional studies are fewer in number, but at least one study showed that 20 weeks of vigorous exercise performed for 30 minutes, three times per week, resulted in a decreased prevalence of the metabolic syndrome (from 16.9% to 11.8%) in 621 men and women aged from 17 to 65 years.[178] That is, of the 105 participants with the metabolic syndrome at baseline, 32 no longer had the syndrome at the end of the study.

3.11.4 Cardiorespiratory Fitness and the Metabolic Syndrome

The relationship between cardiorespiratory fitness, as measured by VO_{2max}, and the metabolic syndrome has not been studied as extensively as the relationship with physical activity.[189–191] However, cardiorespiratory fitness can be more objectively measured and may be more predictive of the metabolic syndrome than physical activity per se. Cardiorespiratory fitness has been shown to be predictive of the metabolic syndrome, with men of low fitness (VO_{2max} <29.1 $ml \cdot kg^{-1} \cdot min^{-1}$) being almost seven times more likely to have metabolic syndrome compared with those men with a VO_{2max} ≥35.5 $ml \cdot kg^{-1} \cdot min^{-1}$.[83] Over a four-year period, and after controlling for age, BMI, socioeconomic status, presence of CVD, smoking, and alcohol consumption, the incidence of metabolic syndrome was found to be 47% and 75% lower in middle-aged men with a VO_{2max} of 29.0–35.6 and ≥ 37.0 $ml \cdot kg^{-1} \cdot min^{-1}$, respectively, compared with those men whose VO_{2max} was less than 28.9 $ml \cdot kg^{-1} \cdot min^{-1}$.

The relationship between aerobic fitness and the prevalence of the metabolic syndrome appears to hold for women as well. Women with a VO_{2max} of 11 METs or greater had a prevalence of the metabolic syndrome that was one-third to one-fourth that of women of lower fitness.[192]

The precise amount and intensity of physical activity required to prevent or reverse the clustering of risk factors known as the metabolic syndrome has yet to be definitely determined. While there is evidence to suggest that regular, moderate-intensity physical activity (such as walking 30 minutes on most days, if not every day, of the week) may be preventive of the metabolic syndrome, other evidence suggests that activity of greater intensity may be required to optimally minimize risk. Greater cardiorespiratory fitness has demonstrated an even stronger negative association with the metabolic syndrome. Attainment of higher levels of fitness requires more vigorous physical activity.[11]

3.11.5 Muscular Strength and the Metabolic Syndrome

Evidence from the Aerobics Center Longitudinal Study (ACLS) suggests that even after controlling for age, examination date, smoking status, alcohol intake, number of metabolic syndrome risk factors at baseline, family history of diabetes, hypertension, and early onset coronary artery, men above the 75th percentile for muscular strength have a 24% lower risk for developing the metabolic syndrome compared with men in the lowest strength category.[190] Others have also illustrated the benefits of resistance training and increases in muscular strength for metabolic risk.[193–195] Muscular fitness appears to add another level of protection against the metabolic syndrome in men and may help with daily and long-term glycemic control. However, strength training is recommended as an adjunct to regular aerobic exercise, but not the sole or primary form of activity to prevent or manage the metabolic syndrome[196].

3.12 CONCLUSION

CVD, in all its forms, represents the greatest threat, by far, to health and longevity in the United States and the world. The major risk factors for CVD are well known, and their prevention and/or management are crucial in reducing the prevalence of CHD, stroke, hypertension, and HF. Greater physical activity and especially greater cardiovascular

fitness have been shown to significantly reduce the risk of CVD. The reduction in risk is largely mediated via the risk factors as described in this chapter. As such, an appropriate and individually prescribed program of regular physical activity or exercise should be a standard lifestyle intervention for individuals of all ages and abilities.

CLINICAL APPLICATIONS

- Increased levels of cardiovascular and physical activity lower the risk factors for CVD as well as multiple other factors such as obesity, metabolic syndrome, and diabetes.
- The higher the fitness levels, the lower the risk of CVD.
- Aerobic conditioning and physical activity provide more benefits in terms of lowering cardiovascular risk compared with strength training, although resistance strength training can also add additional benefits.
- Assessment of cardiovascular fitness should be part of all physician visits.
- Prescription for physical activity should be part of all physician visits.
- Guidelines for Physical Activity are available, including the Physical Activity Guidelines for Americans 2008 (to be updated in 2018) and guidelines from the American College of Sports Medicine. These guidelines can be used as a basis for exercise and physical activity prescription.

4 Clinical Strategies for Managing Dyslipidemias

Mary Hannan, PhD, APRN, AGACNP-BC, Thanakrit Jeamjitvibool, MSN, RN, and Ulf G. Bronas, PhD, ATC, FSVM, FAHA

KEY POINTS

1. Dyslipidemia, in the form of abnormalities in total cholesterol, low-density lipoprotein, triglycerides, and/or a reduced level of high-density lipoprotein, is a significant risk factor for cardiovascular disease.
2. Treatment of dyslipidemia is guided by cholesterol levels, cardiovascular risk, and patient-specific factors.
3. A heart-healthy lifestyle is the cornerstone of the treatment of dyslipidemia, including healthy diet, exercise, maintaining a healthy weight, avoidance of tobacco, and moderation of alcohol.
4. Pharmacologic therapy for dyslipidemia requires a multipronged approach with a focus on the utilization of 3-hydroxy-3-methyl-glutaryl-coenzyme-A (HMG-CoA) reductase inhibitors (statins).
5. Lipoprotein (Lp-a) and apo B_{100} have a demonstrated relationship with CVD risk. There is the consideration of intensive pharmacological therapy for patients with diagnosed Lp-a.

4.1 BACKGROUND

Dyslipidemia is defined as abnormal levels of lipids in the blood and may include elevated total cholesterol (TC), low-density lipoprotein cholesterol (LDL-C), and/or triglycerides (TG), and/or a reduced level of high-density lipoprotein cholesterol (HDL-C), alone or in combination.[1] Dyslipidemia is a prevalent condition in the United States, with almost 28% of the U.S. population having elevated LDL-C levels.[2] Additionally, elevated serum lipoprotein(a) is a risk factor for atherosclerotic cardiovascular disease. Environment and lifestyle play a large role in dyslipidemias, with a polygenic mode of inheritance. Familial hypercholesterolemia, an inherited monogenic autosomal dominant form, is much less common.[3] Although lipids contribute to many vital functions in the body, abnormal levels of lipids and their lipoprotein carriers contribute significantly to atherosclerosis and the development and progression of CVD.

4.2 ELEVATED TOTAL AND LDL CHOLESTEROL

Dating back to the 1970s, large longitudinal observational studies have demonstrated an association between total cholesterol and risk of CVD, even in the presence of other major risk factors.[4–8] Other observational studies have found that apolipoprotein B_{100} (apo B_{100}) is a strong predictor of coronary artery disease (CAD).[9,10] There also have been studies that have shown an association between lipoprotein-a (Lp-a) with increased risk of CAD.[9,11,12] Lp-a has an additional glycoprotein attached to the apo B_{100} and is considered a prominent monogenetic lipid disorder. Lp-a has proatherogenic and proinflammatory properties contributing to atherosclerotic cardiovascular disease (ASCVD) and a prothrombotic environment.[13,14] A meta-analysis of 36 prospective cohort studies with 126,634 participants found that after adjusting for age and sex, a higher level of Lp-a (one standard deviation [SD] higher concentration) increased the risk of myocardial infarction and CAD by 13% and ischemic stroke by 10%.[15] Guidelines are cautious and do not recommend universal testing as of yet, but it may be reasonable to measure Lp-a in individuals with hypercholesterolemia or with a history of ASCVD (or in a first degree relative). Primary prevention includes aggressive lifestyle change and statin drugs.[16] For secondary prevention, higher statin drug dosages, PCSK9 inhibition, niacin, or consideration of apheresis may be suggested.[16] However, it should be mentioned that statins have no effect on reducing Lp-a levels.[17] To date, there is no pharmacotherapy that specifically reduces Lp-a, although several trials are investigating Apo-antisense nucleotide and antisense oligonucleotides (Mipomersen) for the reduction of Lp-a.[13] To date, niacin, Mipomersen, and PCSK9 inhibitor have been found to have a 20–30% Lp-a lowering effect on top of total LDL lowering effects.[18–20]

Randomized controlled trials (RCTs) using cholesterol-lowering drugs such as statins (HMG-coenzyme A reductase inhibitors), cholesterol absorption inhibitors, cholestyramine, niacin, and fibrates have been successful in reducing CAD risk.[11,12,21,22] A landmark meta-analysis of large-scale (>30,000 participants) placebo-controlled statin trials found that statins resulted in a mean reduction of 30% in initial or recurrent CAD events over an average of 5.4 years.[22] Further analysis indicated that this CAD reduction was primarily related to a 28% reduction in LDL-C, with some benefits being derived from a 20% reduction in TG and an increase of 5% in HDL-C. Additionally, statins have pleiotropic antiatherosclerotic effects, which can further contribute to the reduction in the development and progression of CAD.[23,24]

DOI: 10.1201/9781003227793-5

4.3 HIGH-DENSITY LIPOPROTEIN

Low HDL-C also is associated with the development and progression of atherosclerosis.[25] Support for the protective role of HDL-C against CAD has been shown by numerous RCTs through several cardioprotective factors, including antioxidant effects, improved endothelial function, anti-inflammatory effects, reduction in endothelial-derived adhesive proteins, antithrombotic and profibrinolytic effects, reverse cholesterol transport from foam cells to the liver, and even regression of atherosclerotic plaques.[22,25–28] Conversely, in a meta-analysis of over 100 trials, it was found that increasing HDL-C alone does not reduce the risk of cardiovascular events.[29] Supporting this finding, a recent pooled analysis of 37 cohort studies involving 3,524,505 participants and more than 612,027 deaths found that the risk (hazard ratio) for all-cause mortality followed a J-shaped curve related to high and low HDL-C with an all-cause mortality hazard ratio of 1.03 (95% confidence interval [CI]: 1.01–1.05) for each 10 mg/dL increase in HDL-C level and 1.10 (95% CI: 1.09–1.12) for each 10 mg/dL decrease in HDL level.[30] These findings require further investigation to elucidate the physiological pathways.

HDL-C removes cholesterol from the cell membrane and transports it to the liver for disposal in the bile as cholesterol or as bile acids.[31] Cholesterol acyltransferase (LCAT), an enzyme carried by HDL and activated by HDL's apo A-I, acts by esterifying HDL's newly acquired cholesterol, and the resulting cholesterol ester (CE) is drawn into the core of HDL. Cholesterol ester transfer protein (CETP) is another enzyme involved in reversed cholesterol transfer by catalyzing the transfer of CE from HDL to other lipoproteins in exchange for TG. If CETP is inhibited via pharmacological measures or inherited mechanisms, there is a resultant increase in HDL-C levels, which is postulated to reduce atherogenesis. However, it appears that drugs that impair the function of CETP result in an increased level of HDL-C as designed, but in contrast to a hypothesized reduction in atherogenesis, this does not protect against CAD and may even promote progression of CAD and result in increased risk of morbidity and mortality.[32–35] These studies suggest that very high levels of large HDL particles laden with cholesterol may lose their cardioprotective properties and may even be atherogenic.[36] Interestingly, individuals who have a specific genetic variant of apo A-I (i.e., apo A-I Milano) have low levels of HDL-C and a very low risk of CAD, and vegetarians generally also have reduced levels of HDL-C (and LDL-C) and have a low risk of CAD.[37,38]

4.4 TRIGLYCERIDES

Triglyceride levels are elevated for about an hour following a meal, primarily as part of TG-rich chylomicron. In the fasting state, TGs are primarily carried by very low-density lipoprotein (VLDL). Apo C-II (carried by chylomicrons and VLDL) activates lipoprotein lipase (LPL), found in the capillaries of skeletal and heart muscle as well as the adipose tissue. Associated LPL then acts on the TG of the lipoproteins to release free fatty acids and glycerol.[31] The triglyceride-rich VLDL is the precursor for circulating LDL via intermediate-density lipoprotein (IDL), which (together with other apo B_{100}-containing remnants of VLDL) may be able to cross the arterial endothelium and contribute to atherogenesis.[39]

Hypertriglyceridemia is another concerning type of dyslipidemia. Primary hypertriglyceridemia was recently found to be associated with incident CAD events (hazard ratio [HR] 1.79, 95% CI: 1.32–2.43), although the relationship was attenuated when adjusted for other cardiovascular risk factors (HR 1.53, 95% CI: 1.06–2.20).[40] This relationship has not been consistently found, particularly in studies that adjusted for HDL-C and other CAD risk factors.[41,42] For example, a meta-analysis of 6 cohorts involving 46,000 men and 10,000 women found that each 1 mmol/l (88.5 mg/dl) increment in TG level was associated with increased risk of CAD by 76% in women and 32% in men, but reduced to 37% and 14% for women and men, respectively, after adjustment for HDL-C.[42] In a review, it was found that lowering TG levels was associated with lower risk of major vascular events, even after adjustment for LDL-C lowering.[43]

4.5 NON-HDL CHOLESTEROL AND APO B

Older and current guidelines recommend lowering cholesterol levels within all apo B-containing lipoprotein particles (i.e., non-HDL-C, TC minus HDL-C) as a secondary therapeutic goal, following primary targeting of LDL-C, in the presence of elevated TG.[42,44] In observational studies, non-HDL-C was found to be a predictor of CVD.[45] Since LDL and VLDL (and its remnants following TG lipolysis) each contain one molecule of apo B, it is postulated that the plasma level of apo B represents the total atherogenic particle number.[44,46,47] A strong correlation (0.8–0.9) exists between non-HDL-C and apo B, but they are only modestly concordant.[36]

4.6 LIPID CLASSIFICATION AND TREATMENT TARGETS

The 2018 American College of Cardiology (ACC)/American Heart Association (AHA) Guideline on the Management of Blood Cholesterol to Reduce Atherosclerotic Cardiovascular Risk in Adults emphasizes classification and treatment of hyperlipidemia (HLD) based on risk of atherosclerotic CVD (ASCVD) and the importance of a patient–clinician discussion about level of risk.[48] The Guideline recommends, prior to shared decision-making about initiating therapy for HLD, the assessment of risk for ASCVD, which includes evaluation of LDL-C levels and the assessment of other patient-specific factors that influence ASCVD risk.[48] The guidelines also recommend evaluating the influence of lifestyle changes and lipid lowering medications by assessing

a fasting lipid panel 4 to 12 weeks after initiation of statin therapy or dose adjustment, and then every 3 to 12 months thereafter.[48]

Specifically, the 2018 ACC/AHA guidelines recommended that statin therapy is started based on age, diabetes status, LDL-C level, presence of ASCVD, and ASCVD risk (Table 4.1). We refer the reader to these guidelines for full details. To estimate ASCVD risk, this guideline advocates for the use of the ASCVD Risk Predictor Plus.[48,49] The ACC/AHA guidelines emphasize monitoring the efficacy of statin therapy at lowering LDL-C to the desired intensity.[48] High-intensity treatment is considered to be >50% lowering of LDL-C, moderate intensity is considered to be lowering of LDL-C by 30–50%, and low intensity is considered to be lowering of LDL-C by <30%.[48] The intensity of statin treatment depends on the degree of ASCVD risk (Table 4.1).[48] The ACC/AHA guidelines do not strongly advocate for the use of pharmacotherapy other than statins for primary prevention, but ezetimibe and PCSK9-I are discussed in the recommendations for those with clinical ASCVD.[48] Although some studies have found cholesterol lowering from niacin, bile acid sequestrants, cholesterol absorption inhibitors, fibrates, or omega-3 fatty acids,[50] these therapies are not a part of the clinical treatment algorithms in the 2018 AHA/ACC guidelines.[48] The 2018 AHA/ACC guidelines emphasize the importance of clinician–patient discussion on pharmacologic therapy and risk reduction when adding non-statin therapies.[51] This guideline also provides clinicians with additional considerations and criteria for the management of HLD in specific populations; for example, when TG ≥500 mg/dl, it is recommended to evaluate for reversible causes and initiate statin therapy.[48] Of note, the 2020 American Association of Clinical Endocrinologists (AACE)/American College of Endocrinology (ACE) guidelines have additional guidelines and recommendations for the treatment of dyslipidemia and prevention of CVD, to which we refer the reader for additional guidance.[52]

4.6.1 Non-Statin Pharmacologic Agents

In the last decades, new non-statin pharmacologic agents have become available to treat dyslipidemia, some of which

TABLE 4.1

Risk Category, Recommended Therapy Intensity, and Expected Response: 2018 AHA/ACC/AACVPR/AAPA/ABC/ACPM/ADA/AGS/APhA/ASPC/NLA/PCNA Guidelines[48]

Patient group	Therapy intensity
Primary prevention	
Age >75 years old	Clinical risk assessment and discussion#
40–75 years old	
40–75 years old with diabetes	Moderate-to-high-intensity statin
40–75 years old and LDL-C ≥70–<190 mg/dl without diabetes	*For all in this category, ASCVD ten-year risk percentage begins the risk discussion*
ASCVD low risk (<5%)	Emphasize lifestyle, reduce risk factors (class I)
ASCVD borderline risk (5–7.4%)	If risk enhancers*,discuss moderate-intensity statin therapy (class IIb)
ASCVD intermediate risk (7.5–<20%)	If risk estimate + risk enhancers* favor statin, initiate moderate-intensity statin to reduce LDL-C by 30–49% (class I)+
ASCVD high risk (≥20%)	Initiate statin to reduce LDL-C by ≥50% (class I)
Patients with severe primary hypercholesterolemia (LDL-C ≥190 mg/dl)	Begin high-intensity statin therapy If the LDL-C remains ≥100 mg/dl consider adding ezetimibe If the LDL-C remains ≥100 mg/dl when taking statin plus ezetimibe, and patients has factors that increase risk of ASCVD, a PCSK9 inhibitor may be considered
Have clinical ASCVD	
ASCVD, not at very high-risk and age ≤75 years old	High-intensity statin (goal: reduce LDL-C ≥50%) (class I)If on maximal statin therapy and LDL ≥70 mg/dl, adding ezetimibe may be reasonable
ASCVD, not at very high-risk and age >75	Moderate- or high-intensity statin is reasonable (class IIa)
Very high-risk ASCVD	High-intensity or maximal statin (class I) If on maximal statin therapy and LDL ≥70 mg/dl, adding ezetimibe may be reasonable** If PCSK9-I is considered, add ezetimibe to maximal statin before adding PCSK9-I (class I)**

*Risk enhancers: family history of premature ASCVD, persistently elevated LDL-C ≥160 mg/dL, chronic kidney disease, metabolic syndrome, preeclampsia, premature menopause, inflammatory diseases, persistently elevated triglycerides (≥175 mg/dl), and if measured, hsCRP ≥2.0 mg/l, Lp(a) >50 mg/dl (>2.0 mmol/l), apo B ≥130 mg/dl, ankle brachial index <0.9.

**If on maximal statin therapy and LDL ≥70 mg/dl or non-HDL-C ≥100 mg/dl, adding PCSK9-I is reasonable (class IIa)

+If risk decision is uncertain: consider measuring CAC in selected adults → If CAC zero: lower risk, if CAC 1–99: favors statin (especially > 55 years old), and if CAC >100 and/or >=75th percentile, initiate statin therapy.

Consider risk reduction, benefits vs. adverse effects, drug–drug interactions, frailty, and patient preferences.

Adapted from Grundy, S.M. et al., *J. Am. Coll. Cardiol.*, 73(24), e285–e350, 2019.

are being used in practice, whereas some are still under investigation.

Ezetimibe is a selective cholesterol absorption inhibitor that works by inhibiting Niemann-Pick C1 like 1 (NPC1L1) protein and by reducing cholesterol absorption in the small intestine.[51] Ezetimibe targets the uptake of cholesterol absorption at the jejunal enterocyte brush border and can lower LDL-C and non-HDL-C.[53] The CAD IMPROVE-IT trial investigated ezetimibe plus statin therapy compared with statin therapy alone in 18,000 patients who had been hospitalized for acute coronary syndrome (ACS) and found a statistically significant difference in LDL-C levels and improved cardiovascular outcomes (absolute risk difference 2.0).[54] As previously described, ezetimibe is a component of the treatment algorithm to lower LDL-C in 2018 AHA/ACC guidelines.[48]

The PCSK9 (proprotein convertase subtilisin/kexin type 9) inhibitors are another class shown to be beneficial when used with a statin. PCSK9 inhibitors are human monoclonal antibodies to PCSK9, which bind to PCSK9 and increase LDL receptors by increasing recycling of receptors to the cell surface, which should decrease LDL-C.[51,53,55] Landmark trials have supported the use of PCSK9 inhibitors in decreasing CAD risk. The FOURIER trial, a placebo-controlled trial of over 27,000 patients, reported that the addition of evolocumab (PCSK9 inhibitor) to statin therapy lowered LDL-C by 59% and reduced the risk of cardiovascular events.[56] The ODYSSEY trial, which utilized the PCSK9 inhibitor alirocumab in over 2,000 patients over 24 weeks, reported that the difference in LDL-C between the placebo and alirocumab group was 62%, and this effect remained at 78 weeks.[57] The PCSK9 inhibitor bococizumab was evaluated in the SPIRE-1 and SPIRE-2 trials, which found a 56% reduction in LDL-C compared with the placebo group, which had a 2.9% increase in patients with high cardiovascular risk at 14 weeks.[58] Bococizumab further reduced the risk of cardiovascular events in the high-risk patients (HR: 0.79, p=0.02) but not the low-risk group (HR: 0.99, p=0.94). The trial was, however, stopped prematurely due to the finding of high rates of the development of antidrug antibodies.[58] Inclisiran was studied in over 1,500 participants in the ORION-11 trial, and it was found that LDL-C level was reduced by approximately 50% (−52.3%, 95% CI: −48.8, −57.7%; p < 0.001).[59] The ongoing ORION-4 trial will recruit a total of 15,000 participants aged >55 years old with ASCVD and elevated TC (>155 mg/dl) to evaluate the effect on cardiovascular outcomes.[60] As previously described, the PCSK9 inhibitors are a component of the treatment algorithm to lower LDL-C in 2018 AHA/ACC guidelines.[48]

Bempedoic acid, an adenosine triphosphate (ATP) citrate lyase inhibitor, is an approved non-statin medication.[61] The Clear HARMONY trial tested the safety and efficacy of bempedoic acid in 2,230 patients and found that at 12 weeks, bempedoic acid reduced the mean of LDL-C by 19.2 mg/dl (mean difference from placebo: −18.1%, 95% CI: −20.0, −16.1; p < 0.001).[62] A meta-analysis of seven RCTs similarly found that bempedoic acid therapy significantly reduced LDL-C by 17.1–23.5% (mean difference (MD): −20.3%, 95% CI: −23.5, −17.1; I^2: 43%).[63]

Evinacumab is an angiopoietin-like protein 3 inhibitor drug that was found to reduce LDL-C by 33.12% (MD: −33.12, 95% CI: −48.64, −17.61), triglycerides by 50.96% (MD: −50.96, 95% CI: −56.55, −45.36), and HDL−C by 12.77% (MD: −12.77%, 95% CI: −16.36, −9.19) compared with placebo.[64] This medication is approved and in use clinically.

4.7 ROLE OF LIFESTYLE IN THE MANAGEMENT OF DYSLIPIDEMIA

Lifestyle, including diet, body weight, physical activity, alcohol consumption, and smoking status, plays a role in blood lipid levels in the population, although heritability can make a substantial contribution as well. With this in mind, it is clear why lifestyle is a key aspect of the management of dyslipidemia, as supported by both the 2018 ACC/AHA Guideline on the management of blood cholesterol and the 2019 ACC/AHA Guideline on the Primary Prevention of Cardiovascular Disease.[1,48]

4.7.1 Impact of Diet (See Also Chapter 7)

It has been established that eating patterns associated with reduced rates of dyslipidemia and CVD include:

- A diet emphasizing vegetables, fruits, legumes, nuts, whole grains, and fish[1]
- Vegetarian and near-vegetarian diets[65,66]
- Mediterranean-style diets[4,67–70]
- The Dietary Approach to Reduce Hypertension (DASH) diet[71–74]
- The "Prudent Heart Healthy Diet," advocated by the AHA (formerly the AHA Step II Diet), ATP III, and the U.S. Department of Agriculture (USDA) and U.S. Department of Health and Human Services (DHHS), Dietary Guidelines for Americans 2005,[45,73,75,76] and the AHA diet[73]

Overall, when looking at these diets in summary, dietary patterns to improve blood lipids are characterized by (1) a low intake of saturated fat, trans fat, and dietary cholesterol through a reduction in the consumption of red meat, hard fats, and full-fat milk, (2) increased intake of whole grains, legumes, fruits, and vegetables, and (3) a moderate intake of fish, poultry, and low-fat or fat-free milk and dairy products.

The 2018 ACC/AHA Guideline on the management of blood cholesterol and the 2019 ACC/AHA Guideline on the Primary Prevention of Cardiovascular Disease encourage a heart-healthy diet that emphasizes the intake of vegetables, fruits, nuts, whole grains, lean vegetable or animal protein, and fish and minimizes the intake of trans fats, red meat

and processed red meats, refined carbohydrates, and sweetened beverages.[1,48] The guideline also supports a reduction in calories from trans fat and saturated fat, with only 5–6% of total calories coming from saturated fat, an adjustment to appropriate calorie requirements, and personal and cultural food preferences.[48] The 2017 Update to the 2016 ACC Expert Consensus Decision Pathway on the Role of Non-Statin Therapies for LDL-Cholesterol Lowering in the Management of Atherosclerotic Cardiovascular Disease Risk similarly advocates that lifestyle modification is needed before and after initiation of cholesterol-lowering medications.[51]

Observational studies and RCTs have found that the variance in mean TC levels was related to the variation in mean percentage of energy from saturated fatty acids (SFAs).[4,38,67,68] Metabolic ward studies have shown that omega-6 polyunsaturated fatty acids (PUFAs), particularly linoleic acid (18:1, n-6), have a cholesterol-lowering effect, as illustrated by the Keys equation:[77] $\Delta TC = 1.3\ (2\Delta S - \Delta P) + 1.5\ \Delta Z$ (ΔTC is the change in total cholesterol; ΔS is the change in percent of total calories provided by SFAs; ΔP is the change in percentage of energy from omega-6 PUFAs; and ΔZ is the square root of the dietary cholesterol expressed in mg per 1,000 kcal of dietary energy). This equation shows that for every 1% reduction in SFAs, serum TC is expected to be reduced by 2%. The relatively small impact of dietary cholesterol on blood cholesterol is due to the limited absorption of dietary cholesterol, with about two-thirds of circulating cholesterol synthesized de novo by the liver from acetyl coenzyme A products of metabolism.[78] It should be noted that only three long-carbon-chain SFAs have been shown experimentally to be responsible for increasing TC (lauric [12:0], myristic [14:0], and palmitic [16:0] acid). These SFAs appear to markedly downregulate hepatic synthesis of LDL apo B/E cell receptors, which reduces the removal of circulating LDL as well as VLDL, IDL, and apo B_{100}-containing lipoprotein remnants and results in a significant increase in cholesterol level.[78,79] Stearic acid (18:0) and SFAs with 10 or fewer carbons have no effect on TC and are not included in the Keys equation.[77] Omega-6 PUFAs, in contrast, lower cholesterol levels by upregulating hepatic LDL receptors, increasing the removal of lipoproteins, and reducing the rate of conversion of VLDL to LDL. The ATP III recommendation is to keep intake of omega-6 PUFAs to 10% or less of daily energy intake, as higher intake appears to lower HDL-C levels. Linoleic acid (18:2, n-6), the parent compound for the omega-6 family of PUFAs, is found in sunflower, corn, and soybean oils, as well as in seeds and nuts. Linoleic acid forms arachidonic acid (AA; 20:4, n-6) via enzymatic stepwise elongation of its carbon chain. AA is the precursor of prostaglandins and eicosanoids via cyclooxygenase (COX) enzyme activity and is essential for regulation of blood circulation, blood clotting, and inflammatory responses.[31]

Omega-3 PUFAs are a family of long-chained, essential fatty acids required in the diet. They have an initial double bond/unsaturated carbon atom at the third position from the methyl end of the molecule, rather than the sixth as for omega-6 PUFA. There has been increased interest in omega-3-PUFA due to its importance for eye and brain health, and its postulated contribution to primary and secondary prevention of CAD.[79–81] The parent compound of this family is α-linolenic acid (ALA;18:3, n-3). Its carbon chain is enzymatically converted to longer chains, and it eventually becomes the more unsaturated fatty acids, eicosapentaenoic acid (EPA; 20:5, n-3) and docosahexaenoic acid (DHA; 22:5, n-3). It should be noted that DHA competes with AA for conversion via COX enzyme to alternative eicosanoids and prostaglandins, which are believed to be cardioprotective (Table 4.2) Because of the limited conversion of ALA to EPA and DHA, all three are currently considered essential dietary nutrients; however, DHA appears to be the most biologically active form of the omega-3 PUFAs.[82] ALA is primarily present in vegetable oils, particularly canola and soybean oils, whereas fatty fish such as salmon, mackerel, herring, and sardines are rich sources of EPA and DHA. The apparent relationship between omega-3 fatty acids and cardiovascular health was first observed during studies of the unique dietary habits of the Greenland Inuit.[83] Despite a diet consisting primarily of very fatty meat from sea mammals, they had a surprisingly low rate of CVD. This was eventually attributed to their high intake of EPA and DHA from these food sources. Other epidemiological observational studies have reported an inverse association of fish or fish oil supplement consumption with morbidity and mortality from CVD.[84] The cardioprotective effects of these fatty acids has further been confirmed in animal models and by primary and secondary CAD prevention trials,

TABLE 4.2

Experimentally Identified Mechanisms Postulated to Contribute to the Apparent Cardioprotective Effects of Omega-3 PUFAs [85, 86, 88]

- Reduced dyslipidemia (decreased TG and VLDL-C, and increased HDL-C)
- A moderate reduction in elevated blood pressure
- Improved endothelial function and endothelial-dependent and independent vasoreactivity
- Anti-inflammatory effects, inhibiting progression of atherosclerosis
- Antithrombotic effects
- Increased parasympathetic activity, as evidenced by increased heart rate variability
- Improved myocardial electrical stability, reducing risk of a fatal ventricular arrhythmia

indicating a 20–30% reduction in fatal and nonfatal CAD events.[85,86] It appears that a modest intake (e.g., one to two portions per week) of fatty fish that contains high amounts of omega-3 fatty acids may reduce the risk of CAD and is suggested as part of a healthy diet.[87]

DHA and EPA fish oil–based supplements have been found in older epidemiological studies to reduce TG (6% to 10% per gram of EPA and DHA), VLDL-C, VLDL-TG, and non-HDL-C, and increase HDL-C.[89] Additionally, intake of fatty acids from fish or fish oil supplements has been found by some studies to reduce rates of all-cause mortality, cardiac death, and sudden death,[90] but this has not been consistently found, and controversy still lingers. A recent Cochrane Review found that increasing EPA and DHA intake has minimal effect on cardiovascular health.[91] However, a meta-analysis from 2019 involving 127,477 participants found a significantly lower risk of ischemic CVD events and mortality with marine omega-3 supplementation (rate ratio [RR] = 0.92).[144] These findings were supported in a meta-analysis by Khan et al. in 2021 in 149,051 participants, indicating that EPA mono-therapy is more effective compared with EPA+DHA therapy, and overall CVD events and mortality were significantly reduced.[81] Additionally, Icosapent ethyl, a highly purified eicosapentaenoic acid ethyl ester, lowers triglyceride levels and reduced CVD morbidity and mortality in the Reduction of Cardiovascular Events with Icosapent Ethyl–Intervention Trial (REDUCE-IT, HR = 0.75 with 2 g supplement vs. placebo), suggesting that purified EPA is beneficial.[92] Since over-the-counter fish oil supplements are not controlled by the Food and Drug Administration (FDA), they are not recommended for treating dyslipidemia, and current guidelines recommend eating two servings of fatty fish per week, such as salmon, sardine, mackerel, herring, trout, tuna, and anchovies, for primary and secondary CVD prevention as described earlier. However, prescription grade or purified EPA and DHA may be considered for patients with hypertriglyceridemia. For example, clinicians may consider prescribing icosapent ethyl (ethyl ester of EPA) for individuals with high levels of triglycerides who are already on a statin and who are at high cardiovascular risk.[52,92,93] The ongoing RESPECT-EPA trial should provide further clarification on the efficacy of EPA and ASCVD.[94]

The Seven Countries Study was one of the first to explore the benign relationship of monounsaturated fatty acids (MUFAs) in the diet to risk of CAD.[5] Approximately 80% of the fatty acids contained in olive oil are MUFAs, particularly oleic acid (18:1, n-9). Oleic acid either has no effect on blood lipids or reduces TC, but it appears to have no effect on HDL-C or TG.[95] However, the presence of MUFAs in LDL makes it less susceptible to oxidation. MUFAs are plentiful in olive oil, canola and peanut oil, avocados, nuts, and fish.

Trans fatty acids (TFAs) have attracted attention in recent years due to their adverse effects on blood lipids. The FDA mandates inclusion of quantities of TFAs on food labels along with those of SFAs and PUSFs, and an FDA ruling deemed hydrogenated oils as not safe for use in human food.[96] It should be noted that only a limited quantity of TFAs occurs naturally in meat and dairy products, while the 2.6% of daily energy intake of TFAs results from intake of margarines and shortenings used in food preparation. This is due to the formation of TFAs by the partial hydrogenation of the double bonds of unsaturated fatty acids in liquid vegetable oils to solidify them in order to make products more heat-stable and increase shelf life.[97] TFAs appear to promote cholesterol synthesis and a concomitant increase in LDL-C levels. But more importantly, in contrast to SFAs, they increase LP(a) and lower HDL-C levels.[98]

A diet high in non-digestible fiber, particularly β-glycans and pectin, may have a modest beneficial effect on TC and LDL-C levels.[38,99] Soluble fibers are found in whole grains (especially oats), fruits and vegetables, and beans and legumes. Soluble fibers prevent reabsorption of bile salts in the small intestine, which results in upregulation of hepatic LDL receptors, thereby enhancing LDL removal and reducing LDL-C levels. An intake of 30 g/day of soluble fiber has been associated with a 5 mg/dl reduction in total LDL-C levels, particularly the smaller, dense, atherogenic LDL particles, thereby reducing fatal and nonfatal CAD events.[38,100–103] Dietary fiber also slows gastric emptying and glucose absorption, and this decreases insulin response, which reduces hepatic lipogenesis and promotes satiety. The 2018 AHA/ACC Guidelines on the Management of Blood Cholesterol do not include a discussion or recommendation regarding fiber intake.[48]

Plant steroids and stanols (when esterified with a fatty acid, or when emulsified) are plentiful in vegetable oils, seeds, and nuts.[104] Past research found that PUFA margarines with or without the addition of 2 g/day of sterols/stanols to the diet may result in a reduction of 21 mg/dl in LDL-C (a 9–27% reduction) and non-HDL-C levels.[104,105] LDL-C removal is enhanced via an upregulation of LDL receptors in the liver, in part due to competitive inhibition of dietary and biliary cholesterol uptake in the small intestine.[38] The 2018 AHA/ACC Guidelines do not discuss or include recommendations regarding these products.[48] The European Society of Cardiology (ESC)/European Atherosclerosis Society (EAS) guidelines from 2019 recommend supplementation with 2 g plant sterols (phytosterols) as a therapeutic strategy to reduce cholesterol in patients with dyslipidemia as adjunct pharmacotherapy in addition to statins if the treatment goal is not achieved.[106] This is in contrast to several other organizations, including the National Institute for Health and Care (NICE) in the United Kingdom, which cautions against the use of plant sterols/stanols due to their genetic association with atherogenesis in some studies.[107,108] Thus, despite the apparent cholesterol lowering capability of plant sterols/stanols, there have been no studies indicating CVD risk reduction and some studies indicating higher CVD risk. Therefore, much additional research is needed in this area, and no recommendations can currently be made.

Plant-derived antioxidants including vitamin E and β, other carotenes, water-soluble vitamin C, and a large variety of non-nutrient phytochemicals are postulated to reduce the development and progression of CAD by preventing oxidative stress and reducing LDL oxidation and endothelial dysfunction.[99,109] Vitamin E, which is found in vegetable oil, nuts, and seeds, is transported by LDL and has been associated with reduced CAD risk and reduction of oxidized LDL.[99,109] However, it should be noted that numerous large-scale randomized controlled clinical trials and meta-analyses have failed to demonstrate any protective effect against CVD mortality by supplementation of antioxidant vitamins (vitamin E, vitamin C, or beta carotene).[99,109–111] Flavonoids are a type of plant chemical (phytochemicals) found in fruits, vegetables, tea, red wine (and grape juice, from which wine is derived), and cocoa bean products. *In vitro* studies have shown phytochemicals to be potent inhibitors of LDL oxidation.[99] In a prospective cohort study, flavonoid consumption was associated with lower risk of death from CAD.[112] However, there have been inconsistent results from clinical trials, and evidence does not clearly support their use in a clinical setting.[99,113]

Moderate alcohol intake of one to two drinks per day has been associated with an approximately one-third lower risk of mortality from CAD when compared with either no or heavy alcohol consumption, possibly due to both antithrombotic effects and ethanol-involved increased HDL-C levels (by ~12%).[99,114] However, it should be noted that alcohol also produces a concomitant increase in TG and VLDL production and therefore raises non-HDL-C levels. Moreover, excessive use of alcohol has other harmful effects. Thus, it is considered unethical to encourage non-drinkers to start using alcohol for prevention of CAD.

4.8 WEIGHT MANAGEMENT

Health consequences associated with excess body weight include dyslipidemia, metabolic syndrome, and thereby an increased risk of type 2 diabetes and CAD.[115] Thus, weight reduction is a critical component in the management of dyslipidemia. The 2018 AHA/ACC Guidelines on the Management of Blood Cholesterol recommend caloric intake to avoid gaining weight or to lose weight in those who are overweight or obese.[48] Of note, if exercise is combined with reduced energy intake, fat-free mass is generally better preserved during weight reduction, and weight regain appears to be less likely.[96–98] It is essential to include behavioral modification related to diet and physical activity to successfully achieve and maintain an ideal body weight.[115–117]

A 10% loss in weight may result in a significant decrease in TC of 30.5 mg/dl (–13.2%), LDL–C 15.1 mg/dl (–11.3%), VLDL–C 15.5 mg/dl (–36.5%), and TG 58.4 mg/dl (–32.2%); HDL-C initially declines during the active weight loss phase and then increases by 5.5 mg/dl (+12.6%) after weight stabilization.[118] In a meta-analysis, Nordmann et al.[119] compared the effects of a reduced-fat diet (to 25–35% [current recommendation] of daily energy in four of these studies and to 10% in one study) with a low-carbohydrate diet (unlimited in protein and fat) in five studies on weight loss and cardiovascular risk factors. The mean weight loss at six months was significantly greater on the low-carbohydrate diet, while at 12 months there was no statistically significant difference between the low-carbohydrate and the reduced-fat diets. However, the reduction in TC and LDL-C was more favorable on the low-fat compared with the low-carbohydrate diets (mean difference in LDL-C between diets was –5.4 mg/dl). Interestingly, changes in HDL-C (+4.6 mg/dl) and TG (–22.1 mg/dl) were significantly more favorable on the low-carbohydrate diets. A meta-analysis by Hu and colleagues of 23 trials found that patients who followed low-carbohydrate diets compared with low-fat diets experienced a small but statistically significant lower reduction in TC (2.7 mg/dl) and LDL-C (3.7 mg/dl) but a greater increase in HDL-C (3.3 mg/dl) and a greater decrease in TG (–4 mg/dl), but these findings were not examined for long-term effects.[120]

A randomized study investigated the effects of weight loss and blood lipid changes in three diets—a low-carbohydrate, non-restricted-calorie diet with reduced fat (<35% of daily energy); a restricted-calorie diet, following AHA guidelines; and a restricted-calorie Mediterranean-type diet.[121] The mean weight loss after the two-year follow-up was 2.9 kg for the AHA diet, 4.4 kg for the Mediterranean diet, and 4.7 kg for the low-carbohydrate diet. There was a mean increase in HDL-C of 8.4 (+22.4%), 6.3, and 6.4 (+16%) mg/dl for the low-carbohydrate, AHA, and Mediterranean diets, respectively. TG reduction (23.7 mg/dl) was more favorable with the low-carbohydrate diet. Surprisingly, in this study there were no significant changes in LDL-C in any group.

The combination of dietary modification and regular exercise has consistently been shown to be effective for achieving and maintaining long-term weight reduction (~1 kg/week greater weight loss than dieting alone).[115–117] Aerobic exercise (as well as resistance exercise) may attenuate the fat-free mass loss that will occur with weight loss.[117] Regular aerobic exercise for 60–90 minutes per day is critical for preventing weight regain.[122,123] However, exercise alone is generally not effective for inducing sizable weight loss, unless one performs supervised, large-volume, prolonged aerobic exercise on five to seven days per week.[117]

4.8.1 Exercise Effects

It has been well established that increased physical activity and exercise training reduce morbidity and mortality from CAD through multiple cardioprotective effects, including improving dyslipidemia.[124–127] Studies have consistently shown that aerobic exercise training results in an increase in HDL-C of 2–3 mg/dl, or about 4–5%, with an associated increase in apo A-I and LPL activity.[128–131] However, it should be noted that there is a great deal of variability in the response of HDL-C following exercise training[132] that

appears to be related to genetic factors as well as weight change.[133–137] Exercise-induced reductions in LDL-C and TG appear to be rare in the absence of an associated weight loss.[128–131] The majority of controlled studies on the effect of exercise on blood lipids have used a standard exercise prescription of moderate-to high-intensity aerobic exercise for 30–60 minutes three times per week, with a weekly energy expenditure of 900–2,000 kcal (or about 10–20 MET hours) for at least 12 weeks (~15–20 miles/week of walking).[128–131] Of note, a recent meta-analysis study compared the effectiveness of 5 exercise types on cardiometabolic health in obese and overweight adults and found that among 81 RCTs, combined treatment (endurance training and resistance training) reduced TC significantly more than control (mean difference: –21.35, 95% CI: –33.36, –9.34).[138] The 2018 AHA/ACC Guideline advises that adults should participate in physical activity three to four times per week and that the activity should be 40 minutes in length and at a moderate-to-vigorous intensity.[48]

4.8.2 Cigarette Smoking

Cigarette smoking has been associated with reduced apo A-I and HDL-C levels by about 4 to 6 mg/dl, or 11–14% lower than in non-smokers.[139–141] More importantly, smoking cessation appears to result in a rapid improvement in HDL-C (an average 6–8 mg/dl increase).[142] In addition, smokers have been reported to have slightly higher LDL-C levels than non-smokers. These adverse effects of smoking on blood lipids are postulated to be due both to nicotine and to carbon monoxide exposure.[143]

4.9 CONCLUSIONS AND RECOMMENDATIONS

Lifestyle, particularly diet and physical activity, is a major contributor to dyslipidemia and resulting CVD. Table 4.3 summarizes the effects on dyslipidemia of specific dietary components and other aspects of lifestyle reviewed in this chapter.

CLINICAL APPLICATIONS

- Dietary patterns to improve blood lipids are characterized by (1) a low intake of saturated fat, trans fat, and dietary cholesterol through a reduction in the consumption of red meat, hard fats, and full-fat milk, (2) increased intake of whole grains, legumes, fruits, and vegetables, and (3) a moderate intake of fish and poultry and low-fat or fat-free milk and dairy products.
- To improve lipid profile, decrease SFAs, trans fats, and total cholesterol, moderate alcohol intake, and increase omega-6 PUFAs, omega-3 PUFAs, MUFA, and soluble fiber.
- Weight reduction, exercise, and smoking cessation are essential.
- Pharmacotherapy to treat dyslipidemia includes the use of statin drugs based on degree of ASCVD risk with consideration of the addition of PCSK9-I and ezetimibe to achieve desired LDL-C levels.

5 Lifestyle Management and Prevention of Hypertension

Mary Hannan, PhD, APRN, AGACNP-BC, Thanakrit Jeamjitvibool, MSN, RN, and Ulf G. Bronas, PhD, ATC, FSVM, FAHA

KEY POINTS

1. Lifestyle interventions play a critical role in the management of hypertension.
2. Physical activity and exercise training can reduce blood pressure through a variety of beneficial physiological mechanisms.
3. A healthy diet consisting of high intake of fruits, vegetables, and whole grains is associated with lower blood pressure.
4. Weight loss and maintaining a healthy body weight through comprehensive lifestyle changes improve blood pressure.
5. Although pharmacotherapy is the mainstay for the treatment of hypertension, guidelines recommend that lifestyle interventions should be prescribed in conjunction with medications for patients with hypertension.

5.1 BACKGROUND

Hypertension is a well-established risk factor for cardiovascular disease (CVD) morbidity and mortality.[1] The global prevalence of hypertension has doubled in the last 30 years.[2] Despite major advances made in the understanding of hypertension physiology and pharmacological treatment of hypertension, blood pressure continues to be poorly controlled in the approximately 116 million U.S. adults diagnosed with hypertension.[3] Hypertension management guidelines highlight the critical role of lifestyle interventions in managing hypertension as a critical adjunctive therapy to pharmacologic treatment. In brief, some guidelines and their lifestyle intervention recommendations include:

- The 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA Guideline for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults: A Report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines (henceforward referred to as the 2017 ACC/AHA Guideline for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults) advocates for non-pharmacologic interventions to prevent and treat hypertension, consisting of: (1) weight loss to ideal body weight, (2) the Dietary Approaches to Stop Hypertension (DASH) dietary pattern, (3) sodium restriction to <1,500 mg/day, (4) increased intake of dietary potassium (3,500–5,000 mg/dl), (5) physical activity consisting of 90–150 minutes/week of aerobic or dynamic resistance exercise and three sessions/week of isometric resistance exercise, and (6) moderation of alcohol intake (≤2 drinks/day in men, ≤1 drink/day in women).[4] Of note, the guidelines also emphasize the need for team-based care models of management, including multidisciplinary care, for adults with hypertension to achieve optimal outcomes.[4,5]
- From a global perspective, the 2018 European Society of Cardiology/European Society of Hypertension (ESC/ESH) Guidelines for the management of arterial hypertension recommend lifestyle interventions for the control of blood pressure, which include smoking cessation, healthy diet, reduced salt intake, moderate alcohol intake, weight control, and regular exercise.[6] The 2020 International Society of Hypertension Global Hypertension Practice Guidelines recommend similar lifestyle interventions, as well as the integration of stress reduction and avoidance of air pollution.[7]

The 2017 AHA/ACC Guideline for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults has established classifications and treatment thresholds for hypertension (Table 5.1).[4] Treatment targets for blood pressure in those with hypertension were investigated through the Systolic Blood Pressure Intervention Trial (SPRINT) study with over 9,000 adults (mean age 67.9 years) who at baseline had a systolic blood pressure (SBP) >130–180 mmHg and increased risk of cardiovascular events.[8] The study compared intensive treatment to achieve blood pressure targets of SBP < 120 mmHg with standard targets of SBP < 140 mmHg.[8] The SPRINT trial was stopped early after approximately three years of follow-up due to a lower all-cause mortality (hazard ratio: 0.73, 95% confidence interval [CI] 0.6, 0.9) and a lower incidence (1.65%/year versus 2.19%/year) of the composite

outcome of myocardial infarction, acute coronary syndrome (ACS), stroke, heart failure, or death in the intensive treatment group compared with the standard target group, but the intensive treatment-lowering target group had significantly higher rates of adverse events than the standard target group.[8] Although these results are promising, the study's measurement of blood pressure through research methods (the mean of three readings after five minutes of rest without a staff member present during readings) and the applicability of the results to populations excluded from the trial, including those with congestive heart failure, severe chronic kidney disease, secondary hypertension, institutionalized older adults, and those with low cardiovascular risk, have caused controversy.[9–11] Ideal blood pressure targets have continued to be investigated since the SPRINT trial. A Cochrane Review, which included 11 randomized trials involving over 38,000 participants, found that in adults with hypertension, there appears to be no additional benefit of lowering blood pressure to less than target levels of <140/90 mmHg.[12]

5.2 MEASUREMENT OF BLOOD PRESSURE

The 2017 ACC/AHA Guideline for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults emphasizes proper blood pressure measurement technique (level IC recommendation) and highlights how differences may arise between blood pressure measured in different settings (please see the Guideline for an in-depth explanation of blood pressure measurement).[4] In brief, the Guideline recommends that blood pressure is measured according to six clearly defined steps: proper patient preparation, proper technique, proper measurements, proper documentation, averaging of readings, and providing readings to patients. The steps highlight the importance of five minutes of rest before measurement, the use of correct cuff size applied to the skin, arm placement, bilateral arm measurement, and utilizing the average of more than two readings obtained on at least two occasions. The Guideline also supports (level IA recommendation) that out-of-office blood pressure measurements are needed to confirm a diagnosis of hypertension and when titrating medications.[4] Of note, the U.S. Preventive Services Task Force recently released an evidence report highlighting that although office-based blood pressure screening has accuracy limitations, there are minimal direct harms of office-based blood pressure screening.[13]

5.3 ETIOLOGY OF HYPERTENSION AND RELATIONSHIP TO CARDIOVASCULAR DISEASE

Primary or essential hypertension, the most common type of hypertension in the United States (90–95%), has no specific known underlying cause, whereas secondary hypertension results from medical conditions such as kidney disease, renal artery stenosis, or adrenal tumors (e.g., pheochromocytoma, primary aldosteronism, and Cushing's disease).[14,15] There are modifiable risk factors associated with the development of essential hypertension, including high body mass index (BMI) (>25 kg/m^2), excess alcohol consumption, low levels of physical activity, and a diet rich in sodium as well as low in calcium, potassium, and magnesium.[14–20] Additionally, hypertension more commonly develops in those with a family history of hypertension, as well as in those who are older. Men are more commonly diagnosed with hypertension than women, possibly because there may be a need for sex-specific cut-off levels for hypertension diagnosis, but this is an area still under investigation.[21] There is increasing evidence that health inequity, institutional and structural racism, and social vulnerabilities may increase the risk of an individual developing hypertension. For example, having social vulnerabilities in the economic, education, health and health care, neighborhood and built environment, and social and community context domains was associated with a higher risk of developing hypertension (adjusted relative risk ratio 1.16 (95%CI 0.99, 1.36) for individuals with one vulnerability and 1.49 (95% CI 1.20, 1.85) for at least two vulnerabilities, compared with having no vulnerabilities) in the REGARDS study (Reasons for Geographic and Racial Differences in Stroke).[22] With this in mind, there is a great interest in developing multi-level interventions to promote health equity in the management of hypertension in the United States.[23] There is a critical need for further investigation in this area of research.

From a physiological perspective, any factor that increases cardiac output or total peripheral vascular resistance can increase blood pressure, since blood pressure is determined hemodynamically by the product of these two variables. Other contributing factors to an increase in blood pressure include endothelial dysfunction, increased sympathetic nervous system activation, and renin-angiotensin-aldosterone system (RAAS) activity. It is postulated that a sustained elevation in blood pressure can reset the baroreceptors, leading to hypertrophy of the arteriolar smooth muscle and increase in peripheral vascular resistance, which are the principal hemodynamic disturbances associated with essential hypertension.[14] Hypertension-induced left ventricular hypertrophy (LVH) is postulated to be related to an increase in both pre-load and after-load (i.e., chronic volume and pressure overload), resulting in eccentric or concentric volumetric ventricular changes associated with dysfunctional systolic contraction.[14,15,17,18] The reader is referred to a review on the topic by Rosendorff et al.[24]

5.4 PHYSICAL ACTIVITY, EXERCISE, AND HYPERTENSION

It is well established that physical activity and exercise influence blood pressure and hypertension. Observational studies have consistently reported an inverse association between leisure time physical activity, physical fitness, and the development and severity of hypertension, even after adjusting for other risk factors.[25–37] For example, Kokkinos et al. reported in a cross-sectional study an 8–9 mmHg lower systolic and 4–5 mmHg lower diastolic mean 24-hour ambulatory blood pressure in individuals with high and moderate physical fitness compared with persons with low fitness levels.[38] A review by Liu et al. found a dose-related relative risk reduction for hypertension of 6% for every ten MET hours per week of leisure time physical activity.[39]

The effect of exercise training on blood pressure has also been well established in countless randomized controlled trials (RCTs) and meta-analyses.[40–55] Overall, these studies have shown that moderate-intensity aerobic exercise training of 30–60 minutes/session three times/week for 12–16 weeks improves blood pressure.[56,57] Studies have found a mean reduction of 2.6–4.7 mmHg in SBP and 1.8–3.1 mmHg in diastolic blood pressure (DBP) in resting blood pressure levels in normotensive individuals and a reduction of 6–10 mmHg in SBP and 2.4–7.6 mmHg DBP in those with hypertension.[54] Differences in blood pressure reduction from exercise have been found to be related to the intensity of exercise training and based on participant BMI, sex, and age.[40–53,56–59] From these data, there is support that moderate-intensity (40–70% of maximal aerobic capacity) aerobic exercise training for 30–60 minutes on three to five days/week is effective for both prevention and management of hypertension. In a systematic review, the dose of exercise recommended for patients with hypertension based on the FITT (frequency, intensity, time, type) principle is aerobic exercise of any type on most, if not all, days per week at a moderate intensity (40 to <60% VO_2max) for 30–60 accumulated minutes/day as well as dynamic resistance exercise of any resistance type on 2–3 days per week at a moderate intensity for 10–12 repetitions of 8–10 exercises.[60] Interestingly, a recent Cochrane Review of 73 trials found that there is moderate-strength evidence that even moderate-intensity walking as physical activity probably reduces SBP.[61] Additional research is needed to establish blood pressure reduction in response to reducing sedentary time.

Immediately following cessation of a bout of aerobic exercise, there is a temporary reduction in SBP (5–15 mmHg) and DBP (4–6 mmHg) that appears to last for several hours (up to 24 hours).[57,62–64] It is postulated that the mechanisms of this acute blood pressure reduction include:

- Immediate decrease in sympathetic adrenergic stimulation of the precapillary vessels
- Attenuated response to alpha-adrenergic stimulation
- Laminar flow–mediated release of endothelial-derived vasodilatory chemicals (e.g., nitric oxide, prostacyclin, and adenosine)
- Resetting of the arterial and cardiopulmonary baroreceptor operating points
- Neural adaptations involving central vasopressin V_1 receptors and substance P receptors[63–68]

There have been inconsistent findings on the influence of resistance exercise training on reducing blood pressure.[56,57,69] Meta-analyses have reported a blood pressure reduction of approximately 3–5 mmHg SBP/3.5–3.9 mmHg DBP in normotensive individuals.[56,69,70] The recommendation for resistance exercise training is that it should only be used as a supplement and not a substitute for aerobic exercise training, and the strength of the evidence of these recommendations is weak overall.[60] The 2017 ACC/AHA Guideline for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults discusses how 90–150 minutes/week of dynamic resistance exercise and three sessions/week of isometric resistance exercise are associated with beneficial effects on both SBP and DBP.[4] Additionally, the 2019 ACC/AHA Guideline on the Primary Prevention of Cardiovascular Disease recommends, in addition to aerobic exercise, that individuals with borderline hypertension or hypertension participate in isometric resistance and dynamic resistance exercises.[71] The reader is referred to the American College of Sports Medicine's guidelines and contraindications to exercise testing and training in patients with hypertension.[72]

5.4.1 Mechanism

There have been many postulated and plausible mechanisms for the blood pressure–reducing effects of exercise training. Poiseuille's law explains that a small change in vessel diameter has a large effect on resistance to fluid

flow (i.e., inversely proportional to the fourth power of the vessel radius).[57] Therefore, a reduction in total peripheral vascular resistance, specifically by a change in small vessel diameter, may be responsible for at least one aspect of the blood pressure reduction with exercise training.[56] The exercise-induced reduction in peripheral vascular resistance is postulated to be mediated by several factors, including:

- Improved vascular endothelial function and arterial elasticity/compliance from increased nitric oxide (NO) synthase activity from exercise-induced laminar shear-stress and prolonged NO activity via reduced oxidative deactivation of NO, and reduction of collagen deposition on the media of the arteries
- Reduction in endothelial-derived endothelin-1
- Attenuation of alpha-adrenergic receptor response and reduced sympathetic tone
- Reduction in peripheral vascular resistance
- Improved baroreceptor reflex sensitivity
- Reduced circulating catecholamines[56,73–80]

The effects of exercise training on the RAAS are less well known. There have been a few reports of exercise training reducing renin activity and angiotensin-II activity in normotensive persons, but this has not been reported in hypertensive adults.[81,57] There is an improvement in insulin sensitivity with exercise training that has been associated with increased renal sodium excretion.[57,82] Exercise training–induced vascular adaptations also include an increase in the number of skeletal muscle precapillary and capillary vessels (i.e., angiogenesis) and adaptations in vascular structure, including vascular remodeling (arteriogenesis) resulting in a larger conduit artery lumen diameter, which further contributes to reduced vascular resistance.[57,83] The epigenetic impact on the exercise-induced reduction in blood pressure is less well known.

TABLE 5.2
DASH Diet

Nutrient	Percentage of total caloric intake
Total fat (% of total kcal)	25–35%
Saturated fat	<7%
Trans fats	<1%
Monounsaturated fats	15%
Polyunsaturated fats (with an Omega-6 to 3 ratio of 3 to 4 to 1)	≤10%
Cholesterol (% of total kcal)	≤200 mg/day
Protein (% of total kcal)	About 18%
Carbohydrates (% of total kcal)	50–60%
Dietary fiber (g/day)	31
Potassium (mg/day)	4,700
Calcium (mg/day)	500
Sodium (mg/day)	1,500–2,400
Number of servings per day based on 2,000 kcal diet	
	Daily servings[a] / **Servings per NIH DASH recommendations[b]**
Fruits	7–8 / 4–5
Vegetables	4–5 / 4–5
Grains	4–5 / 6–8
Low-fat dairy products:	2–3 / 2–3
Meats, poultry, fish	≤2 / ≤6
Nuts, seeds, dry beans	4–5 / 4–5/week
Fats, oils	2–3 / 2–3
Sweets	≤5/week / ≤5/week

5.5 DIETARY MODIFICATIONS IN THE PREVENTION AND MANAGEMENT OF HYPERTENSION

Diet is well established to be associated with hypertension, with meta-analyses supporting that healthier diets are associated with a decreased likelihood of developing hypertension (odds ratio [OR] 0.81, 95% CI 0.67, 0.97).[84] A healthy diet is consistently recommended as part of the lifestyle treatment plan for adults with hypertension in the guidelines.[4,71] Reduced sodium intake and increased intake of potassium, calcium, and magnesium, as well as moderation of alcohol consumption, have been effective at reducing blood pressure.[85–88] Diets that have been shown to improve blood pressure include the DASH (summarized in Table 5.2), Mediterranean, low-carbohydrate, Paleolithic, high protein, low–glycemic index, low-sodium, and low-fat diets.[89] A systematic review and network meta-analysis compared the effect of different dietary approaches on blood pressure among hypertensive and pre-hypertensive patients and found that the DASH diet is the most effective diet in reducing both SBP and DBP based on high-quality evidence.[89] The total blood pressure reduction using the DASH diet is approximately 11/6 mmHg.[78] In a hallmark trial by Appel and colleagues, the DASH diet led to a reduction in blood pressure of ~11.4/5.5 mmHg in hypertensive participants and 3.5/2.2 mmHg in pre-hypertensive participants.[86]

Other dietary studies have reported that a diet high in fruits and plants resulted in blood pressure reductions of 6–10 mmHg in normotensive participants and 12–16 mmHg in those with hypertension.[85,88] Moreover, increased dietary fiber intake (11.5–14 g/day) was associated with a small reduction in SBP (1.1–1.6 mmHg) and DBP (1.3–2.0 mmHg).[91–93] In summary, a diet rich in fruits, vegetables, and whole grains is consistently recommended for blood pressure management.[4,90,94–96]

5.5.1 Effect of Sodium Restriction

Prospective studies, cross-sectional studies, animal studies, clinical trials, and meta-analyses have established a positive independent association between sodium intake and blood pressure.[46,97,98] Sodium restriction is consistently in the lifestyle recommendations of the guidelines, including the 2017 ACC/AHA Guideline for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults, which recommends reducing sodium chloride intake to 1.5 g/day.[4] A hallmark dose–response sodium restriction–blood pressure trial was the DASH-Sodium Trial, which compared three levels of reduced sodium intake (150, 100, and 50 mmol/day) with changes in blood pressure and found a dose–response relationship between reduced sodium intake and SBP reduction.[87] A systematic review and network meta-analysis found that low-sodium dietary approaches were more effective to reduce SBP and DBP than low-fat diets (mean difference: −4.42, 95% CI: −7.12, −1.72, mean difference: −3.10, 95% CI: −4.52, −1.68, respectively).[89] Overall, sodium restriction has been found to reduce elevated SBP levels by 4.7–7 mmHg and elevated DBP levels by 2.5–2.7 mmHg, reduce the risk of progression of elevated blood pressure to hypertension, and potentiate the effects of pharmacological treatment.[46,85,97–102] It is important to note that there is a great inter-individual variability in blood pressure response to sodium restriction.[85,87,101,102]

5.5.2 Effects of Increased Dietary Potassium Intake

Fluid homeostasis and electrolytes influence blood pressure, with serum sodium levels promoting fluid retention in response to reduced serum potassium levels, whereas increased serum potassium levels lead to an increase in renal sodium excretion (natriuresis) and an associated diuresis.[103] Although clinical trials have reported mixed blood pressure responses to increased dietary potassium intake, increasing dietary potassium intake to 3.5–5.0 g/day has been associated with reduction of 3.49 mmHg (95% CI: 1.82, 5.15 mmHg) in SBP and 1.96 mmHg (0.86, 3.06 mmHg) in DBP in patients with hypertension.[96,104] However, the combination of a diet rich in potassium and low in sodium does not appear to be additive in its influence on blood pressure.[85] Currently, a dietary eating pattern similar to that of the DASH diet is recommended to consume 4.7 g/day of dietary potassium.[90] The 2017 AHA/ACC Guidelines recommend 3,500–5,000 mg/day of potassium via dietary intake.[4] Of note, patients with conditions associated with impaired urinary excretion of potassium (e.g., kidney disease) or who are using medications that reduce potassium excretion may need to consume a lower amounts of potassium as instructed by their healthcare provider.[16,85]

5.5.3 Effects of Alcohol Consumption

A J-shaped, dose-dependent association between alcohol consumption and blood pressure has been demonstrated in clinical trials. Relatively light (defined as blood alcohol concentration < 0.08% or < 0.08 g of alcohol/deciliter) alcohol consumption has been found to have no effect on blood pressure, whereas higher (defined as blood alcohol concentration ≥0.08% or ≥0.08 g of alcohol/deciliter) alcohol consumption increases blood pressure.[97,105–108] Controlled trials have demonstrated that a 50–70% reduction of alcohol consumption independently reduces blood pressure by approximately 3.5/3 mmHg, whereas a 10 g/day increase in alcohol consumption is associated with a blood pressure increase of 2/1 mmHg.[46,108] Additionally, when considering the acute effects of alcohol on blood pressure, a recent Cochrane Review of 32 trials, primarily conducted in men, found that high doses of alcohol (>30 g) decreased blood pressure for up to 12 hours after being consumed, but then increased blood pressure for 13 hours after being consumed.[109] Current recommendations are to limit alcohol intake (no more than two drinks/day for men and no more than one drink/day for women) for those with elevated blood pressure or hypertension, with a drink being defined as a serving of either 12 oz beer, 5 oz wine, or 1.5 oz of 80-proof distilled spirits.[4,16,85]

5.5.4 Effect of Omega-3 Polyunsaturated Fatty Acids

Fatty fish and fish oil supplements are rich in long-chain omega-3 polyunsaturated fatty acids, which are postulated to play a role in blood pressure regulation via the production of eicosanoids and prostaglandins. Small-scale studies in patients with hypertension using large doses of fish oil supplements (>3 g/day) have reported a blood pressure reduction of 2.3–4.0 mmHg in SBP and 2.2–2.5 mmHg in DBP.[46,110–112] In a recent meta-analysis, it was found that the optimal intake of omega-3 fatty acids for blood pressure lowering was 2–3 g per day, with potentially additional benefits on blood pressure lowering in those at high risk for CVD.[113] The evidence of omega-3 fatty acids as an adjunctive therapy to reduce high blood pressure or the risk for heart disease remains inconclusive. However, the Food and Drug Administration (FDA) does find that evidence is sufficiently credible to allow these claims on food and dietary supplements containing eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Overall, the evidence supports EPA and DHA omega-3 fatty acids reducing CVD risk by reducing blood pressure levels, albeit additional research is required.[114–117]

5.6 WEIGHT MANAGEMENT

The association between obesity and hypertension has been well established by both observational studies and clinical trials.[85,118] A reduction in body weight of 5–10 kg in overweight individuals reduces blood pressure by approximately 6–12/5–8 mmHg.[46,85,119–123] Exercise training remains an important part of a plan to manage weight, although exercise training alone generally results only in minimal (~2 kg) weight

loss.[124] Regular exercise training supports maintenance of lost weight and reduces the loss of lean body mass.[125–127] The combination of exercise and a reduction in energy intake generally results in a greater blood pressure reduction than either alone.[127,128] In a Cochrane Review, weight loss diets alone were found to reduce body weight, SBP (mean difference: –4.5 mmHg, 95% CI: –7.2, –1.8 mm Hg), and DBP (mean difference: –3.2 mmHg, 95% CI: –4.8, –1.5), but this review included a limited number of studies with a small number of participants.[129] In a recent update to the Cochrane Review on the long-term effects of weight-reducing diets on blood pressure, the authors found again that weight loss diets reduced blood pressure in individuals with primary hypertension.[130] The guidelines recommend that adults who are overweight or obese with elevated blood pressure or hypertension are counselled to achieve weight loss.[4]

5.7 COMPREHENSIVE LIFESTYLE MODIFICATION

Intervention trials that use comprehensive lifestyle modification to lower blood pressure have had encouraging results. The most notable large-scale trials are the PREMIER[131] and the Exercise and Nutritional Interventions for Cardiovascular Health (ENCORE)[132] studies. These RCTs have reported a mean reduction in blood pressure in hypertensive individuals of 11–16 in SBP and 6–10 mmHg in DBP following comprehensive lifestyle interventions (including weight reduction). In addition, the ENCORE trial reported a significant reduction in mean 24-hour ambulatory blood pressure in the comprehensive intervention group.[132] These studies support guidelines and the value of comprehensive therapeutic lifestyle interventions for the prevention and management of hypertension.[16,100]

5.8 COMPLEMENTARY THERAPIES

Complementary therapies also may have a role in the management of hypertension. We will be discussing some complementary therapies that have been evaluated. In meta-analysis, music-based interventions have found a trend towards decreased SBP from 144 mmHg (95% CI 137, 152) to 134 mmHg (95% CI 124, 144), and DBP from 84 mmHg (95% CI 78, 89) to 78 mmHg (95% CI 73, 84). [133] Meta-analysis comparing the effectiveness of three different traditional Chinese exercises (Tai Chi, Baduanjin Gigong, and Wuqinxi Gigong) combined with antihypertensive drugs found that Tai Chi plus drugs (weighted mean difference (MD) –12.42 mmHg, 95% CI –15.29, –9.55), and Baduanjin Gigong plus drugs (MD –7.03 mmHg, 95% CI –9.80, –4.26) were superior to antihypertensive drugs alone.[134] Yoga has also been found to have a significant but small effect on SBP (–4.17 mmHg, 95% CI –6.35, –1.99) and DBP (–3.62 mmHg, 95% CI –4.92, –1.60).[135] Transcendental meditation was similarly found to have a potentially small effect on lowering SBP levels (mean difference –4.26, 95% CI –6.09, –2.43) and DBP levels (mean difference –2.33, 95% CI –3.70, –0.97).[136] Garlic has also been explored as having a novel role in the reduction of blood pressure,[137–140] and the largest of these meta-analyses found that garlic reduced SBP by 3.75 mmHg (95% CI –5.04, –2.45) and DBP by 3.39 mmHg (95% CI –4.14, –2.65) compared with controls.[139] Although promising, much additional research is needed in this area before conclusive recommendations can be made.

5.9 PHARMACOLOGICAL MANAGEMENT OF HYPERTENSION

Pharmacological management, alongside lifestyle modifications, continues to play a critical role in the management of hypertension. We recommend reviewing the guidelines for an in-depth review of pharmacologic management of hypertension. In brief, the 2017 ACC/AHA Guideline recommends initiating antihypertensive medications when the blood pressure is 130–139/80–89 if the patient has clinical atherosclerotic heart disease or an estimated ten-year cardiovascular disease risk of greater than 10%.[4] The 2014 Evidence-Based Guideline for the Management of High Blood Pressure in Adults (JNC-8) recommends initiating pharmacologic treatment when blood pressure is >150/90 in those over the age of 60 and >140/90 in those under the age of 60.[117] The 2019 ACC/AHA Guideline on the Primary Prevention of Cardiovascular Disease recommends that pharmacologic management is initiated to achieve a goal of <130/80 for individuals with stage 1 hypertension and a 10% or higher atherosclerotic cardiovascular disease (ASCVD) risk for primary prevention of cardiovascular disease.[71] The AHA Statement on the Management of Stage 1 Hypertension in Adults With a Low 10-Year Risk for Cardiovascular Disease recommends that those with stage 1 hypertension and no atherosclerotic disease or a ten-year CVD risk <10% be initially managed with non-pharmacologic therapy, but with the consideration to start pharmacologic therapy if the blood pressure remains uncontrolled at three to six months.[141]

Patient-specific, multiple antihypertensive drugs are often required to achieve blood pressure goals, so it is imperative that the prescribing clinician pays particular attention to contraindications, drug interactions, and comorbidities when selecting antihypertensive drug therapy. The reader is referred to the guidelines for a more complete discussion of pharmacological therapy.[4,117] Numerous classes of antihypertensive drugs are available, including but not limited to thiazide and potassium-sparing diuretics, beta-adrenergic blockers, alpha-adrenergic blockers, angiotensin converting enzyme inhibitors (ACE inhibitors), angiotensin receptor blockers (ARBs), calcium channel blockers (CCBs), centrally acting drugs, and direct-acting vasodilators.[16,142] Of note, the 2017 ACC/AHA Guideline defines first-line agents as thiazide diuretics, CCBs, and ACE inhibitors or ARBs, but we refer the reader to the Guideline for a full discussion on this topic.[4] To potentiate the efficacy of pharmacotherapy, initiation of the previously described lifestyle modifications is strongly recommended throughout the guidelines.[4,117]

TABLE 5.3
Clinical Application/Lifestyle Modifications for Management of Hypertension

Modification	Recommendation	Approximate blood pressure reduction
Physical activity and exercise	Regular aerobic exercise 120–150 min/week or 60–90 min/day for weight reduction and maintenance Dynamic resistance exercise 90–150 min/week Isometric resistance exercise three sessions/week	2–9 mmHg
Healthy diet	Consume a diet rich in fruits, vegetables, and whole grains; moderate in fat-free or low-fat dairy products; reduced saturated fat and cholesterol, such as the DASH dietary pattern	8–11 mmHg
Reduced sodium/salt intake	Reduced sodium/salt intake (1.5 g/day of sodium or 3.8 g/day of sodium chloride or at least 1,000 mg reduction in current intake)	2–7 mmHg
Adequate potassium intake	Increase intake to 3,500–5,000 mg/day (level of DASH diet) from content from fruits, vegetables, and low-fat dairy products	2–5 mmHg
Limit alcohol consumption	≤2 drinks/day for men≤1 drink/day for women	2–4 mmHg
Healthy weight	Maintain a BMI between 18.5 and 24.9 kg/m^2	2–10 mmHg/10 kg weight loss

Adapted from Whelton, P.K. et al., *Hypertension* 71(6), e13–e115, 2018; Flack, J.M., Adekola, B., *Trends Cardiovasc. Med*., 30(3), 160–164, 2020; Williams, B., et al., *Eur. Heart J*., 39(33), 3021–3104, 2018.

5.10 SUMMARY OF CONCLUSIONS

The available evidence is robust in supporting therapeutic lifestyle changes for the prevention and management of hypertension and as adjuncts to pharmacotherapy of hypertension, as summarized in Table 5.3.

6 Dietary Guidelines for Americans, 2020–2025: National Nutrition Guidance

Elizabeth B. Rahavi, RDN, Jean M. Altman, MS, Eve E. Stoody, PhD, and Monica K. Esquivel, PhD, RDN, CSSD

KEY POINTS

- The foods and beverages that people consume have a profound impact on their health.
- The *Dietary Guidelines for Americans* is updated every five years and reflects the current body of science related to what to eat and drink to meet nutrient needs, promote health, and reduce risk of chronic disease.
- More than half of all American adults have at least one chronic disease or condition that may be related to a poor quality diet and physical inactivity. A fundamental premise of the *Dietary Guidelines* is that just about everyone, no matter their health status, can benefit from shifting food and beverage choices to better support healthy dietary patterns.
- The ninth edition of the *Dietary Guidelines for Americans, 2020–2025* takes a lifespan approach, highlighting the importance of healthy dietary patterns at every stage of life from infancy through older adulthood.
- The *Dietary Guidelines* is a customizable framework that can be used to support healthy dietary patterns. Health professionals are vital to the translation of the *Dietary Guidelines* into programs and strategies and are uniquely positioned to support behavioral and systems change. The Federal government provides a number of free resources to assist them in these efforts.

6.1 INTRODUCTION

The scientific connection between food and health has been well documented for many decades, with substantial evidence showing that healthy dietary patterns can help people achieve and maintain good health and reduce the risk of chronic diseases throughout all stages of the lifespan. Yet, Federal data show that from the first edition of the *Dietary Guidelines for Americans* in 1980 through today, Americans have fallen far short of meeting its recommendations, and diet-related chronic disease rates have risen to pervasive levels and continue to be a major public health concern.

Table 6.1 describes the high rates of nutrition- and physical activity–related chronic diseases and their related risk factors. These diseases affect all ages—children, adolescents, adults, and older adults—though rates vary by several factors, including race/ethnicity, income status, and body weight status.

Given its aim to prevent further disease incidence by promoting health and reducing chronic disease risk, the *Dietary Guidelines for Americans, 2020–2025*[1] focuses on the general public, including healthy individuals, as well as those with overweight or obesity and those who are at risk of chronic disease. The importance of following the *Dietary Guidelines* across all life stages has been brought into focus even more with the emergence of COVID-19, as people living with diet-related chronic conditions and diseases are at an increased risk of severe illness from the novel coronavirus.

Grounded in the current body of scientific evidence on diet and health that is relevant to all Americans, the *Dietary Guidelines* is a critically important tool for health professionals, policymakers, and many other professionals. It is designed to help people make food and beverage choices all through life that are enjoyable and affordable and that also promote health and help prevent chronic disease.

6.2 BACKGROUND

Every five years since 1980, a new edition of the *Dietary Guidelines for Americans* has been published. The *Dietary Guidelines* is required under the 1990 National Nutrition Monitoring and Related Research Act, which states that every five years, the U.S. Department of Agriculture (USDA) and U.S. Department of Health and Human Services (HHS) must jointly publish a report containing nutritional and dietary information and guidelines for the general public. The statute (Public Law 101-445, 7 U.S.C. 5341 et seq.) requires that the *Dietary Guidelines* be based on the preponderance of current scientific and medical knowledge. The 2020–2025 edition of the *Dietary Guidelines*

DOI: 10.1201/9781003227793-8

TABLE 6.1

Facts about Nutrition-Related Health Conditions in the United States

Health Condition	Facts
Overweight and Obesity	• About 74% of adults are overweight or have obesity. • Adults ages 40 to 59 have the highest rate of obesity (43%) of any age group, with adults 60 years and older having a 41% rate of obesity. • About 40% of children and adolescents are overweight or have obesity; the rate of obesity increases throughout childhood and teen years.
Cardiovascular Disease (CVD) and Risk Factors: • Coronary heart disease • Hypertension • High LDL and total blood cholesterol • Stroke	• Heart disease is the leading cause of death. • About 18.2 million adults have coronary artery disease, the most common type of heart disease. • Stroke is the fifth leading cause of death. • Hypertension, high LDL cholesterol, and high total cholesterol are major risk factors in heart disease and stroke. • Rates of hypertension and high total cholesterol are higher in adults with obesity than those who are at a healthy weight. • About 45% of adults have hypertension.[a] • More Black adults (54%) than White adults (46%) have hypertension. • More adults ages 60 and older (75%) than adults ages 40 to 59 (55%) have hypertension. • Nearly 4% of adolescents have hypertension.[b] • More than 11% of adults have high total cholesterol, ≥240 mg/dL. • More women (12%) than men (10%) have high total cholesterol, ≥240 mg/dL. • 7% of children and adolescents have high total cholesterol, ≥200 mg/dL.
Diabetes	• Almost 11% of Americans have type 1 or type 2 diabetes. • Almost 35% of American adults have prediabetes, and people 65 years and older have the highest rate (48%) compared with other age groups. • Almost 90% of adults with diabetes also are overweight or have obesity. • About 210,000 children and adolescents have diabetes, including 187,000 with type 1 diabetes. • About 6–9% of pregnant women develop gestational diabetes.
Cancer[c] • Breast cancer • Colorectal cancer	• Colorectal cancer in men and breast cancer in women are among the most common types of cancer. • About 250,520 women will be diagnosed with breast cancer this year. • Close to 5% of men and women will be diagnosed with colorectal cancer at some point during their lifetime. • More than 1.3 million people are living with colorectal cancer. • The incidence and mortality rates are highest among those ages 65 and older for every cancer type.
Bone Health and Muscle Strength	• More women (17%) than men (5%) have osteoporosis. • 20% of older adults have reduced muscle strength. • Adults over 80 years, non-Hispanic Asians, and women are at the highest risk for reduced bone mass and muscle strength.

[a]For adults, hypertension is defined as systolic blood pressure (SBP) >130 mmHg and/or diastolic blood pressure (DBP) >90 mmHg.
[b]For children, hypertension was defined using the 2017 American Academy of Pediatrics (AAP) Clinical Practice Guideline.
[c]The types of cancer included here are not a complete list of all diet- and physical activity–related cancers.
LDL: low-density lipoprotein.

builds from the 2015 edition with revisions based on the *Scientific Report of the 2020 Dietary Guidelines Advisory Committee*[2] and consideration of input from Federal agencies and public comments.

The *Dietary Guidelines* is designed for policymakers and nutrition and health professionals to help all individuals and their families consume a healthy, nutritionally adequate diet. The information in the *Dietary Guidelines* is used to develop, implement, and evaluate Federal food, nutrition, and health policies and programs. It also is the basis for Federal nutrition education materials designed for the public and for the nutrition education components of USDA and HHS nutrition programs. State and local governments, schools, the food industry, other businesses, community groups, and media also use *Dietary Guidelines* information to develop programs, policies, and communication for the general public.

Although many recommendations have remained relatively consistent over time, the *Dietary Guidelines* also has built upon previous editions and evolved as scientific knowledge has grown. The *Dietary Guidelines for Americans, 2020–2025* reflects this in three important ways.

The first is its recognition that diet-related chronic diseases, such as cardiovascular disease, type 2 diabetes, obesity, and some types of cancer, are very prevalent among Americans and pose a major public health problem. Today,

more than half of adults have one or more diet-related chronic diseases or conditions. As a result, recent editions of the *Dietary Guidelines* have focused on healthy individuals, as well as those with overweight or obesity and those who are at risk of chronic disease. A fundamental premise of the *2020–2025 Dietary Guidelines* is that just about everyone, no matter their health status, can benefit from shifting food and beverage choices to better support healthy dietary patterns.

The second is its focus on dietary patterns. Researchers and public health experts, including registered dietitians, understand that nutrients and foods are not consumed in isolation. Rather, people consume them in various combinations over time—a dietary pattern—and these foods and beverages act synergistically to affect health. The *Dietary Guidelines for Americans, 2015–2020* puts this understanding into action by focusing its recommendations on consuming a healthy dietary pattern. The *2020–2025 Dietary Guidelines* carries forward this emphasis on the importance of a healthy dietary pattern as a whole—rather than on individual nutrients, foods, or food groups in isolation.

The third is its focus on a lifespan approach. This edition of the *Dietary Guidelines* highlights the importance of encouraging healthy dietary patterns at every life stage from infancy through older adulthood. It provides recommendations for healthy dietary patterns by life stage, identifying needs specific to each life stage and considering healthy dietary pattern characteristics that should be carried forward into the next stage of life. For the first time since the 1985 edition, the *2020–2025 Dietary Guidelines* includes recommendations for healthy dietary patterns for infants and toddlers.

6.3 OVERVIEW OF THE *DIETARY GUIDELINES FOR AMERICANS, 2020–2025*

The *2020-2025 Dietary Guidelines* provides four overarching Guidelines (Figure 6.1) that encourage healthy eating patterns at each stage of life and recognize that individuals will need to make shifts in their food and beverage choices to achieve a healthy pattern. The Guidelines also explicitly emphasize that a healthy dietary pattern is not a rigid prescription. Rather, the Guidelines are a customizable framework of core elements within which individuals make tailored and affordable choices that meet their personal, cultural, and traditional preferences. The Guidelines are supported by Key Recommendations that provide further guidance on healthy eating across the lifespan. Their call to action is "Make Every Bite Count with the Dietary Guidelines for Americans."

6.3.1 The Guidelines

1. **Follow a healthy dietary pattern at every life stage.** At every life stage—infancy, toddlerhood, childhood, adolescence, adulthood, pregnancy, lactation, and older adulthood—it is never too early or too late to eat healthfully.
   - For about the first 6 months of life, exclusively feed infants human milk. Continue to feed infants human milk through at least the first year of life, and longer if desired. Feed infants iron-fortified infant formula during the first year of life when human milk is unavailable. Provide infants with supplemental vitamin D beginning soon after birth.
   - At about 6 months, introduce infants to nutrient-dense complementary foods. Introduce infants to potentially allergenic foods along with other complementary foods. Encourage infants and toddlers to consume a variety of foods from all food groups. Include foods rich in iron and zinc, particularly for infants fed human milk.
   - From 12 months through older adulthood**,** follow a healthy dietary pattern across the lifespan to meet nutrient needs, help achieve a healthy body weight, and reduce the risk of chronic disease.
2. **Customize and enjoy nutrient-dense food and beverage choices to reflect personal preferences, cultural traditions, and budgetary considerations.** A healthy dietary pattern can benefit all individuals regardless of age, race or ethnicity, or current health status. The *Dietary Guidelines* provides a framework intended to be customized to individual needs and preferences, as well as the foodways of the diverse cultures in the United States.
3. **Focus on meeting food group needs with nutrient-dense foods and beverages and stay within calorie limits.** An underlying premise of the *Dietary Guidelines* is that nutritional needs should be met primarily from foods and beverages—specifically, nutrient-dense foods and beverages. Nutrient-dense foods provide vitamins, minerals, and other health-promoting components and have no or little added sugars, saturated fat, and sodium. A healthy dietary pattern consists of nutrient-dense forms of foods and beverages across all food groups, in recommended amounts, and within calorie limits.

   The core elements that make up a healthy dietary pattern include:
   - Vegetables of all types—dark green; red and orange; beans, peas, and lentils; starchy; and other vegetables
   - Fruits, especially whole fruit
   - Grains, at least half of which are whole grain
   - Dairy, including fat-free or low-fat milk, yogurt, and cheese, and/or lactose-free versions and fortified soy beverages and yogurt as alternatives

FIGURE 6.1 The Guidelines.

- Protein foods, including lean meats, poultry, and eggs; seafood; beans, peas, and lentils; and nuts, seeds, and soy products
- Oils, including vegetable oils and oils in food, such as seafood and nuts

4. **Limit foods and beverages higher in added sugars, saturated fat, and sodium, and limit alcoholic beverages.** At every life stage, meeting food group recommendations—even with nutrient-dense choices—requires most of a person's daily calorie needs and sodium limits. A healthy dietary pattern doesn't have much room for extra added sugars, saturated fat, or sodium—or for alcoholic beverages. A small amount of added sugars, saturated fat, or sodium can be added to nutrient-dense foods and beverages to help meet food group

recommendations, but foods and beverages high in these components should be limited. The limits are:

- **Added sugars**—Less than 10 percent of calories per day starting at age 2. Avoid foods and beverages with added sugars for those younger than age 2.
- **Saturated fat**—Less than 10 percent of calories per day starting at age 2.
- **Sodium**—Less than 2,300 milligrams per day—and even less for children younger than age 14.
- **Alcoholic beverages**—Adults of legal drinking age can choose not to drink, or to drink in moderation by limiting intake to 2 drinks or less in a day for men and 1 drink or less in a day for women, when alcohol is consumed. Drinking less is better for health than drinking more. There are some adults who should not drink alcohol, such as women who are pregnant.

6.3.2 Healthy Dietary Patterns

A dietary pattern represents the totality of what individuals habitually eat and drink, and parts of the pattern act synergistically to affect health. A healthy dietary pattern consists of nutrient-dense forms of foods and beverages across all food groups, in recommended amounts, and within calorie limits. Achieving a healthy dietary pattern at each life stage not only supports health at that point in time, but also supports health in the next life stage and possibly for future generations. If healthy dietary patterns can be established early in life and sustained thereafter, the impact on health could be significant. Establishing and maintaining a healthy dietary pattern can help minimize diet-related chronic disease risk. Conversely, consuming foods and beverages that are not nutrient-dense may lead to disease expression in later years. High intakes of such foods (i.e., an unhealthy dietary pattern) throughout the lifespan can increase the risk of developing chronic diseases.

The good news is that at any stage of life, individuals can make efforts to adopt a healthy dietary pattern and improve their health. The Healthy U.S.-Style Dietary Pattern, USDA's primary Dietary Pattern, provides a framework for healthy eating that all Americans can follow. It is based on the types and proportions of foods Americans of all ages, genders, races, and ethnicities typically consume, but in nutrient-dense forms and appropriate amounts. The Healthy Vegetarian Dietary Pattern and the Healthy Mediterranean-Style Dietary Pattern are variations that also exemplify a healthy dietary pattern. These USDA Dietary Patterns have 12 calorie levels to meet the needs of individuals across the lifespan ages 2 and older.

For the first time, the Healthy U.S.-Style and Healthy Vegetarian Dietary Patterns are provided for toddlers ages 12 through 23 months who are no longer receiving human milk or infant formula. These patterns are designed to meet nutrient needs while not exceeding calorie requirements and while staying within limits for overconsumed dietary components, such as added sugars, saturated fat, and sodium. These patterns are provided at four calorie levels.

The Healthy U.S.-Style Dietary Pattern is carried forward from the *2015–2020 Dietary Guidelines for Americans.* The 2,000-calorie level of the pattern is shown in Table 6.2. The USDA Dietary Patterns can be found in Appendix 3 of the *Dietary Guidelines for Americans, 2020–2025.*

The components of healthy dietary patterns recommended were developed by integrating findings from systematic reviews of scientific research, food pattern modeling, and analyses of current intake of the U.S. population:

- Systematic reviews of scientific research examine relationships between the overall diet and health outcomes.
- Food pattern modeling assesses how well various combinations and amounts of foods meet nutrient needs and accommodate limits.
- Analyses of current intakes identify areas of potential public health concern.

Together, these complementary approaches provide a robust evidence base for healthy dietary patterns that both reduce risk of diet-related chronic disease and promote nutrient adequacy.

6.3.3 Estimated Calorie Needs per Day

The amount of calories a person needs each day varies depending on a number of factors, including the person's age, sex, height, weight, level of physical activity, and pregnancy or lactation status. Due to reductions in basal metabolic rate that occur with aging, calorie needs generally decrease for adults as they age. In addition, a need to lose, maintain, or gain weight affects how many calories should be consumed. Estimated amounts of calories needed are provided in Appendix 2 of the *Dietary Guidelines for American, 2020–2025.* These estimates are based on the Estimated Energy Requirements (EER) equations[3] established by the National Academy of Sciences, Engineering and Medicine (NASEM) using reference heights (average) and reference weights (healthy) for each age-sex group.* These amounts are estimates. The best way to evaluate calorie intake, in comparison to calorie needs, is by measuring body weight status. After release of the 2020–2025 edition of the *Dietary Guidelines*, NASEM released updated *Dietary Reference Intakes for Energy*, which provide similar estimates.[4]

* For children and adolescents, reference height and weight vary. For adults, the reference man is 5 feet 10 inches tall and weighs 154 pounds. The reference woman is 5 feet 4 inches tall and weighs 126 pounds.

TABLE 6.2

Healthy U.S.-Style, Dietary Pattern at the 2,000-Calorie Level, with Daily or Weekly Amounts from Food Groups, Subgroups, and Components

Food Group[a]	Daily Amount[b] of Food From Each Group(vegetable and protein foods subgroup amounts are per week)
Vegetables	2½ c eq/day
--Dark green	1½ c eq/week
--Red and orange	5½ c eq/week
--Beans, peas, lentils	1½ c eq/week
--Starchy vegetables	5 c eq/week
--Other	4 c eq/week
Fruits	2 c eq/day
Grains	6 oz eq/day
--Whole grains	≥3 oz eq/day
--Refined grains	<3 oz eq/day
Dairy	3 c eq/day
Protein Foods	5½ oz eq/day
--Seafood	8 oz eq/week
--Meat, poultry, eggs	26 oz eq/week
--Nuts, seeds, soy products	5 oz eq/week
Oils	27 g/day
Limit on Calories for Other Uses (% of calories)[b]	240 kcal/day (12%)

[a]Definitions for each food group and subgroup are compiled in Appendix 3 of the *Dietary Guidelines for Americans, 2020–2025*.

[b]Food group amounts shown in cup (c) or ounce equivalents (oz eq). Oils are shown in grams (g). Amounts will vary for those who need <2,000 or >2,000 calories per day. Quantity equivalents for each food group are:

- Vegetables and fruits, 1 cup-equivalent is: 1 cup raw or cooked vegetable or fruit, 1 cup vegetable or fruit juice, 2 cups leafy salad greens, ½ cup dried fruit or vegetable.
- Grains, 1 ounce-equivalent is: ½ cup cooked rice, pasta, or cereal; 1 ounce dry pasta or rice; 1 medium (1 ounce) slice bread; 1 ounce of ready-to-eat cereal (about 1 cup of flaked cereal).
- Dairy, 1 cup-equivalent is: 1 cup milk, yogurt, or fortified soymilk; 1½ ounces natural cheese such as cheddar cheese or 2 ounces of processed cheese.
- Protein Foods, 1 ounce-equivalent is: 1 ounce lean meat, poultry, or seafood; 1 egg; ¼ cup cooked beans or tofu; 1 Tbsp peanut butter; ½ ounce nuts or seeds.

[c]Foods are assumed to be in nutrient-dense forms, lean or low-fat and prepared with minimal added sugars, refined starches, saturated fat, or sodium. If all food choices to meet food group recommendations are in nutrient-dense forms, a small number of calories remain within the overall limit of the pattern (i.e., limit on calories for other uses). The amount of calories depends on the total calorie level of the pattern and the amounts of food from each food group required to meet nutrient goals. Calories up to the specified limit can be used for added sugars, saturated fat, and/or alcohol, or to eat more than the recommended amount of food in a food group.

Note: The total dietary pattern should not exceed *Dietary Guidelines* limits for intake of added sugars, saturated fats, and alcohol; be within the Acceptable Macronutrient Distribution Ranges for protein, carbohydrate, and total fats; and stay within calorie limits. Values are rounded. See Appendix 3 in the *Dietary Guidelines, 2020–2025* for all 12 calorie levels of the Patterns.

6.3.4 Most Americans Do Not Follow a Healthy Dietary Pattern

The typical eating patterns currently consumed by many in the United States do not align with the *Dietary Guidelines* (Figure 6.2). For Americans ages 2 and older, Healthy Eating Index (HEI)-2015 scores indicate that intakes are not consistent with recommendations for a healthy dietary pattern. Average diet quality has slightly improved in the past ten years, but the average score of 59 (on a scale from 0 to 100) indicates that people have much room for improvement. Differences in overall HEI scores are seen across age, sex, race-ethnic, and income subgroups and by pregnancy and lactation status, though poor diet quality is observed across all groups. With each step closer to a diet that aligns with the core elements of a healthy dietary pattern, HEI scores will increase, and risk for chronic disease will decrease.*

When compared with the Healthy U.S.-Style Pattern, most Americans have substantial room for improvement:

* Data source for Healthy Eating Index 2015 scores: What We Eat in America, National Health and Nutrition Examination Survey (NHANES) 2015–2016, ages 2 and older, day 1 dietary intake data, weighted. For more information on the HEI, see: www.fns.usda.gov/healthy-eating-index-hei. Accessed April 20, 2023.

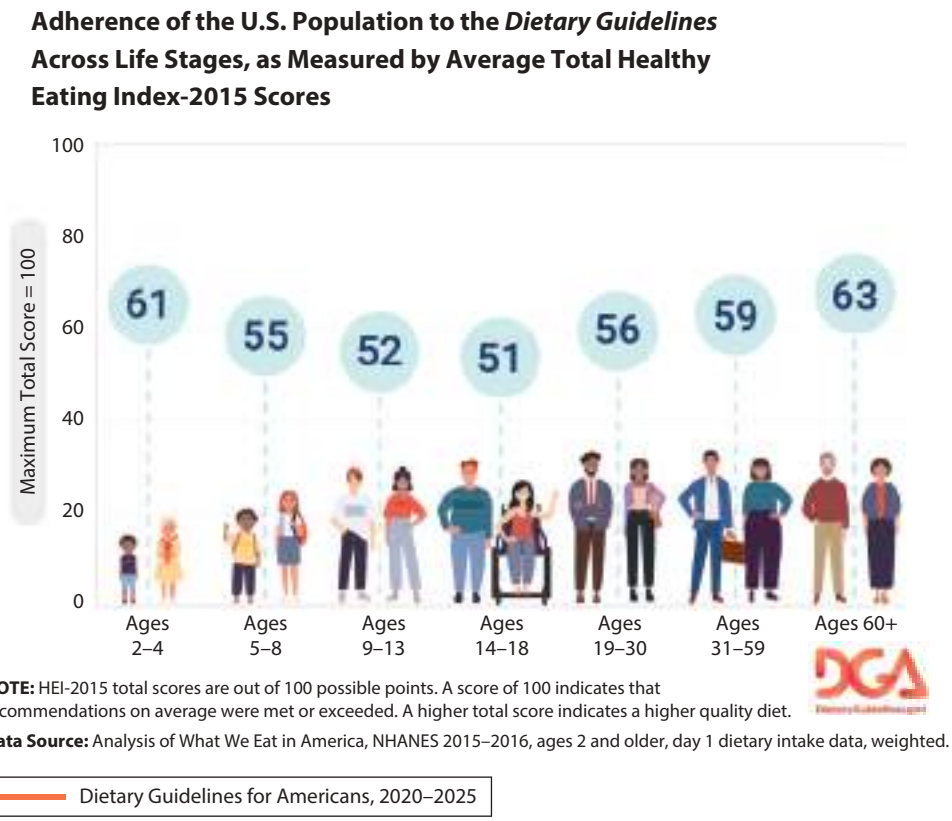

FIGURE 6.2 Healthy Eating Index scores by life stages.

- More than 80% have dietary patterns that are low in vegetables, fruits, and dairy.
- More than half of the population are meeting or exceeding total grain and total protein foods recommendations, but are not meeting the recommendations for the subgroups within each of these food groups.
- Most Americans exceed the recommendations for added sugars, saturated fats, and sodium.

Among nutrients, calcium, potassium, dietary fiber, and vitamin D are considered nutrients of public health concern because low intakes are associated with health concerns. For young children, individuals capable of becoming pregnant, and who are pregnant, low intake of iron also is of public health concern.

6.3.5 Key Dietary Principles

To help people meet the Dietary Guidelines and Key Recommendations, the following are important principles when making decisions about nutrient-dense food and beverage choices to achieve a healthy dietary pattern.

- Meet nutritional needs primarily from foods and beverages. The *Dietary Guidelines* are designed to meet the Recommended Dietary Allowances and Adequate Intakes for essential nutrients, as well as Acceptable Macronutrient Distribution Ranges, all set by NASEM. An underlying premise of the *Dietary Guidelines* is that nutritional needs should be met primarily from foods and beverages—specifically, nutrient-dense foods and beverages. In some cases, when meeting nutrient needs is not otherwise possible, fortified foods and nutrient-containing dietary supplements are useful. It is important to note that the nutrient density and healthfulness of what people eat and drink often is determined ultimately by how a food item, dish, or meal is prepared, at home and away from home or produced by a manufacturer. Based on the U.S. food supply and marketplace, healthy dietary patterns are achievable through thoughtful, informed choices one decision, one meal, one day at a time—and consistently over time.
- Choose a variety of options from each food group. Enjoy different foods and beverages within each food group. This can help meet nutrient needs—and also allows for flexibility so that the *Dietary Guidelines* can be tailored to meet cultural and personal preferences. All forms of foods, including fresh, canned, dried, frozen, and 100% juices, in nutrient-dense forms, can be included in healthy dietary patterns.
- Pay attention to portion size. Portion size is a term often used to describe the amount of a food or

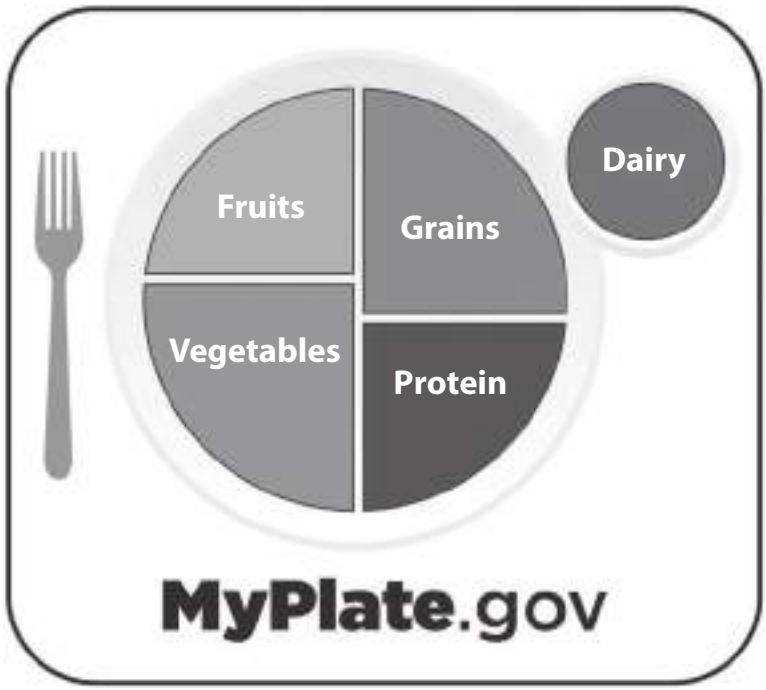

FIGURE 6.3 Federal nutrition symbol.

beverage served or consumed in one eating occasion. It is important to pay attention to portion size when making food and beverage choices, particularly for foods and beverages that are not nutrient-dense. A concept that can help people choose appropriate portions is serving size. This term is included on the Nutrition Facts label and refers to the amount of a food or beverage that is customarily consumed—it is not a recommendation of how much to eat or drink. Consuming less than the stated serving size results in consuming fewer calories and other nutrients or food components. Some products may have multiple servings per package.

For most individuals, no matter their age or health status, achieving a healthy dietary pattern will require changes in food and beverage choices. Some of these changes can be accomplished by making simple substitutions, while others will require greater effort to accomplish. The 2020–2025 edition of the *Dietary Guidelines* presents overall guidance on choosing nutrient-dense foods and beverages in place of less healthy choices and also discusses special nutrition considerations for individuals at each life stage—infants and toddlers, children and adolescents, adults, individuals who are pregnant or lactating, and older adults.

6.4 IMPLEMENTATION BY HEALTH PROFESSIONALS

Eating should be enjoyed, and a healthy dietary pattern can be enjoyable, from early life to older adulthood. The science reviewed to inform the *Dietary Guidelines* represents the diversity of Americans, including all ages and life stages, different racial and ethnic backgrounds, and a range of socioeconomic statuses. A healthy dietary pattern can benefit all individuals regardless of age, race or ethnicity, or current health status.

The *Dietary Guidelines* provides a framework intended to be customized to fit individual, household, and Federal program participants' preferences, as well as the foodways of the diverse cultures in the United States. The U.S. population is diverse in myriad ways. The *Dietary Guidelines* framework purposely provides recommendations by food groups and subgroups—not specific foods and beverages—to avoid being prescriptive. This framework approach ensures that people can "make it their own" by selecting healthy foods, beverages, meals, and snacks specific to their needs and preferences.

The food groups include a broad variety of nutrient-dense food and beverage choices. In every setting, across all cultures, and at any age or budget, there are foods and beverages that can fit within the *Dietary Guidelines* framework. Health professionals can support healthy dietary patterns by considering the following:

- Start with personal preferences: Exposure to different types of food is important early in life to better develop a child's interest and willingness to eat and enjoy a variety of foods. Through each life stage that follows, a key starting point for establishing and maintaining a healthy dietary pattern is to ensure that individual and/or family preferences—in nutrient-dense forms—are built into day-to-day choices.

- Incorporate cultural traditions: Cultural background can have significant influence on food and beverage choices. Customizing the *Dietary Guidelines* framework to reflect specific cultures and traditions is an important strategy to help communities across the country eat and enjoy a healthy dietary pattern. Nutrient-dense culturally relevant foods and beverages are part of all of the food groups. Spices and herbs can help flavor foods when reducing added sugars, saturated fat, and sodium, and they also can add to the enjoyment of nutrient-dense foods, dishes, and meals that reflect specific cultures. Relying on the expertise of professionals in nutrition and in specific cultural foodways can help people prepare foods healthfully while retaining heritage.
- Consider budget: Despite a common perception that eating healthfully is expensive, a healthy dietary pattern can be affordable and fit within budgetary constraints. There are a range of strategies that can be used to help individuals and families follow a healthy dietary pattern, including advanced planning; considering regional and seasonal food availability; and incorporating a variety of fresh, frozen, dried, and canned options.

6.4.1 Translating the *Dietary Guidelines* to Support Nutrition Education

The *Dietary Guidelines* is developed and written for a professional audience. Therefore, its translation into actionable consumer messages and resources is crucial to help individuals, families, and communities achieve healthy dietary patterns. With the needs of health professionals in mind, the USDA and HHS have developed a variety of tools that can help health professionals with disseminating food and nutrition messages based on the *Dietary Guidelines* to the public. These resources include MyPlate and a myriad of health professional resources available at DietaryGuidelines.gov.*

MyPlate (Figure 6.3). MyPlate† is the Federal nutrition symbol to help Americans make healthy food choices based on the *Dietary Guidelines for Americans*, which replaced the Food Pyramid in 2011. MyPlate serves as a visual reminder to build a healthy eating pattern by making healthy choices across the food groups. MyPlate is also used by professionals across multiple sectors and settings to help increase awareness about how to make healthy food and beverage choices over time. Created to be used in various settings and to be adaptable to support the needs of specific population groups, the MyPlate symbol and its supporting consumer resources bring together key elements of healthy dietary patterns. The MyPlate consumer messages can be used in a variety of educational materials for the public.

MYPLATE CONSUMER MESSAGES

A healthy eating routine is important at every stage of life and can have positive effects that add up over time. It's important to eat a variety of fruits, vegetables, grains, dairy or fortified soy alternatives, and protein foods. When deciding what to eat or drink, choose options that are full of nutrients. Make every bite count.

Think about how the following recommendations can come together over the course of your day or week to help you create a healthy eating routine:

- Make half your plate fruits and vegetables.
  - Focus on whole fruits.
  - Vary your veggies.
- Make half your grains whole grains.
- Vary your protein routine.
- Move to low-fat or fat-free dairy milk or yogurt (or lactose-free dairy or fortified soy versions).
- Choose foods and beverages with less added sugars, saturated fat, and sodium.

The benefits of healthy eating add up over time, bite by bite. Small changes matter. Start Simple with MyPlate.

Health Professional Resources Available at DietaryGuidelines.gov. USDA and HHS developed a variety of resources to help promote healthy eating across the lifespan from birth to older adulthood based on the *Dietary Guidelines for Americans, 2020–2025.* Many of the resources available on the website can be used in their entirety or adapted for different purposes to support and supplement nutrition education, programs, and policies. For example, a suite of print materials can be printed out and used directly with patients and clients. These print materials cover topics that are central to building a healthy dietary pattern, such as how to build a healthy eating routine, eating healthily for key life stages, including pregnancy and breastfeeding, birth to age 2, kids and teens, and older adults, and how to cut down on over-consumed nutrients such as added sugars, saturated fat, and sodium.

The Customizing the *Dietary Guidelines* Framework handout is especially useful in helping individuals with understanding the range of food and beverage options that are available within each food group. Effort was made to expand the list of food and beverage options within this handout to provide not only frequently consumed foods and beverages within each food group, but also less frequently consumed foods that may be more readily consumed among different population subgroups. In this way, this resource could be more reflective of the variety

* For more information, see: U.S. Department of Agriculture and U.S. Department of Health and Human Services, DietaryGuidelines.gov: www.dietaryguidelines.gov/. Accessed April 25, 2023.

† For more information, see: U.S. Department of Agriculture, MyPlate.gov: www.myplate.gov/. Accessed April 25, 2023.

of cultural foodways within the United States. Similarly, the food sources of select nutrients tables available on DietaryGuidelines.gov provide food sources of calcium, potassium, dietary fiber, and vitamin D, which as noted earlier, are considered dietary components of public health concern for the U.S. population. Iron is also a nutrient of concern for infants, particularly those receiving mostly human milk, and individuals of childbearing age. The food sources of select nutrients lists provide examples of a variety of nutrient-dense foods and beverages that are some of the highest sources of these dietary components. Health professionals are encouraged to use these lists to help individuals identify foods and beverages they enjoy—those that reflect their personal preferences and cultural traditions—and that also help meet their food group and nutrient needs. These food sources of select nutrients lists also reflect both frequently consumed sources and less frequently consumed sources with the goal of providing foods and beverages that better reflect the variety of cultural foodways within the U.S. population.

DietaryGuidelines.gov also offers resources that can be downloaded and adapted for a variety of purposes. Health professional presentation slides based on the *Dietary Guidelines* can be downloaded and used in their entirety, or single slides can be integrated into a different presentation. Health professionals are encouraged to use these slides to host their own presentation on healthy eating across life stages or for a specific life stage, including infants and toddlers, children and adolescents, adults, people who are pregnant or lactating, and older adults.

Figures from the *Dietary Guidelines for Americans* are also available to use. These figures can be used as a standalone handout, pulled into presentation slides as supporting data points, adapted and shared through social media channels, or used in flyers. Some key figures provided on DietaryGuidelines.gov include ones within this chapter that focus on how well Americans are doing at meeting dietary recommendations, as well as other figures that help to support education related to nutrient density and how nutrient-dense choices can be made at the food level, at a meal, and throughout the day.

Resources available on DietaryGuidelines.gov, including print handouts, figures, and graphics, are available in both English and Spanish.

6.5 SUPPORTING HEALTHY DIETARY PATTERNS FOR ALL AMERICANS

Everyone has a role to play to support access to healthy foods and beverages in multiple settings nationwide where people live, learn, work, play, and gather. Having access to healthy, safe, and affordable food is crucial for an individual to achieve a healthy dietary pattern. Concerted efforts within communities, businesses and industries, organizations, government, and other segments of society are needed to support individuals and families in making lifestyle choices that align with the *Dietary Guidelines*.

In 2019, 10.5% of households were food insecure at least some time during the year. Food insecurity occurs when access to nutritionally adequate and safe food is limited or uncertain. Food insecurity can be temporary or persist over time, preventing individuals and families from following a healthy dietary pattern that aligns with the *Dietary Guidelines*. The prevalence of food insecurity typically rises during times of economic downturn as households experience greater hardship. Government and nongovernment nutrition assistance programs help alleviate food insecurity and play an essential role by providing food, meals, and educational resources so that participants can make healthy food choices within their budget. Each of the life stage chapters within the *Dietary Guidelines* highlights examples of these programs, such as the Supplemental Nutrition Assistance Program (SNAP), that are available to alleviate food insecurity.

Food access is also important to consider. Food access is influenced by diverse factors, such as proximity to food retail outlets (e.g., the number and types of stores in an area), ability to prepare one's own meals or eat independently, and the availability of personal or public transportation. The underlying socioeconomic characteristics of a neighborhood also may influence an individual's ability to access foods to support healthy eating patterns.

Individuals may also need support in making healthy choices at home, at work, and in the community to build healthy dietary patterns. For some adults, preparing and consuming healthy meals at home will mean adopting a new habit and/or learning new skills, such as meal planning. For others, it may entail small changes to current routines. Planning meals and snacks in advance with food groups and nutrient-dense foods and beverages in mind can support healthy eating at home and improve dietary patterns of individuals and families. Preparing meals with family and friends also presents an opportunity for greater connection and enjoyment around food. For adults who are parents, guardians, or caregivers of children or adolescents, preparing meals also provides an opportunity to teach valuable cooking skills and model behaviors that support the adoption of healthy dietary patterns across younger life stages.

Health professionals play an important role in supporting healthy eating behaviors. Helping individuals become more aware of the foods and beverages that make up their typical dietary patterns and identifying areas for improvement can empower individuals to make changes to the types of foods they purchase or prepare. Teaching skills like cooking and meal planning and helping individuals understand how to read labels or make healthy menu substitutions also will support the adoption of a healthy dietary pattern. In settings where individuals spend their time, changing organizational practices, approaches, and/or policies to support improved dietary patterns also is needed. Strategies include offering healthy meals and snacks in cafeterias and vending machines, or implementing educational programs. Or, communities can support farmers' markets, community gardens, and related educational programming efforts.

6.6 THE DIETARY GUIDELINES LIFE STAGE APPROACH

This chapter has provided guidance about the fundamentals of a healthy dietary pattern described in the *Dietary Guidelines*. These fundamentals are remarkably consistent across life stages; however, the *Dietary Guidelines* also takes a closer look at each of the life stages. The *Dietary Guidelines* includes a chapter focused on the unique nutritional needs of infants and toddlers. Subsequent chapters present recommended dietary patterns, describe current nutrition intakes, and provide tailored nutrition information specific to children and adolescents, adults, individuals who are pregnant or lactating, and older adults, respectively.

6.7 ADDITIONAL RESOURCES

These resources are intended to complement existing Federal nutrition information and guidance that can be found at websites such as www.DietaryGuidelines.gov, www.healthfinder.gov, www.nutrition.gov, and www.MyPlate.gov. Additional information on vitamin, mineral, and macronutrient recommendations are available in the Dietary Reference Intakes, accessible at www.nal.usda.gov/fnic/dietary-reference-intakes. Finally, best practices that can be used to increase healthy and safe food options for employees can be found in the *Food Service Guidelines for Federal Facilities* at www.cdc.gov/obesity/strategies/food-serv-guide.html.

CLINICAL APPLICATIONS

- Communicate the value of a healthy lifestyle, including healthy eating, to your patients and clients and use resources available at DietaryGuidelines.gov and MyPlate.gov.
- Assist individuals with identifying a dietary pattern that is right for them based on their calorie needs; personal health; and cultural, ethnic, traditional, and personal preferences as well as an individual's budget and other issues of accessibility, such as access to healthy food.
- Encourage food and beverage choices that meet the Key Recommendations for food groups, subgroups, nutrients, and other components to contribute to overall healthy dietary patterns.
- Help individuals become more aware of the foods and beverages that make up their own or their family's eating patterns and identify areas, such as modifying recipes and/or food selections, where they can make shifts to align with the *Dietary Guidelines*.
- Establish and maintain sectors and settings that support healthy dietary patterns and encourage regular physical activity as part of a healthy lifestyle.

7 Nutrition and Cardiovascular Disease

James M. Rippe, MD

KEY POINTS

- Cardiovascular disease (CVD) remains the leading killer of both men and women in the United States, resulting in over 37% of annual mortality.
- Nutritional practices play a pivotal role in the likelihood of developing CVD.
- Dietary patterns that include increases in fruits and vegetables, whole grains, seafood (particularly oily fish), legumes and nuts, and low or non-fat dairy products, and are lower in red meats and processed meats, and low in sugar sweetened beverages and refined grains have been repeatedly shown to lower the risk of CVD.
- Implementation of plant based diets such as those recommended by the American Heart Association and Dietary Guidelines for Americans will be a key mandate for clinicians to help their patients adopt healthier eating habits.

7.1 INTRODUCTION

Cardiovascular disease (CVD) is the largest source of morbidity and mortality in the United States and elsewhere in the developed world.[1] CVD accounts for over 37% of all mortality in the United States. There are hundreds, if not thousands, of studies to support the concept that daily lifestyle practices and habits exert profound effects on the likelihood of developing CVD. While many lifestyle practices are associated with positive benefits in both prevention and treatment of CVD, nutrition clearly plays a pivotal role.[2–6]

Multiple studies have demonstrated that a diet containing more fruits and vegetables, fish (particularly oily fish), whole grains and fiber, and also remaining in caloric balance, lowers the risk of CVD.[2–7] Other positive lifestyle decisions such as maintaining a proper body weight,[8,9] engaging in at least 30 minutes per day of physical activity,[10] and avoiding smoking and tobacco products[3] can also reduce the risk of CVD. These practices together can reduce the risk of CVD over 80% and diabetes by over 90% in both men and women. Indeed, participation in only one of these activities on a regular basis can reduce the risk of both CVD and diabetes by over 50%.[11,12]

Between 1980 and 2000, mortality rates from CVD fell by 40%[13]. Reductions in major lifestyle risk factors, such as increased physical activity, smoking cessation, and better control of cholesterol and blood pressure, accounted for approximately one-half of these reductions. Unfortunately, obesity and diabetes have moved in the opposite direction and have the potential to wipe out all the gains achieved by other lifestyle related risk factors, unless these negative trends can be reversed.[13] Between 1990 and 2013, deaths from CVD rose from 26% to 32% globally. This appears to be due to epidemiologic transitions that have occurred during this period of time.[2] Nutritional factors play a significant role in many of the components of either positive or negative lifestyle decisions or practices.

This chapter will focus on nutrition. Nutrition will be placed, however, in a broader lifestyle context with an emphasis on physical activity as well as energy balance and weight maintenance. This overall approach to lifestyle medicine is consistent with the approach taken by the American Heart Association (AHA) in multiple documents and scientific statements,[3–6], the Dietary Guidelines for Americans (DGA) 2020–2025 as well as multiple other resources,[8–14] and mission statements and position statements from the Academy of Nutrition and Dietetics.[15]

Nutritional guidelines offered by the AHA[3] and other evidence based documents, such as the 2013 AHA/American College of Cardiology (ACC) Guidelines on Lifestyle Management to Reduce Cardiovascular Risk[5] and the 2020 Strategic Plan for Improving Cardiovascular Health and Lowering Cardiovascular Risk from the AHA[4] as well as the report from the Dietary Guidelines Advisory Committee 2020–2025,[7] are very similar. All place an emphasis on not only nutrition but a broader approach toward positive lifestyle factors to improve cardiovascular health and reduce the risk of CVD.

7.2 BACKGROUND

Consensus statements and recommendations from a variety of organizations issued over the past ten years regarding nutritional strategies for improving cardiovascular health are very similar. Often, these recommendations have drawn upon the same database, in general, and in particular, large epidemiologic studies. These guidelines have often referred to each other. These published consensus statements form the basis of the recommendations made in this chapter and include the following:

- Diet and Lifestyle Recommendations Revision 2021: A Scientific Statement from the American Heart Association Nutrition Committee[3]
- Defining and Setting National Goals for Cardiovascular Health Promotion and Disease Reduction: American Heart Association Strategic Impact Goals through 2020 and beyond[4]

DOI: 10.1201/9781003227793-9

- 2013 AHA/ACC Guidelines for Lifestyle Management to Reduce Cardiovascular Risk: A Report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines[5]
- Dietary Guidelines 2020–2025 Advisory Committee Report
- Dietary Guidelines for Americans 2020–2025[7]

These consensus statements consistently recommend a dietary pattern higher in fruits and vegetables, whole grains (particularly high fiber), non-fat dairy, seafood, legumes, and nuts. The guidelines further recommend that those who consume alcohol (among adults) do so in moderation. The guidelines are also consistent in recommending diets lower in red and processed meats, refined grains, sugar sweetened foods, and saturated and trans fats. All of these guidelines have also emphasized the importance of balancing calories and physical activity as a strategy for maintaining healthy weight and thereby, further reducing the risk of CVD.[3–7]

The national guidelines on nutrition and cardiovascular health are also consistent with each other with regard to overall strategies for reducing cardiovascular health risk factors. For example, the AHA Strategic Goals for 2020 and beyond offer some specific guidance in the area of nutrition.[4] While recognizing that recommending an optimal pattern for CVD risk reduction is a complicated task, the 2020 Strategic Plan defines dietary goals as "in the context of a diet that is appropriate in energy balance pursuing and overall dietary plan consistent with DASH (Dietary Approaches to Stop Hypertension)." Eating plans recommended by the AHA include, but are not limited to, the following recommendations:

- Fruits and vegetables ≥4.5 cups/day
- Fish ≥ two 2½ ounce servings/week (preferably oily fish)
- Fiber rich/whole grain ≥1.1 grams fiber/10 grams carbohydrate, three 1 ounce equivalent servings/day
- Sodium ≤1,500 milligrams/day
- Sugar sweetened beverages ≤460 calories (36 ounces)/week

These recommendations represent a reasonable starting point and have been expanded upon in other guidelines and recent reviews.

Dietary guidance over the last 25 years has moved from specific foods and nutrients to a greater emphasis on dietary patterns. Thus, dietary patterns will be discussed in some detail in this chapter.

The emphasis in nutrition guidelines has also shifted to the critical aspect of implementing recommendations.[16,17] It is clear that nutrition plays a key role in many aspects of preventing CVD, but it is also recognized that despite consistent recommendations and guidelines for many decades, a distinct minority of Americans are following most of these guidelines. For example, with regard to nutrition and hypertension, fewer than 20% of individuals with high blood pressure currently follow the DASH diet.[18] It has also been estimated that fewer than 15% of adults in the United States consume the recommended number of fruits and vegetables.[19] The problem of how to encourage people to actually implement heart healthy guidelines in their daily lives remains an important topic, which will be discussed toward the end of this chapter.[20,21] There has also been an increased emphasis on how to incorporate behavioral medicine techniques into nutrition and other positive aspects of a positive lifestyle. This is another area of considerable ongoing research.

7.3 DIETARY PATTERNS

The 2020–2025 Dietary Guidelines for Americans focused on integrating available science and systematic reviews of scientific research, food pattern modeling, and analysis of the current intake of the U.S. population to develop the "Healthy U.S.-Style Eating Pattern."[7] This approach allowed the blending of the overall diet, including constituent foods, beverages, nutrients, and health outcomes. In addition, the food pattern modeling allowed more flexibility in amounts of foods from all food groups to establish healthy eating patterns that met nutrient needs and also accommodated limitations such as those for saturated fats, added sugars, and sodium. Finally, this approach allowed analysis of current intakes, identifying areas of potential public health concern. With this approach, the DGA 2020–2025 indicated the following:

- Within the body of evidence higher intakes of vegetables and fruits consistently have been identified as characteristic of healthy eating patterns; whole grains have been identified as well, although with slightly less consistently." Other characteristics of healthy eating patterns have been identified with less consistency including fat free or low fat dairy, seafood, legumes and nuts. Lower intakes of meats including processed meats, poultry; sugar sweetened foods, particularly beverages; and refined grains have also been identified as characteristics of healthy eating patterns.

Additionally, DGA 2020-2025 provided input on various dietary and health related components.

- Healthy U.S.-Style Eating Pattern
  Following the guidelines outlined in the preceding paragraph, the U.S. DGA 2020–2025 developed the U.S.-Style Healthy Eating Pattern for the 2,000 calorie level, including daily or weekly amounts from various food groups and components, which are found in Table 7.1.
  The DGA 2020–2025 Guidelines also emphasize that calories should be balanced and that intake

TABLE 7.1
Healthy U.S.-Style Eating Pattern at the 2,000 Calorie Level, with Daily or Weekly Amounts from Food Groups, Subgroups, and Components

Food Group	Amount in the 2,000-Calorie-Level Pattern
Vegetables	2½ c-eq/day
Dark green	1½ c-eq/wk
Red and orange	5½ c-eq/wk
Legumes (beans and peas)	1½ c-eq/wk
Starchy	5 c-eq/wk
Other	4 c-eq/wk
Fruits	2 c-eq/day
Grains	6 oz-eq/day
Whole grains	≥3 oz-eq/day
Refined grains	≤3 oz-eq/day
Dairy	3 c-eq/day
Protein Foods	5½ oz-eq/day
Seafood	8 oz-eq/wk
Meats, poultry, eggs	26 oz-eq/wk
Nuts, seeds, soy products	5 oz-eq/wk
Oils	27 g/day

of calories from added sugars, saturated fats, and alcohol should be limited so as to not exceed acceptable macronutrient distribution ranges for calories from protein, carbohydrates, or total fats. The Healthy U.S.-Style Eating Pattern is also designed to meet recommended daily allowances (RDA), adequate intakes of potential nutrients, as well as acceptable macronutrient distribution ranges (AMDR) set by the Food and Nutrition Board of the Institute of Medicine (IOM). Flexibility within the dietary pattern also allows minor modifications to enable the Mediterranean diet or DASH diet to be followed within these overall guidelines.

- Low Fat Diets
  Lower fat diet consumption has been generally accepted in clinical guidelines for CVD prevention.[3,5] This pattern forms the basis of numerous other diets to be discussed in this chapter.
  Briefly, low fat diets are based on total fat consumption of 25–35% of total calories, with saturated fat (SFA) no more than 7–10%, trans fat (TFA) less than 1%, and unsaturated fat, mainly monounsaturated fat (MUFA), and Omega 3 polyunsaturated fat (*N-3* PUFA) consisting of the rest of the calories from fat. This diet also calls for dietary cholesterol of less than 300 milligrams/day.[3,22,23]
  These recommendations can be met by emphasizing fruits and vegetables, low fat dairy products, including 1% milk, and low fat meat.[24] Some controversy remains about the type and amount of carbohydrates consumed. It should also be noted that the food matrix for SFAs has been an area of recent research, with some suggestion that SFAs coming from dairy products are less likely to cause an adverse increase in risk factors for CVD compared with other sources of SFAs.[25,26] The AHA/ACC Guidelines on Lifestyle Management recommend that consumption of SFAs should not exceed 6% of calories.[5]
- Low Carbohydrate Diet
  Low carbohydrate diets are typically defined as containing up to or less than 45% of total calories from carbohydrates (30–130 grams of carbohydrates/day). Studies of low carbohydrate diets have shown reduction in triglycerides (TG) and an increase in high-density lipoprotein (HDL) cholesterol (HDL-C).[27,28]
  One study that compared low carbohydrate with low fat and Mediterranean diets found greater weight loss in the low carbohydrate diet over the course of one year. A two-year dietary intervention, the randomized controlled DIRECT trial,[29] which involved 322 moderately obese participants comparing low fat with low carbohydrate and Mediterranean diets, found that the low carbohydrate diet was most effective in short-term weight loss, decreasing TG and increasing HDL-C levels. At four-year follow up, however, there were no significant differences among the three arms.
  There are insufficient data from long-term trials to demonstrate the benefits of a low carbohydrate diet compared with low fat and Mediterranean diets for reduction of the risk of CVD.
- Mediterranean Diet
  The Mediterranean diet was originally described as the one typically consumed in countries bordering the Mediterranean Sea.[30,31] It is characterized by relatively high fat intake (40–50% of total daily calories), of which SFA comprises ≤8% and MUFA 15–25% of calories. The Mediterranean diet is also characterized by high Omega 3 fatty acid intake from fish and plant sources and low Omega 6–Omega 3 ratios. It features seasonal, local fresh vegetables, fruits, whole bread, grains, legumes, nuts, and olive oil. Red meat is avoided. Moderate amounts of low fat dairy products as well as eggs, chicken, and fish are allowed. Small to moderate quantities of wine are encouraged with meals in non-Islamic countries.
  A recent, multi-center, randomized intervention study in Spain in individuals with high cardiovascular risk, but no overt evidence of cardiovascular disease at enrollment, were divided into three diets as follows: the Mediterranean diet supplemented with extra virgin olive oil, the Mediterranean diet supplemented with mixed nuts, or a control diet (advised to reduce dietary fat).[32] The primary

endpoint was an incidence of major cardiovascular events such as myocardial infarction, stroke, or death from cardiovascular causes.

The two Mediterranean diets resulted in a decrease of approximately 30% in major cardiovascular events compared with the control diet, providing strong evidence that a Mediterranean diet supplemented with extra virgin olive oil or nuts reduces the risk of major CVD events.

- DASH Diet[17]

  The DASH diet, initially formulated in the 1990s,[18] has undergone several modifications and iterations since that time.[33,34] The initial goal was to lower blood pressure and CVD incidence by nutritional means. The DASH diet features vegetables and fruits as well as low fat dairy products, whole grains, chicken, fish, and nuts. It is low in fat, red meat, sweets, and soft drinks. The DASH diet provides more calcium, potassium, magnesium, and dietary fat and less fat and sodium than the typical Western diet.[34] The typical composition of the DASH diet is found in Table 7.2.

  Subsequent studies have substituted some of the carbohydrates with MUFAs and also have further decreased sodium in the diet. All of these modified DASH diets have significantly reduced both systolic and diastolic blood pressure by 7 to 9 mmHg compared with the typical Western diet.

  A study combining the DASH diet with a lifestyle program aiming to reduce overweight, increase physical activity, and restrict sodium and alcohol intake (the ENCORE Trial)[35] showed additional decreases in both systolic and diastolic blood pressure, which were reduced by 14.2 mmHg and 17.4 mmHg, respectively.

  Unfortunately, even in individuals with high blood pressure, fewer than 20% are currently following the DASH diet.[18]

- Vegetarian Diet

  A variety of vegetarian diets are available, including vegan (consuming no animal products), lacto-ovo vegetarian (consuming milk and eggs), and pesco vegetarian (individuals who consume fish along with a vegetarian diet).

  There are no data to suggest that one form of vegetarian diet is superior to others with regard to CVD risk.[36–39] Few randomized controlled trials (RCTs) have been performed on vegetarian diets, and they have typically been small. They have typically resulted in lower blood pressure compared with usual Western diets. Some observational studies have suggested that vegetarians experience improved health outcomes compared with non-vegetarians.[40] However, a variety of characteristics of vegetarian diets could account for these findings, including fewer meats and inclusion of plant based foods. Furthermore, vegetarians are often more health conscious than other individuals, although other factors could contribute to the lower reported incidence of CVD. It should be noted that vegetarian diets (and other low fat diets) can vary dramatically depending on the specific foods consumed.

- Japanese Diet

  There has been recent interest in Japanese diets, particularly those from Okinawa, which has among the lowest CVD rates in the world.[40,41] The traditional Japanese diets emphasize fish, soybean products, seaweed and vegetables, fruits, and green tea and are low in meat. It should be noted that Japanese diets often contain high sodium from soy sauce and have been linked to a higher risk of strokes.[42] There have been relatively few studies of Japanese diets, so many issues remain to be determined.

- Prudent Diet

  In a sense, the low fat diet, Mediterranean diet, DASH diet, and vegetarian diet all would fit in what has been called the "Prudent diet" category. A recent publication compared this diet pattern, which contains high levels of fruits, vegetables, legumes, fish, poultry, and whole grains, with a typical Western pattern, which contains higher intakes of red meat, processed meat, refined grains, French fries, and sweets/desserts.[43] In this study, the Western pattern was associated with a higher risk of mortality from cardiovascular disease (22% higher; 25% confidence interval [CI], 1–48), cancer (15%; 95% CI, 3–30), and all causes (21%; 95% CI, 12–32).

- Plant Based Diets

  There has been a recent surge in evidence and publications concerning "plant based" diets.[44] Essentially, these diets are defined by an emphasis on plants, including fruits and vegetables. Low fat diets and low carbohydrate diets can both be turned into plant based diets. The Mediterranean diet, DASH diet, vegetarian diets, and Japanese diets are all, in essence, plant based diets, since they emphasize fruits and vegetables, legumes, and nuts, and limit the amount of red meat, processed meat, sweets, and oils. It should be noted that the health benefits of plant based diets may vary according to the foods chosen. A recent article compared a "healthy" plant based diet with an "unhealthy" plant based diet.[45] The "healthy" plant based diet resulted in decreased risk of heart disease, while the "unhealthy" plant based diet did not.

7.4 INDIVIDUAL FOOD ITEMS

Numerous studies, including RCTs of risk factors for CVD as well as prospective cohort studies of disease endpoints,

TABLE 7.2
Following the DASH Eating Plan

Food Group	Servings Per Day			Serving Sizes	Examples and Notes	Significance of Each Food Group to the DASH Eating Plan
	1,600 Calories	2,000 Calories	2,600 Calories			
Grains*	6	6–8	10–11	1 slice bread 1 oz dry cerealt ½ cup cooked rice. pasta, or cereal	Whole wheat bread and rolls, whole wheat pasta, English muffin, pita bread, bagel, cereals, grits, oatmeal, brown rice. unsalted pretzels and popcom	Major sources of energy and fiber
Vegetables	3–4	4–5	5–6	1 cup raw leafy vegetable ½ cup cut-up raw or cooked vegetable ½ cup vegetable juice	Broccoli, carrots, collards, green beans, green peas, kale, lima beans, potatoes, spinach, squash, sweet potatoes, tomatoes	Rich sources of potassium, magnesium, and fiber
Fruits	4	4–5	5–6	1 medium fruit ¼ cup dried fruit ½ cup fresh, frozen, or canned fruit ½ cup fruit juice	Apples, apricots, bananas, dates, grapes, oranges, grapefruit, grapefruit juice, mangoes, melons, peaches, pineapples, raisins, strawberries, tangerines	Important sources of potassium, magnesium, and fiber
Fat-free or low-fat milk and milk products	2–3	2–3	3	1 cup milk or yogurt 1½ oz cheese	Fat-free (skim) or low-fat (1%) milk or buttermilk; fat-free, low-fat, or reduced-fat cheese; fat-free or low-fat regular or frozen yogurt	Major sources of calcium and protein
Lean meats, poultry, and fish	3–6	6 or less	6	1 oz cooked meats, poultry, or fish 1 egg‡	Select only lean meats: trim away visible fat; broil, roast, or poach; remove skin from poultry	Rich sources of protein and magnesium
Nuts, seeds, and legumes	3 per week	4–5 per week	1	½ cup or 1½ oz nuts 2 Tbsp peanut butter 2 Tbsp or ½ oz seeds ½ cup cooked legumes (dry beans and peas)	Almonds, hazelnuts, mixed nuts, peanuts, walnuts, sunflower seeds, peanut butter, kidney beans, lentils, split peas	Rich sources of energy, magnesium, protein, and fiber
Fats and oils§	2	2–3	3	1 tsp soft margarine 1 tsp vegetable oil 1 Tbsp mayonnaise 2 Tbsp salad dressing	Soft margarine, vegetable oil (such as canola, com, olive, or safflower), low-fat mayonnaise, light salad dressing	The DASH study had 27 percent of calories as fat, including fat in or added to foods
Sweets and added sugars	0	5 or less per week	≤2	1 Tbsp sugar 1 Tbsp jelly or jam ½ cup sorbet, gelatin 1 cup lemonade	Fruit-flavored gelatin, fruit punch, hard candy, jelly, maple syrup, sorbet and ices, sugar	Sweets should be low in fat

* Whole grains are recommended for most grain servings as a good source of fiber and nutrients.

† Serving sizes vary between ½ cup and 1¼ cups, depending on cereal type. Check the product's Nutrition Facts label.

‡ Because eggs are high in cholesterol, limit egg yolk intake to no more than four per week; two egg whites have the same protein content as 1 oz of meat.

§ Fat content changes serving amount for fats and oils. For example, 1 Tbsp of regular salad dressing equals one serving: 1 Tbsp of a low-fat dressing equals one-half serving; 1 Tbsp of a fat-free dressing equals zero servings.

Abbreviations: oz = ounce; Tbsp = tablespoon; tsp = teaspoon

provide consistent and strong evidence for cardiovascular effects of certain specific foods in contrast to individual nutrients. These studies represent the combined benefits of composite effects and interactions of multiple factors within foods rather than isolated nutrients. Most foods that fit into dietary patterns that have been demonstrated to lower the risk of CVD will be emphasized in this section.

7.4.1 Fruits and Vegetables

In RCTs, diets that emphasize the consumption of fruits and vegetables have been repeatedly shown to produce substantial improvements in risk factors for CVD, including lipid levels, blood pressure, insulin resistance, inflammatory biomarker levels, and weight control.[3,4,6,46] These same benefits have not been duplicated with supplements and are not dependent on dietary macronutrient composition (e.g. fat, protein, or carbohydrates). These benefits appear to result from phytochemicals and fiber found in fruits and vegetables as well as increased bioavailability of these nutrients in their natural state and replacement of less healthful food in the diet. Both cohort studies and RCTs together support strong evidence that fruit and vegetable consumption lowers CVD risk[3,4,6,46] Considerable research is currently underway to determine which specific types of fruits and vegetables are most beneficial to lower CVD risk.

7.4.2 Whole Grains and Dietary Fiber

Whole grains contain the endosperm, bran (the outer layer of the whole grain), and germ in relative proportions as they exist in the intact grain.[47] Refined grains, in contrast, retain only the endosperm. Dietary fiber consists of the remnants of edible plant lignin, polysaccharides, and associated substances that are resistant to digestion by the human gastrointestinal tract and enzymes.[48] Fiber includes the following: insoluble fiber (including cellulose and lignin), which is found in some vegetables, some fruits, and whole grains (including wheat germ); and soluble fiber, which includes pectin, fruits, guar gum, and mucilage.[49] Soluble fiber also is found in oat bran and legumes. Eating whole grains decreases total cholesterol by between 7 and 8 mg/dL and low-density lipoprotein cholesterol (LDL-C) levels by 6.9 mg/dL, according to a recent Cochrane analysis.[50]

The National Cholesterol Program (ATP III),[51] AHA, and Academy of Nutrition and Dietetics (AND)[52] all have guidelines that include recommendations to increase fiber intake. Whether or not added fiber when used as a food supplement can similarly lower risk factors for CVD is controversial.

The Food and Drug Administration (FDA) has approved a health claim for the soluble fiber from whole oats, whole grain barley products, and barley beta fiber.[53] The DRI recommends 25 grams of fiber for adult women and 38 grams for adult men per day. This corresponds to 14 grams of dietary fiber/1,000 kcal.[49]

7.4.3 Fish

Fish and other seafood contain a variety of healthful substances, including unsaturated fat, vitamin D, selenium, and long chain Omega 3 PUFAs. Some studies have suggested that fish oil has direct anti-arrhythmic effects, but studies in individuals with pre-existing arrhythmias have been inconsistent.[54] Fish oil has been shown to lower triglyceride levels, systolic and diastolic blood pressure, and resting heart rate. Based on these physiologic benefits, regular fish consumption is associated with lower incidence of CVD and risk of cardiac death.[55] For this reason, the AHA dietary recommendations include the consumption of two fish meals (preferably oily fish) per week.[2,3] It is not clear whether the benefits of eating fish can be reproduced by consuming fish oil supplements.

7.4.4 Nuts

Nuts, including tree nuts and peanuts, are nutrient dense foods that are high in unsaturated fats and other bioactive compounds as well as high quality vegetable protein, fiber, minerals, tocopherols, and phytosterols and phenolic compounds.[56] While peanuts are not technically tree nuts, and are typically considered ground nuts or legumes, they are widely identified in research and in the consumer mind as in the same grouping as tree nuts. Additionally, peanuts have a nutrient profile similar to tree nuts.

Epidemiologic studies have consistently shown a negative association between nut consumption and CVD risk.[57] Numerous research studies have shown that consumption of nuts can lower LDL-C concentration by approximately 10 mg/dL, while not significantly changing HDL-C levels. Triglycerides have also been shown to be reduced by >20 mg/dL in subjects with elevated blood cholesterol, though not in those with normal TG levels.

7.4.5 Meat

Dietary patterns that include lower consumption of red meat have been consistently demonstrated to lower CVD risk.[58,59] Various constituents of red meat, including SFAs, cholesterol, and in processed meat, high levels of salt, have been shown to increase factors for CVD. In one research study, both unprocessed and processed meat consumption was associated with higher CVD risk. Such consumption replaced foods with cardiac health benefits such as nuts, fish, and low fat dairy products. Consumption of red meat and processed meats has also been associated with weight gain, which may also increase the risk of CVD.

7.4.6 Dairy Products

Dairy products are rich in minerals such as calcium, potassium, and magnesium, protein (casein and whey), and vitamins (riboflavin and Vitamin B12) and may exert potential benefits by effectively lowering the risk for CVD. The

presence of saturated fat in full fat dairy products has raised concern related to potential adverse CVD effects.[60] For this reason, most dietary guidelines recommend low fat dairy products rather than full fat dairy products.

The inclusion of low fat dairy products as part of an overall heart healthy diet has been demonstrated to significantly lower blood pressure, lipid levels, and insulin resistance independent of changes in weight.[61,62] Due to the multi-component nature of such trials, however, it is difficult to sort out the specific benefits of dairy products.

Recent research has suggested that the matrix in dairy products may make the SFAs in them less hazardous in terms of CVD risk than other SFAs.[24,25] The DGAs 2020–2025 recommend that adults consume three cups of low fat milk or the equivalent on a daily basis.[7] This is far greater than the average serving of one cup per day consumed by adults in the United States. Children and adolescents also consume far below recommended levels.

The health effects of other dairy products such as yogurt, cheese, and butter are the subject of considerable research and require further study.

7.4.7 Soy

The protein found in soybeans is typically referred to as "soy" and is often used to replace animal protein in individual diets.[63] Soybeans contain no cholesterol, are low in saturated fat, and contain considerable protein. Soy is the only vegetable to contain all eight amino acids. The effect of soy on CVD risk has been inconsistent.

7.4.8 Sugar Sweetened Beverages (SSBs)

The effect of SSBs on cardiovascular disease risk is controversial. Some epidemiologic studies have suggested that increased consumption of SSBs increased the risk of heart disease, diabetes and obesity.[64–66] These studies, however, have not been supported by a number of RCTs.[67,6]. The AHA recommends that adult males consume no more than 150 kcal/day and adult females no more than 100 kcal/day in the form of SSBs.[69] The 2020 Strategic Plan from the AHA recommends no more than 460 kcal/week from SSBs.[4] The DGAs 2020–2025 recommend no more than 10% of calories from added sugars,[7] a recommendation also mirrored by the FDA.[70] This recommendation is exceeded by over 80% of the population in the United States.

It should be noted that while the consumption of added sugar has increased over the past 40 years in the United States,[71] this increase is relatively less than the increase in the consumption of fats and flour products. The consumption of all added sugars combined actually decreased from 19% of total calories in 1972 to 17% of total calories in 2010.[72]

SSBs may be an indication of an overall poor quality diet. For this reason, it seems reasonable to recommend no more than moderate consumption of SSBs in an overall cardiac healthy diet.

7.4.9 Alcohol

Alcohol consumption has been demonstrated in various studies to have both beneficial and adverse cardiovascular outcomes.[73–75] Heavy alcohol consumption (three alcoholic drinks/day or more for men and two or more alcoholic drinks/day for women) has been associated with increased risk of cardiomyopathy and higher risk rates of atrial fibrillation.[76] Heavy alcohol consumption is also associated with a variety of other non-cardiac, adverse health consequences such as motor vehicle accidents.[77] Conversely, moderate alcohol consumption (up to two drinks/per day for men and one drink/day for women) has been shown to result in a lower incidence of CVD and diabetes (DM).[78] These effects may be the result of moderate alcohol consumption raising HDL-C, reducing systematic inflammation, or improving insulin resistance.

7.4.10 Coffee and Caffeine

Coffee is consumed throughout the world and is a leading source of caffeine. Other sources of caffeine include primarily tea, cocoa products, cola beverages, and "energy drinks."[79] Caffeine is the best characterized compound in coffee. It has been estimated that 80–90% of adults regularly consume caffeine containing beverages and food. Coffee consumption has long been suspected of being a contributing factor to the development of CVD. Accumulating data over the past few years, however, have suggested no harmful relationship, and possibly even a protective association, between moderate coffee drinking and CVD mortality.[80] Furthermore, a recent study reported that the incidence of type 2 DM was lowered in individuals who consumed four or more cups of coffee a day compared with those who drank fewer than two cups per day.[81]

7.4.11 Tea

Tea is also widely consumed throughout the world. Numerous varieties of teas are available. Most of the tea consumed in Western countries (78%) is black tea, while 20% is green tea, which is the most commonly consumed tea in Asian countries, and Oolong tea (2%), which is mainly consumed in southern China. Several studies have suggested that tea consumption may protect against the incidence and progression of CVD.[82,83] These findings may result from improvement of endothelial function by the interaction between tea components and nitric oxide (NO).[84] This interaction appears to be the result of polyphenol-like flavonoids known as catechins in the tea resulting in the increased bioavailability of NO, which plays a significant role in endothelial function and arterial dilation.

7.4.12 Eggs

Over many years, the public were cautioned to limit egg consumption due to the high cholesterol content of egg yolks and the potential association with CVD.[85] However, subsequent

research has demonstrated that in contrast to SFAs and TFAs, dietary cholesterol, in general, and cholesterol in eggs, in particular, have minimal effects on blood cholesterol.[86] Eggs are also a good source of high value protein and a variety of vitamins and minerals. DGA Guidelines 2020–2025 have, nonetheless, continued to recommend restriction of dietary cholesterol to less than 300 milligrams/day.[7]

7.4.13 Garlic

Garlic preparations have been investigated for both prevention and treatment of CVD. Studies have included raw garlic, garlic powder tablets, oil of garlic, and aged garlic extract. Long-term observational studies, however, for garlic are not available. In view of short-term trials on the effect of garlic on factors for CVD showing modest effects,[87] it appears that garlic may reduce platelet aggregation, but its effect on other CVD risk factors is controversial.

7.4.14 Chocolate

Cocoa is similar to green teas with regard to the content of polyphenols. It is important to recognize that chocolate and cocoa are not the same thing.[88] While cocoa powder is used in the production of chocolate, fat and sugar are the major components of chocolate, creating a higher caloric content. Although the polyphenols from the cocoa may have some benefit for reducing risk factors for CVD, it is more appropriate to potentially recommend cocoa rather than chocolate due to the increased calories from sugar and fat in chocolate.

7.5 NUTRITIONAL SUPPLEMENTS

7.5.1 Salt and Sodium

Virtually every heart healthy dietary plan recommends a reduction in sodium.[3–5,7] Dietary sodium may come in a variety of forms, including processed food (a major source of sodium), table salt, snacks, etc. As dietary sodium intake increases, so does blood pressure.

A number of studies have shown that reduction in salt intake lowers the risk of CVD.[3–5,7,89–91] For this reason, the AHA established the interim goal of 2,300 mg/day of sodium and less than 1,500 mg/day in individuals with hypertension, African Americans, and middle or older age Americans.[92] However, the current average intake of sodium in the United States is 3.4 g/day. Several studies have suggested that lower intakes and higher intakes both increase the risk of CVD compared with the average amount currently being consumed by Americans.[93] Thus, considerable controversies remain in the area of sodium consumption and CVD risk.

7.5.2 Vitamin D

Vitamin D consumption is associated with decreased risk of bone disease based on well-designed studies. Vitamin D may also play a role in a variety of other health issues, including lowering the risk of CVD.[94] At the current time, however, there are insufficient data to recommend increased consumption of vitamin D as a strategy for lowering the risk of heart disease.

7.5.3 Antioxidant Vitamins E and C

Some observational studies initially suggested that antioxidant vitamins E and C were associated with lower risk of CVD. However, RCTs in this area have been largely disappointing. In fact, in several studies, increased mortality was found in individuals with pre-existing late stage atherosclerosis receiving antioxidant supplements with vitamin E or C.[95]

7.6 AHA/ACC DIET AND LIFESTYLE RECOMMENDATIONS

In 2021, the AHA summarized diet and lifestyle recommendations in a Scientific Statement from the AHA Nutrition Committee.[3] These recommendations were also included in 2013 with the AHA/ACC Guideline for Lifestyle Management to Reduce Cardiovascular Risk, which also provided specific clinical guidelines.[5] Numerous studies and research have supported these goals, but the basic framework from these two documents has stood the test of time and will be utilized in this chapter as a point of departure. Since many of the recommendations of these two documents have already been discussed in the sections on Dietary Patterns and Food, specific recommendations will be handled with brief summaries.

The AHA documents started from the fundamental premise that improving diet and lifestyle represents a critical component to an overall strategy to prevent CVD. Both documents differ from previous guidelines in recommending a broader approach to not just diet, but overall lifestyle. The combination of diet and physical activity, in particular, has been emphasized. Both documents emphasize both public health and clinical applications. With this in mind, the following goals have been outlined.

7.6.1 Consume an Overall Healthy Diet

This recommendation starts from the premise that we need to move from individual nutrients to overall dietary patterns such as already discussed in this chapter. It was recognized that RCTs of the whole diet are difficult and expensive to conduct. Numerous cohort and other epidemiologic studies support the concept that dietary patterns consisting of a variety of fruits and vegetables, whole grains, fat free and low fat dairy products, legumes, poultry, lean meats, and fish (preferably oily fish) consumed at least twice a week have been associated with lower risk of CVD.[3–5,94–97] This pattern is consistent with the U.S. Healthy Eating Plan, the Mediterranean diet, and the DASH diet, which have already been discussed in this chapter.

7.6.2 Aim for a Healthy Body Weight

The AHA Guidelines utilize the framework from the IOM establishing healthy body weight as defined as a body mass index (BMI) of 18.5–24.9 kg/m^2. Overweight is defined as a BMI between 25 and 29.9 kg/m^2, and obesity is defined as a BMI of ≥30 kg/m^2. This goal also recognizes that obesity is related to multiple other risk factors for CVD, such as dyslipidemias, high blood pressure, and diabetes, and that obesity in and of itself represents a risk factor for CVD.[98–102] Issues related to obesity management are handled in detail in Chapters 41–44.

7.6.3 Aim for a Desirable Lipid Profile

Elevations in total cholesterol as well as LDL cholesterol are established risk factors for CVD. As levels of LDL cholesterol increase, so does the risk of developing CVD. The following levels of LDL have been defined: optimal (less than 100 mg/dL); near or above optimal (100–129 mg/dL); borderline/high (130–159 mg/dL); high (160–189 mg/dL); very high (190 mg/dL or more).[52, 103, 104]. Several different guidelines have been published for managing LDL. However, dietary changes such as following an overall AHA Healthy Diet Plan are foundational to nutritional approaches to managing total cholesterol and LDL cholesterol.

Triglycerides and HDL cholesterol levels are also related to CVD risk and can be affected by both diet and body weight. Triglyceride levels of >150 mg/dL are considered abnormal.[105] Elevated triglycerides and low HDL are often seen together and are components of the metabolic syndrome.[106,107] Dietary recommendations for elevated triglycerides are virtually the same as those for low HDL cholesterol and elevated LDL cholesterol.

7.6.4 Aim for a Normal Blood Pressure

Elevated blood pressure represents a significant risk factor for both CVD and stroke. Nutrition clearly plays a significant role in blood pressure control. Issues related to optimum levels of blood pressure control have become somewhat controversial. Recommendations from the Joint National Commission VII (JNC VII) defined a normal blood pressure as <120/80 mmHg, and defined a diastolic blood pressure of 80–89 mmHg and 120–139 mmHg systolic as prehypertension, with >140/90 mmHg as "hypertension."[107] These were also the recommendations made by the AHA 2020 Strategic Plan.[4]

The committee appointed to develop the JNC VIII Guidelines made somewhat different recommendations. They issued the following statement:

> There is strong evidence to support treating hypertensive individuals aged 60 or older to a BP goal of <150/90 mmHg and hypertensive persons 30–59 years of age to a diastolic goal of <90 mmHg. However, there is insufficient evidence in hypertensive persons younger than 60 years for a systolic goal or in those younger than 30 years for a diastolic goal, so the panel recommends a BP of <140/90 mmHg for those groups based on expert opinion.[108]

These guidelines also emphasize that clinical judgement should prevail when considering hypertensive therapy.

The guidelines for blood pressure were revised again in 2017 by the ACC and AHA and established a slightly lower threshold for blood pressure management. These guidelines are based on the findings from the Systolic Blood Pressure Intervention Trial (SPRINT). This trial was conducted in over 9,000 individuals with a mean age of 67.9 years and a systolic blood pressure of 130/180 mmHg and at increased risk of cardiovascular events. The researchers compared targets of SBP less than 120 mmHg with standard targets of SBP less than 140 mmHg. The SPRINT Trial showed a 30% decrease in the composite outcome of myocardial infarction, ischemic heart syndromes, stroke, and heart failure or death compared with the standard target group. These guidelines classify a normal blood pressure as systolic less than 120 mmHg and diastolic less than 80 mmHg. Elevated blood pressure was considered to be 120–129 mmHg and diastolic less than 80 mmHg. Stage 1 hypertension was considered to be 130–139 mmHg and diastolic 80–89 mmHg. Phase 2 hypertension is greater than or equal to 140 mmHg and diastolic greater than or equal to 90 mmHg. In all of these categories, the importance of positive lifestyle habits such as regular exercise and sound nutrition, as well as weight management, was emphasized. See Table 7.3.

It should be emphasized that both of these sets of recommendations support nutritional intervention as a key component of the overall prevention and treatment of high blood pressure. A nutritional pattern consistent with the DASH diet has been clearly demonstrated to help control blood pressure.[18] Unfortunately, a distinct minority of individuals who have high blood pressure actually follow the DASH diet. Other dietary modifications that have been shown to lower high blood pressure include reducing salt intake, establishing a caloric deficit to induce weight loss in overweight or obese individuals, moderate alcohol consumption

TABLE 7.3
Categories of BP in Adults[a]

BP Category	SBP (mmHg)		DBP (mmHg)
Normal	<120	and	<80
Elevated	120–129	and	<80
Hypertension			
Stage 1	130–139	or	80–89
Stage 2	≥	or	≥90

[a] Individuals with SBP and DBP in two categories should be designated to the higher BP category.
BP indicates blood pressure (based on an average of ≥2 careful readings obtained on ≥ occasions), DBP diastolic blood pressure, and SBP systolic blood pressure.

(among those who drink alcohol), and increased potassium intake. Physical activity is also an important recommendation and acts synergistically with diet to further lower blood pressure.

7.6.5 Be Physically Active

All of the major guidelines for nutritional intervention to reduce the risk of CVD also incorporate the recommendation to increase physical activity.[2,3,5]. Increased levels of moderate or vigorous physical activity have repeatedly been shown to lower the risk of CVD. Guidelines such as the AHA/ACC Lifestyle Recommendations and the DGA 2020–2025 as well as the 2006 Nutrition Guidelines from AHA and the Physical Activity Guidelines for Americans 2018[11] all recommend increased physical activity in addition to heart healthy nutritional plans. The best single source of information related to physical activity and reduced CVD and other chronic diseases may be found in the 2018 U.S. Department of Health and Human Services "Physical Activity Guidelines for Americans."[11] This document was designed to complement the Dietary Guidelines for Americans. More physical activity is associated not only with lowering the risk of CVD but also with specific CVD risk factors, including blood pressure, lipid profiles, and blood sugar.

7.6.6 Avoid Use of and Exposure to Tobacco Products

Overwhelming evidence exists from multiple sources that cigarette smoking and the use of tobacco products or exposure to cigarette smoke increase the risks for both CVD and stroke.[110] This evidence has been summarized in multiple other locations, including the AHA 2020 Strategic Plan[3] as well as the AHA/ACC Diet and Lifestyle Clinical Recommendations and Goals. Unfortunately, over 15.5% of U.S. adults still smoke cigarettes, and the rate of decline of cigarette smoking has significantly slowed over the past 20 years.[111] The risks of cigarette smoking for women are currently equivalent to those for men. Substantial benefits, however, in the reduction of risk of CVD accrue in the individual who stops smoking cigarettes. These benefits accrue over a very brief period of time.

7.7 IMPLEMENTING HEART HEALTHY NUTRITION PLANS

A recent emphasis at the AHA and other health oriented associations has been on implementing strategies to help individuals consume a more heart healthy diet. The AHA issued a Scientific Statement in 2009 entitled "Implementing American Heart Association Pediatric and Adult Nutrition Guidelines."[17] While this statement emphasized the complexity of factors that impact on nutritional choices, it also offered a multilevel framework to impact on these factors. This framework started with individual factors, which were then placed more broadly into family factors, environmental factors, the micro environmental, and finally, the macro environmental factors. Each of these interacting domains contains multiple influencers. Specific results related to these interactive factors are beyond the scope of this chapter. Readers are referred to this Scientific Statement for more detail.[17]

In order to positively impact on multiple factors that influence heart healthy nutrition, proven models of behavioral medicine will be required to help individuals adopt positive behavior, in general, and in the area of nutrition, in particular. Models of behavior change are beyond the scope of this chapter, but are found in Chapters 21–24 in this textbook.

7.8 CONCLUSIONS/SUMMARY

Overwhelming evidence exists to support the concept that nutritional practices strongly interact with the likelihood of developing CVD. Recent guidelines related to nutritional practices have placed them in the overall context of positive lifestyle habits and practices. Lifestyle medicine offers a promising framework for impacting on both nutritional practices and other lifestyle factors that impact on the risk of developing CVD. Evidence based guidelines from the Dietary Guidelines for Americans 2015–2020 and 2020–2025, the American College of Cardiology, and the American Heart Association Nutrition Guidelines 2021, as well as the AHA 2020 Strategic Plan, all emphasize that dietary patterns that include fruits and vegetables, whole grains, seafood, legumes and nuts, and non-fat dairy products and alcohol (among adults), and are lower in red meats and processed meats and low in SSBs and refined grains, all support reduced risk of CVD. While these patterns may be achieved in many different ways, it is important that they be tailored to individuals' cultural, biological, and medical needs.

Implementation of the guidelines from these scientific bodies remains the key challenge, which will require the recognition of multiple factors to interact with both individual and population-wide nutritional choices. A detailed and sophisticated understanding of not only the emerging science in nutrition and CVD, but also behavioral medicine, will be essential to accomplish the goal of helping individuals reduce their risk of heart disease through nutritional and other lifestyle practices.

CLINICAL APPLICATIONS

- Plant based diets from the American Heart Association, the American College of Cardiology, and the Dietary Guidelines for Americans are consistent with each other, so any of these can be followed to lower the risk of heart disease.
- The DASH diet has been shown to effectively lower blood pressure in individuals with hypertension.

- Nutrition plays a key role in lowering the risk of cardiovascular disease and should be placed in the context of an overall healthy approach to lowering the risk of CVD, including increased physical activity, weight management, and avoidance of tobacco products.
- Clinicians should routinely recommend that individuals follow diets that are high in fruits and vegetables, whole grains, seafood (particularly oily fish), legumes and nuts, and non-fat daily products, and lower in red meats, processed meats, SSBs, and refined grains to support reduction in the risk of CVD.

8 Optimal Nutrition Guidance for Older Adults

Alice H. Lichtenstein

KEY POINTS

- Diet quality is directly related to optimal physical and cognitive function in older adults.
- Nutrient requirements either stay the same or increase with advancing years, whereas energy requirements decline, increasing the importance of making nutrient-dense food choices.
- Changes in sensory perception and the onset of chronic diseases may necessitate added attention to diet composition in older adults.
- Alterations in social environments and living situations make it important to monitor the ability and desire to obtain, prepare, and consume a high-quality diet.

8.1 INTRODUCTION

In 2015, approximately 46 million individuals living in the U.S. were over the age of 65 years. This number is expected to double to approximately 98 million by the year 2060, representing about 24% of the total population (Figure 8.1). Accompanying this increase, the older population is expected to become more racially and ethnically diverse. They are also expected to work longer and attain a higher level of education than prior generations. Current trends suggest a higher proportion of older adults than previously will be dealing with the challenges of obesity.

Accompanying this shift in the demographic makeup of the U.S. population is an ever-increasing need for specific nutrition guidance to achieve and maintain optimal physical and cognitive function with advancing years. Evidence suggests that within a population, older adults who score in the higher categories for diet quality[1–4] and physical activity measures[5,6] have the best survival rates.

8.2 CURRENT RECOMMENDATIONS

The revamp of the recommended dietary allowances (RDA) by the Food and Nutrition Board of the Institute of Medicine starting in the early 1990s brought about more precise recommendations for individuals above the age of 50 years.[7–14] The current recommendations, termed dietary reference intakes (DRI), include guidance for adults in categories of 31–50 years, 51–70 years, and greater than 70 years.[15] No further distinction is made for individuals aged 70 years and above. This lack of more precise guidance for those over 70 years is likely a consequence of limited information from the older-aged groups.[15] DRI values for most nutrients, including vitamin A, vitamin C, vitamin E, vitamin K, thiamin, riboflavin, niacin, folate, vitamin B_{12}, pantothenic acid, biotin, choline, chromium, copper, fluoride, iron, magnesium, manganese, molybdenum, phosphorus, selenium, and zinc, do not differ between adults above and below the age of 50 years. The nutrient recommendations for three nutrients, vitamin D, calcium, and vitamin B_6, are higher for older adults. The DRIs for vitamin D increased from 600 IU/day for females and males between 51 and 70 years of age to 800 IU/day for both females and males above 70 years of age.[16] The DRIs for calcium increased from 1200 and 1000 mg/day for females and males, respectively, between 51 and 70 years of age to 1200 mg/day for both females and males above 70 years of age.[16] The DRIs for vitamin B_6 increased from 1.3 mg/day and 1.4 mg/day for females and males, respectively, between 51 and 70 years of age to 1.5 mg/day and 1.7 mg/day, respectively, for both females and males above the age of 70 years.[9] Emerging evidence suggests future revisions in the DRIs for individuals over the age of 70 years may be necessary,[17] but any recommendations must await a thorough review of the new literature.

Although the DRIs for most nutrients do not increase with advancing age, with the exceptions of vitamin D, calcium, and vitamin B_6, it can become increasingly difficult to achieve the recommended intakes as individuals advance in years. In general, with increasing years, total energy needs decrease to compensate for diminished requirements associated with lower levels of physical activity, a higher proportion of fat mass relative to lean muscle mass, and a lower basal metabolic rate.[18,19] Similar or slightly higher nutrient needs must be met within the context of reduced food intake and commensurate with lower energy requirements. This can be accomplished by intentionally selecting nutrient-dense foods (high nutrient content per calorie). An icon summarizing salient points related to dietary modification for older adults has been developed to provide specific guidance, termed *MyPlate for Older Adults* (Figure 8.2). Differences from the *MyPlate Food Guide* for the general population include examples that emphasize nutrient-dense foods within each category, illustrations of foods that are particularly convenient for older adults (e.g., bags

DOI: 10.1201/9781003227793-10

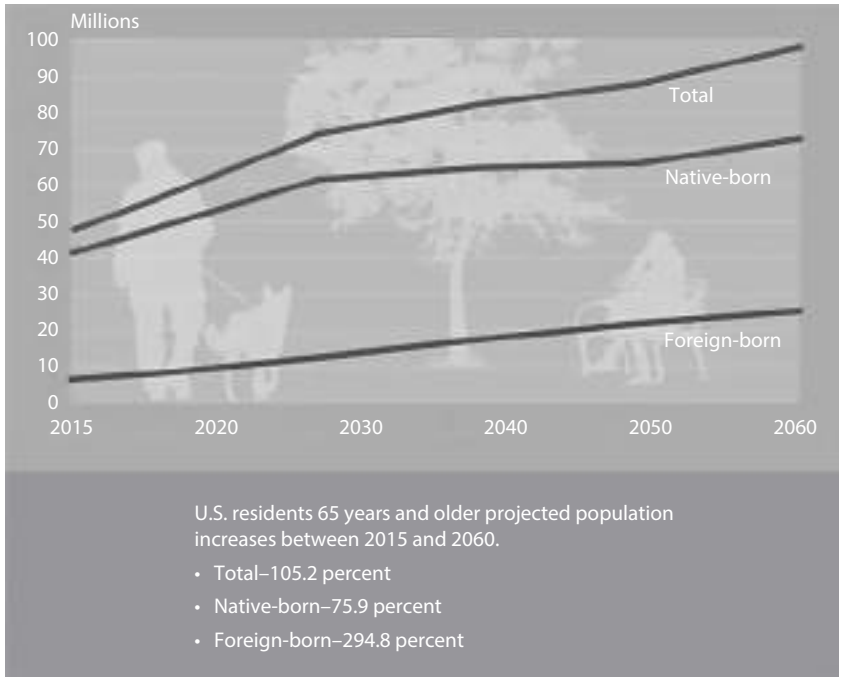

FIGURE 8.1 Projected number of U.S. residents 65 years and older.

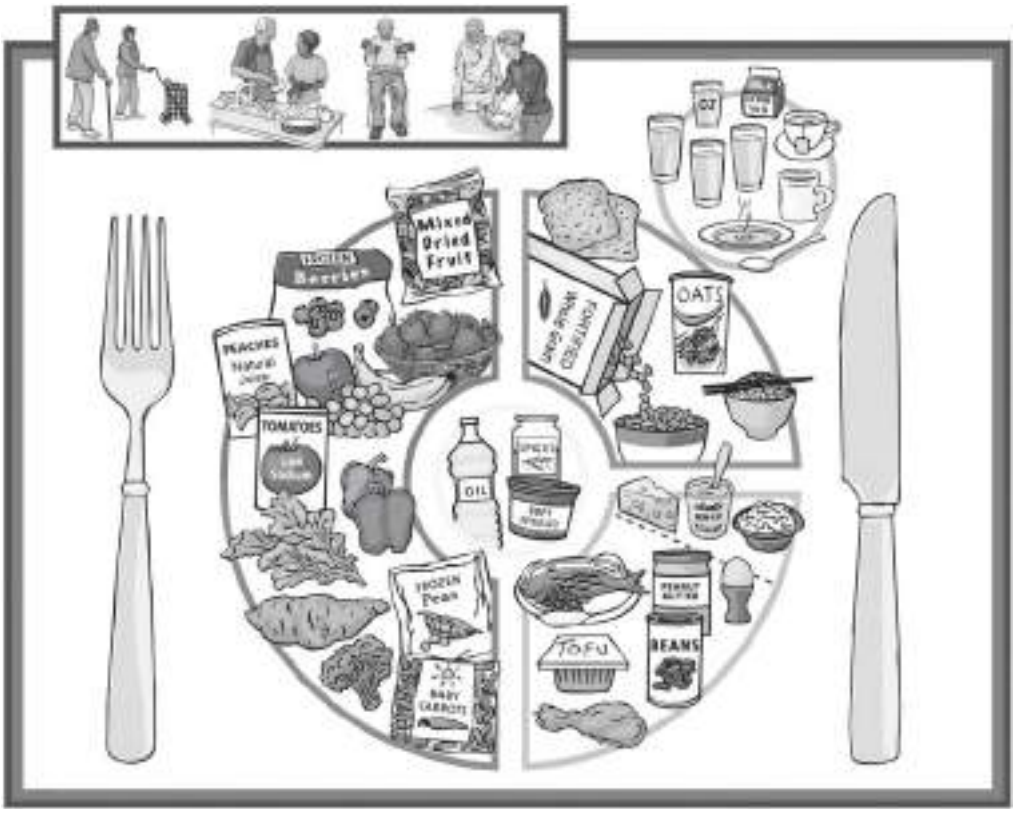

FIGURE 8.2 *MyPlate for Older Adults.*

of frozen vegetables), shift of the dairy group into the protein segment to provide a broader range of protein-rich food options, greater emphasis on fluid by depicting a variety of choices in a separate segment, incorporation of suggestions for regular physical activity as an integral part of the icon, addition of a segment at the center of the plate to emphasize the importance of including healthy oils in the diet and using seasonings (spices and herbs) as an alternative to salt,

and knife and fork on the side of the plate to encourage a focus on enjoying food when eating rather than focusing attention on a hand-held device.[20]

8.3 NUTRIENTS OF CONCERN

Adequacy of some nutrients can be a concern for all adults, particularly older adults. "Nutrients of public health concern" are divided into two categories—those of concern due to overconsumption and those of concern due to underconsumption. The criteria used by the 2020 Dietary Guidelines Advisory Committee to identify nutrients of public health concern include that population intakes are below or above the estimated average requirement or adequate intake, and there is corroborating evidence of adverse effects due to low or high intakes based on biochemical markers of nutrient status. Current nutrients of public health concern for underconsumption are vitamin D, calcium, potassium, fiber, and iron (not a concern for older adults); for overconsumption, nutrients of concern are sodium and saturated fat.

8.3.1 Vitamin D

Adequate vitamin D intake is of concern for older adults.[21] There are a number of factors that may compromise vitamin D status with advancing years. These include decreased efficiency of skin to synthesize vitamin D after exposure to sunlight and tendency to spend less time outdoors to accumulate sun exposure.[22] Limited sun exposure due to latitude or concern about sun exposure because of skin cancer risk can minimize endogenous vitamin D synthesis.[23,24] Additionally, overweight and obese individuals tend to have lower circulating vitamin D concentrations, potentially due to sequestration in the adipose tissue. As rates of overweight and obesity increase in the older population,[18,25] this factor may also contribute to compromised vitamin D status.[26] Up until recently, fluid milk was the only reliable food source of vitamin D in the U.S.[21] Recent changes to the vitamin D fortification regulation have resulted in an increased availability of vitamin D and calcium–fortified juices and juice drinks, and vitamin D-fortified dairy products other than fluid milk.[27,28]

8.3.2 Calcium

The vast majority of calcium in the body resides in bone and teeth. Much smaller but no less important amounts of calcium are critical for the regulation of cell signaling, blood clotting, muscle contraction, and nerve function. The richest naturally occurring and bioavailable source of calcium is dairy products. A wide range of low-fat and nonfat dairy products are currently available. There are two factors to take into consideration when recommending dairy products to older adults. The first is lactose intolerance. With increasing age, the rate of lactose intolerance increases.[29–31] Fortunately, a wide range of lactose-free and low-lactose dairy products are now available, as well as enzyme preparations (lactase) that can be taken when consuming foods containing lactose to decrease the symptoms of lactose intolerance. Although the prevalence of lactose intolerance increases with age, intolerance symptoms among lactose maldigesters tend to decrease with age, suggesting that as people get older, they may have more, rather than less, flexibility in their choice of calcium-rich dairy foods.[30] The second consideration with regard to dairy products is saturated fat. Dairy products can be a major source of saturated fat. Saturated fat intake is associated with an increased risk of developing cardiovascular disease.[32,33] Older adults should be encouraged to take advantage of reduced-fat versions of dairy foods and incorporate sources of unsaturated fat, such as soybean and canola oils, as alternative fats in their diets. Additional sources of dietary calcium are fortified drinks such as calcium-fortified orange juice and plant-based milks.

8.3.3 Potassium

Potassium functions as a critical electrolyte in the body, along with sodium, chloride, calcium, and magnesium. It is also involved with proper heart function, and skeletal and smooth muscle contraction. Rich dietary sources of potassium include fish and plant foods including legumes, vegetables, and fruits. Higher fruit and vegetable intakes have been associated with a number of positive health outcomes, including bone health, blood pressure, metabolic syndrome, stroke, and cardiovascular disease.[34–43]

8.3.4 Fiber

A major function of dietary fiber is its laxative effect in the gut. Whole vegetables and fruits are a good source of dietary fiber, as are whole grains and whole grain products. For this reason, older adults should be encouraged to consume fruits and vegetables in their natural state rather than the juice form. They should also be encouraged to choose whole grain products rather than refined and processed grain products such as those commonly available in large food markets. In general, fiber supplements are not routinely recommended because excessive fiber can decrease the bioavailability of calcium, iron, zinc, copper, and magnesium.[44]

8.3.5 Sodium

Under normal circumstances, small amounts of dietary sodium, along with potassium, help maintain normal blood pressure as well as muscle and nerve function. However, high amounts of dietary sodium are associated with hypertension.[34] Major sources of dietary sodium come from commercially prepared foods, with only a small percentage coming from salt added at the table.[39] There has been a dramatic increase in the availability of reduced-sodium products. Everyone, particularly older adults, should be encouraged to take notice and choose those products.

8.3.6 Saturated Fat

Higher intakes of saturated fat relative to unsaturated fat, both monounsaturated and polyunsaturated, are associated with higher risk of developing cardiovascular disease. Major sources of dietary saturated fat are fats of animal origin and tropical oils. Animal fats include meat and as indicated earlier, dairy fat. Tropical oils include palm, palm kernel, and coconut. Intake can be minimized by choosing lean cuts of meat, as well as limiting both frequency and portion size. Low- and fat-free dairy products are readily available. Ingredient labels can be used to determine whether commercially prepared foods contain tropical oils.

8.3.7 Added Sugar

High levels of added sugar intake have been associated with increased risk of developing obesity, heart disease, and type 2 diabetes, among other disorders.[39,45] Approximately 47% of added sugar in the U.S. diet comes from sugar-sweetened beverages, 31% comes from snacks and sweets, and the balance comes from a combination of other food categories, both obvious and less obvious.[39] The introduction of added sugars as a mandatory requirement of the revised Nutrition Facts labels has made it easier for individuals to compare items within categories so as to choose those with less added sugar, and has spawned the development of reduced-sugar options.

8.4 SPECIAL DIETARY CONSIDERATIONS FOR OLDER ADULTS

The area of maintaining optimal nutrient status in older adults must be considered in terms of physiological factors and psychological factors. Special attention to both of these factors is critical for ensuring optimal health outcomes.

8.4.1 Organ Systems

The way the body handles nutrients can change with advancing age. These changes are mostly due to changes in the functioning of organ systems, which can ultimately impact health outcomes (Table 8.1). Interestingly, few adverse nutritional consequences resulting from advancing years have been noted that are independent of ancillary biological changes. These exceptions include vitamin B_{12}, vitamin D, and calcium. With increasing years, many individuals experience a decline in gastric hydrochloric acid secretion.[46] The resulting hypochlorhydria causes a decline in the bioavailability of vitamin B_{12}. As previously noted, due to the diminished capacity to synthesize endogenous vitamin D, older adults may be at a compromised vitamin D status, and as a result, for calcium. Impairments or decreases in the function of the heart, blood vessels, and kidneys can stress the normal demands on everyday life. Changes in body composition (decreased lean muscle mass and increased fat mass) result in diminished basal metabolic rates, energy needs, and capacity for physical activity.[47] Increased use of prescription and nonprescription medications, chronic drug therapy, and decreased capacity of the liver to metabolize drugs can compromise nutrient utilization. These factors should be evaluated on a regular basis by the health care provider.

TABLE 8.1
Potential Biologic Changes Contributing to Altered Nutrient Status in Older Adults

System	Change
Digestive system	↓ Hydrochloric acid secretion
	↓ Digestive juice secretion (pancreas and small intestine)
	↓ Absorptive capacity (malabsorption)
	↓ Muscles tone large intestine (↓ gastrointestinal motility)
	↑ Chronic blood loss due to ulcers and hemorrhoids
Liver	↓ Hepatic and biliary function
	↓ Rate detoxification
Heart	↓ Cardiac output
	↓ Strength and flexibility of blood vessels
Kidneys	↓ Blood flow
	↓ Glomerular filtration
Senses	↓ Acuity vision and hearing
	↓ Taste (loss taste buds, mainly salt and sweet)
	↓ Smell
Skin	↓ Synthesis vitamin D
Body composition	↓ Lean muscle mass
	↑ Fat mass
	↓ Mobility
	↓ Dexterity
Immune system	↓ T cell-mediated function
	↑ Susceptibility to infection and malignancy
Pharmacokinetics	↑ Prescription and nonprescription drug use
	↑ Chronic drug therapy
	↓ Capacity to metabolize drugs
Mouth	↓ Salivary secretion
	↑ Altered bite pattern due to tooth loss

8.4.2 Taste and Smell

Retaining the desire to eat a variety of foods is integral to ensuring optimal nutrition for older adults. This issue is of particular concern because diminished taste and smelling acuity associated with aging can lead to poor appetite. This change includes loss of taste bud acuity, primarily with respect to salty and sweet food items, and a resulting greater sensitivity to acid and bitter food items.[48] Other changes frequently observed in older adults include a diminished sense of smell. Older adults with poor odor perception have lower nutrient intakes than those with good odor perception.[49–51]

8.4.3 Vision, Dexterity, and Mobility

Diminished vision, dexterity, and mobility can make food acquisition and preparation difficult, which can severely alter the variety and quality of foods consumed (Table 8.2).

TABLE 8.2
Activity of Daily Life Factors That May Contribute to Compromised Food Intake in Older Adults

Factor	Change
Oral cavity	↑ Peritoneal disease
↑ Ill-fitting dentures	
↓ Salivary gland secretions	Mobility
↓ Physical activity	
↓ Respiratory capacity	↓ Lean muscle mass (strength, physical disability)
↑ Physical isolation	Senses
↓ Acuity (taste, smell, sight)	Dexterity
↑ Arthritic involvement finger and hand joints	
↑ Tremor	↓ Manual dexterity
Energy needs	↓ Energy requirements
↓ Caloric intake	
	↓ Volume

TABLE 8.3
Psychosocial Factors Contributing to Compromised Food Intake in Older Adults

Factor	Change
Companionship	↑ Loss of spouse
↑ Social isolation	
↑ Loss of companions	↓ Social interaction secondary to ↓ mobility
Mental state	↑ Depression
↑ Mental deterioration (dementia)	
↑ Alcoholism	↑ Loneliness
↑ Chronic disease	Economic
↑ Fixed income (poverty)	
↓ Choice and availability	↓ Quantity needs
↓ Variety	Nutrition knowledge
↑ Susceptibility to food fads	↑ Susceptibility to nutrient supplement claims
Housing	↑ Change in status (loss of home)
↓ Independence	

Difficulty in opening jars, cans, or packaged foods due to arthritis or diminished strength can lead to decreased variety and ability to consume preferred foods. Small accommodations in an individual's environment, such as ergonomically designed kitchen aids (e.g., can openers and scissors), kitchen reorganization (e.g., eliminating clutter and moving frequently used items to most accessible places), and shifts to the use of partially prepared foods, can minimize a decline in diet quality. For example, resealable bags of frozen vegetables and fruits are particularly good choices for older adults because they allow easy apportioning of single or double servings, minimize pre-preparation (which can be difficult or even painful with advanced years), eliminate waste due to spoilage, reduce the need for frequent trips to the market, and provide variety during long periods of inclement weather. Likewise, purchasing boneless chicken breasts can decrease preparation and cooking times, and is adaptable to the preparation of individual small portions. Older adults may not automatically take advantage of newer forms of common food items (e.g., prewashed greens, precut fruit, shredded cheese) and require some regular guidance in this area.

8.4.4 Social Factors

In addition to declines in physical capacity associated with the aging process, there are also changes in the social environment of older adults that can have an impact on nutritional status (Table 8.3). With increasing years, the loss of a spouse or other family members with whom an individual shared and prepared meals is common. This can lead to social isolation, especially during mealtime, and diminished desire to prepare well-balanced and varied meals. Due to deterioration in mental or economic status, older adults are frequently faced with having to adapt to a new living environment. This can result in dramatic changes in mealtimes, food preparation, and foods available. The onset of chronic disease can further limit food choices and make older adults susceptible to the lures of food fads or dietary supplements promising a fountain of youth. Succumbing to these claims can drain scarce resources from food purchases and result in overconsumption of individual nutrients. The latter can interfere with prescription drug actions or utilization of essential nutrients. Depression frequently accompanies the aging process in individuals without adequate support to make the necessary adaptations that come with advancing age. Older adults are also at increased risk of alcohol abuse. All of these factors may contribute to poor food consumption patterns.[52]

8.5 PHYSIOLOGICAL CHANGES OF CONCERN IN OLDER ADULTS

Nutrient-related chronic diseases particularly prevalent in middle and later years include cardiovascular disease, cancer, type 2 diabetes, hypertension, osteoporosis, disorders of dentition and associated senses, and declines in immune function. In some cases, the goals of food and nutrient recommendations for older adults are aimed at delaying the onset of chronic disease, while in other cases they are intended to treat or accommodate the disorder.

8.5.1 Dentition and Associated Senses

Salivary secretions decrease with increasing age. Changes in bite pattern from partial or complete extraction/loss of teeth are common. Poorly fitted dentures can make eating painful and unpleasant. The prevalence of root canals is

higher in older than younger adults.[53,54] Increased incidence of tooth disease in older adults has been related, in part, to high levels of sugar consumption.[55] Any one or a combination of these factors can restrict the type and variety of foods consumed. For example, chewing and swallowing fibrous foods may be difficult due to poor dentition, resulting in a shift toward highly processed foods or juices that are low in fiber content.[56] It is critical when evaluating dietary intakes of older adults to consider possible concerns regarding food textures and preparation methods and to assess dentition.

8.5.2 Cardiovascular Disease

The risk of developing cardiovascular disease increases with age, especially after menopause in females.[57] Higher saturated fat coupled with lower polyunsaturated fat intake has consistently been associated with higher rates of cardiovascular disease.[58–60] The American Heart Association/American College of Cardiology[33] and the *2020–2025 Dietary Guidelines for Americans*[39] recommend dietary patterns that are rich in vegetables and fruits, whole grains, legumes (beans), fat-free and low-fat dairy products, fish, and lean meat. No specific recommendations for dietary change are made for adults as they age. The response to these recommendations in terms of plasma lipids appears consistent for both genders and all adult age groups.[32]

8.5.3 Osteoporosis

Age-related or type II osteoporosis (bone loss) is positively associated with the aging process. Osteoporosis is estimated to affect 200 million women worldwide—approximately one-tenth of women aged 60, one-fifth of women aged 70, two-fifths of women aged 80, and two-thirds of women aged 90.[61] In men, it is estimated that the residual lifetime risk of experiencing an osteoporotic fracture over the age of 50 is 27%.[61] Age-associated bone loss is attributed to diminished estrogen production, decreased calcium absorption from the gastrointestinal tract, decreased calcium resorption by the kidney, decreased rates of physical activity, compromised vitamin D status, and decreased calcitriol production secondary to hyperparathyroidism.[61,62] In older adults, calcium balance is favorably affected by vitamin D intake and negatively affected by high sodium, protein, alcohol, and caffeine intakes.[62] Supplemental calcium and vitamin D in postmenopausal women living in northern latitudes (42°N) may minimize bone loss.[63] Because serum osteocalcin, calcidiol, and vitamin D fluctuate seasonally due to sun exposure, vitamin D intake is particularly important during the period of winter and spring in this group. These data strongly support routinely screening older adults for vitamin D status.

8.5.4 Glucose Intolerance/Type 2 Diabetes

The incidences of glucose intolerance and type 2 diabetes mellitus increase with age.[64,65] The increased incidence has been strongly associated with weight gain in later years. Lifestyle interventions have been demonstrated to be efficacious in preventing or delaying the onset of type 2 diabetes mellitus.[66–68] These include regular daily physical activity, achieving and maintaining a healthy body weight, and dietary modification consistent with that advocated for the prevention and treatment of cardiovascular disease.

8.5.5 Hypertension

The incidence of hypertension increases with age.[57] This increase is associated with changes in the vasculature and kidneys, and is exacerbated by excess weight gain. A number of clinical trials have demonstrated clear benefits of dietary modification to treat hypertension in older adults. The DASH (Dietary Approaches to Stop Hypertension) dietary pattern, rich in vegetables, fruits, and fat-free and low-fat dairy products, reduces blood pressure in individuals with a wide range of characteristics. Further coupling this dietary pattern with sodium restriction has been shown to further reduce blood pressure.[43]

8.5.6 Immune Function

The most commonly associated age-related change in the immune response is cell-mediated function.[69,70] Limited data suggest vitamin E supplementation may be beneficial in decreasing the incidence of respiratory infections in older adults living in residential settings.[71]

8.5.7 Cancer

The incidence of cancer shows tremendous variability on the basis of worldwide distribution, type, and site in the body. The incidence of all types of cancer increases with age. Support for a diet/cancer incidence link comes from data suggesting associations between markedly divergent food consumption patterns and incidence rates of cancer among different population groups.[72] Some data have been reported for associations involving the following dietary components: alcohol intake (laryngeal), calcium and vitamin D intake (stomach, colon, breast), fat intake (breast, colon, prostate), fiber intake (breast), and antioxidant vitamin and/or orange and dark green vegetable intake—vitamin A and beta-carotene, vitamin C, vitamin E, and trace elements (wide range of sites).[72–76] Results from randomized controlled supplementation trials are limited and not encouraging.[77] At this time, the general dietary guidance to reduce cancer risk is consistent with the dietary guidance to prevent the onset of chronic diseases of concern in the twenty-first century.

8.6 CONCLUSIONS

The aim of dietary guidance specifically targeted for older adults is to maintain optimal health and forestall the onset of chronic disorders. The actual dietary recommendations, for the most part, are consistent throughout the adult life cycle.

Evidence suggests that there is a direct relationship between the nutrient quality of the diet and survival rates. Due to decreased levels of physical activity, decreased metabolic rates, and increased proportions of fat to lean muscle mass, energy requirements decline with advancing years, yet nutrient requirements remain unchanged or increase. This situation requires a greater emphasis on choosing nutrient-dense foods within each food category. Special attention needs to be given to adapting living environments with advancing years to retain the ability to acquire and prepare food. Changes in social situations that could impact on food intake should be monitored on a regular basis. Evidence suggests that diet and lifestyle interventions can forestall the onset of cardiovascular disease, osteoporosis, diabetes, hypertension, immune function, and possibly some types of cancer. There are no data to suggest a person is too old to benefit from improvements in diet quality. The definitions for old age and expectations for the period of time individuals can remain active, productive, and live independently are expanding. Efforts toward improving diet quality and levels of physical activity with advancing years should keep up with this trend.

CLINICAL APPLICATIONS

- The major goal of dietary guidance specifically targeted for older adults is to maintain optimal health and forestall the onset of chronic disorders.
- Diet quality is directly related to physical and cognitive functioning in later years. The adoption of healthy lifestyle practices should be encouraged.
- Nutrient requirements either stay the same or increase with advancing years, whereas energy requirements decrease. Attention needs to be given to ensuring adequate nutrient intake and avoiding excess energy intake.
- Advancing years are often accompanied by declines in sensory perception such as taste, smell, vision and dexterity, and mobility. Such alterations may necessitate added attention to dietary behaviors in older adults.
- Special attention should be given to adapting living environments with advancing years to retain the ability to acquire and prepare food.

9 Effects of an Active Lifestyle on Water Balance and Water Requirements

Gethin H. Evans, Lewis J. James, Ronald J. Maughan, and Susan M. Shirreffs

KEY POINTS

- Water is essential to life, with body water content normally tightly regulated and remaining relatively constant from day to day.
- The main factors influencing total body water content are body mass and body fatness (lean tissue has a much higher water content than adipose tissue).
- Large excursions from euhydration are associated with loss of functional capacity and if sufficiently large, are potentially fatal.
- Water losses are increased by increasing ambient temperature and humidity and by increasing levels of physical activity.
- A variety of foods and beverages normally contribute to total daily water intake.

9.1 INTRODUCTION

The ability to regulate body water content and the osmolality of tissues within a relatively narrow range is one of the defining characteristics of all animal life. Small excursions in these parameters are normal, but large changes are incompatible with survival. This close regulation must be achieved in the face of a continuous, but variable, loss of water and salts from the body. Humans can survive for several weeks without food, but deprivation of water for even a few days can be fatal, with survival time dictated largely by the rate of water loss. Water comprises about 50–70% of body mass, making it the most abundant component in the human body, except in the very obese. This gives about 40–42 L of water in the average 70-kg male: because of their generally higher relative body fat content, females normally have a lower body water content than males of the same mass. A change—whether an increase or decrease—of more than about 10% of this value carries a number of risks, but regulatory and behavioral mechanisms normally intervene long before this point is reached. Approximately two-thirds of this water is found in intracellular compartments, with the remaining third in extracellular compartments. Euhydration is defined as body water levels being within about 0.2% of normal in temperate conditions and within about 0.5% when in the heat or during exercise.[1] Individuals are considered to be hypohydrated (reduced body water) or hyperhydrated (increased body water) outwith these limits. Both of these conditions, if sufficiently severe, can impair all aspects of physiological function and may prove fatal in extreme cases.

Physical activity poses a number of challenges to water and salt homeostasis, including increased rates of water and salt (particularly sodium and chloride) loss. These effects are amplified as the activity level, ambient temperature, and environmental humidity increase. Hard exercise, even if the duration is too short to induce substantial sweat losses, also causes a redistribution of water between body water compartments because of the large changes in osmolality within the active muscles.

Those who are physically active—whether on a recreational or an occupational basis—should be aware of their body's need for water and salt, and should not either ignore or consciously over-ride the physiological signals.

9.2 WATER BALANCE

Water balance occurs when water intake matches water losses, but water intake is episodic, whereas water losses are continuous, so water balance fluctuates throughout the course of a day. Over a 24-hour period, water balance is generally maintained without conscious attention to intake. Avenues of water intake include fluid consumed as drink, in the water content of ingested food, and a small amount generated by oxidative metabolism (Table 9.1). For sedentary individuals in temperate environments, daily water turnover is typically about 2–3 L, with the main avenue of loss via urine, with additional losses via respiration, transcutaneous loss, sweating, and fecal loss. Some individuals exercising in hot conditions may lose this amount in an hour, as sweating is induced to limit the rise of core temperature that occurs in these situations, particularly in hot/humid conditions.

Urine production is regulated by a number of hormones in response to changes in intravascular volume and osmolality: these include arginine vasopressin (AVP), aldosterone, and atrial natriuretic peptide (ANP). Secretion of AVP from the posterior pituitary is induced by an increase in plasma osmolality and a decrease in blood volume, increasing water reabsorption in the renal collecting ducts and the production of a smaller volume of more concentrated urine. A 1-mosm/kg increase in plasma osmolality results in a 0.41-pmol/L increase in plasma AVP concentration,[2]

DOI: 10.1201/9781003227793-11

TABLE 9.1
Estimates of Water Intake and Loss by Various Routes in an Average Sedentary Male Living in a Temperate Climate

Water Intake (mL)	Water Output (mL)
Metabolism (400)	Urine (1400)
Drinking (1500)	Respiration (320)
Food Ingestion (1000)	Skin Loss (530)
	Sweat Loss (650)
	Water Loss in Feces (100)
Total (3000)	Total (3000)

Data are collated from a variety of sources and can vary greatly from day to day within the same individual as well as between individuals.

and a 3-mosm/kg increase in plasma osmolality results in a 250-mosm/kg increase in urine osmolality.[3] A change in blood volume of 7–10% is required for similar magnitudes of change in urine osmolality, making plasma osmolality the main determinant of AVP release.[2]. The renin-angiotensin aldosterone system is activated in response to decreases in blood volume, with aldosterone acting on the collecting ducts of the kidney to increase sodium reabsorption, which in turn, leads to water reabsorption and the production of a smaller volume of more concentrated urine. ANP is secreted from the right atrium in response to increases in blood pressure and leads to an increase in urine volume.

Thirst and habit are major drivers of fluid intake. Thirst is triggered by a complex interaction between physiological, psychological, and behavioral factors.[4] Changes in plasma osmolality and blood volume are thought to play important roles in the thirst response; thus, the same factors that regulate water loss are also involved in water intake. Animal models have suggested that substances such as angiotensin 2, bradykinin, and serotonin may also be involved in thirst response. Genetic factors may also account for some individual variation in thirst response, although the picture is not entirely clear.[5,6] Generally, thirst is considered to be a poor indicator of short-term deviations in body water, given observations that unlimited access to drinks after periods of fluid restriction tends not to fully restore water losses[7] and rapid fluid ingestion in these circumstances appears to alleviate the perception of thirst.[8] The thirst response is considered, however, to be sufficient to restore body water levels over longer time periods.

The European Food Safety Authority (EFSA) reports that total (i.e. water from food and fluid) adequate daily water intake is 2.0 liters for an average adult female and 2.5 liters for an average adult male.[9] Different adequate total water intakes are reported by the Institute of Medicine in the United States, with values reported as 2.7 liters and 3.7 liters for adult females and males, respectively.[10] The values reported by these bodies are an average (or median) volume consumed by healthy adults and are, therefore, classed as adequate intakes rather than recommended intakes. Considerable variation in the volumes of water consumed by healthy adults is observed. For physically active individuals who will lose greater volumes of water via sweating, which is exacerbated in hot environments, achieving the adequate intakes reported is not a guarantee that water intake is sufficient for that individual. For example, many sports/physical activities typically produce a sweat rate of 0.5–1.5 L/hour, but in some well-trained or very large athletes, sweat rates may reach and even exceed 3–4 L/hour. Therefore, there are settings where athletes or physically active individuals may lose more water in sweat than is recommended in these daily adequate intake values for water, meaning that more must be consumed to meet daily requirements in some athletes. It is likely, however, that water intake throughout the day will match water losses due to a combination of habitual fluid intake and the individual's thirst response driving further fluid intake.

9.3 SWEATING, WATER BALANCE, AND WATER TURNOVER

Metabolic heat production at rest is approximately 60 watts, but metabolic demand increases in a linear fashion and can reach 1 kilowatt during moderately hard exercise such as marathon running. This metabolic heat must be dissipated to avoid large increases in core temperature, and this is achieved largely by an increase in sweat rate.

There are many published reports of hydration status, sweat rates, and fluid intake in physically active individuals. Most of these studies have focused on elite athletes undertaking training sessions and/or matches in different environmental conditions. Maughan et al.[11] studied elite football players during a training session in warm conditions and observed a median pre-exercise urine osmolality of 666 mosm/kg (range of 103 to 1254 mosm/kg). During the 90-min training session, median fluid intake was 971 mL with a range of 265 to 1661 mL, and percentage body mass loss was 1.4% with a range of 0.5–2.6%. In a similar study performed in a cold environment, Maughan et al.[12] observed that pre-exercise urine osmolality was 872 mosm/kg (range: 481–1228 mosm/kg), fluid intake was 420 mL (range: 44–950 mL), and percentage body mass loss was 1.6% (range: 0.9–2.5%). Similar results have been observed during competitive football matches[13] and throughout a competitive handball tournament.[14] These studies demonstrate that some individuals are likely to begin exercise in a hypohydrated state (indicated by the high urine osmolality values of these athletes), that there are large inter-individual differences in sweat rate and fluid intake during exercise, and that some individuals are likely to become significantly dehydrated by undertaking relatively short but intense periods of physical activity. A few individuals drink more than they sweat: often, these are those who began exercise in a hypohydrated state.

Sweat consists of water, minerals, and organic components. Consequently, when sweat rate increases during

exercise, it is not just water that is lost. The main electrolytes that are lost via sweat are sodium and chloride at concentrations of approximately 15–80 mmol/L. There is large inter-individual variation in the composition of sweat, leading to large variations in electrolyte loss between individuals.[11,12] This, in addition to the large variation in sweat loss, means that no single hydration strategy is suitable for all physically active individuals, and hydration advice should be tailored to the individual in question.

Body water turnover, or the replacement of water lost over a given period, is approximately 5–10% of total body water content per day for a sedentary individual living in a temperate environment but can increase to 20–40% if prolonged exercise is undertaken in a hot environment. Water turnover is higher in children up to 15 years of age than in adults and higher in physically active individuals than in age-matched sedentary individuals.[15] Leiper et al.[16] reported that average median water turnover in a cool environment for a group of regular cyclists was higher (47 mL/kg/d) than in age-matched sedentary controls (36 mL/kg/d), with the difference in water turnover due primarily to non-renal water losses. When similar measurements[17] were made in recreational runners, water turnover rates were higher (4673 mL/d) than in sedentary age-matched controls (3256 mL/d), but the difference was due to a renal loss, suggesting that voluntary intake was increased beyond the needs dictated by sweat loss.

9.4 HYDRATION STATUS AND PERFORMANCE

Small changes in body water content occur throughout the day and have no measurable effect on physiological function, but large changes clearly have an impact. Despite the substantial volume of research in this area, however, there is no agreement regarding the point at which a reduction in body water is likely to affect physiological function. This is probably due to a variety of factors related to methodological issues in experimental design as well as inter-individual variability, as the factors that limit exercise capacity will also differ.

Case studies demonstrate that prolonged physical activity, especially but not exclusively in hot environments, without fluid ingestion can lead to impaired physiological function, hypernatremia, and collapse.[18] Other case studies demonstrate that extreme over-ingestion of fluid during exercise can also lead to impaired physiological function and hyponatremia, which can prove to be fatal.[19] At some level of dehydration, an effect must become apparent, but this will depend on the exercise model, the environmental conditions, and the individual susceptibility.

A review by Cheuvront and Kenefick[20] concluded that the majority of studies in this area have suggested that a reduction in body mass of 2% or more is likely to reduce endurance exercise performance, particularly when that exercise is performed in a hot environment. This agrees with the 2007 Position Stand on Exercise and Fluid Replacement published by the American College of Sports Medicine.[21]

A number of physiological and psychological mechanisms may contribute to the effect of hypohydration on exercise performance. Gonzalez-Alonso et al.[22] reported that stroke volume was reduced and heart rate increased when dehydrated participants undertook exercise in a hyperthermic environment. In addition to the impact of hypohydration on stroke volume and heart rate, Gonzalez-Alonso et al.[23] also reported a reduction in skin blood flow during exercise in the hypohydrated state. This reduction in skin blood flow will reduce the extent of heat loss at the skin and lead to increases in core temperature. An individual's perception of effort (rating of perceived exertion [RPE]) at a given exercise intensity has been shown to increase when exercising in a hypohydrated state compared with a euhydrated state,[24–26] which is likely to be another mechanism by which a reduction in body water negatively influences exercise performance. Interestingly, Fleming and James[27] demonstrated that habituation to exercise in a hypohydrated state reduced the detrimental effects of a reduction in body water on endurance exercise performance. This effect was not mediated by changes in cardiovascular system function but rather, by habituation reducing RPE.

It has been suggested that a reduction in body water of 3–4% is required to induce detrimental effects on muscle function,[28] although some studies that isolate the effects of hydration report impairments at much smaller degrees of hypohydration.[29] A meta-analysis of 28 published studies[30] concluded that hypohydration results in meaningful reductions in non-body weight–dependent muscle performance and that the method of inducing a reduction in body water was an important consideration. In particular, hypohydration induced by passive means resulted in less of an effect on muscular performance than those that involved an active component. This meta-analysis also concluded that body weight–dependent muscular performance may be improved by a reduction in body water of 3% or more.

Relatively mild levels of hypohydration have been shown to negatively affect cognition. Ganio et al.[31] observed that mild hypohydration of approximately 1.5% body mass resulted in reduced cognitive aspects, such as visual vigilance and visual working memory, when compared with the euhydrated state. Lindseth et al.[32] reported that flight performance and spatial cognition tests were reduced in pilots who were hypohydrated due to low levels of fluid ingestion compared with those who were euhydrated with adequate levels of fluid ingestion. Watson et al.[33] induced hypohydration in their volunteers by a period of fluid restriction that resulted in a reduction in body mass of 1.1%. During a two-hour simulated driving task, more minor driving errors were recorded when participants were hypohydrated than when they performed the task having followed current drinking guidelines. These studies suggest that even mild levels of hypohydration appear to have a negative impact on cognition.

One important consideration and caveat related to hydration and human performance, as well as one of the main criticisms of studies in this area,[34] is that the vast majority (all but a handful of recent studies) have been unblinded. That is, the athletes/participants undertaking the study are aware of which trial is the hypohydrated trial and which is the euhydrated trial (as they either drink or do not). This means the results of these studies may be influenced by placebo or expectation effects, which is particularly important, as many athletes perceive hypohydration to negatively impact their performance.[35] Therefore, the fact that they know which trial they are hypohydrated in could, at least partially, explain the impairment in performance in previous studies.

Recently, this potential methodological limitation in the hydration literature has been examined. James et al.[36] used gastric feeding tubes to give or not to give water to male recreationally active volunteers while they cycled in the heat, without their knowledge. This meant that it was possible to effectively blind the exercisers to the hydration manipulation while also mimicking the physiological and subjective responses typically observed with hypohydration. Interestingly, and counter to the researchers' hypothesis, they reported that endurance performance was impaired by ~8% in the hypohydrated trial with hypohydration equivalent to ~2.4% of body mass. This study demonstrated that hypohydration impairs performance but gave little insight into any expectation effects around hydration. In a follow-up study, also in the heat, the same research group[37] recruited two groups of trained male cyclists and had one group repeat the blinded study design used previously, while the other did everything as would normally be done in a hypohydration study (drink or not drink water during exercise in an unblinded manner), allowing expectation effects to be examined. Interestingly, hypohydration (equivalent to ~3% of body mass) impaired performance in both groups by ~10% and was not different between groups. This provides strong evidence that hypohydration does impair endurance performance and that the effects reported in the literature (at least when hypohydration is equivalent to ~3%) are unlikely to be due to expectation/placebo effects: at least for endurance exercise in the heat, in males.

9.5 HYDRATION FOR RECREATIONAL ACTIVITY (RPE, ENERGY BALANCE)

Physical activity is known to induce numerous health benefits, and lack of cardiorespiratory fitness is considered an independent risk factor for a number of disease states. Physical activity is therefore often prescribed to improve health. While physical activity alone does not appear to induce large degrees of weight loss, it does have beneficial effects on body composition, and the incorporation of physical activity into a weight loss strategy that also includes restriction of energy intake is likely to produce the greatest degree of body mass loss.[38] In addition, the extent of weight regain after a period of weight loss is likely to be lower if physical activity is incorporated into the initial weight loss strategy.[39] Adherence rates to exercise programs are generally poor, however.[40] An individual's RPE during physical activity is a key regulator of self-selected exercise intensity and will likely determine whether that individual continues or terminates an exercise session. Consequently, factors that alter an individual's RPE during exercise might be of importance to ensure compliance with exercise strategies used to promote health.

An individual's perception of effort during exercise is a complex phenomenon involving numerous physiological, psychological, and social factors[41] and is typically assessed using a Borg scale. Briefly, the perception of effort during exercise consists of physiological mediators such as ventilation, availability of energy substrate, and skin temperature activating neuromotor signals. This, combined with psychological factors (such as motivation, mood state, and experience), exertional symptoms (such as heavy breathing and sweat rate), and in the case of elite athletes, performance considerations, is processed by the sensory cortex. This results in a perceptual response that will affect the perceived effort of exercise.[42] The strongest physiological mediators of RPE are respiratory rate, sensation of strain in muscles and joints, perception of body temperature, and limb movement speed. Changes in heart rate, blood lactate concentrations, and oxygen uptake do not correlate as well with changes in RPE.[42] Given the close relationship between core body temperature, sweat rate, skin temperature, and hydration status, it is no surprise that there is interest in determining whether an individual's hydration status influences their perception of effort during exercise.

An important methodological consideration is that few, if any, studies have been carried out to study the effect of dehydration on RPE during exercise. Instead, RPE has been measured as a secondary outcome measure in studies examining the effect of dehydration on other markers of physiological function. A further important methodological consideration is whether an individual begins exercise in a dehydrated state or whether dehydration is accrued throughout exercise.

Cheuvront et al.[43] induced dehydration via heat (three hours of heat exposure that resulted in a 3% reduction in body mass) prior to undertaking a 30-minute exercise trial at 50% VO_{2max} and a 30-minute time trial. No differences in RPE were observed between the euhydrated and dehydrated states. Similarly, Kenefick et al.[44] reduced body water by 1.7–1.8 L via 75 minutes of exercise in hot conditions before a 75-minute heat tolerance test involving running exercise. During this heat tolerance test, there was little difference in RPE when participants were euhydrated compared with when they were dehydrated. Alternatively, Riebe et al.[45] induced a level of 4% dehydration via exercise in the heat before a period of rehydration or no fluid ingestion. During a subsequent exercise test, RPE was significantly higher in the dehydrated state compared with the euhydrated condition. Similar findings of an increase in RPE when previously dehydrated compared with a euhydrated condition

have been observed by Fleming and James[27] and Gonzalez-Alonso et al.[46] On balance, it would seem that beginning exercise in a dehydrated state is likely to lead to a small but meaningful increase in RPE.

Watson et al.[47] reported a significant increase in RPE when participants undertook an intermittent exercise trial at 55% VO_{2max} in hot conditions without fluid ingestion compared with when plain water was ingested to match sweat losses, i.e., dehydration was allowed to accrue. Similarly, Baker et al.[26] observed that three hours of treadmill walking without fluid replacement led to an increase in RPE in comparison to when fluid replacement was allowed. Ishijima et al.[48] reported that 90 minutes of cycle exercise at 55% VO_{2max} without fluid ingestion led to greater RPE than when exercise was undertaken with fluid ingestion. These observations would suggest that dehydration accrued while exercising for longer than about 30 minutes may also lead to a small but meaningful increase in RPE.

The mechanisms underlying the effects of hypohydration on RPE may include both physiological and psychological factors. As discussed previously, hypohydration leads to a reduction in stroke volume and an increase in heart rate[22] as well as a reduction in skin blood flow.[23] Blood-brain-barrier permeability may be altered[47] and cerebral perfusion reduced[49] in response to hypohydration, resulting in direct effects on the central nervous system. Hypohydration also leads to dryness of the mouth, thirst, and headaches, which could ultimately affect mood state and psychological factors that alter the perception of effort.

A substantial body of evidence exists to suggest that starting exercise in a hypohydrated state or allowing hypohydration to occur during exercise results in an increased perception of effort. The effect of hypohydration on RPE is an important consideration for situations of occupational activity as well as the prescription of physical activity for health and wellbeing. Consequently, in these situations, individuals should be provided with the opportunity and education to ensure they are adequately hydrated prior to beginning work or an exercise session to minimize the effect of impaired hydration status on RPE.

9.6 IMPLICATIONS FOR DRINKING STRATEGIES

Much attention has been given to strategies during exercise that may optimize exercise performance. As previously discussed, small acute reductions in body water (as assessed by changes in body mass) are unlikely to cause any negative effects on performance, and therefore, a drinking strategy that restores all body water lost during exercise is unnecessary. Similarly, generic advice to all physically active individuals is not appropriate due to the large inter-individual differences in sweat losses that occur during exercise.

Two main drinking strategies have been promoted in recent years. The first suggests that water and electrolyte losses can be assessed during training in response to different environmental conditions and a pre-exercise strategy implemented in order for an individual to avoid reductions in body water that may negatively influence exercise performance.[27] Alternatively, individuals can drink only when thirsty[50] or *ad libitum* (i.e., as and when they want). While these last two strategies are similar, they differ in that drinking to thirst relies solely on the thirst response to drive fluid intake, whereas drinking *ad libitum* involves other external cues in addition to thirst. Armstrong et al.[51] compared a drinking to thirst strategy with an *ad libitum* strategy in trained cyclists completing a 164-km road cycle at an ambient temperature of 36 °C. Although the percentage body mass lost and fluid intake were the same, the authors concluded that an *ad libitum* strategy may be easier to implement. Also, in situations where sweat rates are very high and/or drink breaks/stations are infrequent, drinking to thirst might be difficult, as ingesting a sufficient volume of fluid to satisfy thirst might not be possible.

It seems clear that a single hydration strategy is not appropriate for all individuals, and numerous confounding factors must be considered. These include the individual's pre-activity hydration status, the extent of water loss incurred, individual preference of taste and familiarity with drinks, the ambient temperature, and the temperature and composition of the drinks. An additional consideration is individual differences in gastrointestinal disturbance that may occur as a result of fluid ingestion during exercise. Relatively high intensity exercise (>70% VO_{2max}) reduces the rate at which fluid is emptied from the stomach,[52] as does ingestion of solutions with relatively high carbohydrate concentration.[53] Consequently, ingestion of large volumes of water and/or solutions containing carbohydrate during exercise may lead to gastric discomfort in some individuals. While there is some evidence that it is possible to train the gastrointestinal system to the ingestion of these volumes,[54] it is still an important consideration when planning hydration strategies during physical activity.

As hypohydration is a common occurrence after exercise, a large body of research on post-exercise rehydration exists. If a single exercise session is completed during the day, there is no need for an aggressive rehydration strategy to be implemented, as normal regulatory processes governing fluid intake will ensure that water balance is maintained over a 24-hour period. If a second exercise session is to be performed on the same day, a post-exercise rehydration strategy may be needed to ensure that this session is not started while hypohydrated. The most important factor to consider is the volume of fluid that is consumed. Shirreffs et al.[55] observed that a volume greater than that lost during exercise is required to account for obligatory urine losses. This is typically translated as 1.5 L of drink for every 1.0 L of net fluid deficit at the end of exercise. It also seems as though the rate at which fluid is ingested is an important consideration, with high rates of fluid ingestion less effective at maintaining fluid balance over a recovery period than low rates of ingestion of the same volume.[56] The composition of a rehydration solution is likely to alter the effectiveness of that solution to maintain fluid balance over a

recovery period. The most important constituent of a rehydration solution is the sodium concentration, as this is the most abundant ion in the extracellular fluid and therefore, has a significant impact on plasma osmolality. The addition of sodium to a rehydration solution has been shown to improve its effectiveness at maintaining fluid balance during a recovery period.[57] The addition of carbohydrate and protein to a solution may also be of benefit, as the addition of these nutrients reduces the rate of gastric emptying and overall water absorption, ensuring that water loss is minimized due to the avoidance of large changes in concentration and volume of the blood/plasma.[58,59] An additional consideration is whether food is ingested alongside a solution. Water is not considered to be an adequate rehydration solution when ingested on its own, as it is rapidly absorbed into the blood and causes a relatively large reduction in plasma volume and a diuresis,[60] but when ingested alongside a meal containing adequate electrolytes, water may be a suitable rehydration solution.[61]

9.7 HYDRATION AS PART OF A HEALTHY LIFESTYLE

As outlined previously, moderate reductions in body water are common as a result of physically active lifestyles, and these reductions may lead to changes in cardiovascular function as well as impairments of cognitive processes and mood. These observations are important for physical performance in elite athletes, for physically active members of the general public, and for those with occupations that involve manual work. What is less clear, perhaps, is the effect of acute and chronic reductions in body water on health. The majority of work in this area has focused on elderly populations, although an increasing amount of research is being undertaken in this space.

Chronic hypohydration is unlikely to result in severe physiological or cognitive health effects, as large deviations in body water will be, at least partially, corrected by mechanisms that regulate body water balance. Consequently, the effects of chronic hypohydration are likely to be relatively mild in most cases. Conversely, large acute reductions in body water could be relatively severe. Few studies have adequately examined the effects of hydration status on chronic disease, but there are some suggestions that low fluid intake (and therefore, hypohydration) may be linked to urinary stones (urolithiasis), constipation, bladder and colon cancer, hypertension, and diabetic ketoacidosis.[62] These observations should be treated with caution, however, due to the lack of studies demonstrating causality. Some recent studies have started to examine the effect of hydration/water intake on disease risk, but many of these studies are epidemiological in design, precluding the elucidation of cause and effect relationships. More work is needed in this area, but recent studies have suggested that drinking additional water might benefit kidney health[63] and those at risk of urinary tract infection.[64] For example, in a 12-month study of women who habitually drank less than 1.5 liters of fluid/day and who had a history of urinary tract infections, it was reported that those who were randomized to consume an additional 1.5 liters water/day had a reduction in urinary tract infections compared with those who did not consume additional water.[64]

The aging process results in a reduction in fat free mass, a reduction in bone mass, and a reduction in total body water, as well as a blunted thirst response, leading to an increased risk of hypohydration in these individuals. Additionally, aging results in a reduction in renal function and a reduced ability to concentrate urine, meaning more water is lost to excrete the same daily osmotic load. Hydration status is known to be a factor in disease progression for a number of medical disorders. Hypohydration is thought to lead to infection, which in elderly populations, can be fatal in up to 50% of cases if not diagnosed early.[65] In an analysis of UK death certificates between 2005 and 2009, it was observed that 667 deaths were due to dehydration compared with 157 as a result of malnutrition: it is, however, difficult to determine whether dehydration was the causative factor in these deaths.[66]

Leiper et al.[67] observed that water turnover, as assessed via a deuterium oxide tracer, was significantly slower in elderly individuals living in a residential care home than in those who lived at home. Similarly, Wolff et al.[68] reported that 12% of elderly patients admitted to hospital from a residential care home were hypernatremic (raised blood sodium levels, indicative of dehydration) upon admission compared with 1.3% of elderly patients who lived at home. The extent of hypernatremia upon admission is related to likelihood of in-hospital mortality, and consequently, patients from residential care homes had a greater likelihood of in-hospital death than those who lived at home. Similar results were reported by El-Sharkawy et al.[69] These observations indicate that elderly individuals, particularly those in care homes, should be targeted by care workers to ensure adequate water ingestion and avoidance of hypohydration.

Quality of life is of primary importance in elderly individuals and is often assessed as a profile of physical, psychological, independence, social relationships, environmental, and spiritual domains. In a study of 82 residents of Australian care homes, Courtney et al.[70] reported that quality of life was positively correlated with clinical care indicators. The three main indicators that affected quality of life were poor hydration status, number of fall incidents, and depression. These areas may be targeted to improve quality of life in residential care, and improvements in hydration may be one of the easiest and most cost-effective ways to achieve this.

It seems clear from this evidence that certain populations, such as the elderly, are more susceptible to the impact that reductions in body water can have on health. Further evidence of this can be seen when examining the effects of changes in environmental temperature on morbidity and mortality. Sardon[71] reports that temperatures throughout Europe were several degrees higher between June and September 2003 compared with other years. In an analysis

of heatwave days in 2003 compared with the same dates in other years from 1990 to 2004, D'Ippoliti et al.[72] observed that there were 7.6% more deaths in Munich, 10.4% more deaths in London, 26.8% more deaths in Rome, and 33.6% more deaths in Milan. In Mediterranean cities, where the heatwave had the largest impact on temperature, the percentage increase in all-cause mortality compared with other years was greatest in those aged 85+ years and was higher in females than males.

Similar observations have been made in Australia. Nitschke et al.[73] analyzed daily ambulance transports, hospital admissions, and mortality over a 13-year period from 1993 and compared heatwaves with non-heatwave periods. Total mortality was unaffected during heatwaves, but ambulance transports and hospital admissions increased by 4% and 7%, respectively. Total mental health and renal health hospital admissions were increased by 7% and 13%, respectively. Similarly, Khalaj et al.[74] surveyed 1,497,655 emergency admissions to hospital in sites across New South Wales. It was observed that on days of extreme heat, hospital admissions for heat illness, dehydration, and electrolyte disturbance were increased, whereas hospital admissions from other causes were not. Individuals with underlying medical conditions affecting the nervous, circulatory, respiratory, and/or renal systems were particularly affected by the high environmental temperatures.

It seems clear that certain populations, particularly the elderly and those with underlying medical conditions, are most at risk of high environmental temperatures and that this is likely to be at least partly due to the effect on hydration status. Warren et al.[75] examined the economic impact of hospital admissions due to hypohydration in US elderly adults. Almost 7% of hospitalizations in 1991 had dehydration listed as a diagnosis, with 1.4% listing it as the primary diagnosis. This resulted in $446 million in Medicare claims, suggesting that hypohydration-related hospital admissions have a significant economic impact. From these observations, it seems that the avoidance of hypohydration in these situations is a relatively straightforward but potentially effective intervention in certain populations for improving public health. It is important to consider how easily changes in hydration can be made, given the easy, low cost (almost free) access to water in most countries. This makes improvements in hydration status a potential quick, easy, and cheap win for health care costs in many parts of the world.

Much attention has been given to the acute and chronic effects of hypohydration, but large acute increases in body water, though less common than hypohydration, can also be hazardous. Over-hydration can occur as a result of the ingestion of water in excess of the amount needed to maintain euhydration, an electrolyte deficit, and/or an inability of the renal system to compensate for these changes by appropriate adjustments of renal function. As with chronic hypohydration, chronic over-hydration is unlikely to lead to serious health consequences in healthy individuals, but occasionally, it can be fatal. If the concentration of sodium in the extracellular space falls, water moves from the interstitial space into the cellular compartment, leading to swelling of cells. In most tissues, this is of little consequence, though it may have implications for a number of cellular functions.[76] If sufficiently severe, however, an increase in intra-cranial pressure will result, and symptoms associated with "water intoxication," including headache, nausea, confusion, and changes in behavior, may appear. If intra-cranial pressure continues to increase, this can lead to central nervous system dysfunction, coma, and death. Exercise associated hyponatremia, brought about by ingesting a greater volume of water than is lost via sweat, has been associated with several deaths and was reported in 13% of finishers of the Boston marathon in 2002 despite these individuals showing no clinical symptoms.[77] A number of non-exercise cases of "water intoxication," brought on due to excessive fluid ingestion, have also been described. These include cases from fraternity initiation practices, co-ingestion of large volumes of fluid with recreational drugs such as MDMA, water ingestion during weight loss plans, and social competitions involving large volumes of fluid intake.[78]

9.8 CONCLUSION

Despite the abundance of water in the human body, it is important to maintain levels within narrow limits. This is achieved by matching water intake and water output. An imbalance between water intake and output leads to either hypohydration or over-hydration. Chronic water imbalances are usually relatively mild, and homeostasis will be restored by normal regulatory processes. Acute imbalances can, if sufficiently severe, lead to changes in physiological function that can affect performance of physical activity and in extreme cases, lead to serious health consequences. Some elite athletes, exercisers, and manual workers have been shown to begin activities in a hypohydrated state even when there is a high risk of potentially harmful hypohydration. Sweat rates and fluid intake during physical activity both vary greatly between individuals. Undertaking physical activity in a hypohydrated state leads to an increase in subjective effort, which may have an impact on exercise performance and self-selected exercise intensity. Some populations, such as the elderly, are more likely to become hypohydrated, and they, and those who care for them, may need specific hydration advice in order to avoid potential adverse health consequences.

CLINICAL APPLICATIONS

High levels of physical activity, especially in warm environments, lead to increased sweat production and therefore, increased losses of water and salt from the body. Hypohydration and hypernatremia are the normal responses to prolonged exercise in the heat, but losses vary greatly between individuals even under the same exercise and environmental conditions and are normally self-limiting. Ingestion of water—especially with the addition of

carbohydrate and salt—can help maintain physiological function and performance capacity. If sweat losses exceed about 2–3% of body mass, performance is usually impaired. Ingestion of plain water or other low-sodium drinks in excess of sweat loss can lead to hyperhydration and the development of hyponatremia. Mild hyponatremia is generally asymptomatic and harmless, but if severe and treated inappropriately, can, on rare occasions, be fatal. Medical support personnel at endurance events must recognize that some of those requiring medical attention may be severely hypohydrated, while others finishing (or failing to finish) alongside them may be hyperhydrated and hyponatremic.

This chapter is based on a similar chapter entitled "Effects of an Active Lifestyle on Water Balance" written for *Nutrition in Lifestyle Medicine*, Humana Press (New York), 2016, also edited by James M. Rippe, MD.

10 Culinary Medicine

Uma Naidoo, MD

KEY POINTS

- Nutrition is a key driver of poor physical health and metabolic disease in the USA and worldwide.
- Culinary medicine is an easy solution to include food as medicine in a clinical discussion.
- Culinary medicine can help teach health professionals and patients to use nutrition to improve physical health, longevity, and quality of life.

10.1 BACKGROUND

Hippocrates of Kos, the Greek physician (460 BC–370 BC) considered to be the father of modern allopathic medicine, is known for his sage-like words about the power of food as medicine, but a lesser-known quote of his aptly captures culinary medicine:

> Just as food causes chronic disease, it can also be the most powerful cure.

Culinary medicine is a new evidence-based field in medicine that blends the art of food and cooking with the science of medicine. Culinary medicine is aimed at helping people reach good personal medical decisions about accessing and eating high-quality meals that help prevent and treat disease and restore well-being.[1]

Over the past approximately four decades, there has been an emerging and fast-growing movement around food, cooking, and ingredients in relation to physical health. Many people who may not know how to cook will frequently be found mesmerized by watching food shows on television. The formation of the Food Network in the early 1990s changed the face of modern television by introducing an entire food focused television network. Seen as a gamble[2] at the time, it is now a household name.

Food as medicine, however, is rooted in a significant deficit: medical doctors are not taught sufficient nutrition information during medical school. A study published in 2015 surveyed all 133 US medical schools with a four-year curriculum about the extent and type of required nutrition education during the 2012/13 academic year. They had a 91% response rate (121 medical schools responded). The study concluded that "many US medical schools still fail to prepare future physicians for everyday nutrition challenges in clinical practice."[3]

The result of this education gap is that medical doctors cannot be expected to adequately or effectively address obesity, diabetes, metabolic syndrome, malnutrition, or even heart disease if they are not taught how to identify and then treat any underlying nutritional causes of these and other diseases.

When reviewing these factors, the developing field of culinary medicine shows promise to support filling that gap in clinical care and potentially improving treatment of patients. With cardiovascular disease remaining the number one killer in the United States, it begs the question: how can we offer more solutions to improve cardiac healthcare along with cancer, chronic pulmonary diseases, diabetes, obesity, and cognitive impairment? After all, these are among the leading causes of death and disability throughout the world in both developed and developing countries.[4] Poor nutrition is the number one cause of illness in the United States and is responsible for more than half a million deaths per year.[5] With such devastating health data, it brings forth the concept that we need more tools in our tool kit, and one of them is nutrition.

10.2 THE HISTORY OF CULINARY MEDICINE

Dr. John LaPuma is credited with writing the first nonfiction trade book about culinary medicine in 2009, called *ChefMD's Big Book of Culinary Medicine: A Food Lover's Road Map to: Losing Weight, Preventing Disease, Getting Really Healthy.*

From this book, "culinary medicine" is described as the art of cooking blended with the science of medicine. As a trained professional chef, Dr LaPuma also shared many recipes that could be used easily by the reader to start to incorporate home cooking again, with the ultimate purpose of improving our health as well. In an academic paper from 2016, the following description emerged, describing what culinary medicine is not:

> Culinary medicine is not nutrition, dietetics, or preventive, integrative, or internal medicine, nor is it the culinary arts or food science. It does not have a single dietary philosophy; it does not reject prescription medication; it is not simply about good cooking, flavors or aromas; nor is it solely about the food matrices in which micronutrients, phytonutrients, and macronutrients are found.[6]

10.3 HEALTH DATA

While the reasons behind the rising rates of obesity and other chronic diseases are multifactorial, one concept could be the difference in time spent cooking over the decades.

DOI: 10.1201/9781003227793-12

The Multinational Time Use Study[7] published in 2003 showed that Italian and French adults spend about 19 more minutes per day cooking than Americans. The Centers for Disease Control and Prevention reported that 36.6% of adult Americans eat at fast food restaurants on a daily basis.[8]

Other research has shown that cooking at home is associated with better nutrient intake as well as fewer overall calories.[9] Analysis of the Nurses' Health Study[10] data found that people who ate 11 to 14 home-cooked lunches and dinners per week had a 14% lower risk of developing type 2 diabetes than those who ate only 6 or fewer home-cooked lunches and dinners per week, and that this association was partly attributed to less weight gain linked with this dining behavior. When you summarize this information, you may conclude that preparing meals at home, spending more time in the kitchen than eating out at restaurants, and eating meals at home will contribute to overall improved physical health. Since most fast food restaurants use cost saving processed vegetable oils, which are pro-inflammatory, this also impacts mental health by causing inflammation. A study by University of São Paulo Medical School presented at the 2022 Alzheimer's Association International Conference (San Diego, CA) suggests that if 20% or more of your daily diet is made up of processed and ultra-processed food, cognitive function could also be impacted.[11] They asked 10,000 Brazilians, with an average age of 51, to record their eating habits for up to a decade. Researchers then looked at the results of cognitive tests—including immediate and delayed word recall, word recognition, and verbal fluency—in relation to the participants' daily diet. The study found that men and women who ate the most ultra-processed foods saw their global cognitive function decline 28% faster than those who ate a diet of non-processed food. The same group had a 25% faster rate of executive function decline compared with people who avoided processed foods in their diet.

Poor diet is the leading cause of death and disability (700,000 deaths/year).[12] Suboptimal diet is associated with many chronic diseases, such as obesity, diabetes, cardiovascular diseases, and cancer. Nearly 50% of deaths related to cardiovascular disease, stroke, and diabetes are also related to poor diet. Suboptimal diet is the number one risk factor for premature death from chronic disease, specifically cardiovascular disease, the number one killer of Americans. The World Health Organization reports that 1.9 billion adults were overweight in 2016, and 650 million were considered obese.[13] The prevalence of obesity in the United States was 30.5% in 1999, and this increased to 42.4% by 2017, according to the Centers for Disease Control.[14] While many factors have contributed to this epidemic, the Western diet, also called the Standard American Diet (SAD), is considered to be a major contributor to the growing rate of obesity in the United States.

Yet despite this data, most Americans continue to eat the SAD, even with compelling data that our current eating patterns predispose us to greater morbidity and mortality for COVID. A study from New York City found that patients with a body mass index (BMI) of 30–34 were 1.8 times more likely to be admitted to an intensive care unit (ICU), and those with a BMI greater than 35 were 3.6 times more likely to be admitted to an ICU.[15]

Culinary medicine can play a key role in helping to rethink what we are eating, looking at healthier but still delicious meal swaps, and integrating the knowledge that we are what we eat.

Since the field has emerged, there have been several advances alongside it, such as the Healthy Kitchens, Healthy Lives (HKHL) Conference, which began in 2006 under the leadership of Dr. David Eisenberg, Director of Culinary Nutrition and Adjunct Associate Professor, Department of Nutrition, Harvard T.H. Chan School of Public Health. This is now an annual conference co-hosted by the Harvard T.H. Chan School of Public Health and the Culinary Institute of America.[16] The intention of this conference is to bring together medical, public health, and culinary experts in a collaborative effort to educate health professionals about food and cooking, and to educate culinary experts about nutrition science and its implications in designing and providing healthier menu options.[17] The participants are tutored by demonstrators from the Culinary Institute of America, who offer practical demonstrations on how to prepare healthy meals and how to use specific foods for a healthy diet.[18]

From the very start, Dr. David Eisenberg envisioned a time when health professionals would build "teaching kitchens" to be used as learning laboratories in hospitals, medical and allied health schools, schools, and allied venues. What occurred was that many alumni, after completing the HKHL conferences over time, were inspired to create their own prototype "teaching kitchens." By 2016, more than 30% of the participants at the conferences confirmed that their host organizations had built or soon would build a teaching kitchen, and for this reason, the "Teaching Kitchen Collaborative" (TKC) was established by the Culinary Institute of America and the Harvard T H Chan School of Public Health in 2016. These initiatives, both the HKHL conferences and the TKC project, have certainly broadened the impact of education of healthcare practitioners to enable them to include culinary medicine principles into clinical practice.

Given that a prior study showed that only 38% of physicians discuss diet during routine office visits, all efforts to move this conversation forward are key.[19]

Dr. Michelle Hauser[20] is the Obesity Medicine Director of the Medical Weight Loss Program in the Stanford Lifestyle and Weight Management Center. Beyond delivering patient care and medical education, Dr. Hauser is a prevention researcher and trained chef. She combines her skills to help patients move away from lifestyles that lead to chronic disease and toward those that promote health and well-being.

Dr. Hauser wrote the first comprehensive Culinary Medicine Curriculum for healthcare professional training programs, now in use in more than 100 countries.[21]

It has been downloaded at least 2379 times in 83 countries by a wide variety of healthcare professionals interested in teaching culinary medicine. This educational resource serves to further spread the message of culinary medicine and allow further education and subsequent use of these healthy eating principles and recipes.

Positive use of the media sharing new frontiers in medicine can be very useful for both consumers and clinicians alike. An example is a feature in the *New York Times* in 2018 titled "The Doctor is Cooking," and in 2019, Time Health Website featured: "Why food could be the best medicine of all."[22,23]

Another positive outcome of raising the awareness of culinary medicine education has been its implementation in medical school electives and/or into medical education. Park (2019)[24] listed the "Necessary Ingredients for a Culinary Medicine Program," which included:

- Culinary medicine faculty (physician or clinician lead trained in culinary medicine, a chef, registered dietitian)
- Operational support for planning and logistics
- Curriculum and recipes (original or licensed)
- A teaching kitchen or other suitable space
- Partners (internal and community partners)

One of the difficulties many hospitals or medical schools face is a shortage of suitable space to host such a curriculum. And as noted earlier, those centers that were able to raise sufficient funds created a Teaching Kitchen Collaborative to host their programs.[17]

Certainly, some medical schools have taken up the challenge to educate their students with hands-on cooking programs. The Goldring Center for Culinary Medicine (GCCM) at Tulane University's School of Medicine is the first dedicated teaching kitchen to be implemented at a medical school.[25] The program was founded in 2012 and taught medical student and community cooking classes at kitchens around the city. By working in locations like churches and community centers, the center strengthened its connection to the New Orleans community. In 2014, the Goldring Center found a permanent home for its teaching kitchen. The center also provides hands-on training for medical students and residents at Tulane through culinary medicine classes, including electives and interdisciplinary seminars. Interns at Tulane University's School of Public Health who are studying nutrition and dietetics also complete rotations and attend a series of classes throughout their internship year. The GCCM also teaches continuing medical education classes for licensed medical professionals, including physicians, physician assistants, nurses, nurse practitioners, dietitians, and pharmacists. They serve the community with free classes where anyone from the public and local community can learn about nutrition and culinary medicine through hands-on cooking classes. The GCCM curriculum is also licensed by medical schools across the United States to increase nutrition education in programs.[26]

Beyond adults, some educational programs have included educating children. The researchers note that programs that include children in hands-on nutrition education appear to promote changes that positively impact the entire family. From this, they designed a dedicated pediatric cooking and nutrition class alongside a community-based culinary medicine class for adults.[27]

Another program based its objectives consistently with the US Presidential Executive Order of July 2019 with the goal to reduce the annual incidence of kidney failure by 25% or more by 2030.[28,29]

In summary, the Culinary Medicine movement is growing and developing in all directions, supporting both clinicians and consumers, as well as children.

Nutritional psychiatry in the United States is in its infancy when compared with culinary medicine but is really the missing clinical component that addresses our brain health and mental well-being.

The first nonfiction trade book on the subject of nutritional psychiatry was published in 2020, called *This Is Your Brain on Food: An Indispensable Guide to the Surprising Foods that Fight Depression, Anxiety, PTSD, OCD, ADHD, and More*.[30] It became a national and international best-seller, and while this is a newer field of psychiatry, the message appeared to resonate with individuals wanting to find a solution to feeling emotionally better using a different tool besides medications or therapy. It has been published in 22 countries and 18 languages thus far. The academic textbook on the same topic is being written, with an expected publication date of 2023. The first time that nutritional psychiatry was included in a chapter of *The American Psychiatric Association Textbook of Psychiatry* was in 2019.

The World Health Organization (WHO) identified that depression and other mental health conditions are on the rise globally and remain a threat to public health. Of these conditions, depression and anxiety disorders are increasing the most.[31]

A study from 2020 showed that diet can be important for the emergence and treatment of mental illness. Adherence to dietary recommendations, anti-inflammatory diet, fish consumption, exclusion of processed foods, and adequate intake of folic acid, magnesium, and different fatty acids were associated with a reduced risk of mental illness.[32]

The research around the gut microbiome and the gut brain ecosystem has also helped unfold the food mood connection. For example, in a large cross-sectional study, the intake of the B vitamins folate (B9) and vitamin B12 was inversely correlated with severity of depression.[33]

In a meta-analysis covering 16 studies, 15 of which were in non–clinically depressed populations, dietary intervention led to a significant improvement in mood but not in anxiety.[34]

The SMILES trial, despite a small cohort of 67, offered a 12-week dietary intervention using a modified Mediterranean diet to target MDD in adults, and showed that diet can help MDD symptoms.[35]

In a scoping review of anxiety conducted by my colleagues and myself, we identified a total of 55,914 unique

results, and 1541 articles met criteria for inclusion. An analysis revealed an association between less anxiety and more fruits and vegetables, omega-3 fatty acids, "healthy" dietary patterns, caloric restriction, breakfast consumption, ketogenic diet, broad-spectrum micronutrient supplementation, zinc, magnesium, and selenium, probiotics, and a range of phytochemicals. The analysis also revealed an association between higher levels of anxiety and high-fat diet, inadequate tryptophan and dietary protein, high intake of sugar and refined carbohydrates, and "unhealthy" dietary patterns. And while results are limited by a large percentage of animal and observational studies, the associations made are useful clinically.[36]

In a review of nutrition as a metabolic treatment for anxiety, it was found that nutrition regulates anxiety disorders by influencing the microbiome and inflammation, and the gut microbiome and inflammation are interrelated and influence anxiety. By acting on the gut microbial ecosystem, regulating inflammation, as well as through other pathways, particular nutritional strategies have been suggested to either harm or help disorders of anxiety. Sugar, processed vegetable oils rich in inflammatory omega-6 fatty acids, artificial sweeteners, and gluten were found to have a negative effect on anxiety, whereas omega-3 fatty acids, turmeric (curcumin), vitamin D, and ketogenic diets were thought to have a therapeutic effect.[37]

The mechanisms associated with the development of mental health symptoms are thought to be related to underlying inflammation and neuroinflammation.[38]

Of note, though, more than a century ago, the treatment of melancholia by Lactic Acid Bacillus was proposed![39]

Interestingly, as far back as 1893, the *British Medical Journal* published a call for medical students to attend four sick care and convalescent cookery courses to "gain practical information on matters of such vital importance to their future patients."[40] Yet despite this gap being identified 129 years ago, it is only in the past 2 decades that such changes, like the introduction of nutrition education and culinary medicine, have begun.

In reflecting on the newer and emerging field of culinary medicine, it is important to realize that unless a person has an allergy, a food intolerance, or a disease that requires restricting a certain food, cooking and making healthier choices are easy and can have significantly positive health and mental health benefits.

This book is the fourth edition of the *Lifestyle Medicine* book and the first time a chapter on culinary medicine has been included. The *American Journal of Lifestyle Medicine* began its culinary medicine column in 2019. These represent forward thinking areas of the food as medicine movement.

CLINICAL APPLICATIONS

1. Culinary medicine principles can be utilized by medical students and clinicians to change the narrative in clinical visits, e.g.,
   a. a cooking demo as part of an OP group visit
   b. a nutrition discussion: simple tips on how to navigate the supermarket aisles.
2. Since nutrition education is lacking in many US medical schools, physicians may need to bridge this gap by engaging in post graduate education in culinary medicine, nutritional psychiatry, and lifestyle medicine.
3. The more that physicians embrace the food as medicine movement, the greater the impact will be on day-to-day clinical care of patients.

11 Nutrition, Lifestyle, and Environment

T. Colin Campbell, PhD

KEY POINTS

- Although the word "nutrition" is widely spoken, it remains exceedingly confusing and contentious because of its focus on discrete parts.
- Nutrition is the metabolic expression of food, upon consumption, centered on a symphony of nutrient effects within and among cells, within and among organs.
- Nutrition metabolism is comprised of countless nutrients and nutrient-like substances acting in a manner whereby its whole effect is greater than the sum of its parts, as Aristotle said.
- The nutrition protocol for health is essentially the same for all ages, for both genders, and for health promotion as well as for disease prevention and disease reversal.
- Nutrition dysfunction is best corrected not by single nutrients but by whole foods.
- Nutrition is best characterized as a wholist philosophy, unlike the reductionist philosophy of contemporary medical practice.
- Lifestyle medicine would be more appropriately described as lifestyle health; "medicine" places too much emphasis on the use of pharmaceuticals.
- The most easily applied and scientifically justified dietary recommendation is to consume a diet of plant foods in their whole food form, however prepared.
- The science of nutrition, as told here, is not taught in medical schools.
- Reimbursement for nutrition care by primary care physicians, dietitians, nurses, and physician assistants must enjoy more equivalence with disease treatment care.
- The U.S. National Institutes of Health (NIH), the leading biomedical research agency composed of 27 institutes, has no dedicated Institute for Nutrition.

Understanding nutrition has long been confusing and contentious, even though it has been widely discussed. For a more formal definition, nutrition is the biological expression of food upon its consumption, digestion, absorption, and metabolism, with an ultimate purpose of maintaining and restoring health and preventing disease. In many cases, the same dietary protocol can reverse or treat most chronic degenerative diseases, which account for most deaths in economically affluent societies. Unfortunately, our present understanding of nutrition, which can be traced back to the middle 1800s and early1900s, is largely responsible for the production and consumption of foods that seriously compromise human health while simultaneously degrading environmental, even , health. It is urgent that the society at large, both professionally and publicly, develop a reliable, easily understood definition of nutrition.

Even though there is abundant evidence showing what good nutrition can do, reality suggests that authoritative institutions pay little or no attention. Medical schools offer only about 20 contact hours during an entire medical school training program,[1] or by comparison, <1% of total contact hours for an undergraduate nutrition major. Among the 27 institutes of the U.S. National Institutes of Health, a leading health research funding agency in the world, none is dedicated to nutrition. Primary care physicians receive little or no compensation for nutrition-responsive consults. Dieticians are trained and accredited within a system controlled by the Academy of Nutrition and Dietetics, which boldly advertises support from the food and drug corporate sectors. Dietary guidelines, marginally revised every five years since 1980, are created by a government agency headed by a politically appointed Secretary beholden to the livestock industry. I challenge the reader to name a biomedical discipline offering more benefit for human health than nutrition yet being treated as if it had nothing to offer.

After more than six decades in research, education, and policy making on the topic of food and health and becoming more aware of the origin of nutrition confusion, it is not surprising that during the coronavirus pandemic, there has been no mention of nutrition, when it has so much to offer. Indeed, dismissing nutrition exposes a violation of the concept of science itself. Rather than employing scientific principles to investigate hypotheses wherever they may lead, we hear about "science" serving an intended purpose, a process more aptly described as technology. For example, during this pandemic, the public is told to "follow the science," meaning the tracking of disease trends and discovering a pharmacologic solution to treat disease, as if this were all there is. The possibility that nutrition might be important in controlling this viral disease[2–5] has been totally ignored. It is difficult to comprehend such irresponsible behavior for a disease having such profound social, economic, and political implications.

Yet, rather strangely, many people want to believe that nutrition is important, however it is defined. As much as 85% of the U.S. national health care budget is dedicated

DOI: 10.1201/9781003227793-13

to the management of "diet-related" chronic diseases.[6] In parallel, 86% of people over 65 years have been diagnosed with one or more of these chronic diseases.[7] Another way to recognize the importance of nutrition is to reflect on its absence and how we offset that missing link. Here's a hint. Worldwide, the United States ranks #1 in per capita spending[8] for prescription drugs. "Nearly 9 in 10 (89%) adults 65 and older report that they are taking any prescription medicine," according to the Kaiser Family Foundation.[9] Relying on prescription drugs, however, does not mean superior health. Arguably, it's the contrary. Sixty to seventy percent of people in the United States take at least one prescription drug per day with adverse effects,[10] making the use of these products the third leading cause of death.[11–13]

Extensive literature now suggests that two main types of food have questionable nutritional value: a) foods derived from animals and b) "foods" fabricated and composed of plant food fragments enriched in refined carbohydrates and oils. Each of these food groups correlates with high rates of chronic degenerative disease that are associated, in the United States, with "by far the lowest life expectancy" among economically developed countries, according to the Commonwealth Fund.[14]

As previously stated, nutrition is the biological expression of whole food upon its consumption, digestion, absorption, and metabolism of its many nutrients working together throughout the body to optimize health. Unfortunately, we focus on individual nutrients as if they acted independently, a wellspring for confusion. A scientifically reliable, simply applied message that honors this complexity might be to address two perspectives on nutrition,[1] *the relative inability of individual nutrients to optimize health* and[2] the *type and form of foods to consume that relies on the comprehensive nutrient effects to optimize health*.

A focus on individual nutrients serves as the basis for recommending daily allowances (RDAs), assessing food quality, establishing guidelines for food labeling, and ultimately, developing highly influential dietary guidelines. This focus is called reductionism, which offers an endless supply of detailed information, a source for endless confusion.

Recognizing this confusion first arose (for me) in the 1980s[15,16] when it was reported that nutrients consumed in isolation, as in supplements, do not necessarily function in the body in the same way as when consumed in whole foods. They may even have opposite effects.[15,17] Healthy, whole foods contain countless nutrients and nutrient-like chemicals, which upon their consumption, act from within highly integrated networks of interdependent enzyme catalyzed reactions and events within cells, between cells, and within and between organs. These activities are exceptionally dynamic. They are coordinated and optimized within nanoseconds of time throughout the body by complex neurologic and hormonal systems, which instantly signal distant body parts. Focusing on one nutrient, one functional target, and one outcome cannot represent the whole health effect. If we continue to insist that nutrition be interpreted in this reductionist manner, then the far-reaching benefits of nutrition for human health will forever be ignored.

This questionable focus on individual items arose, for me, from a so-called "local theory of disease" discussion during the 1700s–1800s to explain cancer.[18] Surgeons believed that cancer could simply be resolved by surgical removal. Subsequently, this belief in localized effects morphed into further assumptions of simplicity, as if this represented the best of science. Specific chemicals (carcinogens) cause specific cancers acting on specific mechanisms that might be targeted by specific drugs. Target drug treatment became a hallmark of the War on Cancer initiated in 1971. After three decades, this protocol proved to be disappointing, because evidence was accumulated to show that cytotoxic chemotherapy increases five-year survival by only 2.1%.[19] And further, simplifying biology in this arbitrary and reductionist manner became the primary basis for the entire pharmaceutical industry, which refuses to acknowledge a nutrition-based hypothesis unless single nutrient activities are assumed.

This single nutrient idea, however, also is questionable. For example, consumption of beta-carotene rich foods (whole plants) was shown to be inversely associated in a dose-dependent manner with lung cancer mortality among heavy smokers,[20] but in a subsequent report, isolated beta-carotene in supplement form significantly *increased* lung cancer within only five years.[15,21] Statins, which are targeted to a specific enzyme in the cholesterol synthesis pathway, decrease blood cholesterol and cardiovascular disease events by upwards of 20%, but with adverse side effects[22] In contrast, whole food, plant-based (WFPB) nutrition quickly and safely decreases blood cholesterol within days with few or no adverse side effects, thus being consistent with a 90% lifetime reduction in coronary heart disease for diets nearly void of animal protein.[23–25]

In contrast to the nineteenth-century "local theory" hypothesis for cancer and its evolution into reductionism, a counter theory called "the constitutional nature of disease"[26] offered a perspective that forecast whole food nutrition. Ample evidence now supports this hypothesis, which reverses/treats a broad range of degenerative diseases. I call this *wholism* ("w" intended), which relies on the *in vivo* process of homeostasis, and which acts like a default mechanism to optimize health. In contrast to the huge infrastructure costs of prolonged disease care and medication costs associated with side effects, wholist nutrition provides superior health at far less cost than a reductionist-dependent reliance on pills and procedures. A wholist nutrition protocol, further described later, addresses a broad spectrum of disease conditions and in many instances, both prevents and reverses disease with the same protocol. Relying on reductionist theory in the present medical care paradigm is why medical schools do not teach nutrition, why primary health caretakers (physicians, nurses) are not adequately compensated for nutrition advice, and why there is no dedicated institute of nutrition at the premier medical research funding agency, NIH. Nutrition as a health science

is negated. The sinister implications of this perspective cannot be overstated.

Wholist nutrition favors the consumption of *whole foods*, meaning that all nutrients in food are generally consumed together, however these foods are prepared. This practice contrasts with the consumption of "convenience" foods, which are re-formulations of isolated parts of whole foods, especially using added fats/oil, refined sugars, and salt. These components are parts of healthy, whole foods, but they often do not retain these properties when used independently. They add flavors with addictive-like behavior, good for commerce but not for human health.[27]

When choosing foods *to* eat, one nutrient has influenced food choice more than any other, for well over a century. It is the protein of animal-based foods, long understood to be "high quality" compared with the protein of plant-based foods. Very simply, high quality means a higher proportion of consumed protein being retained for body growth,[28] helpful for livestock growth and production but not for humans. Nonetheless, the assumption of high-quality protein is a long-standing, powerful marketing message, while few, if any, know its origin. It generally remains buried in our subconscious mind. Retaining more animal protein also increases serum cholesterol[29,30] and heart disease,[29] increases growth hormone and cancer,[31] increases activation of chemical carcinogens and mutations,[32,33] increases serum estrogen,[34,35] resulting in earlier menarche and more breast cancer,[36] decreases natural killer cells[37] that suppress viral diseases and cancer, and decreases physical endurance,[38,39] among other health outcomes. Not surprisingly, these effects are never voiced in the public narrative, for they would question the highly revered concept of high-quality animal-based protein.

It seems to me that this reverence mainly started when protein was isolated from meat experimentally fed to a dog in 1839.[40] It was deemed essential for the dog's life. It was named after the Greek word *proteios*, meaning "first" or "prime importance,"[41] indicating an even more profound reverence for eating animals going back to biblical times in the Judeo-Christian world.[42] Thereafter, influential scientists called protein (i.e., from animals) "life itself" and the "stuff of civilization."[40,41] Since then, many families have planned their meals primarily around their choice of protein (animal-based), if they could afford it. From my youth on our family dairy farm, we certainly did, and I had no reason to question this view when I did a doctoral dissertation with an objective to promote animal protein consumption.[43]

During my subsequent research career, experimental animal studies (rats, mice) conducted over three decades were especially instructive. Animal protein (as casein) but not plant protein markedly promoted[44] experimental cancer development, which could be turned on and off, respectively, simply by increasing or decreasing consumption of animal protein or by replacing it with plant protein. Because this finding was so provocative, it was important to identify the key mechanism for this effect, both to establish biological plausibility and to identify a mechanism that might be amenable to inhibition, perhaps pharmaceutically.

In a long series of experiments over a dozen years, at least ten candidate mechanisms were identified, as mentioned earlier.[45] Interestingly, animal protein increased activities of eight mechanisms that normally promote cancer development but decreased two "fail-safe" mechanisms that help us to avoid cancer. Each mechanism is known to have a specific function, identity, and cellular location. All ten mechanisms, some increasing and some decreasing in response to increased dietary animal protein, acted in unison to cause the same result, a truly remarkable response. It demonstrated a central theme of wholism, which presented a critical challenge to our conventional method for understanding nutritional biochemistry and function.

I suggest that a multi-mechanistic, intricately woven network of interdependent "mechanisms" is a generalizable algorithm having broad application. It stands to reason that it should apply across species, among nutrients,[45] at varied intervention times from disease prevention to disease reversal,[46–49] and in a broad spectrum of health and disease events, like heart disease, diabetes, obesity, chronic kidney disease, and certain autoimmune diseases. This breadth of effect documents Aristotle's suggestion over two millennia ago that the whole is greater than the sum of its parts. I suggest that it is a fundamental principle of biology and a core theme of lifestyle medicine, provided that we re-imagine the meaning of "lifestyle medicine." In popular conversation, "medicine" generally refers to pharmaceuticals, and its emphasis is on parts, which is the antithesis of nutrition and its emphasis on whole. While advocating for a new perspective on healthcare, with its greater emphasis on natural health practices, I suggest that it be described in this way, so that nutrition retain its true meaning of whole food instead of nutrient parts.

Consistent with this perspective is the evidence obtained in human epidemiological studies. Mortality rates for multiple degenerative diseases show linear correlations with the consumption of animal protein or its co-variates. These include heart disease and cholesterol intake,[50] breast cancer and saturated (mostly animal) fat intake,[51,52] breast cancer and meat intake,[53] prostate cancer and non-fat milk intake,[25] renal cancer and animal protein intake,[54] and colon cancer and meat intake.[54] Each of these linear correlations intercepts very near the x/y origin, which suggests zero disease risk with zero animal protein intake. These correlations, however, do not rely on disease occurrence caused by animal protein alone, a reductionist interpretation. There is more. Because total food intake is limited by calorie intake, increased consumption of animal foods customarily associates with decreased consumption of plant foods with their own disease-preventative nutrients, all of which strengthen and expand the wholist effect.[45] Then, when combining this evidence with the evidence on biological plausibility, the inference drawn in favor of wholist nutrition is unusually impressive.

While the evidence discussed here concerns prevention and treatment of disease, it also applies to health maintenance, such as physical fitness. A Yale University study 125

years ago showed an impressive increase in 15 strength and endurance tests among young men when they switched to a low protein, mostly plant-based diet.[38] The same benefit also occurred for already fit athletes.

In the late 1970s, interest was emerging in the cancer research community on a possible role for nutrition, especially nutrition provided by foods of plant origin. As the only nutrition researcher on a review committee of cancer researchers of the U.S. National Cancer Institute (of NIH), I was asked to comment on how this interest in a nutritional effect on cancer might be interpreted. Because this evidence inferred cancer prevention by plant foods, I chose the words "plant-based" to emphasize its empirical basis and to distinguish it from the animal rights motivation of vegetarianism. Shortly thereafter, when testifying in Federal Trade Commission hearings over a three-year period on health claims being made by the rapidly emerging nutrient supplement industry, I added the word "whole," thus giving the description "whole food, plant-based."

These nutrition benefits are not limited by geography or ethnicity; thus, the pleasurable flavors and foods associated with ethnic cuisines may be retained without compromising the nutritional effect. Very simply, individuals merely need to consume a variety of foods of plant origin, as much as possible in the whole food form. This advice is best considered as a goal, not as a mandate. Although sources of carbohydrates, as main sources of energy, vary among societies (rice, wheat, corn, white potatoes, sweet potatoes, or camote beets), these complex, natural carbohydrates generally provide very similar health benefits, notwithstanding allergy-related responses for certain individuals. Leafy (bok choy, sea vegetables, spinach, cabbage, broccoli, kale) and fruiting plant foods (fleshy fruits, seeds, nuts, etc.), virtually unlimited in variety, also possess the same health effects. Without confusing what is vegetable or fruit and what is grain or seed, it is far more important not to lose sight of the commonality of a variety of plant-derived foods, regardless of geography or ethnicity. This concept of nutrition is international in scope.

This proposal for a new concept of nutrition mostly concerns the association of nutrition with chronic degenerative diseases. I would be remiss, however, if I failed to consider a similar effect of nutrition on viral diseases, especially the COVID-19 pandemic. A recent report of ours[2] summarized correlations of nutrient risk factors with hepatitis B virus (HBV)-induced primary liver cancer, based on an observation of 8990 adults in rural China collected in 1989. When limiting the interpretation only to the highly significant cause–effect correlations ($p < 0.001$), consumption of more plant source foods associated with a higher HBV antibody prevalence, lower antigen prevalence, and lower disease mortality. In contrast, consumption of animal-based foods (average animal protein as a percentage of total diet calories was only about 10% of Western experience) associated with higher prevalence of HBV antigen (active virus), lower prevalence of HBV antibody, and higher liver cancer mortality. This effect of a cluster of highly significant associations all pointing in the same direction is unusually convincing.

In a separate HBV-transgenic mouse study, animal protein markedly increased hepatocellular carcinoma while decreasing circulating natural killer cells (T cells).[37] These findings, obtained more than three decades ago, suggest that even a relatively small quantity of animal-based foods is able to repress antibody prevalence (human study) and natural killer cell (T-cell) activity (animal study), while promoting liver cancer (animal and human studies). I suggested that this evidence, published in early 2021, might apply to COVID-19. A few months later, other researchers[3,4] showed a substantial decrease in COVID-19 disease severity for individuals using plant-rich diets. Over 90% of the COVID deaths occur in individuals over 65 years who are diagnosed with diseases readily prevented, even reversed, by this same plant-oriented diet. Cancer, cardiovascular diseases, chronic kidney disease, chronic lung diseases, diabetes mellitus, hypertension, immunosuppression, and obesity are the main co-morbid diseases.[55,56]

Although there are reports on nutrition in viral disease etiology and treatment, almost all concern individual nutrients, not the whole food nutrition presented here. An impressive commentary on immune system complexities was reported just prior to the COVID-19 pandemic, although it, too, chiefly focused on single nutrient effects.[5] Specific benefits may occur with nutrient supplements or nutrient-fortified foods, but it is likely that these effects will be short-lived, null, or even the reverse of that which occurs with whole foods.

Choosing the right food is critical for us to bring under control two colossal societal problems, personal health and its costs[6] and environmental and planetary destruction.[57] And in choosing the right food, we must collectively understand nutrition, for it is the scientific rationale for global warming, climate change, and environmental degradation. An increasing number of publications on the association of climate change with livestock production are now appearing, especially since the seminal 2009 report of Goodland and Anhang[58] at the World Bank, who estimated 51% or more of global warming as being caused by livestock production. Since then, others have affirmed that same estimate, even concluding that it may be as high as 87%.[59]

I recommend two sources of information impressively connecting the consumption of food with environmental problems. Dana Hunnes at University of California, Los Angeles[60] discusses a baffling array of several serious environmental problems. The public narrative usually accompanying information of this type is to assume specific causes of specific problems and in doing so, not to see the possibility of there being a common cause. Hunnes emphasizes livestock agriculture as being that common cause. Compared with plant-based agriculture, seven to ten times more land is required to produce an equivalent amount of food calories from animal-based agriculture[59] primarily to meet the widespread public demand, consciously or unconsciously, for consuming high-quality animal protein.

Rationalizing the consumption of animal food for its protein is a myth from at least two perspectives. First, animal protein is not high quality, and second, rationalizing consumption of animal food for its protein causes less consumption of disease-preventative whole plant-based foods, which further compromises our health and shortens our life expectancy.

My second recommendation is that of Jim Hicks, who succinctly and boldly emphasizes the association of environmental degradation with livestock agriculture in a series of so-called "SOS memos," now standing at 159. Hicks urgently describes in these memos[61] and in his books[62,63] the climate change disaster, especially emphasizing the distressing difficulty for authoritative individuals and institutions to take this matter seriously. Hicks's weekly SOS memos are a powerful and constant reminder of the urgency of this impending disaster.

In conclusion, I suggest that the concept of "lifestyle medicine" embrace a larger dimension than its sole reference to "medicine," which may give too much emphasis to pharmaceuticals. I suggest that improving our lifestyle should consider the effects of our eating habits not only on our personal health and its costs but also on our environmental surroundings. For many people, this is a growing concern, which can be a motivation for changing our lifestyle.

CLINICAL APPLICATIONS

- Consume a variety of plant-derived foods, available in all ethnic cuisines.
- Consume these foods in the whole food form, so that our body (Nature) can choose which nutrients to use.
- Permanently adopting this diet occurs only when sufficient time is allowed for taste adaptation, perhaps one to three months.
- As a first priority, consider using this diet to reverse (treat) many chronic degenerative diseases.
- Consider using this diet for physical performance as well as mental health.
- Limit use of added oil, refined sugar, and salt.
- Flavors and spices are acceptable.

12 The Health Benefits of Regular Physical Activity

James M. Rippe, MD

KEY POINTS

1. Regular physical activity is one of the most important things that individuals can participate in to improve their short- and long-term health and quality of life.
2. Increased physical activity lowers the risk of various chronic diseases and can also serve as an adjunct to treatment.
3. Increased physical activity plays crucial roles for individuals at all stages of their lives.
4. The Physical Activity Guidelines 2018 Scientific Report (PAGA 2018) provides an exhaustive and important summary for the benefits of physical activity for individuals at all stages of their lives and in various physical conditions. All clinicians should be familiar with this seminal document.
5. Physicians play a critically important role in urging their patients to make positive decisions in their lives concerning physical activity.
6. The central recommendation from the PAGA 2018 states that individuals should be encouraged to participate in 150 minutes of moderate to vigorous physical activity or more each week and strength training sessions twice a week with at least one day separating the two sessions.
7. Only 25% of individuals engage in regular physical activity necessary to meet the guidelines from the Centers for Disease Control (CDC), the American College of Sports Medicine (ACSM), and PAGA 2018.

12.1 INTRODUCTION

What individuals do in their daily lives profoundly impacts on short- and long-term health and quality of life. This is the essence and cornerstone of lifestyle medicine. These habits include regular physical activity, proper nutrition, weight management, avoiding tobacco products, stress reduction, adequate sleep, and many other practices. All of which we have put together in the discipline of "lifestyle medicine."[1]

Among the various important practices that individuals can perform in their daily lives, there is no single lifestyle habit or practice more powerfully associated with improved short- and long-term health and quality of life than regular physical activity. An enormous and compelling literature generated over the past few decades demonstrates that moderate to vigorous physical activity profoundly impacts the likelihood of developing chronic disease. Regular physical activity also exerts a uniquely powerful impact on quality of life.[2] In addition, regular physical activity has been found in multiple studies to play a role not only in the reduction and risk of chronic disease, but also as an adjunct and component of treatment.

For all of these reasons, physical activity is a cornerstone for the prevention and treatment of virtually every chronic metabolic disease. This is acknowledged in the guidelines of multiple professional organizations, including the American Heart Association (AHA),[3] American Academy of Pediatrics (AAP), American Diabetes Association (ADA),[4] PAGA 2018, and many others.[5–15] Regular physical activity is the cornerstone to the recommendations for Healthy People 2020[7] and also the Healthy People 2030 Guidelines.[8] The PAGA 2018 Scientific Report provides an enormous and compelling body of evidence for the multiple benefits of regular physical activity. These benefits extend throughout the lifespan and for multiple chronic diseases as well as issues related to quality of life. The American College of Sport Medicine (ACSM) has been a leader for many decades in this area.[9] The American College of Lifestyle Medicine (ACLM)[10] and the AHA[11] have also played significant roles in advocating more physical activity and have recommended physical activity as a key component of preserving health and improving quality of life.

Despite the enormous body of evidence now available concerning the positive relationship between physical activity and health, the medical community has been slow to embrace this concept as an important component of regular healthcare and counseling. It has been estimated that fewer than 40% of physicians regularly counsel their patients on the importance of regular physical activity.[12] This is a wasted opportunity, since over 70% of individuals see their primary care physician at least once a year.

The American public has also been slow to embrace the habit of regular physical activity. It has been estimated that fewer than 25% of adults in the United States meet the recommended levels of physical activity, which include 30 minutes of moderate to vigorous physical activity on most, if not all, days (accumulating at least 150 minutes of moderate intensity physical activity per week) and fitness based

DOI: 10.1201/9781003227793-15

in two sessions of musculoskeletal strength training each week.[13] These guidelines are recommended by virtually every major professional organization in the area of physical activity.

12.2 THE RELATIONSHIP BETWEEN MODERATE AND VIGOROUS PHYSICAL ACTIVITY AND THE RISK OF DEVELOPING CHRONIC DISEASE

Enormous data are available spanning a wide spectrum of chronic diseases showing that individuals who are physically active decrease their risk of these conditions compared with inactive individuals.[12] The PAGA 2018 provides a wealth of evidence related to chronic conditions showing the benefits of regular physical activity to both lower the risk of chronic disease and assist in its treatment. Some of these benefits occur after a single acute bout of physical activity. Others require a consistent increase of physical activity throughout the lifespan. Among the conditions where regular physical activity can benefit are cardiovascular disease (CVD), some cancers, diabetes (T2DM), dementia, brain health, and risk of falling and other injuries, particularly in older individuals.[2]

Importantly, the benefits of physical activity occur in children as young as 3 years old, continue all the way up through adolescence, and are prominent in adults, even individuals over the age of 65. A summary of the physical activity–related health benefits that are enumerated in the PAGA 2018 Scientific Report is found in Table 12.1.

There is also a strong relationship between increased physical activity and multiple aspects of improved quality of life. Individuals who are physically active have less anxiety, depression, and stress, in general, and feel better and sleep better.[2] All of these improvements result in higher quality of life for individuals who participate in regular physical activity.

The benefits of physical activity are so profound in lives that some investigators have likened physical activity to a "polypill" that contributes to virtually every aspect of health. These individuals have argued that if exercise were actually a pharmaceutical treatment, it would be impossible for the pharmaceutical industry to keep it in supply!

12.3 PHYSICAL ACTIVITY AND CHRONIC DISEASES

12.3.1 Cardiovascular Disease

Regular physical activity significantly reduces the risk of CVD and all-cause mortality.[14] As recommended by PAGA 2018 and various documents from the ACSM, AHA, and ACLM, the recommendation of 150 minutes of moderate intensity physical activity per week as well as two strength training sessions per week will substantially lower the risk of CVD and all-cause mortality, as depicted in Figure 12.1.

Further reductions in mortality are also available for individuals who engage in physical activity above 150 minutes per week, which is also indicated in Figure 12.1. It is important to point out, however, that even small amounts of physical activity can result in lowering both CVD and all-cause mortality. Also indicated in Figure 12.1, there is no lower threshold to the benefits of increased physical activity with regard to reduction of risk of all-cause mortality. Even individuals who engage in moderate or vigorous physical activity for as little as 30 minutes per week achieve a 20% reduction in cardiovascular disease.

Unfortunately, only 25% of adults meet the minimum recommendations from PAGA 2018 and CDC for over 150 minutes of moderate intensity physical activity per week. Young people are even less likely to follow the recommended standards. Fewer than 20% of adolescents perform the 60 minutes or more of daily physical activity recommended by the PAGA 2018.[13]

On the other end of the spectrum, individuals who participate in more than 150 minutes of physical activity per week can continue to achieve more reductions in the risk of CVD. However, the return on this additional investment of time is much less than for the first 150 minutes.

If individuals who are physically active are compared for risk of CVD with sedentary individuals, the sedentary individuals are at 150–240% higher risk. In addition, it should be noted that regular physical activity lowers the risk of adult weight gain and helps control high blood pressure, thus reducing the rate of hypertension.[2,16] Increasing amounts of physical activity also lower the risk of stroke and heart failure in a dose-dependent relationship.

Despite these known benefits, physicians have typically not emphasized the role of regular physical activity in reducing the risk of heart disease. In one survey of 175 primary care physicians, only 12% were aware of the recommendations from ACSM or PAGA 2018.[17] The relationship between physical activity and reduction of risk of heart disease is described in more detail in Chapter 21.

12.3.2 Physical Activity and Diabetes, Prediabetes, and the Metabolic Syndrome

Lifestyle modalities such as physical activity are the cornerstones of diabetes care. Recommendations for people with diabetes from PAGA 2018 are similar to those for reducing the risk of CVD.[3] The ADA also recommends that physical activity sessions should be at least 10 minutes with the goal of 30 minutes per day, or more, on most days of the week. These are somewhat more vigorous recommendations than those of PAGA 2018. Individuals with diabetes should also be encouraged to reduce time spent in sedentary activities such as working at a computer, watching T.V., or other activities while sitting or lying down (except sleep). There are good data on the association of sedentary activity with increased risk of diabetes.

According to the ADA Consensus Report on Physical Activity and Diabetes, prior to starting an exercise program,

TABLE 12.1

Physical Activity–Related Health Benefits for the General Population and Selected Populations Documented by the 2018 Physical Activity Guidelines Advisory Committee

Children	
3 to <6 years of age	**Improved bone health and weight status**
6 to 17 years of age	**Improved cognitive function (ages 6 to 13 years)**
	Improved cardiorespiratory and muscular fitness
	Improved bone health
	Improved cardiovascular risk factor status
	Improved weight status or adiposity
	Fewer symptoms of depression
Adults, all ages	
All-cause mortality	Lower risk
Cardiometabolic conditions	Lower cardiovascular incidence and mortality (including heart disease and stroke)
	Lower incidence of hypertension
	Lower incidence of type 2 diabetes
Cancer	Lower incidence of **bladder**, breast, colon, **endometrium**, **esophagus**, **kidney**, **stomach**, and **lung cancers**
Brain health	**Reduced risk of dementia**
	Improved cognitive function
	Improved cognitive function following bouts of aerobic activity
	Improved quality of life
	Improved sleep
	Reduced feelings of anxiety and depression in healthy people and in people with existing clinical syndromes
	Reduced incidences of depression
Weight status	**Reduced risk of excessive weight gain**
	Weight loss and the prevention of weight regain following initial weight loss when a sufficient dose of moderate to vigorous physical activity is attained
	An additive effect on weight loss when combined with moderate dietary restriction
Older adults	
Falls	Reduced incidence of falls
	Reduced incidence of fall-related injuries
Physical function	**Improved physical function in older adults with and without frailty**
Women who are pregnant or postpartum	
During pregnancy	**Reduced risk of excessive weight gain**
	Reduced risk of gestational diabetes
	No risk to fetus from moderate intensity physical activity
During postpartum	**Reduced risk of postpartum depression**
Individuals with pre-existing medical conditions	
Breast cancer	**Reduced risk of all-cause and breast cancer mortality**
Colorectal cancer	**Reduced risk of all-cause and colorectal cancer mortality**
Prostate cancer	**Reduced risk of prostate cancer mortality**
Osteoarthritis	**Decreased pain**
	Improved function and quality of life
Hypertension	**Reduced risk of progression of cardiovascular disease**
	Reduced risk of increased blood pressure over time
Type 2 diabetes	**Reduced risk of cardiovascular mortality**
	Reduced progression of disease indicators: hemoglobin A1c, blood pressure, blood lipids, and body mass index
Multiple sclerosis	**Improved walking**
	Improved physical fitness
Dementia	**Improved cognition**
Some conditions with impaired executive function (attention deficit hyperactivity disorder, schizophrenia, multiple sclerosis, Parkinson's disease, and stroke)	**Improved cognition**

Benefits in **bold** font are those added in 2018; benefits in normal font are those noted in the 2008 Scientific Report. Only outcomes with strong or moderate evidence of effect are included in the table.

Source: 2018 Physical Activity Guidelines Advisory Committee Scientific Report. Washington, DC. Part D: Integrating the Evidence. D5-6.

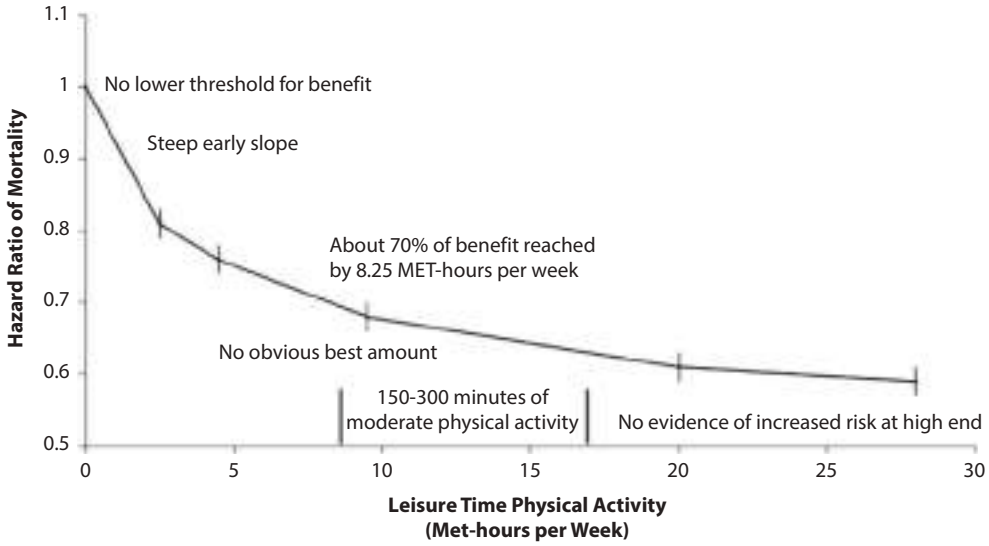

FIGURE 12.1 Relationship of moderate to vigorous physical activity to all-cause mortality with highlighted characteristics common to studies of this type. Source: All-cause Mortality, Cardiovascular Mortality, and Incident Cardiovascular Disease. Part F. Chapter 6. In 2018 Physical Activity Guidelines Advisory Committee Scientific Report. Washington, DC: U.S. Department of Health and Human Services, 2018.

medical providers should perform a history of cardiovascular risk factors in order to customize physical activity regimens for individual needs.[18] Both the ADA and PAGA 2018 provide detailed recommendations for physical activity in individuals with diabetes.

In addition, regular physical activity plays an important role in preventing pre-diabetes from turning into diabetes. The Diabetes Prevention Program (DPP)[19] as well as the Da Qing Study[20] and the Finnish Diabetes Prevention Study[21] all showed significant reductions in pre-diabetes turning into diabetes for individuals who are engaged in regular physical activity. In the DPP, individuals who were engaged in 150 minutes per week of physical activity and in addition, lost 7% of body weight lowered their risk of pre-diabetes advancing to diabetes by 58%. It should also be noted that in some studies, up to 80% of individuals over the age of 70 have pre-diabetes. Several studies have now suggested that only 9% of these individuals will proceed to develop diabetes over a seven-year period. These recent studies may influence the ADA in favor of even stronger recommendations of physical activity and some moderation in how pre-diabetes is treated.

The metabolic syndrome also benefits from increased physical activity. The metabolic syndrome is a cluster of metabolic abnormalities that significantly increases the risk of CVD.[22] Core interventions for the metabolic syndrome include regular physical activity at the same levels recommended for CVD and diabetes. In addition, following proper nutrition such as Dietary Approaches to Stop Hypertension (DASH) or Mediterranean or comparable diets is also recommended by the ADA. A detailed summary of physical activity and other lifestyle modalities for diabetes, pre-diabetes, and metabolic syndrome can be found in Chapter 20.

12.3.3 Physical Activity, Weight Gain, and Obesity

It is currently estimated that 73% of adults in the United States are either overweight (body mass index [BMI] ≥25 kg/m^2 to ≤30kg/m^2), obese (BMI ≥32 kg/m^2), or severely obese (BMI ≥35 kg/m^2).[23] Regular physical activity has been shown in numerous studies to reduce the likelihood of weight gain and is also vitally important for long-term maintenance of weight loss.[24,25] More detail on physical activity, weight gain, and obesity can be found in Chapter 20.

12.3.4 Physical Activity and Cancer

Numerous cancers have been linked to inactive lifestyle. Physical activity has been shown to play an important and positive role in lowering the risk of many cancers in the first place and helping in their treatment.[26] The PAGA 2018 Scientific Report has greatly expanded the literature for a number of cancers where there is strong evidence that increased physical activity can play multiple positive roles. Every clinician should discuss and prescribe physical activity to cancer patients in terms of the entire spectrum of their treatment. Physicians should also include counseling relative to reducing the risk of developing many cancers and discuss the benefits of physical activity with all patients.

Physicians may understand the role of physical activity in metabolic diseases such as CVD, diabetes, and T2DM. However, many physicians are not aware that regular physical activity can significantly reduce the likelihood of developing cancer. Other known lifestyle related preventable causes of cancer include tobacco use, alcohol intake, diet,

obesity, and behaviors that increase exposure to oncogenic viruses. The issue of various lifestyle modalities and their role in reduction of risk of cancer is discussed in detail in Chapters 21 through 23.

12.4 PHYSICAL ACTIVITY AND WOMEN'S HEALTH INCLUDING PREGNANCY

Physical activity is a vitally important lifestyle behavior for women throughout their lifespan. Guidelines from AHA, ASCM, PAGA 2018, and the American College of Obstetrics and Gynecology (ACOG) all recommend 30 minutes of moderate intensity physical activity on most days of the week[27] with the goal of accumulating 150 minutes of moderate intensity physical activity per week. Numerous studies have shown that women who engage in regular physical activity lower their risk of a variety of chronic diseases, including heart disease. For example, women who engage in exercise for 1.5 hours or more per week reduce their risk of heart disease by 30%. Multiple other studies have shown that similar reduction in the risk of heart disease and other chronic diseases occurs in women who are physically active.[28–30] More details about the relationship between regular physical activity and women's health may be found in Chapters 20 and 21.

12.5 PHYSICAL ACTIVITY AND ITS RELATIONSHIP TO BRAIN HEALTH AND COGNITION

As the population in the United States and other industrialized countries continues to grow older, finding cost effective ways of improving brain health and cognition assumes ever increasing importance. A significant relationship exists between physical activity and various aspects of cognition and brain health.[31] This relationship is often underestimated or ignored by physicians and patients.

Regular physical activity has been demonstrated to improve cognition and lower the risk of various forms of dementia, including Alzheimer's disease.[31] PAGA 2018, as well as the Presidential Advisory from AHA and the American Stroke Association (ASA), recommends increased physical activity as a key modality in improving brain health.

Regular physical activity improves sleep and has been demonstrated to reduce feelings of anxiety and depression in healthy people and also in those with significant affective symptoms. Both PAGA 2018 and the Presidential Advisory from AHA and ASA recommend physical activity as a modality for improving brain health. In fact, the AHA/ASA Presidential Advisory entitled "Optimizing Brain Health" includes physical activity as a key recommendation.[31] The relationship between physical activity and brain health has been demonstrated across a lifespan and is particularly important in a population over the age of 65, where there is an increasing prevalence of cognitive decline and dementia. Additional information in this area may be found in Chapter 20.

One theory for why physical activity is beneficial for brain health is that it helps establish cognitive reserve. This is discussed in more detail in Chapter 21. Researchers in the area of Alzheimer's disease have emphasized that regular physical activity should start well before the older years to reduce the likelihood of Alzheimer's disease. Increasingly, Alzheimer's disease is being regarded as at least somewhat a function of inflammation. This is one theory for why physical activity reduces the risk of Alzheimer's disease.

12.6 PHYSICAL ACTIVITY IN YOUTH

Physical activity results in multiple benefits for children. The 2008 Physical Activity Guidelines for Americans recommended 60 minutes of moderate intensity physical activity per day for children between the ages of 6 and 17.[32] This recommendation was expanded in PAGA 2018, since additional data were available to indicate that there are also benefits for children aged three to six.[2] In addition to lowering risk of heart disease and weight gain in children, physical activity has been demonstrated to improve bone health and weight. In addition, muscular fitness, cognitive function, and respiratory fitness are also improved in individuals aged 6–17 through regular physical activity. These issues are dealt with in more detail in Chapter 22.

12.7 PHYSICAL ACTIVITY IN OLDER ADULTS

Multiple benefits for older adults are derived from increased physical activity. Individuals in this age group are particularly susceptible to cognitive decline and dementia, both of which have been shown to be reduced in individuals who participate in regular physical activity.[33] Regular physical activity has also been demonstrated to result in decreased likelihood of falls and fall-related injuries. Aerobic physical activity and musculoskeletal strength are important as well as balance and flexibility exercises.[34,35] Recommendations from PAGA 2018 for obtaining 150 minutes of moderate intensity physical activity and two sessions of strength training per week also apply to individuals over the age of 65, although it may be necessary to modify these levels slightly depending on the current level of fitness of these individuals.

12.8 PHYSICAL ACTIVITY IN INDIVIDUALS WITH CHRONIC CONDITIONS

Regular physical activity has been associated with reduced risk of a variety of chronic conditions, including some cancers (e.g., breast cancer, colorectal cancer, prostate cancer), as well as improved quality of life and function in individuals with osteoarthritis.[26] The roles of regular physical activity in individuals with chronic conditions are discussed in multiple chapters throughout this book.

12.9 OVERCOMING SEDENTARY BEHAVIOR

Over the past decade, there has been increased scientific interest in data related to the increased risk of chronic disease from sedentary behavior. It is currently estimated that children and adults spend approximately 7.7 hours per day (55% of waking time) in sedentary pursuits. Sedentary behavior is also associated with increased risk of CVD, T2DM, obesity, and the metabolic syndrome. Of note, the highest risk of CVD occurs in individuals who are in the least active group and also get the least amount of physical activity. Individuals who participate in higher levels of physical activity can largely ameliorate the health risks of sedentary behavior.

12.10 THE ROLE OF PHYSICIANS IN PROMOTING INCREASED PHYSICAL ACTIVITY

Physicians are a trusted source of information. Physician counseling has been shown in a number of studies to play an important role in multiple, positive lifestyle behaviors, including physical activity, weight management, proper diet, and avoidance of tobacco. It is incumbent upon physicians to include these issues in every counseling visit with every patient.[36] Physicians should also take a leadership role in their communities, state, and nation in developing public policy that is friendly to these lifestyle endeavors. A more detailed discussion on ways to promote physical activity is found in Chapter 20.

12.11 EVALUATING PATIENTS FOR INCREASED PHYSICAL ACTIVITY AND PRESCRIBING INCREASED PHYSICAL ACTIVITY FOR HEALTHY INDIVIDUALS AND SPECIAL POPULATIONS

A variety of resources are available from multiple organizations, including the Exercise in Medicine Movement (EIM)[37] and ACSM, to assist physicians in evaluating individuals prior to recommending increased physical activity and providing exercise prescriptions both for the healthy population and for those with chronic disease. These tools are spelled out in considerable detail in Chapters 20 and 21. It should be noted that for normal intensity physical activity, a formal evaluation is often not necessary. PAGA 2018 emphasizes that it is important to remove barriers to getting people started on physical activity. However, this document also provides instances where evaluation from a physician who is knowledgeable about physical activity will be helpful for both the safety and the benefit of patients. This would be particularly true for older or very sedentary individuals and also with those who have either diabetes or a history of CVD.

My research team at Rippe Lifestyle Institute (RLI) has been routinely prescribing physical activity to our patients and research subjects for over 25 years. In this chapter, we will provide some background to the processes that we use.

12.12 PRE-PARTICIPATION SCREENING

Both the PAGA 2008 and 2018 make the important statement that in the area of physical activity, "some is better than none." Both of these guidelines and the ACSM recommend that clinicians have a discussion on physical activity with every patient and make it as easy as possible for individuals to become physically active. A good way to start this discussion is to utilize a Two-Question Questionnaire that is supported by the U.S. National Physical Activity Plan and the EIM initiative. Tools to inaugurate this discussion were developed at Stanford University and involve asking the following two questions:

- On average, how many days per week do you engage in moderate or strenuous physical activity (like a brisk walk)?
- On average, how many minutes do you engage in exercise at this level?

Answers to these two questions will give a clinician a good place to start to help individuals gradually increase their physical activity and ultimately achieve guidelines from the PAGA 2018 Scientific Report and the CDC as well as the AHA. More detailed tests are available for people who need more extensive pre-evaluation testing. These are discussed in multiple chapters throughout the book, including Chapters 20 and 21.

12.13 PRINCIPLES OF EXERCISE PRESCRIPTION

The framework that ACSM has developed for exercise prescription goes by the acronym "FITT":[38]

- Frequency
- Intensity
- Time
- Type

It should be emphasized, however, that this framework would be more relevant for individuals who have previously been sedentary and simply want to obtain more physical activity in their lives. A counseling session during the regular clinical visit with a physician should suffice for these individuals. Clinical judgement will determine if more precise exercise prescription is necessary. There are also professionals who can help in this, such as exercise physiologists.

12.14 AEROBIC PHYSICAL ACTIVITY/ EXERCISE PRESCRIPTION

Aerobic physical activity is defined as those activities that require oxygen to provide energy. These activities typically

involve large muscle groups, which are used in repeated rhythmic fashion. While there are many forms of physical activity that can certainly be included in this area of "aerobic activity," the most common form is walking. Recent advances in technology have given us the ability to prescribe this type of physical activity with more precision than we had in the past. Even though the PAGA 2018 Scientific Report recommends individuals to participate in 150 minutes of aerobic physical activity per week, individuals who have been sedentary and who want to start at a lower level and work up slowly should be encouraged. Remember to emphasize the mantra "some is better than none."

As already indicated, walking is the most popular form of aerobic physical activity. When physicians are asked about what kind of physical activity they would recommend for their patients, over 90% say walking. My laboratory at RLI has been a leading source of walking research for the past 25 years. In fact, we coined the term "Fitness Walking" with the publication of our first book by that name in the early 1980s.[39] My team and I at RLI have published extensively in the walking literature and have written five books on walking, which are available through my Amazon book page. Of course, there are many other forms of aerobic activities, such as stationary cycling or swimming. PAGA 2018 recommends activities that are low impact and less likely to cause injuries than, for example, contact sports.

12.15 MUSCULAR FITNESS

Muscular fitness is also an important component of physical activity for a variety of reasons. Improving muscle fitness can reduce the risk of injuries during activities of daily living as well as helping to maintain balance and the ability to safely perform all types of physical activity. To improve muscle fitness, a good place to start is to recommend patients seek professional guidance, which may be available from a certified fitness trainer or health club or YMCA. The highest levels of fitness trainers also carry a fitness training certification from the ACSM. When working on muscular fitness, it is important to include exercises involving all the major muscle groups. A trained fitness professional can take their patients through the way to perform these exercises safely. PAGA 2018 recommends two sessions of musculoskeletal strength training per week separated by at least one day. Unfortunately, only about 10% of adults engage in regular muscular training.

12.16 FLEXIBILITY

Flexibility is the ability of a joint to move through a whole range of motion. This is an important part of an overall, comprehensive program for physical activity. It is particularly important for the aging population, since lack of use and the aging process itself can lower this parameter. We at RLI typically recommend flexibility programs for all individuals whom we see in our clinic or research facility.

Flexibility is also highlighted in multiple ways in multiple publications and the PAGA 2018 Scientific Report. We typically recommend to individuals that they utilize their stretching program both before and after exercise in order to also focus on mind/body issues.

12.17 BALANCE

Balance is a very important part of an overall plan for physical activity, and balance exercises should be a component of the exercise prescription. This is particularly important for older individuals. Improved balance can be built either by utilizing specific balance exercises or by increasing physical activity and muscular fitness. A wide variety of balance exercises is also available through various ACSM publications.

12.18 MIND/BODY APPROACHES

There has been an increasing emphasis in exercise prescriptions on recognizing the interactions between mind and body. This is a powerful way of helping people understand that there are both multiple health and fitness benefits as well as psychological benefits from increased physical activity. This topic is so important that we have devoted an entire chapter to mind/body strategies. (See Chapter 30.)

12.19 DURATION OF WORKOUT

For many years, it was thought that the duration of physical activity needed to be at least 30 minutes per session to achieve maximum benefits. This was reduced to 10 minutes per session in the 1980s in a Position Statement from the ACSM and by the American Medical Association in 1995.[40] However, the publication of PAGA 2018 reports that any duration of physical activity can yield important benefits. It is important to emphasize to patients who have been sedentary that such strategies as taking the stairs at work or walking across the parking lot when shopping can all add up to increased levels of physical activity. Many people have utilized fitness tracking devices to determine the number of steps that they take each day with the goal of achieving 10,000 steps.

12.20 SPECIAL POPULATIONS

Some modifications for physical activity programs may be necessary for special populations. The general guidance from PAGA 2018, however, remains for individuals to attempt to accumulate 150 minutes of moderate intensity physical activity per week. Special population groups include pregnant individuals, cancer survivors, older individuals, overweight individuals, and many other populations. Recommendations for each of these are handled in separate chapters in this book.

12.21 EXERCISE ADHERENCE

Some benefits of physical activity occur immediately following each session. Most of the long-term benefits, particularly with regard to reduction of risk of chronic diseases, accrue to individuals who stay with an exercise program for a lifetime. We have developed a strategy for helping people stick with their exercise programs. The last section of this chapter details the tips we have developed.

12.22 TIPS FOR STARTING AND STAYING WITH A PROGRAM OF REGULAR PHYSICAL ACTIVITY

Over the years, we at RLI have developed a list of tips to help people stay with their exercise program. The key is to find forms of exercise that are low in injury, involve socialization, and are enjoyable. Here is a brief list that we often give to individuals who are either just starting or having trouble staying with an exercise program:

- Exercise with others
- Establish a specific time and place
- Find an activity you enjoy
- Keep a journal
- Enlist the support of family and friends
- Set realistic goals
- Purchase appropriate equipment
- Vary your exercise routines
- Chose forms of exercise that are low in injury potential
- Upgrade your fitness program as you progress
- Reward yourself

12.23 PUBLIC HEALTH CONSIDERATIONS

Regular physical activity is, of course, very important for every individual. However, there are often issues that involve public health considerations, which can be beneficial to people who are trying to increase their exercise program and either facilitate or discourage people from physical activity. Many health clubs and YMCAs offer specific exercise programs for either older adults, youths, healthy adults, or individuals with specific medical needs. The community can be involved in the built environment and facilitating types of facilities, such as parks and trails, that will encourage people to become involved in increased physical activity. New technologies, such as wearable activity trackers and web based internet, can also enhance the likelihood of increased physical activity. These factors are all discussed in more detail in Chapter 20. Physician leadership in all of these areas will facilitate more community involvement and is an important part of the patient healthcare provider role.

12.24 STEPS IN PROMOTING REGULAR PHYSICAL ACTIVITY

A number of factors that involve not only the individual but also the community and the environment impact on the likelihood of people starting and staying with an exercise and physical activity program. These factors are discussed in more detail in Chapter 20.

12.25 CONCLUSIONS

Physical activity plays a critically important role in enhancing the health of individuals and communities in the United States and other countries. The multiple benefits of physical activity are applicable to the entire age range and involve healthy individuals as well as individuals with chronic conditions. Increased physical activity is one of the most powerful mechanisms that all physicians can recommend to their patients to improve their health. Multiple chapters throughout this book will discuss specific aspects of physical activity and how to prescribe it for both healthy individuals and special populations.

CLINICAL APPLICATIONS

Physician recommendation is a powerful motivator to help people improve their lifestyle in multiple areas, including physical activity.

Physicians should recommend increased physical activity to all patients.

Physical activity not only plays an important role in decreasing the risk of chronic diseases, but also serves as an adjunct to their treatment.

Physical activity plays an important role in improving quality of life for individuals.

Counseling on physical activity and its benefits should be a routine part of every physician encounter with patients.

13 Implementation of the Exercise Prescription

Rachele M. Pojednic, PhD, EdM, FACSM and
Jennifer L. Trilk, PhD, FACSM, DipACLM

KEY POINTS

- Physician-directed implementation of the exercise prescription is effective in helping patients make long-term lifestyle changes.
- Exercise and physical activity referral networks are not currently being utilized effectively, but successful strategies and programs have been identified and can be used as models for the future.
- Healthcare professionals can learn effective exercise and physical activity referral practices and implement them in clinical practice.
- Personal trainers, exercise physiologists, physical therapists, and health coaches can be important members of a physician's referral network.

13.1 INTRODUCTION

Substantial evidence supports the efficacy of clinician-initiated physical activity counseling, prescription, and referral, which has led to the recommendation of exercise being considered a standard component of clinical care in healthcare settings.[1,2] Physical activity assessment in clinical settings is feasible and valid,[3] and for the first time, the scientific report of the Physical Activity Guidelines for Americans 2018 concluded that "the primary care setting may be an appealing venue for offering physical activity counseling or referral and represents a scalable opportunity to influence population-level physical activity if effective approaches can be implemented."[4] Research strongly shows that exercise prescription and referral to exercise professionals is effective in helping patients make long-term lifestyle changes.[5–7] To that end, physical activity counseling has a United States Preventive Services Task Force (USPSTF) Level of Evidence B recommendation,[8] and physical activity and nutrition counseling must be included in new health plans under the Affordable Care Act's Prevention and Health Promotion activities for populations at increased risk of cardiovascular disease.

The Physical Activity and Health Innovation Collaborative (PA IC) of the National Academies of Sciences, Engineering and Medicine has specifically called upon healthcare settings to expand the use of the physical activity vital sign (PAVS)[9] within the scope of electronic health records.[10] The best current evidence suggests that the three-question PAVS and the two-question Exercise Vital Sign can ascertain compliance with the PA Guidelines and take less than one minute to administer.[3,11] Importantly, these assessment tools are scientifically sound and often lead to clinician-directed PA counseling and/or referral, which results in improvements in patients' physical activity.[12]

While all healthcare providers should be educated on implementing counseling, prescription, and referral practices,[13], physicians specifically, are beginning to answer the call and are successfully including exercise counseling in their practices.[1, 14] However, there are still inconsistencies in exercise counseling and referral practices in the healthcare setting.[15] This is due, in part, to a research-to-practice gap in scalable practices to guide the integration between the healthcare and fitness sectors.[15,16] This chapter will identify challenges to implementing exercise referral systems as well as successful real-world models of the exercise prescription. It will further outline the range of trained exercise professionals who serve as the providers ready to implement the exercise prescription.

13.1.1 Challenges to Implementing the Exercise Prescription

Clinicians and healthcare providers agree that exercise is powerful medicine and that exercise prescriptions can be an effective strategy to increase physical activity in the clinical population. While a robust referral network should connect clinicians and trained exercise professionals,[17] scalable systems bridging the gap between these professionals remains elusive, and several perceived barriers to integration exist. Roughly 50% of physicians believe[18] that they play an important role in promoting exercise to their patients, yet also reported that only 20% of patients or fewer were provided with an exercise prescription. Approximately one-quarter of physicians did not refer patients to exercise professionals because they were not adequately informed about the local exercise facilities available,[18] and fewer than 20% of physicians collaborated with exercise professionals. This is despite the fact that nearly 75% of physicians expressed interest in such a partnership if it were available to them.[18] Moreover, although physicians reported being familiar with health clubs and generally believed health clubs to be an appropriate venue for their patients,[19] fewer

DOI: 10.1201/9781003227793-16

than half of the physicians recommended health clubs to their patients.[16] Lastly, clinicians believed that access to and cost of health clubs and personal trainers present an important barrier to their patients.[16]

While barriers perceived by individual physicians, exercise professionals, and patients present challenges to implementation, there are also institutional barriers to consider. In a recent review of over 50 research articles examining implementation barriers to integrating exercise into real-world cancer care, 243 barriers were identified across all levels of the healthcare system,[20] with nearly 40% of barriers existing at the organizational level. Lack of structures to support exercise integration and absence of staff/resources to facilitate delivery were among the most common issues reported.

Given that several obstacles make implementation of the exercise prescription and referral process difficult, it is important to take a closer look at current successful systems in place for effective referral. Specifically, it is critical that the roles of exercise professionals as well as successful community programs are examined, and that systems are understood and best practices followed. Indeed, clinical counseling, prescription, and referral to an exercise specialist can result in increased physical activity for patients who are insufficiently active.[17,21] It is important to note, however, that these systems are only just emerging and leave much room for expansion and improvement.

13.1.2 Exercise Professionals Ready to Implement Exercise Prescriptions

13.1.2.1 Personal Trainer

A certified personal trainer (CPT) is a fitness professional who works with mostly healthy individuals to achieve their exercise goals.[22] The job entails conducting fitness evaluations and creating performance programs for clients. Various assessments can and should be done in order to design a proper fitness plan, including, but not limited to, a preparticipation screening, submaximal aerobic exercise test, and muscular, flexibility, and body composition tests. Using such information will help the personal trainer develop appropriate cardiorespiratory, strength and conditioning, and stretching programs. These professionals also promote positive health behavior and motivate their clients.

According to the Institute for Credentialing Excellence, there are 12 personal trainer certifying organizations accredited by the National Commission of Certifying Agencies (NCCA) (Institute for Credentialing).[23] Among the organizations offering a CPT certification are the American College of Sports Medicine (ACSM), the National Academy of Sports Medicine (NASM), the National Strength and Conditioning Association (NSCA), and the American Council on Exercise (ACE). Within these organizations, additional certifications may be offered for specific areas of expertise. For example, in addition to the CPT certification, NSCA offers a Certified Strength and Conditioning Specialist (CSCS) certification, and ACSM offers an Exercise Is Medicine® (EIM) credential.

CPTs generally work at gyms, in fitness and community centers, and in corporate wellness programs. In addition to CPTs, Group Exercise Instructors (GEI) play an integral role in fitness facilities.

Currently, there is no standardized process for physicians to refer patients to a CPT. However, ACSM created an exercise referral model through the EIM® initiative (see later).[24] In an effort to help connect primary care practitioners (PCPs) with CPTs and to deliver physical activity prescriptions, EIM® also created an exercise professional credential. Anyone who holds an NCCA accredited fitness professional credential is eligible to obtain the EIM® credential.[25] In addition, the ACE offers an NCAA-accredited Certified Medical Exercise Specialist credential,[26] which was created to help train CPTs to create programs for clients with a range of medical conditions. ACE Certified Medical Exercise Specialists must hold a bachelor's degree in exercise science or a related field and have completed 500 hours of work experience designing and implementing exercise programs for apparently healthy individuals and/or high-risk individuals.

13.1.2.2 Exercise Physiologist

An exercise physiologist is a health professional who helps diagnose and treat a number of diseases through exercise. They work with clients and/or patients to provide exercise prescriptions based on health history and physical assessment.[22] Common areas of focus include cardiovascular, pulmonary, and metabolic diseases. Exercise physiologists can work in a number of settings—both clinical and nonclinical. Weight management and obesity are other traditional areas where exercise physiologists may be employed, while cancer care is a growing specialty for exercise physiologists.[27] In addition to hospitals and clinics, exercise physiologists can work in fitness and wellness centers as well as corporate, government, and university settings.[28]

In the United States, there are currently two certifications for exercise physiologists, each of which requires a minimum of a bachelor's degree. The ACSM offers exams for the certified exercise physiologist (ACSM-EP) and the certified clinical exercise physiologist (ACSM-CEP).[28] While it is not necessarily required for exercise physiologists to obtain a certification, many employers do require it.

One of the most popular areas of the exercise physiology profession is cardiac rehabilitation. According to the Clinical Exercise Physiology Association (CEPA), approximately 45% of exercise physiologists work in cardiac rehabilitation.[29] Even though cardiac rehabilitation is one of the largest venues for exercise physiologists, there is evidence that it is not being used enough. According to the American Heart Association, "[D]espite being recommended by guidelines, rates of referral to cardiac rehabilitation are historically suboptimal."[30] Referral rates depend highly on procedure type and where the procedure was performed, as some institutions and/or departments vary.

13.1.2.3 Physical Therapist

According to the American Physical Therapy Association (APTA), the role of a physical therapist (PT) is to "examine each individual and develop a plan using treatment techniques to promote the ability to move, reduce pain, restore function, and prevent disability."[31] The PT profession also involves working with patients in a preventive manner, as this can help prevent the loss of mobility before it occurs through the development of an exercise program. Much like an exercise physiologist, a PT's job begins with a patient assessment or evaluation. This includes taking a medical history and performing tests and measures to identify problems, both existing and potential. After a general review is conducted, PTs use the gathered information to design and implement a plan of care.

In the United States, the education requirement for PTs is a Doctorate of Physical Therapy (DPT).[31] In addition to obtaining a degree, PTs must pass a state licensure exam. PTs work in a variety of settings, including, but not limited to, outpatient clinics and offices, inpatient rehabilitation facilities, home care, research institutes, hospices, fitness centers, and sports training facilities. The American Board of Physical Therapy Specialties (ABPTS) offers several certifications for PTs. The following are areas of specialization: cardiovascular and pulmonary, clinical electrophysiology, geriatrics, neurology, oncology, orthopedics, pediatrics, sports physical therapy, and women's health. Though a certification is not required to work in any particular field, the goal of ABPTS is to promote high-quality physical therapy through acknowledging the knowledge and skill of specialty areas.[32] A referral to PT is typically required under most insurance companies.

While physical therapy is often seen as a rehabilitation profession, the job function of a PT includes preventive aspects. PTs are not only an excellent resource for prevention of injury but are also in a good position to promote a physically active lifestyle. As reported by the APTA, PTs are knowledgeable and skilled professionals who can provide non-treatment physical activity advice.[33] As they are easily accessible to a number of populations, they could have a more predominant role in public health.

13.1.2.4 Health Coach

A health coach is a certified professional trained in patient-/client-centered behavior change who can work in concert with the exercise professional to implement the exercise prescription. Typically, health coaches work with individuals to facilitate healthy lifestyle changes like achieving adequate physical activity, improved nutrition, smoking cessation, and stress reduction. While health coaches do not diagnose conditions, prescribe treatments like exercise, or provide psychological interventions, they are able to work with individuals to provide guidance and personalized motivation to create behavior change strategies and goal setting. Specifically, health coaches "assist clients to use their insight, personal strengths and resources, goal setting, action steps and accountability toward healthy lifestyle change."[34] Often, health coaches will hold multiple certifications or even content-relevant degrees (e.g., Exercise Science or Nutrition) that aid in their practice. In 2017, the National Board of Health and Wellness Coaches (NBHWC) was formed, in partnership with the National Medical Examining Board, to develop an accredited certification, the National Board Certified Health & Wellness Coach (NBC-HWC).[34] Coaches are often self-employed but can also work at gyms, in fitness and community centers, and in corporate wellness programs, and are also becoming part of integrated care teams in some healthcare settings. Currently, there is no standardized process for physicians to refer patients to a health coach, although there are programs approved by the American Medical Association (AMA) for direct referral and reimbursement being implemented for NBH-HWCs in the Department of Veteran's Affairs.[35]

13.1.3 Successful Programs

Programs for the successful implementation of the exercise prescription can be brief or highly comprehensive. This section will examine evidence-based strategies to engage patients, from utilizing systems as simple as referral guides to cultivating an entire hospital-wide referral scheme.

13.1.3.1 Referral Guides

A straightforward and effective strategy to use limited clinical time for exercise referral may simply be to refer patients to a list of regionally offered community programs. Indeed, many community departments and health agencies have collected local information to develop resource collections, with the goal of increasing provider awareness of the scope and array of existing community resources. These resource collections can be utilized as referral guides to provide contact information to patients in electronic or paper form. Some clinicians have demonstrated concerns over the simplicity and usefulness of referral guides[36] and emphasize that the guides (1) do not eliminate the need for individualized counseling, (2) must be updated frequently, and (3) may provide information about programs unfamiliar to the practitioners. However, when utilized in practice, referral guides have actually been shown to be effective and can be helpful because "providing patients with specific activity suggestions was more effective than providing general advice in facilitating behavior change."[36] Moreover, as technology advances, there is the opportunity to utilize smartphone applications in conjunction with, or in addition to, referral guides in order to provide up-to-date and personalized recommendations.

13.1.3.2 Physical Activity Vital Sign (PAVS)

The PAVS can be used individually by providers in healthcare settings and has begun to be added to electronic health records.[10] PAVS was created by investigators at the Department of Family and Preventive Medicine at the University of Utah, Salt Lake City, Utah, to implement

in family medicine clinics in the Utah Health Research Network, and can be administered in <30 seconds.[11] The best current evidence suggests that the three-question PAVS can ascertain compliance with the Physical Activity Guidelines for Americans.[3] Importantly, these assessment tools are scientifically sound and often lead to clinician-directed PA counseling and/or referral, which results in improvements in patients' physical activity.[12]

The PAVS consists of two specific questions:[9,11]

1. On average, how many days per week do you engage in moderate to vigorous physical activity (like a brisk walk)? ____days
2. On average, how many minutes do you engage in physical activity at this level? ____minutes
   Total minutes per week of physical activity (multiply #1 by #2) ____minutes per week
   A third question can be added, and ACSM EIM® suggests:[24]
3. How many days a week do you perform muscle strengthening exercises, such as bodyweight exercises or resistance training? ____days

13.1.3.3 Diabetes Prevention Program for Patients with Prediabetes

Proven to be successful in preventing the onset of type 2 diabetes, the Diabetes Prevention Program (DPP) is an evidence-based program available nationwide that physicians can easily refer patients to. It is generally a 12-month program in which participants attend 16 weekly core sessions and are subsequently followed month to month through regular maintenance sessions. The goal of the DPP is to help individuals with prediabetes prevent the onset of type 2 diabetes by making better food choices, increasing their level of physical activity, and losing excess weight. DPP programs have been shown to be twice as effective as approaches that are less structured.[37,38]

According to the AMA[39] website, the AMA and the Centers for Disease Control (CDC) recommend that physicians take measures to prevent diabetes in their patients by screening them for prediabetes and referring them to the DPP if positive. The CDC website provides a list of available DPP programs across the nation, which physicians can access at any time. To address the barrier of insufficient finances, many DPPs are now covered through Medicare and other health insurance providers, thus making the referral process easier and providing even more incentive to patients.

The YMCA DPP[40] is one example of a program that physicians can easily refer patients to. There are more than 200 YMCA sites throughout the country that run the DPP, and there is a large body of evidence supporting the program's effectiveness.[37] For instance, an existing partnership between the YMCA, UnitedHealth Group, and the CDC brought the DPP to nearly 30,000 participants in more than 1,000 locations across the country.[37]

13.1.3.4 SilverSneakers and Enhance Fitness for Older Adults

SilverSneakers is a no-cost gym membership for eligible seniors to which physicians can refer patients.[41] Targeted toward older adults, ages 65 and up, this is a fitness program covered by many Medicare Advantage plans. Participants receive access to more than 15,000 gyms and fitness centers in the network in addition to online and streaming classes, and membership includes fitness classes by SilverSneakers trained instructors.

Enhance Fitness (EF) is a nationally disseminated program for older adults that offers group-based exercise classes in community settings.[42] Each class lasts 1 hour and follows a set format, including exercises targeting cardiovascular endurance (20–25 min), strength (20 min), and balance and flexibility (10 min), all of which are adaptable to individual ability level. While EF is not covered by Medicare, it is often subsidized by and integrated into healthcare systems.

Programs like SilverSneakers and EF have demonstrated positive benefits on overall physical function as well as fall prevention in older adults.[43] In addition to increased fitness and fall prevention, these programs have also been shown to be significant healthcare cost–saving programs.[44, 45]

13.1.3.5 American College of Sports Medicine's Exercise Is Medicine® Model

In 2015, the ACSM developed a multi-component conceptual model, called Exercise Is Medicine® (EIM),[24] for healthcare settings to integrate PA assessment and prescription as a part of their clinical workflow, and refer patients to evidence-based PA programs.[1,24] The EIM® model is designed to improve the reach of evidence-based PA interventions by identifying and engaging patients who would benefit from increased PA. The individual components of the EIM® model include: 1) assessing PA levels of patients, 2) providing brief PA counseling and/or a PA prescription, and 3) referring patients to PA resources for further guidance. Individual components of the EIM® model have been deployed in U.S. and international health settings, demonstrating moderate-to-strong evidence bases for PA assessment,[9,46–50] prescription,[51–53] and referral.[54–56]

To date, the largest implementer of the EIM® model is Exercise Is Medicine Greenville® (EIMG®; www.EIMGreenville.org).[57] In 2016, the University of South Carolina School of Medicine Greenville, Prisma Health System, and the YMCA of Greenville, educated by the EIM® conceptual model, designed and implemented a clinic-to-community program to comprehensively integrate PA across multiple primary care practices, connecting patients to evidence-informed PA programs delivered in community settings. With 8 inpatient hospitals and more than 100 outpatient facilities and affiliated doctor offices,[58] Prisma Health is the first and largest health system in the United States committed to a multi-level process of implementation of PA by integrating all EIM® model components

into their clinical workflow and connecting patients with chronic diseases to community-based PA programs.[57] EIMG® is the first full-scale example of an initiative bringing together medical practitioners, clinical staff, health system administrators, health behavior researchers, public health and exercise professionals, and patients from diverse backgrounds around PA promotion.

Prisma Health clinics receive standardized onboard training to: 1) assess PA levels at the clinic visit and identify EIMG®-eligible patients, 2) provide patient education on the benefits of PA using the ACSM's Prescription for Health Series, and 3) initiate an electronic referral process through the health system's EPIC electronic health records to the EIMG® referral team, who subsequently connect Prisma Health patients to participating YMCAs to implement the exercise prescription. Patients are eligible for engagement in EIMG® at participating Prisma Health clinics if they are between the ages of 18 and 80, are physically inactive (<150 minutes per week of moderate intensity aerobic activity) or have a chronic condition (i.e., overweight/obese, hypertension, type 2 diabetes, stable heart disease) that is positively impacted by PA. Referred patients are guided by EIMG®-qualified and credentialed exercise professionals through a 12-week evidence-informed PA program. Through EIMG®, patients with lifestyle-related chronic disease learn how to reduce their risks and improve their overall health by adopting healthy behaviors that include exercise and movement. In order to ensure long-term success, upon completion of the 12-week program, participants are encouraged to continue in EIM® in the maintenance program. There is an individual cost for the program ($249 for the 12-week program, which includes membership to the PA facility) that currently is not covered by Medicaid.

The YMCAs of Greenville understand that EIMG® will only succeed as a population health strategy if it is affordable and delivered equitably. Therefore, the YMCA of Greenville provides substantive in-kind support for operations of the program, as well as securing a percentage of their annual giving campaign to EIMG® so that no patient is turned away due to their inability to pay. To date, >$300,000 has been set aside for patient scholarships, a model that can be replicated by other YMCAs and communities outside of Greenville, SC. Between 2017 and 2019, 70%, 57%, and 73% of patients each year received scholarships covering 5–100% of the costs to participate in the 12-week PA program.[59]

Preliminary results published from EIMG® demonstrated that from 2016 to 2019, 210 patients completed the program (>60% graduation rate). Also, patients diagnosed with hypertension receiving usual care who were referred by their HCP and graduated from the program decreased body weight ($p = 0.001$) and systolic and diastolic BP ($p < 0.001$), and were highly satisfied (>4 on a 5-point Likert scale) with the program and personnel.[59]

13.2 SUMMARY

Physicians generally view exercise as an important component of a healthy lifestyle and have begun to use physical activity vital signs and exercise prescriptions in their practices. Still, data indicate that only 20–30% of physicians are actively prescribing physical activity, signaling room for improvement. Barriers to implementation of the exercise prescription do exist, including time, knowledge of programming, and professionals. However, these barriers can be overcome with simple clinical strategies and a robust referral network. Physical activity and exercise professionals such as personal trainers, exercise physiologists, physical therapists, and health coaches are trained to work with patients to implement physical activity and exercise prescriptions, as noted in Table 13.1. Moreover, there are several clinic-based strategies, such as referral guides and referral to community-based programming, that can be utilized to educate and encourage patients to implement, or "fill," their own exercise prescriptions. While writing the physical activity or exercise prescription falls in the

TABLE 13.1
Physical Activity and Exercise Professionals

Physical activity professional	Target population	Reason for referral
Personal trainer	Non-specific	Works with individuals to achieve their exercise goals. Conducts fitness evaluations and creates performance programs for clients. Uses various assessments to design an appropriate fitness plan. Promotes positive health behavior and motivates clients.
Exercise physiologist	Non-specific	Helps diagnose and treat a number of diseases through exercise in either a clinical or a nonclinical setting. Works with individuals to provide exercise prescription based on health history and physical assessment.
Physical therapist	Non-specific	Examines individuals and develops a plan using treatment techniques to improve the ability to move, reduce pain, restore function, and prevent disability. Works with patients in a preventive manner in order to prevent the loss of mobility before it occurs. Based on various assessments and tests, PTs use the gathered information to design a plan of care.
Health coach	Non-specific	Works with individuals to facilitate healthy lifestyle changes like achieving adequate physical activity, improved nutrition, smoking cessation, and stress reduction. Provides guidance and personalized motivation to create behavior change strategies and goal setting.

purview of the physician, practical execution relies on a robust network of systems and professionals designed to support patient engagement and behavior change. Creating these networks is critical for the successful implementation and future of the use of physician-directed exercise prescriptions.

CLINICAL APPLICATIONS

- Physicians generally view exercise as an important component of a healthy lifestyle and have begun to use physical activity vital signs and exercise prescription in their practices.
- Barriers to prescribing exercise exist, including time, knowledge of programming, and professionals.
- Barriers can be overcome with simple clinical strategies and a robust referral network.
- Clinic-based strategies of implementation can include referral guides and referral to community-based programming that can be utilized to educate and encourage patients to "fill" exercise prescriptions.

14 The Role of Physicians in Promoting and Prescribing Increases in Physical Activity

James M. Rippe, MD

KEY POINTS

1. Physician counseling has been repeatedly demonstrated to be one of the most powerful motivators for encouraging patients to make positive lifestyle decisions.
2. Unfortunately, fewer than 40% of physicians counsel their patients about physical activity.
3. Since >70% of individuals see their primary care physician at least once a year, there is a great opportunity to increase the likelihood of patients engaging in physical activity levels.
4. Currently, less than 25% of the adult population meets the recommended levels of physical activity in the Physical Activity Guidelines for Americans 2018 Scientific Report.
5. Physician recommendation for physical activity should include aerobic exercise, strength training, balance, and flexibility.
6. Increased physical activity levels among physicians themselves can yield a variety of personal health benefits and also increase the likelihood that they will counsel their patients about physical activity.

14.1 INTRODUCTION

There is no longer any serious question that regular physical activity yields multiple benefits for both short- and long-term health and quality of life.[1] Regular physical activity significantly reduces risk factors for many chronic diseases, including cardiovascular disease (CVD), type 2 diabetes (T2DM), some cancers, metabolic syndrome, and many other conditions.[1,2] Regular physical activity also serves as an important component of the treatment of many chronic diseases. Virtually every professional organization includes physical activity as a key, evidence based guideline for both prevention and treatment of chronic diseases.[3]

As a cardiologist and lifelong exerciser, I am both professionally and personally committed to regular physical activity. In addition, my research organization, Rippe Lifestyle Institute (RLI), has included regular physical activity as a key component of virtually every study that we have performed over the last 25 years and every patient we have seen in our clinic. Regular physical activity is also a key component that we have combined with other lifestyle factors in our various lifestyle medicine publications. For these reasons, I feel very strongly that there are both academic and personal reasons why every physician should include promotion and prescription of regular physical activity in every office visit.

Even though there are well-documented benefits for physical activity, unfortunately, the medical community has not been as active as it should have been in the promotion and prescription of regular physical activity. In fact, a number of studies have shown that 40% or fewer of physicians include discussion of physical activity in office visits with patients.[4]

It has been a struggle to get people to engage in meaningful amounts of physical activity. It has been estimated that 75% of adults in the United States do not meet current physical activity guidelines promulgated by the Physical Activity Guidelines for Americans (PAGA) 2018 (Figure 14.1).

Adolescents also are not obtaining enough physical activity. In addition to the known benefits of regular physical activity, increasing evidence exists now that an inactive lifestyle contributes to multiple, long-term, adverse health consequences. The World Health Organization (WHO) ranked physical inactivity as the fourth leading cause of death worldwide.[5]

Physician recommendation is a powerful motivator to encourage people to make behavioral changes. In fact, a number of studies have shown that physician recommendation is the most powerful source to help people make changes in their habits and practices. For this reason, there is a clear mandate for physicians to become involved in recommending physical activity to every patient that they see.[6]

The purpose of this chapter is to provide both a framework and overall guidance to help physicians and other healthcare workers engage in counseling and recommendations to increase physical activity for every patient that they see and in their own lives.

DOI: 10.1201/9781003227793-17

14.2 THE ROLE OF PHYSICAL ACTIVITY IN LIFESTYLE MEDICINE

Lifestyle medicine is the discipline that explores how daily habits and actions impact on short- and long-term health and quality of life. While there are many factors in these daily habits and actions that powerfully impact on health and quality of life, physical activity is arguably the most important of all of these factors. In fact, in the area of cardiovascular medicine, an inactive lifestyle is a more powerful predictor of CVD than any other risk factor, including hypertension, dyslipidemia, and obesity.[7]

The field of lifestyle medicine has grown dramatically over the past two decades. In the first major textbook of lifestyle medicine, which I edited, I was pleased to have named this field in 1999.[8] Subsequently, a number of organizations have adopted the framework of lifestyle medicine to describe the importance of lifestyle choices in maintaining good health and provide background and education for physicians and other healthcare workers who wish to become involved in this field.[9] The most prominent organization in this area is the American College of Lifestyle Medicine (ACLM) which has grown over 1,200% in its membership between 2003 and 2020. This makes lifestyle medicine the most rapidly growing specialty within the area of medicine.

14.3 PHYSICAL ACTIVITY PROMOTION AND INVOLVEMENT OF PHYSICIANS AND OTHER HEALTHCARE PROFESSIONALS

The world is in the midst of what has been described as an epidemic of non-communicable diseases. This is in contrast to previous epidemiologic eras. For example, in the 1900s, communicable diseases, such as infectious diseases, resulted in the top three causes of death in the United States and accounted for 30% of all deaths.[10] By 2014, seven out of the ten top causes of death were attributable to chronic non-communicable diseases.[11] For example, CVD and cancer represent 46% of all deaths each year in the United States and also represent the majority of healthcare expenditures in the United States.[12] While the link between lifestyle and CVD is well recognized, many people do not recognize that lifestyle habits and actions such as cigarette smoking, an inactive lifestyle, and also conditions such as obesity result in the majority of cancer deaths. It has been estimated by the WHO that lifestyle habits and actions contribute to 75–80% of chronic disease.[13] There is no longer any doubt that lifestyle issues, in general, and physical activity, in particular, represent critically important targets for medical intervention.

14.4 CALLS FOR MORE PHYSICIAN AND OTHER HEALTHCARE PROFESSIONAL INVOLVEMENT FOR RECOMMENDING PHYSICAL ACTIVITY

The emphasis on lifestyle factors may be traced back to the clarion call issued by U.S. Surgeon General, Julius Richmond, in 1979 in his report "Healthy People, a Surgeon General's Report on Health Promotion and Disease Prevention."[14] Recommending increased physical activity was a major theme of this report, as well as the recommendation that the healthcare sector should lead in the promotion of this activity.

Healthy People Reports have subsequently been issued and updated every decade. A number of changes in emphasis

have occurred, but the importance of physical activity has remained an essential focus. For example, the Healthy People 2020 contained multiple recommendations concerning the importance of regular physical activity, including the central recommendation of increasing the proportion of physician office visits in both children and adults where recommendations for increased physical activity occur.[15]

The initial framework for the Healthy People 2030 also includes the recommendation to improve built environments such as sidewalks, bike lanes, trails, and parks to increase the likelihood of physical activity.[16] This framework also focuses on both schools and childcare settings and workplaces as important venues where increased physical activity can be achieved. In all of these settings, increased physician involvement is emphasized as a central component of improving levels of physical activity for the population.

Among the specific recommendations related to physical activity in Healthy People 2020 was encouraging the proportion of adults to engage in early physical activity of at least moderate intensity 150(+) minutes per week and increasing the proportion of adults who perform muscle strengthening activities on two or more days per week. Similar objectives were also listed for adolescents. The Healthy People 2020 document also recommended increasing the proportion of elementary schools that require daily physical education for all students and also increasing the number of adolescents who participate in daily school physical education. Many other recommendations for increased physical activity from Healthy People 2020 are consistent with other national guidelines and particularly, the Physical Activity Guidelines for Americans 2018 Scientific Report (PAGA 2018).[2]

14.5 PHYSICAL ACTIVITY RECOMMENDATIONS: THE NATIONAL PERSPECTIVE

The first U.S. National Activity Plan was released in 2010 and subsequently updated in 2016.[17] The healthcare section was identified as one of the nine major areas identified in both of these plans. These plans include a recommendation to prioritize efforts in healthcare to promote physical activity, as well as recognizing physical inactivity as preventable and treatable, since it carries both health and cost implications. The U.S. National Activity Plan also emphasized the importance of partnering across sectors and extending education in the area of physical activity in the training of all healthcare professionals.

14.6 THE ROLE OF PROFESSIONAL ORGANIZATIONS IN PROMOTING PHYSICAL ACTIVITY

A number of professional organizations have become involved in recommending and promoting increased levels of physical activity. The most prominent organization in this area has been the American College of Sports Medicine (ACSM).[18] The ACSM has been the professional home of exercise physiologists and other healthcare professionals with a particular interest in exercise for many decades.

Recently, the ACSM has joined forces with the American Medical Association (AMA) in the initiative entitled "Exercise Is Medicine" (EIM).[4] The goal of EIM is "for the healthcare community to make physical activity a standard part of the medical paradigm for the prevention and treatment of non-communicable diseases (NCDs) in healthcare systems." The EIM initiative was initially launched in the United States, but has now spread to more than 40 countries. This initiative started as an effort to increase awareness of the important health benefits of increased physical activity. The focus has now broadened, however, to include implementation of a standard model to help primary care physicians prescribe physical activity as well as recommend access to community resources. The EIM initiative has also provided multiple tools to help guide physicians through the steps to increase physical activity. One of these tools is the "Healthcare Providers Action Guide." This is a free source of information, which can be downloaded from the EIM website as well as other resources. More detailed information about the EIM program can be found in Chapter 19.

In addition to ACSM, the American Academy of Geriatrics, the American College of Preventive Medicine, the American Academy of Pediatrics, and the American Academy of Orthopedic Surgeons have all issued statements encouraging their members to recommend increased physical activity for all patients.[19]

The American Heart Association (AHA) has also been a leader in emphasizing the importance of physical activity and other lifestyle actions in the prevention of CVD. In fact, one of the Councils of the American Heart Association actually changed its name in 2013 from the "Council on Nutrition, Physical Activity and Metabolism" to the "Council on Lifestyle and Cardiometabolic Health."[20] Lifestyle has been emphasized for both the improvement of lipids and control of blood pressure in multiple scientific statements issued by the AHA. Among these statements, in 2013, the AHA and the American College of Cardiology (ACC) issued guidelines for lifestyle medicine to reduce cardiovascular risk. These guidelines included a major emphasis not only on diet but also on physical activity. Diet is particularly important in the area of lipid management and the combination of proper nutrition and weight management. Physical activity was recommended to play a very important role in blood pressure management and weight management in combination with proper nutrition.[21]

14.7 THE RATIONALE FOR MORE PHYSICIAN INVOLVEMENT

Numerous studies have demonstrated that physicians play a unique role in influencing patients' behavior. These studies have documented that physicians are the most trusted

source of physical activity information and that patients prefer to receive their initial advice concerning physical activity from their physician as opposed to other healthcare providers such as physical therapists or dietitians.[22–24] There is also evidence that a physician's advice may serve as a catalyst for change by making patients more aware of health information and programs and making this information more relevant.[25]

Since over 70% of adults see their primary care physician each year, physicians can play a powerful role and have a significant responsibility in recommending physical activity.[26–28] There seems to be some progress in this area, although a distinct minority of physicians recommend physical activity during counseling sessions with their patients. In 2010, only 32% of adults who saw a physician received advice about physical activity. More recent studies have suggested that up to 40% of patients who see physicians have received recommendations for increased physical activity.[29] Physicians need to recognize that patient visits represent a potent opportunity for recommending multiple lifestyle changes, including physical activity.

14.8 EDUCATIONAL RESOURCES

A number of educational resources are currently available to provide physicians and other healthcare workers with evidence based information concerning various aspects of physical activity. Formal medical education, unfortunately, still does not emphasize physical activity enough.[30] In 2012, a systematic review of behavior change counseling in medical schools showed that increased physical activity was the least addressed topic of all health behaviors reviewed, following smoking, nutrition, and alcohol/drug use.[31] In 2014, another systematic review showed that only 11 programs in medical schools existed that were focused on physical activity counseling, and that the content of these programs was inconsistent with regard to program duration and placement within the curriculum.[32] These results suggest that medical students and other physicians in training do not achieve adequate levels of training with respect to prescribing physical activity.[33]

A number of professional organizations and documents are currently available to provide education for physicians in the area of physical activity. Perhaps the most comprehensive of these documents for recommendations comes from the Physical Activity Guidelines for Americans 2018 Scientific Report (PAGA 2018).[2] This extensive, evidence based document provides comprehensive documentation of the benefits of regular physical activity for multiple population groups throughout the lifespan and summarizes scientific literature, while providing extensive background references.

ACSM also provides numerous tools for practicing physicians and their patients regarding physical activity. These may be obtained by visiting the ACSM website (acsm.org). The ACLM also provides education for various aspects of lifestyle medicine through the Lifestyle Medicine Education Collaborative (LMEd).[34] This program was created in 2013 and has been accepted by half of all medical schools. The LMEd program also has supplied a collection of peer reviewed materials through the MEDEd platform, which is maintained by the Association of American Medical Colleges.

CME opportunities also exist in the area of physical activity promotion. These will be listed at the end of this chapter.

14.9 PRE-PARTICIPATION SCREENING

Both the Physical Activity Guidelines for Americans 2008 and the PAGA 2018 Scientific Report embrace the concept that when it comes to physical activity, "some is better than none." With this in mind, both the ACSM and the PAGA 2018 recommend that clinicians have a discussion with every patient they see to discuss physical activity. This is particularly true of individuals who are very inactive.

To initiate this process, the first order is pre-participation screening. This is simply to inquire of individuals how much physical activity they currently do and then to begin to work with them to increase the amount of physical activity in order to ultimately reach the guidelines recommended by the PAGA 2018: to accumulate 150 minutes of moderate to vigorous physical activity on a weekly basis and participate in two strength training sessions per week. It should be emphasized, however, that for inactive individuals, even a physical activity level of 30 minutes per week is sufficient to yield significant reduction in risk for both all-cause mortality and specifically, mortality from CVD.[35] The rationale for this is depicted in Figure 14.2.

One good way of starting the conversation about physical activity is to use the recommendations incorporated by both the U.S. National Physical Activity Program and the Exercise Medicine Initiative, which utilize a tool consisting of two questions that was developed by Stanford University:

- On average how many days a week do you engage in moderate or strenuous physical activity (like a brisk walk)?
- On average how many minutes do you engage in exercise at this level?

Once these questions are answered, the clinician has a good place to start to help an individual to gradually increase their physical activity, with the goal of ultimately meeting the guidelines from the PAGA 2018 Scientific Report. The screening could involve a brief questionnaire called the "PARQ."[36] This stands for "Physical Activity Readiness Questionnaire" (Table 14.1).

14.10 PHYSICAL ACTIVITY AND EXERCISE PRESCRIPTION

It is important to emphasize again that the key for sedentary individuals is simply to obtain more activity in their lives. Thus, the typical exercise prescription, which is

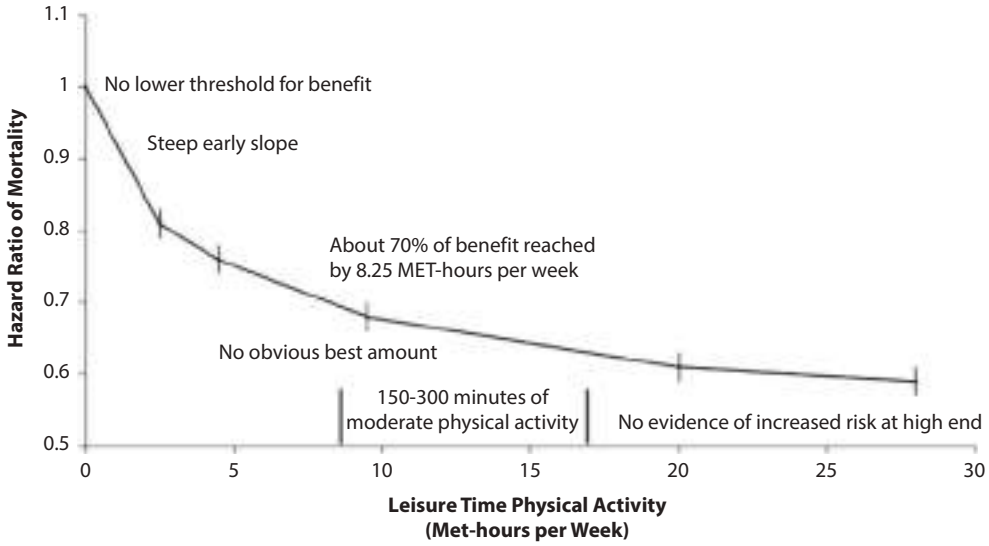

FIGURE 14.2 Relationships of moderate-to-vigorous physical activity to all-cause mortality, with highlighted characteristics common to studies of this type. (From the 2018 Physical Activity Guidelines Advisory Committee. 2018 Physical Activity Guidelines Advisory Committee Scientific Report. Washington DC: U.S. Department of Health and Human Services; 2018.)

prescribed by exercise physiologists according to the principles endorsed by organizations such as ACSM, may not be not necessary for individuals who have been sedentary and simply want to incorporate more physical activity into their lives.

If the clinician wants to be more precise in terms of exercise and the physical activity prescription, the framework developed by ACSM, which goes by the acronym FITT, can be utilized:

- Frequency
- Intensity
- Time
- Type

Typically, the frequency is three or more times a week of moderate physical activity, recommended at a level of 50–70% of VO_{2max} heart rate and at a perceived exertion considered to be "moderate." "Time" denotes the number of minutes that the individual is involved in physical activity. "Type" denotes the kind of physical activity performed.

Overall, the ACSM considers the following five points:[18]

1. All individuals should engage in at least 20–60 minutes of aerobic physical activity of at least a moderate intensity on at least 5 days per week.
2. Additional health and fitness benefits can be achieved by adding more time in moderate intensity activity or by substituting more vigorous activity.
3. Previously inactive men and women and people at risk for heart, metabolic (diabetes), and renal diseases should first consult a healthcare provider before initiating a program of vigorous physical activity to which they are unaccustomed.
4. Persons with symptomatic heart, diabetes, or renal disease who would like to increase their physical activity should be evaluated by a healthcare provider and provided with an exercise program appropriate for their clinical status.
5. Muscular strength–developing activities (resistance training) should be performed at a minimum of two times per week with at least one day between sessions. Flexibility and balance exercises should be included in a prudent overall program.

14.11 PHYSICAL ACTIVITY AND FITNESS EVALUATION

The vast majority of individuals who wish to increase the amount of physical activity in their lives may do so without a formal evaluation. This is a position supported by the PAGA 2018 Scientific Report and ACSM. This does not mean that physicians should not discuss the importance of physical activity safety and the benefits of physical activity with all patients.

There may be times when particular clinical circumstances may warrant a more formal evaluation. This may be particularly true for individuals who have a history of coronary heart disease or individuals who have been extremely inactive. In these settings, a variety of potential activity or fitness evaluations are appropriate. These evaluations may include a variety of different exercise tests, including a treadmill or bike test. For some patients, it may be appropriate to take a pencil and paper test rather than one of the physical activity tests. Background materials are also provided in numerous resources from ACSM.

TABLE 14.1

Physical Activity Readiness Questionnaire (PAR-Q)

Data Collection Sheet

NAME:_____ DATE:_____HEIGHT:_____in. WEIGHT:_____lbs.
AGE:_____PHYSICIANS NAME:_____ PHONE:_____

Questions Yes No

1. Has your doctor ever said that you have a heart condition and that you should only perform physical activity recommended by a doctor?
2. Do you feel pain in your chest when you perform physical activity?
3. In the past month, have you had chest pain when you were not performing any physical activity?
4. Do you lose your balance because of dizziness or do you ever lose consciousness?
5. Do you have a bone or joint problem that could be made worse by a change in your physical activity?
6. Is your doctor currently prescribing any medication for your blood pressure or for a heart condition?
7. Do you know of any other reason why you should not engage in physical activity?

If you have answered "Yes" to one or more of the above questions, consult your physician before engaging in physical activity. Tell your physician which questions you answered "Yes" to. After a medical evaluation, seek advice from your physician on what type of activity is suitable for your current condition.

GENERAL & MEDICAL QUESTIONNAIRE
Occupational Questions Yes No

1. What is your current occupation?
   _____
2. Does your occupation require extended periods of sitting?
3. Does your occupation require extended periods of repetitive movements? (If yes, please explain.)
   _____

4 Does your occupation require you to wear shoes with a heel (dress shoes)?

5 Does your occupation cause you anxiety (mental stress)?

Recreational Questions Yes No

6 Do you partake in any recreational activities (golf, tennis, skiing, etc.)? (If yes, please explain.)
_____
_____

7 Do you have any hobbies (reading, gardening, working on cars, exploring the Internet, etc.)? (If yes, please explain.)
_____
_____

Medical Questions Yes No

8 Have you ever had any pain or injuries (ankle, knee, hip, back, shoulder, etc.)?
(If yes, please explain.)
_____
_____

9 Have you ever had any surgeries? (If yes, please explain.)
_____
_____

10 Has a medical doctor ever diagnosed you with a chronic disease, such as coronary heart disease, coronary artery disease, hypertension (high blood pressure), high cholesterol or diabetes? (If yes, please explain.)
_____
_____

11 Are you currently taking any medication? (If yes, please list.)
_____
_____
_____

14.12 DURATION OF WORKOUT SESSIONS

For many years, it was thought that the duration of physical activity needed to be 30 minutes in order to yield important benefits. This was subsequently modified to 10-minute sessions and accumulating 30 minutes per day.[37] This latter approach was incorporated in the guidance from the ACSM and the 2008 Physical Activity Guidelines for Americans. In the decade between 2008 and 2018, however, abundant new information became available indicating that physical activity sessions of less than 10 minutes per session could also result in significant health and fitness benefits. For this reason, the PAGA 2018 Scientific Report recommended that any duration of physical activity could yield important benefits. This is particularly important to emphasize to patients who have been sedentary. Sedentary individuals should be advised that even small amounts of regular physical activity, such as taking the stairs at work or parking further away from stores or walking across the parking lot when shopping, if done on a regular basis can yield important health and fitness benefits. Thus, the barrier of physical activity sessions needing to take 10 minutes or more has now been essentially removed.

14.13 PHYSICAL ACTIVITY AND EXERCISE PRESCRIPTION FOR SPECIAL POPULATIONS

Some modifications in physical activity programs may be necessary for special populations. In general, the same recommendation of trying to achieve 150 minutes of moderate intensity aerobic physical activity and two-weekly sessions of muscular strength training per week should apply to most individuals.

Some modifications may be necessary in some populations or with populations with special needs. For example, the PAGA 2018 Scientific Report recommends that children try to accumulate 60 minutes of moderate intensity activity on most, if not all, days. Older adults (over the age of 65) can typically achieve 150 minutes of moderate intensity physical activity per week, but may also wish to supplement aerobic physical activity with balance exercises on 2–3 days per week to improve balance and decrease the risk of falling.

Physical activity for most women is the same as for men. During pregnancy and postpartum, however, there may be some slight modifications, although the physical activity guideline of 150 minutes of moderate intensity physical activity per week will be appropriate for most individuals. Issues related to physical activity for special populations are described in great detail in the Physical Activity Guidelines for Americans 2018 Scientific Report.

14.14 GETTING STARTED

As already indicated, individuals who recommend increased physical activity for patients can utilize the two question program developed at Stanford University as described previously in this section. The goal is to make it simple for physicians to open the discussion with all patients regarding the importance of increased physical activity.

14.15 UTILIZING EXPERTS

A variety of experts are available to help physicians in the goal of increasing physical activity for patients. Physicians may refer to professionals such as exercise physiologists at a health club or a local YMCA.[18] It is important to ensure that the physical activity referral is given to a professional with appropriate credentials. It may be useful to inquire if the individual has the ACSM Registered Clinical Exercise Physiologist (RCEP) certification.[38] This is the gold standard for individuals prescribing physical activity and exercise. This certification identifies people who have a minimum of a Master's Degree in Exercise Science and 600 documented hours of experience in a variety of areas. This background ensures that patients will be effectively prescribed safe and effective physical activity. Individuals with the ACSM RCEP must also have CPR certification and pass extensive testing of their knowledge and skill levels.

14.16 BE A ROLE MODEL

Physicians should aspire to serve as role models in the area of physical activity for their patients. Numerous studies have shown that there is a strong relationship between a physician's lifestyle and health habits and his/her related counseling practices. This is true in a variety of areas, including smoking cessation, vaccination, and screening practices and for physical activity counseling as well. In fact, in 1 review including 24 studies, there was an 80% correlation between physicians' personal physical activity habits and their behaviors with regard to counseling patients about physical activity.[38] Moreover, a patient's perception of a physician's physical activity behaviors also may play a role in whether or not the patient engages in physical activity.[39]

Finally, there are emerging data that a physician's physical activity helps reduce the likelihood of burnout.[40–42] Burnout has been described as a "symptom of emotional exhaustion, loss of meaningful work, feelings of ineffective interactions with other human beings." Unfortunately, over half of U.S. physicians have reported experiencing substantial symptoms of burnout. In one study of 80 internal medicine residents, it was demonstrated that those meeting U.S. guidelines for physical activity were significantly less likely to experience burnout than those who failed to achieve recommended levels of physical activity.[40]

14.17 RESOURCES

A wide variety of resources are currently available to assist physicians in gaining knowledge of physical activity and transferring this information to their patients. The following are highly recommended.

- Physical Activity Guidelines for Americans 2018 Advisory Committee Scientific Report. This is available at https://health.gov/sites/default/files/201909/PAG_Advisory_Committee_Report.pdf
- American College of Lifestyle Medicine Annual Conference online CMEs and Resources (see curriculum available at LifestyleMedicine.org)
- Lifestyle Medicine Education Collaborative Curricula Resources Webinars (available at LifestyleMedicineEducation.org)
- Multiple ACSM books and other educational resources
- Materials from the Exercise Is Medicine initiative (available at https://www.exerciseismedicine.org/)

14.18 CONCLUSIONS

There is no longer any serious doubt that regular physical activity substantially lowers the risk of various chronic diseases and improves short- and long-term health and quality of life. Given that there is a low level of physical activity currently found in the general population of the United States, it is critically important that members of the healthcare community, and physicians in particular, become involved in recommending physical activity to all patients. Unfortunately, at the current time, only 40% of physicians include counseling on physical activity to their patients. A wide variety of resources are available to help physicians who wish to get started or become knowledgeable in this area. Physical activity is an important part of comprehensive healthcare. In addition, regular physical activity can confer a wide variety of benefits upon physicians themselves and will increase the likelihood that they will counsel on this very important area to their patients.

CLINICAL APPLICATIONS

Physical activity recommendations should be included in every counseling encounter by physicians.

Physicians should emphasize current guidelines for physical activity, such as obtaining 30 minutes of moderate or vigorous physical activity on most, if not all, days, with the goal of accumulating 150 minutes per week as well as two sessions of musculoskeletal exercises per week.

A wide variety of resources are available to help physicians to make proper physical activity recommendations to their patients.

Simple steps, such as making physical activity a part of vital signs, may help clinicians initiate a conversation with their patients to speak about increased physical activity. Utilization of the two question Stanford developed test outlined in this chapter can also assist in this process.

15 Physical Fitness Evaluation

Peter Kokkinos, PhD and Jonathan Myers, PhD

KEY POINTS

- Lifestyle strategies play a significant role in both the prevention and treatment of cardiovascular disease.
- Physical fitness and more specifically, cardiorespiratory fitness is inversely related to the incidence of numerous chronic disease and all-cause mortality.
- Body composition is associated with health outcomes.
- Accurate evaluation of physical activity and body composition status is essential in risk assessment of patients.
- Counseling for physical activity and weight management should be a part of every healthcare visit to improve health outcomes.

15.1 DEFINITION OF PHYSICAL FITNESS

The Centers for Disease Control and Prevention (CDC) and the American College of Sports Medicine (ACSM) define physical fitness as "a set of physical attributes that people have or achieve that relates to the ability to perform physical activity."[1,2] These attributes have important implications for overall health, including one's ability to perform recreational or occupational activities, the determination of disability, injury prevention, and skeletal muscle, bone, and cardiovascular health. Moreover, higher fitness is strongly associated with better long-term health outcomes.[3,4] Engaging in proper physical training leads to an improvement in these physical attributes and physical fitness. The degree of improvement is determined by several factors, including training, diet, rest, psychological factors, and genetics.

15.2 AEROBIC AND ANAEROBIC FITNESS

The energy necessary to sustain life and perform work is extracted by the cells in one of two ways: with the use of oxygen and without oxygen. Historically, the utilization of oxygen to extract energy has been referred to as aerobic metabolism, and extracting energy without utilizing oxygen has been referred to as anaerobic metabolism.

However, it is important to note that muscle cells are never entirely aerobic or anaerobic. Rather, their energy requirements are met through the harmonious interaction of the two systems, with the energy contribution of each system depending largely on the intensity of activity. In general, high-intensity activities derive their energy mainly independently of oxygen, while low-intensity activities utilize oxygen to meet their energy requirements. Therefore, aerobic fitness refers to the ability to provide the required energy for a specific task in which the body's cardiopulmonary system adequately supplies the needed oxygen to the working muscle cells. Conversely, anaerobic fitness refers to the body's ability to provide the required energy for a specific task independently of oxygen. Aerobic activities consist of repetitive, low resistance movements (e.g. walking or cycling) that last over a relatively extended period of time (generally five minutes or more). Anaerobic activities, on the other hand, are characterized by bursts of intense activity lasting a comparatively short period of time (sprinting, lifting a heavy weight, jumping, etc.). It is important to emphasize that these two energy systems (aerobic and anaerobic) are almost always working together in a harmonious way, sharing the responsibility for providing the energy requirements for the working muscles and the entire body. However, one is likely to be the predominant system to provide most of the energy for the particular activity at hand.[5]

15.3 DETERMINING EXERCISE CAPACITY: DIRECT METHOD-OPEN-CIRCUIT SPIROMETRY

The "true" maximum aerobic capacity is the maximum amount of oxygen (referred to as maximal oxygen uptake or VO_2 max) the body can utilize during work. This is assessed in laboratories by *open-circuit spirometry*. VO_2 max is usually determined by a graded exercise test (GXT). A brief description and rationale for this procedure is as follows.

The individual breathes room air via a mouthpiece (nose occluded) or a face mask connected to an automated system (often termed a metabolic cart) by plastic tubes. The mouthpiece or mask is designed in such a way that it allows the measurement of the volume of expired air, while a small sample of the expired air enters the metabolic cart and is analyzed for its oxygen and carbon dioxide (CO_2) content. Oxygen uptake is determined by the product of ventilation and the difference between the O_2 content of the ambient and expired air. After resting samples are taken, the individual is subjected to a standardized exercise protocol on a treadmill or stationary bike. The exercise begins at a very low workload and increases progressively until volitional fatigue or until a clinical indication for stopping is reached. The rate of increase in external work depends on the exercise protocol used, but it is typically recommended that the test be individualized to last between 8 and 12 minutes.

DOI: 10.1201/9781003227793-18

Since the relationship between the increase in workload and oxygen consumption is linear, oxygen requirements also increase. At some point, the individual reaches a volitional fatigue endpoint, and the test is terminated. This level is referred to as the maximal aerobic capacity of the individual. The oxygen utilized by the body at the point of fatigue is referred to as the VO_2 max. The measurement of VO_2 max implies that an individual's physiological limit has been reached. True VO_2 max has historically been defined by a plateau in VO_2 between the final two exercise work rates and requires that maximal effort be achieved and sustained for a specified period. Because this determination is subjective, can be difficult to define, and is rarely observed when patients with cardiovascular or pulmonary disease are tested, the term *peak* VO_2 is more commonly used clinically to express exercise capacity. Conversely, the term VO_2 *max* is more often used to describe exercise capacity in apparently healthy individuals, in whom achievement of a maximal physiological response is more likely. VO_2 max is expressed in milliliters of oxygen per minute (ml/min) or ml of oxygen per kilogram (kg) of body weight per minute (ml/kg/min). The latter is usually the preferred expression, since it allows comparisons between subjects of different weights.

The direct measurement of VO_2 max is most often used for research purposes and has a number of important clinical applications for patients with cardiovascular or pulmonary disease. However, it is not often practical for someone who simply wishes to know the appropriate exercise intensity during his or her training. For this purpose, exercise intensity can be easily determined by the heart rate (HR) that corresponds to the appropriate percentage of oxygen consumption. Since HR and oxygen uptake are continuously recorded during the metabolic test, one can easily match the desired percentage of HR to the corresponding oxygen consumption. The advantage of the direct method is that it is highly accurate. It allows an accurate assessment of the exercise intensity of an individual based on directly measured rather than estimated aerobic capacity. However, it is an elaborate method that requires expensive equipment and trained personnel and is, therefore, cost prohibitive for large populations. It is mostly used in individuals with specific clinical needs and for research purposes.[5]

15.4 DETERMINING AEROBIC FITNESS BY STANDARDIZED TESTS USING INDIRECT METHODS

The need for more practical methods to assess aerobic capacity for large populations led to the development of standardized exercise tests and the common practice of estimating energy requirements from different workloads. An indirect method for estimating the fitness level of an individual is based on the same principle as that for the direct assessment of VO_2 max, with one exception; oxygen consumption is not directly measured. Rather, it is estimated based on treadmill speed and grade utilizing equations derived from the direct assessment of VO_2 max. The actual procedure is similar to that described for the assessment of VO_2 max, with the exception that the individual is not connected to a metabolic cart (no breathing apparatus). While an ECG is monitored, the individual undergoes a standardized exercise protocol on a treadmill or stationary cycle ergometer. The most commonly used exercise protocols in the United States are described in Table 15.1, and these are discussed further later in the chapter. Exercise begins at a very low workload and increases every one to three minutes depending on the exercise protocol. The workload is determined by the speed and elevation of the treadmill, or the resistance if a cycle ergometer is used. HR is continuously monitored and recorded during the entire test, and blood pressure is recorded every two to three minutes.[2,5]

The O_2 consumption for each exercise stage is estimated based on regression equations for walking and running speeds. These equations were based on directly measured energy requirements at submaximal steady states (defined as a constant VO_2) and subsequently used to estimate VO_2 at maximal, non-steady-state work rates during a progressive exercise test.[2] This estimated metabolic demand for a given work rate has conventionally been expressed in metabolic equivalents (METs). One MET represents the amount of oxygen used during resting conditions (approximately 3.5 ml of oxygen per kg of body weight per minute). Thus, any increase beyond the 1-MET level represents higher total body oxygen consumption, directly associated with a higher workload. Based on this rationale, several standardized exercise protocols have been developed to assess the MET level of individuals for clinical and other reasons. The MET level achieved upon termination of the test (the individual reaches volitional fatigue) represents an estimate of the peak aerobic capacity of the individual. Because each MET is equal to approximately 3.5 ml O_2/kg/minute, VO_2 max can be estimated by multiplying the MET level achieved by 3.5.[2,5]. It is important to note that exercise capacity assessed by such exercise tests is in part related to the physical activity status of the individual. However, the ability to perform aerobic work is also determined by age and gender, as well as an important genetic component.[6,7]

As indicated, the regression equations developed to estimate VO_2 at each workload were based on directly measured energy requirements (VO_2) at submaximal steady states (defined as a constant VO_2) and subsequently used to estimate VO_2 at maximal, non-steady-state work rates during a progressive exercise test.[2,8,9]

However, the steady state assumed by these equations is influenced significantly by several factors, including the individual's age, health and fitness status, and walking efficiency and handrail use.[9,10] Therefore, the accuracy of the equation is compromised when applied to compute non-steady-state work rates. In addition, the most often used equations for walking and running speeds, referred to as the ACSM equations, are based on <100 young (19–26 years old) participants, a specific protocol, and were developed

[a]Walking and running speed equations were used.

nearly four decades ago. These factors contributed to the well-documented overestimation of VO_2 max (MET levels) by these equations during a progressive exercise test, especially at higher workloads.[9,11]

The ACSM equations for walking and running speeds are presented here.[2,9,12]

ACSM Walking Equation (Speed 1.9–3.7 miles per hour)
*VO_2 max = [Treadmill Speed (m/min) * 0.1 ml/kg/min] + Speed (m/min) * Treadmill Grade (decimal) * 1.8 ml/min/m] + 3.5 ml/kg/min*

The accuracy of the walking equation is best for treadmill speeds between 1.9 and 3.7 miles per hour or 50–100 m/min (1 mile/h = 26.8 m/min). Walking economy changes above this speed range, and the accuracy of the equation declines.

ACSM Running Equation (Speed >5.0 mph)
*VO_2 max = [Treadmill Speed (m/min) * 0.2 ml/kg/min] + Speed (m/min) * Treadmill Grade (decimal) * 0.9 ml/min/m] + 3.5 ml/kg/min*

Generally, the accuracy of the running equation is best for treadmill speeds >5 mph or 134 m/min. However, the height of the individual influences the speed at which one changes from walking to running. Thus, some individuals may choose to run at speeds as low as 3.7 mph.[12].

We recently developed new equations to estimate VO_2 max in apparently healthy adults and in patients with heart failure (HF) using directly measured VO_2 max instead of steady-state.[13,14] The equation for healthy individuals, referred to as the FRIEND Equation,[13] is based on 7,983 men (n = 4,798) and women (n = 3,183) aged ≥20 years (mean age 47 ± 13 years), who participated in The Fitness Registry and the Importance of Exercise National Database (FRIEND).

FRIEND Equation for Exercise Protocols Using Treadmill
*VO_2 max in ml $O_2 \cdot kg^{-1} \cdot min^{-1}$ = Speed (m/min) * (0.17 + Fractional Treadmill Grade * 0.79) + 3.5*

Comparisons between the predicted values based on the ACSM equations and the FRIEND equation revealed that the ACSM equations overestimated VO_2 max, as previously reported,[2,9,12] with a percent error for the entire cohort of 21.4% (21.4 ± 24.9) versus 5% (5.1 ± 18.3) for the FRIEND equation. When different protocols were considered, the percent error ranged from –32.0 ± 5.1% to 39.8 ± 26.4%. In contrast, the percent error for the FRIEND equation ranged from 1.7 ± 15.4 to 12.8 ± 21.0 (Table 15.1).

15.5 FRIEND EQUATION FOR HF PATIENTS

The FRIEND equation for HF patients[14] was based on 1,453 patients (955 men; mean age ± standard deviation [SD] 56.8 ± 14.6 years and 498 women; mean age 52.1 ± 15.6 years). Treadmill speed and the interaction of treadmill speed and grade were again the main determinates of VO_2 max, with age and gender having only a minor impact. Gender-specific formulas did not yield substantially different findings, and therefore, one formula for men and women was developed.

The HF-specific formula for treadmill testing was as follows.

FRIEND Equation for HF Patients Using Treadmill
*VO_2 max (ml/kg/min) = Speed * (0:17 + Fractional Treadmill Grade * 0:32) + 3:5*
Where speed is in m/min (1 mile/h = 26.8 m/min)

To assess the external validity of the FRIEND equations for HF patients, we applied it to the HF-ACTION cohort (n = 1,612; mean age ± SD 58.6 ± 12.7 years), an NIH-sponsored multicenter, randomized controlled trial to evaluate the effect of medically supervised and home-based exercise training on cardiovascular outcomes in stable outpatients with HF and reduced ejection fraction.[15] The superiority of the FRIEND compared with the ACSM equations in predicting measured VO_2 max was evident regardless of the cohort, especially when applied to the FRIEND HF cohort (percent error 0.04 ± 20.7) (Table 15.2).

We also developed the following correction formula that allows the conversion of estimated METs using the ACSM equations to METs derived using the FRIEND equations.

*FRIEND METS = ACSM-Derived METs – (1.01 * Fractional Grade – 0.07) * Speed (m/min)/3.5*

15.6 PROTOCOLS

The purpose of the test and the person tested are important considerations in selecting the protocol. Exercise testing may be performed for diagnostic purposes, for functional assessment, or for risk stratification. An often ignored but nevertheless, consistent recommendation in the recent exercise testing guidelines is that the protocol is individualized for the patient being tested.[8,9,16] For example, a maximal, symptom-limited test on a relatively demanding protocol would not be appropriate (or very informative) for a severely limited patient. Likewise, a very gradual protocol might not be useful for an apparently healthy, active person. Use of submaximal testing, gas exchange techniques, the presence of a physician, and the exercise mode and protocol should be determined by considering the person being tested and the goals of the test.

Commonly used exercise protocols, their stages, and the MET level for each stage are outlined in Table 15.3. The most suitable protocols for clinical testing should include a low-intensity warm-up phase followed by progressive, continuous exercise in which the demand is elevated to a patient's maximal level within a total duration of 8 to 12

Women	417	56.2 ± 12.9	14.2 ± 4.0	16.0 ± 2.5	20.1 ± 29.5	23.3 ± 5.6	70.2 ± 36.8

minutes.[8,9,16–19]. In the absence of gas exchange techniques, it is important to report exercise capacity in METs rather than exercise time, so that exercise capacity can be compared uniformly between protocols. METs can be estimated from any protocol using standardized equations that have been put into the tabular form.[8,9,20]. In general, 1 MET represents an increment on the treadmill of approximately 1.0 mph or 2.5% grade. On a cycle ergometer, 1 MET represents an increment of approximately 20 W (120 kgm/min) for a 70-kg person. The assumptions necessary for predicting MET levels from treadmill or cycle ergometer work rates (including not holding the handrails, that oxygen uptake is constant [i.e. steady-state exercise is performed], that the subject is healthy, and that all people are similar in their walking efficiency) raise uncertainties as to the accuracy of estimating the work performed for an individual patient. For example, the steady-state requirement is rarely met for most patients on most exercise protocols; most clinical testing is performed among patients with varying degrees of cardiovascular or pulmonary disease, and people vary widely in their walking efficiency.[20] It has therefore been recommended that a patient be ascribed a MET level only for stages in which all or most of a given stage duration has been completed.[21]

15.7 CYCLE ERGOMETER PROTOCOLS

Although there are specific bicycle protocols named for early researchers in Europe, such as Astrand,[22] bicycle ergometer protocols tend to be more generalized than the treadmill. For example, 15- to 25-W increments per 2-minute stage are commonly used for patients with cardiovascular disease, whereas for apparently healthy adults or athletic individuals, appropriate work rate increments might typically be between 40 and 50 W/stage. Most modern, electronically braked cycle ergometers have controllers that permit ramp testing, in which the work rate increments can be individualized in a continuous fashion (see next section).

15.8 VO_2 MAX ESTIMATIONS USING CYCLE ERGOMETRY

O_2 consumption estimations with cycle (leg) ergometry require knowing the work rate.

Work rate during leg ergometer exercise is computed in kg * meters per minute (kg * m/min). Another way to express work rate is in watts, calculated as follows:

$$\text{Watts} = \frac{\text{Kg} * \text{m/min}}{6.12}$$

15.8.1 Estimating Work Rate

To calculate work rate, one needs to know the distance the flywheel travels with each pedal revolution. This is not constant across the different bike manufacturers. Here, we provide the most common cycles in use and the distances per pedal revolution:

Monarch: 6 m per pedal revolution
Tunturi: 3 m per pedal revolution

The ACSM equation is:

$$VO_2 = 1.8\ (\text{Work rate/Body weight in kg}) + 3.5 + 3.5$$

or

$$VO_2 = 1.8\ (\text{Work rate/Body weight in kg}) + 7.0$$

- The 1.8 value represents the resistance imposed by the flywheel which is approximately 1.8 ml/kg/min.
- The first 3.5 represents the O_2 demand cycling at approximately 50–60 revolutions per minute without any resistance.
- The additional 3.5 represents the O_2 demand at rest.

15.8.2 Limitations of the ACSM Equation

It is important to know that the ACSM equation is based on O_2 values measured directly at steady state. Thus, the accuracy of the equation deteriorates progressively at higher work rates. Relatively acceptable accuracy is maintained at work rates between 300 and 1200 kg * m/min or 50–200 watts.

15.9 THE FRIEND EQUATION

Recently, we developed a new equation for estimating VO_2 using cycle ergometry based on 5,100 (3,378 men; mean age 35.9 ± 12.1 years and 1,722 women; mean age 47.5 ± 14.0 years) of the Fitness Registry and the Importance of Exercise National Database. The ACSM equation overestimated VO_2 max for both men and women with an overall relative bias of 15.46% ± 0.13. In contrast, the FRIEND-ergometry equation predicted VO_2 max with an overall relative bias of 0.51% ± 0.11 (Table 15.4).[23]

The non-gender-specific equation is as follows:

FRIEND Equation for predicting VO_2 max using Cycle Ergometer
Men
*VO_2 max in ml O_2/kg/min = 1.76 * (watts * 6.12/body weight [kg]) + 3.5*
Women
*VO_2 max in ml O_2/kg/min = 1.65 * (watts * 6.12/body weight [kg]) + 3.5*
The non-gender-specific equation:
*VO_2 max in ml O_2/kg/min = 1.74 * (watts * 6.12/body weight [kg]) + 3.5*

Measured and estimated oxygen consumption based on the American College of Sports Medicine (ACSM)* and the Fitness Registry and the Importance of Exercise National Database (FRIEND) equations (mean ± standard deviation).

The overestimation of METs by the ACSM equation can be corrected by the following formula:

*ACSM-derived METs – 0.06 * (watts * 6.12/kg) – 3.5*

15.10 RAMP TESTING

An approach to exercise testing that has gained interest in recent years is the ramp protocol, in which work increases constantly and continuously. In 1981, Whipp and colleagues[24] first described cardiopulmonary responses to a ramp test on a cycle ergometer, and many of the gas exchange equipment manufacturers now include ramp software. Treadmills have also been adapted to conduct ramp tests.[19,25,26] The ramp protocol uses a constant and continuous increase in metabolic demand that replaces the "staging" used in conventional exercise tests. The uniform increase in work allows a steady increase in cardiopulmonary responses and permits more accurate estimation of oxygen uptake.[19] The recent call for "optimizing" exercise testing[8,14,16,19] would appear to be facilitated by the ramp approach, because large work increments are avoided, and increases in work are individualized, permitting test duration to be targeted. Because there are no stages per se, the errors associated with predicting exercise capacity alluded to previously are lessened.[8,9,19]

15.11 SUBMAXIMAL TESTING

In general, maximal, symptom-limited tests are not considered appropriate until one month after myocardial infarction (MI) or cardiac surgery. Thus, submaximal exercise testing has an important role clinically for pre-discharge, post-MI, or post-bypass surgery evaluations. Submaximal tests have been shown to be important in risk stratification,[26–29] for making appropriate activity recommendations, for recognizing the need for modification of the medical regimen, or for further interventions in patients who have sustained a cardiac event. A submaximal, pre-discharge test appears to be as predictive for future events as a symptom-limited test among patients less than one month after MI. Submaximal testing is also appropriate for patients with a high probability of serious arrhythmias. The testing endpoints for submaximal testing have traditionally been arbitrary but should always be based on clinical judgment. A heart rate limit of 140 beats per min and a MET level of 7 are often used for patients younger than age 40 years, and limits of 130 beats per min and a MET level of 5 are often used for patients older than 40 years. For those using beta-blockers, a Borg perceived exertion level in the range of 7 to 8 (1 to 10 scale) or 15 to 16 (6 to 20 scale) is a conservative endpoint. The initial onset of symptoms, including fatigue, shortness of breath, or angina, is also an indication to stop the test. A low-level protocol should be used, that is, one that uses no more than 1-MET increments per stage. The Naughton protocol[30] is commonly used for submaximal testing. Ramp testing is also ideal for this purpose, because the ramp rate (such as 5 METs achieved over a ten-minute duration) can be individualized depending on the patient tested.[19]

Submaximal testing can also be used to assess the capacity of apparently healthy individuals to exercise safely or to estimate VO_2 max by extrapolation. The premise of estimating VO_2 max from a submaximal test is based on the linear relationship between HR and oxygen consumption, provided that the work is aerobic in nature. In submaximal test protocols, the HR at each workload is plotted against the workload and extrapolated to VO_2 max at an age-predicted maximal heart rate (typically 220 – age). VO_2 max can be calculated using prediction equations[2] or estimated from values obtained by commonly used exercise protocols if the following assumptions are met: 1) the workload is reproducible; 2) a steady-state HR is obtained during each stage; and 3) a linear relationship exists between HR and oxygen consumption over a wide

range of values. Examples of submaximal tests used to estimate peak VO_2 include the YMCA test, the Astrand test, and others.[22,31,32]

15.12 WALK TESTS FOR CARDIORESPIRATORY FITNESS ASSESSMENT

A number of walking tests have also been developed for estimating cardiorespiratory fitness or assessing the functional status of patients with cardiovascular or pulmonary disease in clinical settings. Advantages of walk tests include the fact that they are easy to perform and are relatively inexpensive, and thus, can be applied to large populations. These include: 1) the 6-minute walk test; 2) the Cooper 12-minute test; 3) the 1.5-mile test; and the 4) Rockport One-mile Fitness Walking Test.[2]

The six-minute walk test is popular for assessing functional status in clinical settings and is mostly used among diseased populations, such as patients with HF, stroke, and peripheral vascular disease. The objective of the test is to cover the greatest possible distance by walking in six minutes. Its obvious advantages are that it requires practically no equipment (other than a stopwatch) and little time.

Although the association between six-minute walk performance and exercise capacity is only modest, peak VO_2 can be estimated from six-minute walk distance by the following multivariate equation along with other readily available information:

$$Peak\ VO_2 = (0.02 * distance\ [m]) - (0.191 * age\ [yr]) - (0.07 * weight\ [kg]) + (0.09 * height\ [cm]) + (0.26 * RPP\ [*10^{-3}])$$

m = meter; kg = kilogram; cm = centimeters; yr = years

RPP = rate pressure product (systolic blood pressure [mm Hg] * heart rate)

The Cooper 12-minute test is based on a similar concept (covering the greatest distance in 12 minutes), while the objective of the 1.5-mile test is to run the distance (1.5 miles) in the shortest period of time. Unlike the six-minute walk test, both of these tests are more suitable for healthy, younger individuals. They also require little or no additional equipment and can be administered to large populations.

The Rockport One-mile Fitness Walking Test involves covering a 1-mile distance in the shortest period of time. However, in addition to the time required to cover the 1-mile distance, the test utilizes peak HR achieved during the last minute of the walk, and an estimate of peak VO_2 is derived. If HR monitoring is not an option during the test, a 10-second HR obtained immediately after the completion of the test can be used as an alternative. However, this is likely to overestimate peak VO_2 compared with that calculated when HR is obtained during the last minute of the walk.

15.13 NON-EXERCISE-TEST ESTIMATES OF CARDIORESPIRATORY FITNESS

The recent call for the inclusion of fitness as a clinical vital sign[33] has placed a renewed focus on non-exercise-test methods to estimate cardiorespiratory fitness (CRF). This is because although CRF has been increasingly recognized as a critical factor in stratifying risk, objective measures of CRF are rarely available during a routine clinical encounter. Thus, the ability to estimate CRF without performing a formal exercise test is attractive, because it can be obtained quickly and inexpensively without exposing an individual to the risk and discomfort of an exercise test. Many non-exercise-test-based equations have been proposed using commonly available information during a typical clinic visit. Non-exercise-test regression equations have typically included age, gender, body mass index (BMI), and self-reported physical activity patterns, although many other health metrics have been employed. In addition to being quick and simple to obtain, these equations have a surprisingly robust correlation with objective fitness measures, typically in the range of 0.50 to 0.80, and they have also been reported to strongly predict outcomes.[34–44] However, limitations of these tools include the fact that they are subjective and that they lack the ability to assess symptoms, ECG, and hemodynamic responses that are available during a formal exercise test. In addition, they tend to underestimate and overestimate CRF at the upper and lower end of the distribution, respectively.

A systematic review of this issue was performed using 13 non-exercise-test equations developed using various combinations of age, gender, body weight (or BMI, percentage of body fat, or waist circumference), physical activity patterns (self-reported or measured), smoking, resting heart rate, or perceived functional ability as predictors of CRF.[37] The R^2 values (with measured or estimated peak VO_2 as the dependent variable) ranged from 0.50 to 0.86. Non-exercise CRF estimates have been shown to be similar in accuracy to submaximal exercise prediction models.[3738,43,44] Although most of these studies have focused on healthy asymptomatic populations, non-exercise-test approaches that include assessment of symptoms during daily activities are more applicable to clinically referred populations. The latter include the Veterans Specific Activity Questionnaire (VSAQ) and Duke Activity Status Index (DASI) and similarly correlate well with measured exercise capacity.[34,35]

Estimates of CRF using these tools have also been shown to provide valid estimates of long-term risk, including mortality.[37,38,43–46] The VSAQ combines a one-page assessment of symptoms during daily activities with age, and was shown to correlate strongly with exercise capacity determined on a treadmill test (multiple R = 0.82). McAuley et al.[40] performed a follow-up study in a group of veterans referred for exercise testing for clinical reasons, who were followed for a mean of 4.5 years. Expressed in tertiles, age-adjusted relative risks for all-cause mortality using the VSAQ were 1.0 (low CRF, referent), 0.54 (moderate CRF),

and 0.22 (low CRF) (p for trend <0.001). Each 1-MET increase in the VSAQ conferred a 10% survival benefit. Similarly, the DASI was developed in a cohort of consecutive subjects undergoing exercise testing for clinical reasons and consists of a 12-item scale related to a patient's ability to perform daily activities. The DASI has been shown to be strongly correlated with peak VO_2 (r = 0.80), and studies have reported it to be a good predictor of risk for adverse outcomes in a variety of populations.[35,48,49] Both the VSAQ and DASI have been widely used both to estimate exercise capacity and to estimate long-term risk in a wide range of clinical populations, and both have been translated into several languages.[34,36,47–52]

In a combined analysis using 8 British cohorts that included 32,319 individuals, a non-exercise-test estimate of CRF was performed using age, gender, BMI, resting heart rate, and self-reported physical activity level.[45] Cardiovascular disease (CVD) and all-cause mortality were determined over a mean of nine years, and 9.4% and 7.4% lower risks of all-cause and 15.6% and 16.9% lower risks of CVD death per 1-MET increase were observed in men and women, respectively. In the Norwegian HUNT study,[39] a similar algorithm was used to estimate CRF among 37,112 individuals who were followed for a mean duration of 24 years. After adjustment for potential confounders, each 1-MET higher CRF was associated with 21% lower CVD mortality for both men and women who were younger than 60 years at baseline; the corresponding lower risks for all-cause mortality were 15% for men and 8% for women. Thus, although these non-exercise-test estimates of CRF are likely population specific and should not be viewed as a replacement for an exercise test when it is clinically necessary, they provide the clinician with a platform for counseling a patient regarding the importance of physical activity. When an exercise test is unavailable or impractical, they also serve to identify individuals with low CRF who are at increased risk.

15.14 MUSCULAR FITNESS

The ACSM defines muscular fitness as the ability of the muscle to perform tasks that require muscular strength or muscular endurance. Strength is an important component of fitness assessment, since it has implications for an individual's functional capabilities, disability, bone health, and insulin resistance, and has been shown to have a strong association with long-term outcomes.[53]

15.14.1 Muscular Strength

Muscular strength is defined as the ability of the muscle or muscle groups to exert force during a voluntary contraction.[1] The maximal force a muscle or group of muscles can exert is traditionally assessed by tests that require maximum effort against the greatest resistance at which one can move through the full range of motion once. This is known as the 1-repetition maximum (1-RM). A percentage of the 1-RM is then used to determine the number of repetitions one should perform to enhance the strength for a specific muscle. Generally, 8–12 repetitions at 40% to 60% of 1-RM are sufficient to enhance muscular strength. An appropriate resistance training regimen involves performing these 8–12 repetitions 1–3 times, 2–3 times per week. While intensities as high as 80% and relatively low numbers of repetitions (such as three to five) have been shown to be quite effective for rapid strength gains, this approach is generally limited to athletes whose performance requires great amounts of force.

It is important to note that intensity for resistance exercise is not always easy to determine, and the 1-RM does not depict a true intensity. The number of repetitions and the percentage of resistance based on 1-RM differ significantly between individuals and muscle groups. Thus, the 1-RM should only be used as a general guideline.[2]

15.14.2 MUSCULAR ENDURANCE

Muscular endurance is defined as the ability of the muscle or muscle groups to perform repetitive contractions over a period of time against resistance, such as lifting a set amount of weight several times.[2] Muscular endurance is assessed by tests requiring more than 12 repetitions. A simple test of muscular endurance is the maximum number of push-ups or sit-ups one can execute without rest.[2]

15.14.3 Tests of Anaerobic Power

Because *anaerobic* power is an important determinant of athletic performance requiring high levels of exertion over short periods, tests have been developed to measure the capacity of the anaerobic energy systems. One of the more common tests of this type is the *Wingate* test, which involves 30 to 120 seconds of high-intensity effort on a cycle ergometer. The resistance is based on body mass (originally 0.075 kp per kg body mass, though this may vary) and is applied after initial inertia and unloaded resistance are overcome. *Peak power* is considered to represent the highest mechanical power generated during any three- to five-second period during the test; *average power* is the average of the total power generated during the test. An underlying assumption of the Wingate test is that peak power reflects the energy-generating capacity of the oxygen-independent high energy phosphates, whereas average power is a representation of one's glycolytic capacity.[54,55] In studies comparing the Wingate test results with athletic performance and laboratory findings, it has been demonstrated to be a good index of these energy systems, although studies are mixed in terms of its ability to predict success in events requiring high exercise intensity.[55]

15.15 BODY COMPOSITION

In the United States and most of the industrialized world, obesity has reached epidemic proportions.[56] Overweight

and obesity are not simply cosmetic problems, but serious health conditions. They are both considered to be leading risk factors for a number of chronic health conditions, including diabetes, hypertension, coronary heart disease, and premature mortality, in developed countries. Although the mechanisms and causes of obesity are poorly understood, experts agree that obesity is largely the result of a chronic imbalance between caloric intake and caloric expenditure. This imbalance is likely the outcome of a complex interaction between genetic and environmental factors.[57]

15.15.1 Definition, Assessment, and Classification of Overweight and Obesity

Body composition is comprised of three major structural components: muscle, bone, and fat. Obesity is defined as the accumulation of excess body fat, usually ≥25% of the total body weight for men and ≥33% for women.[58] Assessing body fat is not a simple task. Several methods have been developed with mixed success. The most commonly used methods and their strengths and weaknesses are presented in the following subsections.

15.15.2 Hydrodensiometry or Underwater Weighing

One of the historically common assessments of body composition is hydrodensiometry or underwater weighing. This method is based on Archimedes' principle, which states that the weight an object loses when immersed in water is equal to the weight of the displaced water resulting from that immersion. The method is still widely used, but is less common today given the advent of DEXA and the fact that it is highly dependent on proper technique.

Percent body fat is estimated from body density, knowing that lean mass (bone and muscle) is denser than body fat. The density of fat is estimated to be 0.90 g/cm^{-3} and 1.10 g/cm^{-3} for fat free tissue.[59,60]

The following two most commonly used equations for estimating body composition from underwater weighing were developed in the late 1950s and early 1960s[59, 60] and are still in use:

$$\% \text{ Body fat} = (495/\text{Body density}) - 450^{57} \text{ (Siri)}$$

$$\text{Body fat} = (457/\text{Body density}) - 414.2^{58} \text{ (Brozek)}$$

For example, if a person weighs 100 kg on land and 5 kg submerged in water, the body density of this person is computed as mass divided by volume:

$$\text{Body density} = 100{,}000 \text{ g}/95{,}000 \text{ cm}^3 = 1.0526$$

Percent body fat is then calculated by the two formulas as follows:

$$\text{Percent body fat} = (495/1.0526) - 450$$
$$= 470.26 - 450 = 20.26$$
$$\text{Percent body fat} = (457/1.0526) - 414.2$$
$$= 434.16 - 414.2 = 19.96$$

Lean body mass (LBM) is then calculated by subtracting body fat from total body weight. Thus, the LBM of this individual weighing 100 kg is approximately 80 kg.

Please note that body density is inversely related to the water temperature. Body density at 4 degrees C or 39.2 degrees F is 1.0 and declines as water temperature increases. For practical reasons, warmer temperatures are generally used to perform underwater weighing, and the appropriate density value for that water temperature is applied.

It is also important to emphasize that the generalized density values of 1.10 for fat free (1.10 g/cm^{-3}) and fat (0.90 g/cm^{-3}) are based on young and middle-aged white men. The density of LBM is higher for blacks (1.113) than whites. This leads to an overestimation of LBM and underestimation of body fat for blacks. Thus, the following modification of the Siri formula has been proposed for blacks:

$$\text{Percent body fat} = (437.4/\text{Body density}) - 392.8^{56}$$

15.15.3 Other Methods

Direct assessment of body fat by densitometry is one of the most accurate methods, but it is generally not practical for large populations. Thus, several indirect techniques have been developed over the years to assess body composition. The most commonly used methods for estimating or assessing body composition and their advantages and disadvantages are described in Table 15.5.[5]

Because direct body fat assessment is impractical for large populations, the American Heart Association (AHA) and other health organizations have adopted BMI as a practical clinical indicator of adiposity.[57] BMI, calculated as weight (kg) divided by height (m) squared (kg/m^2), correlates well with total body fat and is related to cardiovascular and all-cause mortality.[61–63] The estimated BMI for different weights and heights is presented in Table 15.6.

A set of cut-points at five BMI intervals to classify overweight and obesity have been adapted by the National Heart, Lung, and Blood Institute and the World Health Organization.[58] Based on this classification, men and women with a BMI ≥30 kg/m^2 are considered obese (Table 15.7). However, it is important to keep in mind that BMI may not accurately reflect true adiposity for some populations. For example, a relatively muscular male weighing 100 kg, 1.80 m in height and with approximately 20% actual body fat, has a BMI of 30.86 (BMI = 100/1.80^2). Conversely, a male 1.80 m tall, weighing 80 kg, with 30% actual body fat, has a BMI of 24.7. According to the classification system commonly used (Table 15.7), these individuals will be misclassified as obese and normal weight, respectively.[5]

TABLE 15.5
Various Methods of Assessing Body Composition

Method/Techniques	Method of Assessment	Advantages	Disadvantages
Densitometry from Underwater Weighing	Subject fully exhales all air. Then, he/she is submersed in water for only a few seconds. Weight is assessed under water.	It is based on Archimedes' Principle. This method computes percentage body fat from body density (body mass/ body volume).	Expensive and time consuming. Requires a laboratory equipped with a water tank and trained personnel. It also requires that individuals exhale forcefully to reduce all possible air from lungs. Then, they are submersed in water for several trials, each lasting several seconds. This may not be tolerated well by some subjects, who will either not undergo the procedure or make it difficult to obtain an accurate reading.
Dual-Energy X-Ray Absorptiometry (DXA)	Uses two low energy distinct X-ray beams that penetrate bone and soft tissue areas to the depth of 30 cm. Computer software reconstructs the attenuated beams and produces an image of the tissues that can be used to quantify muscle and fat mass.	Quick, takes approximately 12 minutes to complete, and correlates very highly with densitometry. Total body mass or regional tissue mass can be assessed.	Expensive, requires trained personnel.
Bod-Pod	Relatively new procedure that uses an elliptical-shaped box that the subject sits in. It is based on air displacement plethysmography.	Quick, takes approximately three to five minutes, and has high reproducibility. Does not require any special skills by technician.	Expensive. Claustrophobia may be an issue with some participants.
Magnetic Resonance Imaging (MRI)		Can distinguish between changes in muscle mass and fat. Good for studies designed to assess changes in muscle mass (i.e., resistance [weight] training).	Very expensive, requires highly trained technicians. Cost prohibitive for large cohort studies.
Bioelectrical Impedance	A light current is introduced to the individual. Body fat is estimated by opposition to current flow.	Quick, relatively inexpensive.	Tends to overpredict body fat. Requires trained personnel and standardized conditions (hydration, environmental temperature) that may not be possible in all situations.
Skinfolds	Requires a caliper that measures body fat at standardized anatomical body sites.	Relatively easy and inexpensive to perform (requires a caliper). No special laboratory required other than a room for some privacy. Time requirements are only a few minutes per subject, thus allowing large numbers of individuals to be processed.	Skilled and experienced personnel are required.
BMI	Weight and height are needed.	The simplest and least expensive method, requiring only the weight (kg) and height (m) of the individual.	It is only an index of body dimensions. It does not measure body fat, but only assumes that higher BMI translates to higher body fat content. This may or may not be true and can vary greatly for different populations.
Waist circumference and waist-hip ratio	Measurements of waist and hip circumference.	Simple, inexpensive and relatively quick to perform.	Both waist circumference and the waist-to-hip ratio are indices of body composition. They do not measure body fat. However, they both provide an index of fat distribution.

TABLE 15.7
Classification of Body Weight and Obesity Based on BMI and Waist Circumference

	Obesity Class	BMI (kg/m²)	Waist Circumference (cm)	Associated Health Risk
Underweight		<18.5		
Normal		18.5–24.9		Average
Overweight		25.0–29.9	Men: ≥94Women: ≥80	Increased
Obesity	I	30.0—34.9	Men: ≥102Women: ≥102	Moderate
Moderate Obesity	II	35.0–39.9		High
Severe Obesity	III	≥40		Very High

BMI <18 is not recommended, and therefore, these values are not represented in this table.

15.15.4 Waist Circumference

Evidence supports the concept that excess accumulation of adipose tissue in the abdomen, characteristic of male type fat distribution (android, abdominal, or central obesity), is associated with a higher risk for mortality than peripheral distribution of body fat.[65] This is because fat that surrounds the internal organs, known as *visceral fat*, is most closely associated with metabolic disorders that increase cardiovascular risk, including insulin resistance, lipid abnormalities, and heightened markers of inflammation. Since BMI also fails to take body fat distribution into account, waist circumference provides a practical method for assessing mortality risk associated with central distribution of fat if a direct body fat assessment is not available. Waist circumference correlates more strongly with abdominal fat than BMI. Waist circumferences >102 cm for men and >88 cm for women are associated with increased cardiovascular risk.[66,67]

15.15.5 Skinfold Assessment

Body composition estimated by skinfold measurements is based on the premise that approximately one-third of the total body fat is subcutaneous fat and the remaining is visceral fat. Thus, skinfold thickness parallels total body fat and is another method often used to estimate body

composition. Because proportionally more fat is deposited viscerally with advancing age, age-adjusted equations should be used in older men and women. Assuming that the appropriate technique is used and factors that contribute to measurement error are controlled, the technique correlates fairly well with hydrodensiometry (r = 0.70 to 0.90). Accuracy is also compromised with extremely obese or extremely lean individuals.

Over the years, several sites and techniques have been identified and used to assess body composition via skinfolds. A thorough review of anthropometric assessments related to skinfolds is recommended for those interested in a more detailed description of this methodology.[68] These techniques are also reviewed in the ACSM Guidelines for Exercise Testing and Prescription.[2]

CLINICAL APPLICATIONS

The main objective of this chapter is to provide an overview of the procedures and techniques applied to assess physical fitness, which includes cardiorespiratory fitness, muscular strength, muscular endurance, and body composition.

16 Exercise Prescription for Apparently Healthy Individuals and for Special Populations

Paul G. Davis, PhD, ACSM-CEP

KEY POINTS

- Those who regularly practice physical activity carry a lower risk of premature mortality and of contracting several of the most prevalent chronic diseases, including cardiovascular disease, type 2 diabetes, and several cancers. Functional abilities are also likely to be preserved to an older age.
- It is recommended that adults participate in 150–300 minutes of moderate-intensity physical activity, or 75–150 minutes of vigorous-intensity physical activity, per week. Muscle-strengthening exercise should also be practiced on two to three days per week. Balance exercise should also be included for those who may be at risk of falling.
- These guidelines can be met though varying combinations of frequency, intensity, and duration. Enjoyable modes of physical activity should be chosen in order to enhance adherence.
- Everyone should be physically active. If these guidelines cannot be met due to disease or frailty, they should be attained to the best of a person's ability.
- It is considered safe for persons not possessing and without signs and symptoms of cardiovascular, metabolic, or renal disease to participate in moderate-intensity physical activity and if desired, to gradually progress to vigorous-intensity physical activity without prior medical clearance.

16.1 INTRODUCTION

The proper practice of physical activity has become increasingly recognized as an important means of optimizing one's health. Tables 16.1 and 16.2 list the currently documented health benefits of physical activity.[1] *Physical activity* is defined as "any bodily movement that is produced by the contraction of skeletal muscle and that increases energy expenditure above a basal level."[2] *Exercise*, on the other hand, is a more strictly defined subset of physical activity that is "planned, structured, repetitive, and performed with the goal of improving health or fitness" (e.g., cardiorespiratory endurance, muscular strength).[2] Increases in both exercise and overall physical activity can maintain and improve health. Accordingly, this chapter will 1) review the current recommendations for physical activity, 2) discuss prescription of both fitness-oriented exercise and overall physical activity, and 3) discuss prudent alterations to the normal exercise prescription in some of the more prevalent clinical populations.

16.2 PHYSICAL ACTIVITY RECOMMENDATIONS

In 2018, the U.S. Department of Health and Human Services (DHHS) released the second edition of its *Physical Activity Guidelines for Americans*.[2] Using mostly the same evidence base, the World Health Organization (WHO) released its *Guidelines on Physical Activity and Sedentary Behaviour* in 2020.[3] Both these documents provide minor adjustments to their respective recommendations published in 2008 and 2010 and discuss the growth of the evidence base of physical activity's health-based contributions. For adults aged 18 to 64, 150 weekly minutes of moderate-intensity aerobic activity are advocated, with recognition that increasing benefits are likely to accrue through at least 300 minutes per week. Alternatively, 75 to 150 minutes of vigorous-intensity aerobic activity can be performed to amass similar benefits (*moderate-* and *vigorous-intensity* aerobic activity are defined and discussed later). A combination of moderate- and vigorous-intensity activity may also be employed. In addition, resistance training involving all major muscle groups is recommended at least twice weekly. Additional recommendations for children, the elderly, and other special populations are discussed later in this chapter.

As mentioned, both sets of *Guidelines* provide minor adjustments to their earlier reports. Regarding the *accumulation* of moderate-to-vigorous intensity physical activity, there is no longer a premise that only activity bouts of 10 minutes or longer are recognized as being beneficial to health. Newer evidence indicates that moderate-to-vigorous bouts of any time length that are included in one's weekly total lead to health benefits. In addition, there is no *threshold* amount of physical activity needed to produce health benefits. Although not optimal,

DOI: 10.1201/9781003227793-19

TABLE 16.1
Documented Health Benefits of Physical Activity – General Population

Children	
3 to <6 years of age	Improved bone health and weight status
6 to 11 years of age	Improved cognitive function (ages 6 to 13 years)
	Improved cardiorespiratory and muscular fitness
	Improved bone health
	Improved cardiovascular risk factor status
	Improved weight status or adiposity
	Fewer symptoms of depression
Adults, All Ages	
All-cause mortality	Lower risk
Cardiometabolic conditions	Lower cardiovascular incidence and mortality (including heart disease and stroke)
	Lower incidence of hypertension
	Lower incidence of type 2 diabetes
Cancer	Lower incidence of bladder, breast, colon, endometrium, esophagus, kidney, stomach, and lung cancers
Brain health	Reduced risk of dementia
	Improved cognitive function
	Improved cognitive function following bouts of aerobic activity
	Improved quality of life
	Improved sleep
	Reduced feelings of anxiety and depression in healthy people and in people with existing clinical syndromes
	Reduced incidence of depression
Weight status	Reduced risk of excessive weight gain
	Weight loss and the prevention of weight regain following initial weight loss when a sufficient dose of moderate-to-vigorous physical activity is attained
	An additive effect on weight loss when combined with moderate dietary restriction
Older Adults	
Falls	Reduced incidence of falls
	Reduced incidence of fall-related injuries
Physical function	Improved function in older adults with and without frailty

Source: 2018 Physical Activity Guidelines Advisory Committee. 2018 Physical Activity Guidelines Advisory Committee Scientific Report. Washington, DC: U.S. Department of Health and Human Services, 2018. Available at: https://health.gov/paguidelines/second-edition/report/pdf/PAG_Advisory_Committee_Report.pdf

increasing a low level of physical activity to a volume that is still below that recommended in the *Guidelines* will still yield some benefit. In addition, although no threshold has been identified, there is increased emphasis on reducing sedentary behavior. It is now recognized that even in people meeting the physical activity recommendations, habitual prolonged sitting can still lead to health detriments, and additional physical activity may be necessary to counteract them.[1–3]

16.3 EXERCISE PRESCRIPTION

16.3.1 Physical Fitness Parameters

Physical fitness is "the ability to carry out daily tasks with vigor and alertness, without undue fatigue and with ample energy to enjoy leisure-time pursuits and to meet unforeseen emergencies."[2] Elements of physical fitness have traditionally been categorized as either health-related (cardiorespiratory endurance, muscular endurance, muscular strength, body composition, flexibility) or skill/performance-related (agility, balance, coordination, speed, power, reaction time). Definitions of the various physical fitness elements are listed in Table 16.3. The health-related fitness components are certainly important in chronic disease prevention and rehabilitation. However, particularly among the elderly and those with certain musculoskeletal diseases, maintenance of a certain level of skill-related fitness is also critical to independent function and quality of life. For example, the ability to drive a car or cross a busy street safely depends as much on *skill*-related as *health*-related fitness. Conversely, all of the health-related fitness parameters are key elements of various athletic and recreational activities. Therefore, while categorization of these elements may be helpful in developing fitness goals and an exercise plan, one should realize that training toward elements of *both* health-related and skill-related fitness may be prudent with many clients. The most recent version of the *Physical Activity Guidelines for Americans* recognizes this by including cardiorespiratory endurance, muscular strength, and flexibility in both categories and now considers balance more as an element of health.[2]

TABLE 16.2
Documented Health Benefits of Physical Activity—Individuals with Pre-Existing Medical Conditions

Breast cancer	Reduced risk of all-cause and breast cancer mortality
Colorectal cancer	Reduced risk of all-cause and colorectal cancer mortality
Prostate cancer	Reduced risk of prostate cancer mortality
Osteoarthritis	Decreased pain Improved function and quality of life
Hypertension	Reduced risk of progression of cardiovascular disease Reduced risk of increased blood pressure over time
Type 2 diabetes	Reduced risk of cardiovascular mortality Reduced progression of disease indicators: hemoglobin A1c, blood pressure, blood lipids, and body mass index
Multiple sclerosis	Improved walking Improved physical fitness
Dementia	Improved cognition
Some conditions with impaired executive function (attention deficit disorder, schizophrenia, multiple sclerosis, Parkinson's disease, and stroke)	Improved cognition

Source: 2018 Physical Activity Guidelines Advisory Committee. 2018 Physical Activity Guidelines Advisory Committee Scientific Report. Washington, DC: U.S. Department of Health and Human Services, 2018. Available at: https://health.gov/paguidelines/second-edition/report/pdf/PAG_Advisory_Committee_Report.pdf

TABLE 16.3
Health-Related and Performance-Related Physical Fitness Parameters

Health-Related	Performance-Related
Balance—the maintenance of equilibrium while stationary or moving	**Agility**—the ability to rapidly change the position of the entire body in space with speed and accuracy
Body composition—the relative amounts of muscle, fat, bone, and other vital parts of the body	**Balance**
Cardiorespiratory endurance—the ability of the circulatory and respiratory systems to supply fuel during sustained physical activity and to eliminate fatigue products after supplying fuel	**Cardiorespiratory endurance**
Flexibility—the range of motion available at a joint	**Coordination**—the ability to use the senses, such as sight and hearing, together with body parts in performing motor tasks smoothly and accurately
Muscular endurance—the ability of muscle groups to exert external force for many repetitions or successive exertions	**Flexibility**
Muscular strength—the amount of external force that a muscle can exert	**Muscular strength**
	Power—the rate at which one can perform work
	Reaction time—the time elapsed between stimulation and the beginning of the reaction to it
	Speed—the ability to perform a movement within a short period of time

Although physical fitness is dichotomized into health- and performance-related categories, overlap exists between the two (see text).
Definitions from Corbin CB, Lindsey R. *Concepts in Physical Education with Laboratories* (8th edition). Dubuque, IA: Times Mirror Higher Education Group, 1994.

16.3.2 Exercise Training Principles

Although goals and responses to physical activity and exercise training can vary considerably from person to person, three general principles should be considered when developing an exercise plan: *progressive overload*, *specificity*, and *reversibility*.

16.3.2.1 Progressive Overload

Adaptations only occur in physiological systems when the systems are stressed at levels to which they are unaccustomed. In other words, for any physical fitness parameter, a *threshold* of physical activity exists that a person must exceed in order to experience improvement. This minimal amount of training needed depends upon both the baseline level of the variable to be changed and a person's genetic capacity to experience positive changes in the targeted physiological system(s).

Given a steady overload, physiological improvement will level off or plateau after a given period of time. The term *progressive* overload indicates that the training stimulus

must continue to increase in order for further improvement to be recognized. The overall training stimulus can usually be augmented by increasing the *intensity*, *duration*, and/or *frequency* of physical activity.

16.3.2.2 Specificity

Overload will only result in an adaptation to the muscle groups and physiological systems that are stressed in training. Specificity of training applies to the motor units involved (e.g., muscles used, joint angle), speed of contraction, and the energy systems and primary substrates used (e.g., aerobic versus anaerobic metabolism, fat versus carbohydrate). Unless a person is severely untrained (e.g., frail elderly), strength training will do little to improve cardiorespiratory endurance, and vice versa. Furthermore, although distance cycling and running are both aerobic activities using the legs, the carryover from training in one mode to performance improvement in the other is limited. Similarly, while squat training mainly improves quadriceps strength, this improvement may not be recognized when testing with another exercise (e.g., leg extension) that uses different motor unit recruitment and accessory muscles. Therefore, in addition to training specifically toward a person's goals, assessment of improvement should involve testing that is congruent with the training that has been employed. The more specific a person's training goals (e.g., athletic performance), the more important these issues become.

16.3.2.3 Reversibility

Just as the body adapts positively to increases in physical activity, it adapts negatively to inactivity. The rate of deconditioning varies depending on the previous training level and how much it is curtailed. For example casting or extended bed rest can result in sharp, rapid declines in strength and endurance performance. In a more practical sense, fitness levels tend to decline significantly after about two weeks of exercise cessation. Endurance training of two to three days per week and resistance training of at least once per week are generally necessary to maintain previously attained fitness levels.

16.3.3 Cardiorespiratory Endurance Training

Maximal oxygen consumption (VO_{2max}) is the most accurate measure of cardiorespiratory fitness. Although some health benefits can be recognized with the practice of moderate-intensity physical activity that is less likely to improve VO_{2max},[4] strong inverse relationships exist between VO_{2max} and overall mortality and most major chronic diseases.[5] As such, the American College of Sports Medicine has traditionally recommended the following frequency, intensity, time, and type (***FITT***) of exercise for the improvement of cardiorespiratory fitness.[6]

16.3.3.1 Type (Mode) of Exercise

Activities that overload the cardiorespiratory system are repetitive (rhythmic) in nature and involve larger muscle groups. Examples include brisk walking, running, cycling, rowing, and exercising on an elliptical machine. Sports that constantly require intermittent bouts of vigorous body movement, such as basketball, soccer, and tennis, can also contribute to improved cardiorespiratory fitness. Unless medical conditions dictate otherwise, the majority of exercise should be weight-bearing in order to help prevent osteoporosis.

While specificity of training is very important for athletes, persons training more for overall health and fitness purposes will likely benefit from practicing a variety of exercise modes. Such practice will likely lead to fewer overuse injuries and will also add variety to the training regimen, possibly leading to better program compliance. For beginning exercisers, walking is generally a very good activity to include, since it requires little skill and results in fewer overuse injuries than most other modalities.

16.3.3.2 Intensity of Exercise

Improvement in VO_{2max} can usually be attained by exercising regularly at 50–85% of $VO_{2reserve}$ ($VO_{2reserve} = VO_{2max} - VO_{2rest}$). Obviously, this range is wide; the most effective intensity will depend in part upon the duration and frequency of exercise. Nevertheless, larger improvements in VO_{2max} typically occur with higher intensities. However, higher volumes of exercise (to include intensity, duration, and frequency) are more likely to result in overtraining symptoms (e.g., fatigue, injury, decreased performance, suppressed immune function). Exercise training at 60–80% $VO_{2reserve}$ generally results in improved VO_{2max}. However, the intensity threshold for improved VO_{2max} also depends upon baseline fitness level; low-fit, untrained individuals often experience improvement in the light-to-moderate-intensity range, while highly trained and fit individuals might need to spend a considerable amount of their training time above 80% $VO_{2reserve}$ to continue to improve their cardiorespiratory fitness.[6]

As stated in this chapter's introduction, the *Physical Activity Guidelines for Americans* give health-oriented recommendations for both moderate- and vigorous-intensity physical activity. In relative terms, *moderate-intensity* physical activity is defined as activity requiring 40–60% of $VO_{2reserve}$, while *vigorous-intensity* physical activity is anything that requires above 60% $VO_{2reserve}$. While moderate-intensity physical activity may result in some fitness improvement for those starting at a low fitness level, the progressive overload necessary to elicit and maintain improvement lies in the vigorous-intensity range for many people, especially those who are younger and/or more fit.

If a person's VO_{2max} has been measured or estimated through exercise testing,[6] exercise intensity may be prescribed as a given percentage of $VO_{2reserve}$. $VO_{2reserve}$ is calculated by subtracting the estimated value for VO_{2rest} (1 MET = 3.5 $mL \cdot kg^{-1} \cdot min^{-1}$) from VO_{2max}. $VO_{2reserve}$ is then multiplied by the target percentage, and VO_{2rest} is then added back to the product to yield the target VO_2 (Table 16.4).

Knowing the MET ("metabolic equivalent of task") levels of various activities can be useful in prescribing

TABLE 16.4
Calculation of Target Oxygen Consumption ($VO_{2target}$) and Target Heart Rate (HR_{target}) by Reserve Method

$VO_{2target}$[a]

Step 1: Calculate $VO_{2reserve}$

$VO_{2reserve} = VO_{2max} - VO_{2rest}$

Step 2: Multiply $VO_{2reserve}$ by the desired percentage

$VO_{2fraction} = VO_{2reserve} \times$ Target Percentage

Step 3: Calculate $VO_{2target}$ by adding VO_{2rest} to $VO_{2fraction}$

$VO_{2target} = VO_{2fraction} + VO_{2rest}$

***Example*:** You want a person with a VO_{2max} of 35 $mL \cdot kg^{-1} \cdot min^{-1}$ to exercise at 65% $VO_{2reserve}$:

Step 1: Calculate $VO_{2reserve}$

$VO_{2reserve} = 35.0 - 3.5 = 31.5\ mL \cdot kg^{-1} \cdot min^{-1}$

Step 2: Multiply $VO_{2reserve}$ by the desired percentage

$VO_{2fraction} = 31.5 \times 0.65 = 20.5\ mL \cdot kg^{-1} \cdot min^{-1}$

Step 3: Calculate $VO_{2target}$ by adding VO_{2rest} to $VO_{2fraction}$

$VO_{2target} = 20.5 + 3.5 = 24.0\ mL \cdot kg^{-1} \cdot min^{-1}$

HR_{target}

Step 1: Estimate HR_{max}[b]

$HR_{max} = 220 - age$[c]

Step 2: Calculate $HR_{reserve}$

$HR_{reserve} = HR_{max} - HR_{rest}$

Step 3: Multiply $HR_{reserve}$ by the desired percentage

$HR_{fraction} = HR_{reserve} \times$ Target Percentage

Step 4: Calculate HR_{target} by adding HR_{rest} to $HR_{fraction}$

$HR_{target} = HR_{fraction} + HR_{rest}$

***Example*:** You want a 50-year-old person with a HR_{rest} of 70 bpm to exercise at 65% $HR_{reserve}$:

Step 1: Estimate HR_{max}[b]

$HR_{max} = 220 - 50 = 170$ bpm[c]

Step 2: Calculate $HR_{reserve}$

$HR_{reserve} = 170 - 70 = 100$ bpm

Step 3: Multiply $HR_{reserve}$ by the desired percentage

$HR_{fraction} = 100$ x $0.65 = 65$ bpm

Step 4: Calculate HR_{target} by adding HR_{rest} to $HR_{fraction}$

$HR_{target} = 65 + 70 = 135$ bpm

[a]MET values may be substituted for VO_2 ($1\ MET = 3.5\ mL \cdot kg^{-1} \cdot min^{-1}$).
[b]When possible, use HR_{max} from maximal graded exercise test instead of estimation.
[c]Alternatively, the formula "$HR_{max} = 207 - (0.7 \times age)$" may be used.

physical activity after a target VO_2 range has been determined. One MET is an estimation of a person's energy expenditure when seated at rest ($3.5\ mL \cdot kg^{-1} \cdot min^{-1}$). As an example, if a person performs an activity that requires six times the energy requirement of sitting at rest, that activity would carry a MET level of six, requiring a VO_2 of approximately 21 $mL \cdot kg^{-1} \cdot min^{-1}$ ($6 \times 3.5 = 21$). The *Compendium of Physical Activities* (https://sites.google.com/site/compendiumofphysicalactivities/) has been published to provide the MET requirements of more than 800 leisure-time and occupational activities.[7] Table 16.5 includes examples of MET levels for some more common activities. If a target MET range has been determined ($MET_{target} = VO_{2target} \div 3.5$), the *Compendium* can be used to identify activities of appropriate intensity.

Many professionals find it more practical to prescribe exercise intensity by heart rate rather than VO_2. Since heart rate and VO_2 have a linear relationship during graded exercise, a given percentage of heart rate reserve ($HR_{reserve}$) parallels the same percentage of $VO_{2reserve}$ and therefore, may be used in its place. When available, it is preferable to use the maximal heart rate (HR_{max}) attained from a maximal graded exercise test. If a true HR_{max} is not available, an age-predicted value may be used. Just as with the $VO_{2reserve}$ method, HR_{rest} is subtracted from HR_{max} to obtain $HR_{reserve}$. The target heart rate is then derived by multiplying $HR_{reserve}$ by the desired percentage and adding HR_{rest} to the product (Table 16.4).

The most common formula for estimating HR_{max} in adults is "$HR_{max} = 220 - age$." It is most accurate around the age of 40 years and over- and underestimates HR_{max} in younger and older people, respectively. A more accurate formula, "$HR_{max} = 207 - (0.7$ x age)," has been reported.[8] While this formula is slightly more complicated, it may result in a more appropriate intensity prescription, particularly among the elderly. Regardless of the formula used, it is important to realize that HR_{max} has a standard deviation of 10–12 beats per minute (bpm) across the adult age span. This can obviously limit the value of using age-predicted HR_{max} in determining a target heart rate. As such, many professionals prescribe HR_{target} as a range of 10% $HR_{reserve}$ or so. A person's subjective feeling of effort should also be considered during exercise. On a scale of 0 to 10, where sitting is 0 and maximal effort is 10, moderate-intensity activity should yield a rating of 5 or 6 and vigorous-intensity activity of 7 or 8.[2] Such ratings are particularly useful for people who have clinical conditions or take medications that affect the heart rate response to exercise.

As an alternative to the $HR_{reserve}$ method, exercise intensity may be prescribed using a straight percentage of HR_{max} (65–90% HR_{max} is approximately equivalent to 50–85%

TABLE 16.5
Sample Metabolic Equivalent (MET) Levels of Common Physical Activities

Activity	METs	Activity	METs
Walking, 2 miles per hour	2.8	Aerobic dancing	5.0–9.5
Walking, 3 miles per hour	3.5	Golf, using power cart	3.5
Walking, 4 miles per hour	5.0	Golf, walking, pulling/carrying clubs	4.3–5.3
Running, 6 miles per hour	9.8	Tennis	4.5–8.0
Running, 7.5 miles per hour	11.5	Soccer	7.0–10.0
Running, 9 miles per hour	12.8	Washing and waxing car	2.0
Bicycling, 5.5 miles per hour	3.5	Most housecleaning activities	2.5–3.5
Bicycling, 9.4 miles per hour	5.8	Gardening	2.3–5.8
Bicycling, 15 miles per hour	10.0	Mowing lawn, riding mower	2.5
Swimming, sidestroke	7.0	Mowing lawn, walk, power mower	4.5–5.0
Swimming, crawl, ~50 yards per min	8.3	Mowing lawn, walk, hand mower	6.0
Swimming, crawl, ~75 yards per min	10.0	Shoveling dirt or snow	5.3–7.8

$HR_{reserve}$). However, many professionals prefer the $HR_{reserve}$ method, as it is more individualized by taking HR_{rest} into account.

16.3.3.3 Time (Duration) of Exercise

For improvement in cardiorespiratory fitness, 20–60 minutes per session is recommended, with duration and intensity interacting with one another. For example, 20–30 minutes of exercise at a higher intensity can yield similar benefits to 50–60 minutes of exercise at a lower intensity. Similar fitness benefits are recognized regardless of whether exercise is performed continuously or intermittently throughout the day.

16.3.3.4 Frequency of Exercise

Three to five days of exercise have traditionally been recommended for the improvement of cardiorespiratory fitness. While six or seven days per week may be practiced to accumulate the moderate-intensity guidelines of 150–300 minutes per week, such a frequency of vigorous-intensity exercise will likely increase one's chance of injury while yielding few additional health or fitness benefits. Therefore, as with other exercise prescription parameters, exercise frequency should vary with goals. For example, daily or near-daily physical activity is advocated for weight loss or maintenance, while "recovery days" of rest or lighter activity are usually necessary between more intense workouts.

16.3.3.5 Overall Exercise Volume

While vigorous exercise intensity may carry limited advantages for some health parameters, it is the overall volume of physical activity that matters most in improving and maintaining good health; i.e., longer bouts of moderate-intensity and shorter bouts of vigorous-intensity physical activity produce similar benefits. In recognition of a dose–response relationship between physical activity and health, both DHHS and WHO advocate a range of 150–300 weekly minutes of moderate-intensity physical activity, 75–150 weekly minutes of vigorous physical activity, or an appropriate combination of the two.[2,3] While fitness improvement might be minimal, increased physical activity that falls below the lower ends of these ranges is still likely to result in some health benefit ("some activity is better than none"). On the other end, although a higher risk of musculoskeletal injury exists, exceeding the recommended physical activity ranges will likely lead to even greater health benefits. Also, as stated earlier, people spending larger parts of their days in sedentary activities may need to exceed these recommended physical activity ranges in order to counteract the effects of prolonged periods of inactivity.

16.3.3.6 Rate of Progression

Training volume can be increased though alteration of exercise frequency, intensity, and/or duration. Many professionals first choose to implement small changes in exercise duration (5–10 minutes per session), as they are usually well tolerated and may be less likely to negatively affect exercise adherence. Depending upon a person's beginning exercise volume and their goals, frequency and/or intensity may then be increased. Although somewhat anecdotal, the "ten percent rule" is a good rule of thumb; exercise volume (usually quantified by distance or time) should not be increased by more than 10% per week. Overtraining symptoms (e.g., upper respiratory infection, muscle/joint pain) should be recognized, and a reduction of training volume and/or a change of exercise modality should be implemented. Additionally, periodization (changing intensity, duration, and/or overall training volume within and across weeks) can enhance fitness improvement and reduce overtraining symptoms.

16.3.4 Resistance Training

The *Physical Activity Guidelines for Americans* and the *Guidelines on Physical Activity and Behaviour* both

recommend that muscle-strengthening (resistance) activities that involve all major muscle groups be performed on two or more days per week.[2,3] Benefits of resistance training include maintenance or increases in bone mass, insulin sensitivity, and skeletal muscle mass, the latter two being important for those attempting to reduce body fat. Maintenance or gain in strength can also be important in preserving physical function in the elderly and persons with certain disabilities.

16.3.4.1 Type of Resistance

Dynamic resistance exercises alternately overcome (*concentric* contractions) and accommodate (*eccentric* contractions) a given force. This force is often in the form of weights (either "free" weights or stacked weights on various machines) but can also exist in other forms, such as elastic bands or one's own body weight. The type of resistance to be used in training depends largely upon the goals of the participant, and a combination of resistance modes is often employed. More "controlled" modes (e.g., weight machines, resistance bands) are generally safer and less likely to require a spotter, while less controlled modes (e.g., free weights) require more balance and tend to mimic real-life movement more. In addition, lifting in a more stable position (e.g., from a bench) allows more weight to be lifted, resulting in greater strength gain. Lifting from less stable surfaces (e.g., stability balls) requires lowering of the training resistance and will likely result in lower specific strength gain, but causes adaptation over a wider range of motor units, resulting in a more functional training effect. As such, the greatest performance gains may result from employing a combination of resistance modes. Regarding exercise adherence, preference of exercise type should also be considered.

For the purposes of safety and effectiveness (i.e., specificity), proper technique (e.g., keeping back straight, controlling eccentric portion of exercise) should be stressed with any type of exercise. In addition, unless the development of isometric (static) strength is a specific training goal, resistance exercises should be dynamic, generally taking the involved joints through the fullest range of motion possible. This allows a greater number of motor units to be trained, creating more functional benefits.

Regardless of the mode(s) of resistance used, all major muscle groups should be exercised. At least eight to ten different exercises are generally required to target all of the major muscle groups. Accordingly, to encompass the entire body and lessen the chances of strength imbalances, opposing (antagonistic) muscles groups should be exercised. For example, if the abdominal muscles are focused upon in one exercise, another exercise should target the lower back muscles; both the biceps and triceps should be targeted in separate exercises, etc. For practical purposes, multi-joint exercises (e.g., bench press, squat) that simultaneously train more than one muscle group are preferred over single-joint exercises (e.g., triceps extension, leg extension) because they are more time-efficient and tend to represent real-life movements more. However, single-joint exercises can still serve as useful adjuncts, particularly if they mimic a particular movement in a sport or other activity for which a person is training.

16.3.4.2 Amount of Resistance; Repetitions and Sets

To achieve improvements in both muscular endurance and strength, completion of 8 to 12 repetitions of each exercise to a point of *fatigue* (not necessarily *failure*) is recommended. Lifting to fatigue infers that an additional repetition would be difficult to perform without help.[2] Performing 8–12 repetitions to fatigue generally requires a resistance of about 60% of a person's 1-repetition maximum (1RM; the maximum amount of weight that can be lifted in a single effort in that same exercise).[6] Performing fewer than 8–12 repetitions to fatigue (which would employ a greater resistance) will result in more strength gain than gain in endurance, while performing more than 8–12 repetitions (requiring less resistance) will result in more improvement in muscular endurance.

The compilation of repetitions of an exercise performed at one time (e.g., 8–12) is termed a *set*. Multiple sets of an exercise may be performed, with one to three minutes' rest in between being recommended; shorter rest periods are more time-efficient, while longer rest periods allow greater amounts of work to be performed. For beginners, performing a single set of an exercise for 8–12 repetitions to fatigue on a regular basis will almost always result in strength gains. In time, additional sets will likely be necessary for further improvement.[2] For continued improvement, ACSM suggests that four or more sets per week should be performed with each muscle group. More than one exercise may be employed for a given muscle group. For example, both the bench press and dips involve the pectoralis and triceps muscles, but require different movement patterns. Therefore, completing two sets of both of these exercises over the week would satisfy the recommendation of four sets per week for these muscle groups.[6] In short, the number of sets to be performed depends upon the goals of the participant. Health and functional benefits can be recognized with a minimum number of sets, but a dose–response relationship exists between training volume and strength gain.

16.3.4.3 Frequency of Training

For the novice, resistance training sessions should be spaced at least 48 hours apart from one another to allow sufficient recovery.[6] Therefore, two to three sessions per week of resistance training are recommended. With more experienced participants, lifting frequency has little effect on strength gain when training volume (e.g., number of sets) is held constant.[6] If time constraints do not permit all exercises to be performed in a given day, then the same muscle groups should not be exercised on consecutive days (e.g., train the upper body one day and the lower body the next).

16.3.4.4 Rate of Progression

As mentioned earlier, resistance training sets should be performed to fatigue in order for muscular fitness gains to

be achieved. A person should increase the resistance of an exercise when they can perform one or two extra repetitions with good form. To remain in the desired repetition range (e.g., 8–12), increases of 2.5 to 5 pounds are generally appropriate for smaller muscle groups and increases of 5 to 10 pounds are generally appropriate for larger ones.

Even when these criteria are followed, people training for larger gains in muscle size and strength often *plateau*, or fail to experience continued improvement after many months. In this case, *periodization*, the frequent alteration of training intensity, repetitions, sets, and/or resistance mode, can be useful. While beyond the scope of this chapter, ACSM has published a position stand addressing this topic.[9]

16.3.5 Flexibility Training

Maintenance of flexibility, the range of motion around a joint, can be important for the prevention of low back pain and for the maintenance of activities of daily living. While stretching might help prevent injury in activities where one's range of motion is taken to its limits (e.g., gymnastics), there is no conclusive evidence that stretching prevents injury in activities requiring less range of motion (e.g., jogging) or that it prevents muscle soreness.[10,11]

Nevertheless, since flexibility decreases with aging, stretching is an important component of a well-rounded fitness program. Both static stretching, where a person holds a stretch for an extended period, and dynamic stretching, which involves controlled movements (e.g., swinging of arms, high knee stepping) with a gradually increasing range of motion, are effective in increasing flexibility. Static stretching is more effective, and possibly safer, after a person has gone through a warm-up period. In fact, unless a person is getting ready to perform activities that challenge their range of motion, static stretching is usually most effective at the end of an exercise session rather than at the beginning. Prior to activities that challenge one's range of motion, dynamic stretching is effective and also helps warm up the muscles. ACSM recommends that stretching exercises be performed for 10–30 seconds each on at least 2 or 3 days weekly.[6]

16.3.6 Warm-Up and Cool-Down

Both before (*warm-up*) and after (*cool-down*) the conditioning phase of an exercise session, at least five to ten minutes of low-intensity physical activity should be performed. The increased blood flow and body temperature resulting from the warm-up period allow the muscle and connective tissue to become more pliable, reducing the chance of injury during vigorous activities. It also allows a more gradual cardiovascular adaptation to the stress of exercise, which is particularly important for people who are more likely to experience cardiac events. Similarly, a proper cool-down period helps prevent venous pooling in the lower extremities, thereby facilitating venous return to the heart and brain. Muscular endurance activities, such as abdominal exercises, and stretching may also be better performed during the cool-down phase.

16.3.7 Physical Activity Adherence

Specific strategies for enhancing physical activity participation are detailed in Chapter 21. In general terms, the clinician should recognize that a good bit of flexibility exists in how a person can choose to meet physical activity guidelines (i.e., wide ranges exist in the components of FITT) and that physical activity may be practiced in a variety of settings (at home, outside, in a fitness facility, etc.). In addition, leisure-time physical activity may be practiced alone, with a partner, or in a group setting. Everyone should be encouraged to experiment with a variety of exercise regimens and to continue to practice the one(s) they enjoy the most.

Approximately one-quarter of adults worldwide[3] and one-half of U.S. adults[12] fail to meet current guidelines for aerobic physical activity, while approximately three-quarters of U.S. adults fail to meet the combined aerobic and muscle-strengthening activity guidelines.[12]. As patients are more likely to be physically active when such behavior is endorsed by their physicians, *Healthy People 2020* and *Healthy People 2030* both included initiatives for patients with cardiometabolic conditions to receive physical activity counseling during healthcare visits.[15] However, most physicians have received little education on physical activity counseling as part of their medical training. Appropriately, in order to facilitate delivery of prudent physical activity information by healthcare providers, ACSM and the American Medical Association provide an educational website, *Exercise Is Medicine* (http://exerciseismedicine.org).[15] This and other clinician resources are discussed in Chapter 11.

16.4 EXERCISE PRESCRIPTION FOR SPECIAL POPULATIONS

With rare exceptions, everyone should be physically active. However, physical limitations and safety issues sometimes necessitate that the "normal" exercise prescription described previously be altered. As such, this next section discusses recommendations for children and older adults and people with some of the more prevalent chronic diseases. This discussion is only introductory in nature; other sources dedicated to the subject of clinical exercise physiology are available and cover a wider variety of chronic conditions in greater detail.[16,17] Exercise prescription for pregnant women (Chapter 54) and individuals with cardiovascular disease (CVD) (Chapter 67) and obesity (Chapter 37) are detailed elsewhere in this book.

16.4.1 Children and Adolescents

Proper physical activity can help develop and maintain a healthy body weight and cardiometabolic risk profile, can

reduce symptoms of anxiety and depression, and can instill positive habits that may carry over into adulthood. Current *Guidelines* recommend that youth accumulate at least 60 minutes of moderate- and vigorous-intensity physical activity daily.[2,3] These 60 minutes should include a combination of aerobic activities (e.g., bicycling, dancing) and short bursts of activity (e.g., playing tag, soccer) as well as activities that promote muscular fitness (e.g., climbing trees or playground equipment) and bone health (impact activities such as running or jumping rope). The *Guidelines* can be met through structured sports, games, and exercise classes and/or unstructured play. While specific time guidelines are not currently provided, it is also recommended that preschool-aged children (ages three to five years) be physically active throughout the day.[2]

Adults can facilitate physical activity among youth by providing ample opportunity for participation. Two examples of how to do this are by limiting screen time (television, video games, and computers) and increasing the amount of time dedicated to physical activity during the school day. Academic performance is not sacrificed when students are provided with opportunities for daily physical activity in school, such as daily recess, physical education classes, or implementation of physically active learning opportunities in other classes.[18] Many youth will choose to be active when given ample opportunity. However, some cohorts that tend to be less active (adolescent girls, the obese) may benefit from structured exercise programs that include like peers and focus on a variety of activities that are popular within a given gender and age group (e.g., dance for adolescent girls).

Compared with adults, a couple of physiological differences in children are worth noting. First of all, children sweat less than adults and do not acclimatize to heat exposure as quickly. They also possess a delayed thirst response. Therefore, it is important to gradually expose children to exercise in warmer environments and to emphasize frequent fluid intake (every 15–20 minutes). Second, while precise exercise prescription is generally not necessary, adult formulas for maximal heart rate do not apply to children and adolescents, who typically have maximal heart rates of approximately 200–205 bpm. RPE and a noticeable increase in breathing are generally sufficient monitoring tools for health-related physical activity.[2]

16.4.2 Older Adults

Among older adults, proper physical activity can increase and maintain physical function, improve and maintain body composition, promote psychological and cognitive well-being, and assist in primary and secondary prevention of chronic diseases. Keeping in mind that exercise intensity is relative (e.g., a given walking speed may be considered light for one person and vigorous for another), the physical activity guidelines are essentially the same for adults over the age of 65 as they are for middle-aged and younger adults.[2,3] Frail persons, who may have difficulty meeting the guidelines, should practice as much physical activity as they can tolerate with the goal of safely advancing their physical activity into the range recommended for the general population.

In addition to the same endurance and resistance exercise advocated for the general population, older adults at risk for falling should add exercises on two to three days per week that focus on balance. While a wide variety of such activities exist, the ones performed should focus on a person's particular needs. Examples include walking sideways and backward, repetitively standing and sitting, standing with eyes closed, tai chi, etc. Functional resistance exercises can also be useful in this regard. Previously inactive seniors, in particular, may benefit from the services of a properly credentialed personal trainer or exercise class in the beginning stages of an exercise program.

16.4.4 Diabetes Mellitus

Both type 1 and type 2 diabetes mellitus are characterized by abnormally high blood glucose levels. Since physical activity facilitates glucose uptake by skeletal muscle, it can serve as an important mechanism of managing glucose concentration in either disease. In addition, through its effect on weight management, an adequate amount of physical activity (combined with a prudent diet) may assist in partial or more rarely, full reversal of type 2 diabetes. Proper physical activity can also improve one's CVD risk profile. Exercise can also be an effective means of preventing diabetes onset in people with impaired glucose tolerance.[20]

It is generally safe for persons with diabetes to participate in light-to-moderate physical activity as long as they are asymptomatic and are at low risk (ten-year Framingham risk of <10%) for CVD.[6,21] However, a physical examination is recommended before engaging in vigorous-intensity exercise. Although many people with type 1 and 2 diabetes participate independently in exercise and sports, it is recommended that novices begin training with a qualified exercise physiologist, particularly when resistance training is involved, in order to avoid injury and blood glucose abnormalities that are more likely to occur in persons with diabetes.[21]

Chronic hyperglycemia can lead to neural, retinal, and circulatory damage, which can present special problems during and as a result of exercise in persons with more advanced diabetes. Silent ischemia may be present in persons with underlying CVD. In addition to having proper screening for CVD, such patients need to be aware of other warning signs of CVD (e.g., dizziness, unusual shortness of breath). In addition, advanced neuropathy may cause a diabetic patient to be oblivious to foot ulcerations, which are more common due to microcirculatory damage. Therefore, diabetic patients should always exercise with clean, dry socks and proper fitting footwear. In addition, they should check their feet daily for blisters and ulcerations. Non-weight-bearing exercises should be practiced in persons with foot injuries or open sores.[22] Thermoregulation can

also be impaired in persons with advanced diabetes, so particular precaution (e.g., keeping extremities warm, proper hydration) should be practiced in cold and hot weather.

Due to the risk of intraocular hemorrhage, diabetic patients with retinopathies should be carefully screened before participating in exercise. High-impact activities (including running) and high-intensity activities are not recommended. In addition, although it may be beneficial in helping manage blood glucose, higher-intensity resistance training that causes straining on the participant's part is contraindicated due to high increases in blood pressure.[22]

Maintenance of a proper blood glucose concentration is important during and following exercise. As long as they are feeling well, type 2 diabetics may exercise with elevated glucose levels (>300 mg·dL^{-1}), but intense exercise should be avoided until glucose falls below 250 mg·dL^{-1}.[22] However, type 1 diabetics should not exercise in this condition (or with glucose >250 mg·dL^{-1} and presence of ketone bodies), as this represents insulin deficiency, and exercise will likely exacerbate the hyperglycemia.

Hypoglycemia is a more common incident during and following exercise. As such, proper balance and timing of exercise, diet, and medication is important. Due to increased glucose uptake during exercise, insulin or insulin secretagogue doses may need to be decreased in both type 1 and 2 diabetes patients, particularly in the hours preceding exercise. Exercise should not be practiced during times of peak insulin uptake, and insulin injections during the hours before exercise should not be in the vicinity of the exercising muscles. To avoid nocturnal hypoglycemia, it is best not to exercise within a few hours before bedtime. However, if this must be done, a carbohydrate snack should be ingested before going to sleep. In addition, carbohydrates should be consumed following intense or prolonged exercise. While it may vary among individuals, the ideal pre-exercise range for blood glucose is 90–250 mg·dL^{-1}. In its position statement on physical activity/exercise and diabetes, the American Diabetes Association provides guidelines for carbohydrate intake, ketone testing, and potential refrainment from exercise with various baseline glucose concentrations.[22] Considerations for various medication dose adjustments when beginning an exercise program are also discussed. Regardless of medication type, all diabetic patients should be aware of hypoglycemic symptoms (weakness, nervousness, etc.).

With some important alterations, the exercise prescription for persons with diabetes should be very similar to that for healthy adults. The overall volume of physical activity should be 150 minutes per week or greater, recognizing the importance of a dose–response relationship, especially as far as weight management is concerned. Although previously inactive persons should begin exercise at a moderate intensity, progression to mostly vigorous-intensity exercise may lead to a greater improvement in blood glucose concentration.[23] Since exercise-induced alterations in insulin sensitivity can begin to reverse within a few days of inactivity, it is recommended that no more than two days of inactivity be allowed between exercise bouts.[6,22] In fact, daily, or near-daily, physical activity of similar intensity and duration can be useful in maintaining a balance among the glycemic effects of physical activity, diet, and medications. Due to beneficial effects on insulin sensitivity, resistance training is recommended on at least two, and preferably three, days per week in patients without retinopathies.[6,22] With both aerobic and resistance training, increases in exercise volume should occur gradually to avoid disruptions in glycemic control.

Finally, although cardiac reactivity to physical activity should be normal in most diabetics, autonomic neuropathy may result in a blunted heart rate response in some patients. Unless a maximal heart rate has been obtained through graded exercise testing, calculation of a target heart rate using an age-predicted maximum is inappropriate in patients with known or suspected neuropathy. Use of subjective feelings of exertion should be employed instead.

16.4.5 Cancer

Whether currently undergoing treatment or in remission, regular physical activity can yield both physiological and psychological benefits for most cancer patients. Physical activity can help reduce the decline of functional capacity during treatment. Even during palliative care, properly practiced physical activity may prolong independent function and can reduce depressive symptoms and generate a greater sense of control. During recovery, in addition to contributing to a faster and more complete restoration of physical function, proper physical activity can reduce the chances of the reoccurrence of certain cancers, particularly those of the breast and colon. Additionally, since some cancer treatments increase the likelihood of future CVD and diabetes, the practice of physical activity is important in the management of cardiometabolic risk.

Exercise prescription should vary based on the type and severity of cancer. Since the side-effects of cancer treatments can in some cases be nearly as severe as the disease itself, the type and time-course of treatment should be taken into account as well. Similarly, during recovery, a person's capacity to exercise will be affected by any tissue damage they encountered due to the cancer and treatments and how far they are into remission. Potential contraindications to exercise include fever, ataxia, severe fatigue, significant anemia, profound weakness, and any other worsening conditions and should be brought to the attention of one's medical provider.[6,24]

Due to the wide variety of cancers and treatments, there are numerous potential precautions to take when prescribing exercise. In general terms, exercise prescription and progression need to be highly individualized and should vary day-to-day as the patient deals with the side-effects of their treatments and the disease itself. Fatigue will commonly persist for days, and often for weeks or more, following chemotherapy and radiation. Although exercise is generally good for bone health, the bone of cancer patients

may be more susceptible to fracture due to radiation therapy and/or cancer metastases. As such, higher-impact activities should be avoided during cancer treatment and if desired, should be introduced very gradually during recovery. Due to the risk of contamination, bone-transplant patients and patients with low white blood cell counts should take care to exercise in a clean environment. Post-mastectomy patients experiencing lymphedema should attain physician consent before performing upper-body exercise, should wear compression sleeves, and should begin with light-to-no resistance and progress slowly. Also, although water exercise can be very beneficial to some patients, it should be avoided in those with indwelling catheters or central lines and feeding tubes and for those receiving radiation. In addition, patients undergoing radiation therapy may develop severe skin irritations. Therefore, comfortable clothing should be worn, and the skin should be kept dry and clean during and after exercise.[6] In the majority of cases, cancer patients will benefit from beginning their exercise program in a medically supervised setting with an exercise physiologist possessing specialized training. Communication among patients, medical providers, and exercise professionals is key for the individualization of exercise prescriptions, especially during active treatment and for patients with metastatic cancers. Vigorous-intensity (and possibly moderate-intensity) exercise should generally be avoided on the day of intravenous chemotherapy and within 24 hours after treatment.

In general, ACSM recommends that cancer patients perform aerobic physical activity on 3–5 days, accumulating at least 30 minutes per day, realizing that a patient's condition may necessitate periodic adaptation. Although a moderate intensity of 40–60% $VO_{2reserve}$ or $HR_{reserve}$ is recommended, some patients will find this difficult and should adjust their intensity accordingly. For resistance training, the lower end of the Physical Activity Guidelines is generally recommended; eight to ten exercises of major muscle groups, on two to three days per week, at least one set of at least eight repetitions with at least one minute of rest in between. Flexibility training, which can be particularly beneficial following some surgeries, is recommended on two to seven days per week. Static stretches of 10–30 seconds are suggested.[6] With the exception of high-impact activities, a wide range of exercise types can be used to meet a patient's goals. In addition, some exercise modalities, such as tai chi, offer the opportunity to complete moderate-intensity exercise in a supportive group atmosphere.

16.4.6 Arthritis

Both osteoarthritis and rheumatoid arthritis result in pain with movement. This often sets up a vicious cycle in which a person moves less due to pain. In turn, stamina and neuromuscular conditioning decline, which can eventually result in a decreased ability to perform activities of daily living. As functional tolerance deteriorates and arthritic pain increases, physical activity levels will most likely decline further, making the individual less functionally tolerant and more susceptible to hypokinetic diseases. As such, a major objective of exercise in individuals with arthritis is to increase and preserve physical function. Although physical activity may acutely cause pain, chronically practiced physical activity can actually reduce joint pain and stiffness, resulting in a higher quality of life. Also, as arthritis is common in overweight and obese individuals, physical activity can also serve as a means of weight control and cardiometabolic disease risk factor management.

Exercise levels recommended for the general population also increase physical fitness and produce health benefits in persons with arthritis.[6] However, certain adaptations may make physical activity more tolerable and increase compliance. While adequate warm-up is important in all cases, it is particularly important with arthritis, as the increased blood flow warms the joints and makes movement easier and less painful. Since many arthritic patients experience more stiffness and pain in the morning, exercise later in the day is often wise, especially after morning medications have had time to reach their peak effects. In addition, many patients find warm water (83–88 ζF, 28–31 ζC) exercise to be more comfortable than other environments. Out of the water, proper fitting shoes with adequate stability and cushioning may help prevent excessive knee, hip, and/or back pain. Custom-made orthotics may be beneficial for persons with biomechanical abnormalities.

To increase and maintain functional ranges of motion, flexibility exercises are particularly important for patients with arthritis. Although resistance training can increase strength and stability around affected joints, maximal isometric contractions, practiced at a few angles per joint, may be preferable to dynamic contractions in persons who experience higher levels of joint pain. As this becomes less painful, patients can then advance to dynamic exercise with lighter resistance, increasing the resistance as tolerated. With aerobic training, people with more pain and/or less functional tolerance may need to exercise intermittently in the beginning, but should be able to progress to more continuous activity.

Some pain during exercise is to be expected with arthritis. However, if joint pain persists for more than two hours following exercise, the volume of training should be reduced.[6] Pain makes physical activity less enjoyable and is likely to negatively affect exercise compliance. Therefore, patients should not be pushed to a point where they are less likely to continue to stay active.

16.4.7 Disabilities

Depending on the type and extent of disability, proper physical activity may improve physical fitness and functional abilities and may reduce a person's risk for cardiometabolic diseases. The range of disabilities (cerebral palsy, spinal cord injury, stroke, etc.) is too wide to permit a thorough discussion of exercise prescription for each in this chapter. However, a few points are important to remember across many conditions. For example, disabilities resulting in

autonomic impairment will yield abnormal cardiovascular responses to exercise and impaired thermoregulation. Therefore, perceived exertion may be a better gauge of exercise intensity, and special precaution should be taken to prevent hyper- or hypothermia. In addition, adaptations in equipment or clothing may be needed to help persons with particular disabilities perform common exercises. For example, persons with impaired gripping ability may benefit from Velcro gloves when performing resistance exercises or arm ergometry. Shorter bouts of physical activity spread throughout the day may be necessary for persons with very low physical tolerance.

When possible, persons with disabilities should perform the same physical activity recommended for more able-bodied adults.[2,3] When this is not possible, they should perform as much physical activity as they are able to accomplish without undue fatigue. Aerobic, resistance, and flexibility exercise should all be practiced. Even when exercise tolerance is very low, physical inactivity should be avoided to maintain as much functional independence as possible and to avoid hypokinetic diseases.

16.5 SUMMARY

Current physical activity guidelines advocate a well-balanced exercise program to include aerobic, resistance, and flexibility training. To allow for individual preferences and abilities, these guidelines allow a good bit of flexibility among the frequency, intensity, and duration of physical activity, as long as a critical overall volume is met. Health and fitness–related benefits can also be obtained with a variety of exercise modalities. The chosen modalities should be safe for a given individual and should be enjoyable to enhance program adherence.

In addition, disease or disability should not inhibit anyone from being physically active. Individuals who are not able to meet the physical activity levels recommended for the general public should still strive to be as active as possible within the confines of any disease or disability. *Everyone* can benefit from physical activity.

CLINICAL APPLICATIONS

- About one-half of Americans do not meet current recommendations for aerobic physical activity, and approximately two-thirds do not meet the combined recommendations for aerobic and muscle-strengthening activity. This makes physical activity one of the most prevalent risk factors for a number of prevalent chronic diseases and conditions.
- A strong recommendation from a healthcare provider can be a key factor in convincing a patient to make lifestyle changes. Although exercise prescription might need to be quite precise to attain high levels of specific fitness parameters, the healthcare provider need not be intimidated about providing health-related physical activity recommendations, as wide ranges of exercise intensity and duration allow one to improve one's health and fitness. A key factor for adherence is for the patient to participate in activities that they enjoy in an unintimidating environment. Including physical activity as part of their daily schedule is also important.
- The U.S. Centers for Disease Control and Prevention offers useful resources for patients wishing to begin a physical activity program (www.cdc.gov/physicalactivity/basics/index.htm). In addition, the American College of Sports Medicine sponsors Exercise Is Medicine, which offers resources for healthcare providers wishing to promote physical activity to their patients (www.exerciseismedicine.org/).

17 Physical Activity and Health: Key Findings from the Physical Activity Guidelines for Americans 2018

James M. Rippe, MD

KEY POINTS

- Regular physical activity is a powerful modality for lowering the risk of various chronic diseases.
- Recommendations from the Physical Activity Guidelines for Americans 2018 Scientific Report state that adults should try to accumulate 150 minutes per week of moderate intensity physical activity or 75 minutes of strenuous activity and two sessions of resistance strength training.
- The PAGA 2018 Scientific Report is an important document for all individuals practicing lifestyle medicine and should be in every clinician's toolbox.

17.1 INTRODUCTION

Physical activity (PA) plays a significant role in multiple health parameters.[1–9] It is one of the pillars of lifestyle medicine. In some studies, it has been shown that physical activity is more correlated with cardiovascular disease (CVD) than any other parameter.[9]

While the benefits of physical activity are generally known, the relationship between physical activity and multiple health considerations, such as reduction in risk for chronic disease, improved health for both children and adults over the age of 65, as well as the important role in quality of life, sleep, energy, and the ability to live a full life, is often underappreciated. Recently, the scientific basis for regular physical activity was substantially enhanced by the release of the Physical Activity Guidelines for Americans 2018 (PAGA 2018).[7] This seminal document provides robust data in virtually every area of health where physical activity interacts with a variety of parameters. This extensive, evidence based document should be in the toolbox of every lifestyle medicine practitioner. The PAGA 2018 document itself is quite extensive, but the Executive Summary should be familiar to all practitioners of lifestyle medicine and indeed, all physicians and other healthcare professionals. The purpose of this chapter is to provide a brief summary of the key findings from the PAGA 2018.

17.2 LIFESTYLE MEDICINE, PHYSICAL ACTIVITY, AND HEALTH

Increased physical activity plays a significant and beneficial role for individuals at all stages of their lives. In addition to lowering the risk of various chronic diseases, physical activity can also play an important role in their treatment. The recommendations from the PAGA 2018 to incorporate 150 minutes of moderate to vigorous physical activity, or more, each week and strength training twice a week are recommendations shared by the American College of Sports Medicine (ACSM),[10] American Heart Association (AHA),[4,6] and other important scientific organizations. Unfortunately, according to Centers for Disease Control (CDC) criteria, only 25% of individuals engage in regular levels of physical activity necessary to meet these widely accepted guidelines for physical activity and health. Physicians play a very important role in helping people to make the positive decision in their lives to incorporate the recommended levels of physical activity. A summary of the guidelines recommended by the PAGA 2018 is found in Table 17.1. The PAGA Scientific Guidelines Advisory Committee summarized the broad range of these guidelines by saying that when it comes to health, physical activity is a "best buy."

PA confers a wide variety of benefits on physically active individuals. These benefits may occur after a single bout of physical activity, but others require consistent increased physical activity throughout the lifespan. As already indicated, physical activity plays an important role in the quality of life. People who are physically active feel better and sleep better, and are able to accomplish more in their daily lives. In addition, regular physical activity lowers the risk of anxiety, stress, and depression.

17.3 PHYSICAL ACTIVITY AND CARDIOVASCULAR DISEASE (CVD)

Regular physical activity reduces the risk of all-cause mortality and CVD. Even small amounts of physical activity can significantly lower the risk of CVD. As shown in Figure 17.1, the recommended amount of physical activity from the PAGA 2018, 150 minutes of moderate intensity physical

TABLE 17.1

Physical Activity-Related Health Benefits for the General Population and Selected Populations Documented by the 2018 Physical Activity Guidelines Advisory Committee

Children	
3 to <6 years of age	**Improved bone health and weight status**
6 to 17 years of age	**Improved cognitive function (ages 6 to 13 years)**Improved cardiorespiratory and muscular fitnessImproved bone healthImproved cardiovascular risk factor statusImproved weight status or adiposityFewer symptoms of depression
Adults, all ages	
All-cause mortality	Lower risk
Cardiometabolic conditions	Lower cardiovascular incidence and mortality (including heart disease and stroke)Lower incidence of hypertensionLower incidence of type 2 diabetes
Cancer	Lower incidence of **bladder**, breast, colon, **endometrium**, **esophagus**, **kidney**, **stomach**, and **lung cancers**
Brain health	**Reduced risk of dementia**Improved cognitive function**Improved cognitive function following bouts of aerobic activity****Improved quality of life****Improved sleep****Reduced feelings of anxiety and depression in healthy people and in people with existing clinical syndromes**Reduced incidences of depression
Weight status	**Reduced risk of excessive weight gain**Weight loss and the prevention of weight regain following initial weight loss when a sufficient dose of moderate to vigorous physical activity is attained**An additive effect on weight loss when combined with moderate dietary restriction**
Older adults	
Falls	Reduced incidence of falls**Reduced incidence of fall-related injuries**
Physical function	**Improved physical function in older adults with and without frailty**
Women who are pregnant or postpartum	
During pregnancy	**Reduced risk of excessive weight gain****Reduced risk of gestational diabetes**No risk to fetus from moderate intensity physical activity
During postpartum	**Reduced risk of postpartum depression**
Individuals with pre-existing medical conditions	
Breast cancer	**Reduced risk of all-cause and breast cancer mortality**
Colorectal cancer	**Reduced risk of all-cause and colorectal cancer mortality**
Prostate cancer	**Reduced risk of prostate cancer mortality**
Osteoarthritis	**Decreased pain****Improved function and quality of life**
Hypertension	**Reduced risk of progression of cardiovascular disease****Reduced risk of increased blood pressure over time**
Type 2 diabetes	**Reduced risk of cardiovascular mortality****Reduced progression of disease indicators: hemoglobin A1c, blood pressure, blood lipids, and body mass index**
Multiple sclerosis	**Improved walking****Improved physical fitness**
Dementia	**Improved cognition**
Some conditions with impaired executive function (attention deficit hyperactivity disorder, schizophrenia, multiple sclerosis, Parkinson's disease, and stroke)	**Improved cognition**

Benefits in **bold** font are those added in 2018; benefits in normal font are those noted in the 2008 Scientific Report. Only outcomes with strong or moderate evidence of effect are included in the table.

Source: 2018 Physical Activity Guidelines Advisory Committee Scientific Report. Washington, DC. Part D: Integrating the Evidence. D5-6.

activity, substantially lowers the risk of CVD. While there is additional lowering of the risk of CVD for amounts greater than 300 minutes, the incremental benefit is very small. An important part of the relationship between physical activity and CVD illustrated in Figure 17.1 is that even 30 minutes of moderate intensity physical activity lowers the risk of CVD by 20%.

As illustrated in the figure, there is no lower threshold for benefit, and there is a steep, early slope. Regular physical activity has been repeatedly shown to lower the risk of a variety of forms of CVD, including coronary heart disease (CHD), hypertension, heart failure (HF), diabetes, and obesity. Despite the overwhelming evidence that regular physical activity is a powerful tool for lowering the risk of CVD, unfortunately, only 25% of adults achieve levels of PA to meet minimum standards from the CDC.

It should be emphasized that CVD is the leading cause of morbidity and mortality in the United States, with over 37% of mortality coming annually from CVD.[11,12] The amount of benefit from regular physical activity is substantial. When

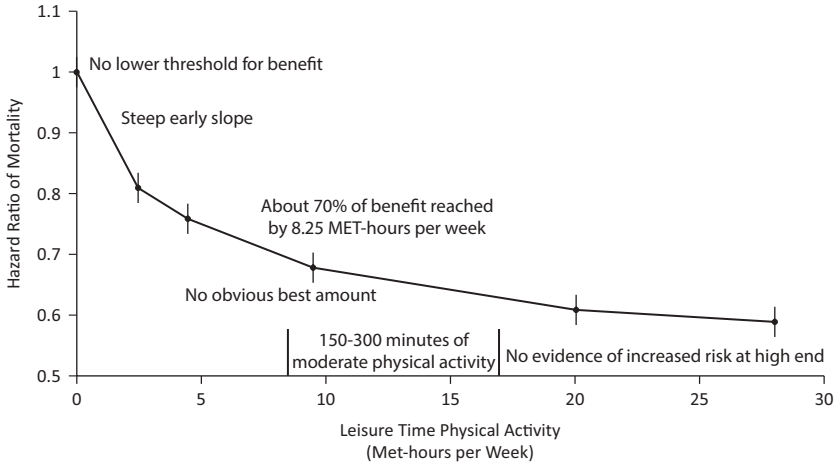

FIGURE 17.1 Relationships of moderate to vigorous physical activity to all-cause mortality, with highlighted characteristics common to studies of this type.

physically active people are compared with sedentary individuals, the risk of CHD is 150–240% higher in sedentary individuals.[9] The recommendations for the amount of physical activity for adults and also older adults (over the age of 65) are very similar. The PAGA 2018 Scientific Report states that adults should optimally strive for at least 150 minutes a week of moderate intensity physical activity or 75 minutes of vigorous intensity physical activity or a combination of the two, and muscle strengthening performed two or more days per week, which will result in additional risk reduction. Individuals who achieve these levels of physical activity achieve approximately 70% reduction in the risk of CVD.

The recommendations are slightly different for children and adolescents. The PAGA 2018 Scientific Report recommends that children and adolescents should perform 60 minutes of moderate intensity physical activity daily. In addition, the PAGA 2018 recommends that vigorous physical activity should be performed at least three days a week. Unfortunately, fewer than 20% of children and adolescents in the United States achieve these levels.[7]

17.4 PHYSICAL ACTIVITY AND THE PREVENTION AND TREATMENT OF CANCER

Physical activity plays a significant role in the prevention and treatment of various cancers.[13–16] Furthermore, numerous cancers are linked to an inactive lifestyle. In the Physical Activity Guidelines for Americans 2008, both breast and colon cancer were cited as cancers where physical activity particularly lowered the risk.[17–21] In the PAGA 2018, this list was greatly expanded to include bladder cancer, colon cancer, endometrial cancer, gastric cancer, renal cancer, and thyroid cancer.[7]

Cancer is very prevalent in the United States and around the world. Nearly one in six deaths worldwide are attributable to cancer, which equates to 8.8 million deaths annually.[14] Global cancer is expected to rise over the next 20 years by 70%. In 2016, over 15.5 million living Americans (approximately 4.8% of the population) have been diagnosed with cancer at some point in their lives. On average, 38% of American women and 48% of American men will be diagnosed with invasive cancer at some point in their lives.[22]

Physical activity or lack thereof plays an important role in the likelihood of developing cancer.[23,24] Other known lifestyle and preventable causes of cancer include tobacco use, alcohol intake, poor diet, and obesity. Clearly, lifestyle habits and practices are vitally important in lowering the risk of cancer.

Unfortunately, most people in the general public regard cancer as a "act of God" and do not understand the powerful role that daily habits and actions play. Physicians should counsel patients on this aspect of lifestyle and cancers in every clinical encounter.

17.5 PHYSICAL ACTIVITY, DIABETES, PRE-DIABETES, AND THE METABOLIC SYNDROME (METS)

Regular physical activity is a cornerstone in both the treatment and prevention of diabetes, pre-diabetes, and the metabolic syndrome.[25–27] For this reason, routine physical activity should be recommended for individuals in all of these categories. The level of aerobic activity that should be recommended is the same as for non-diabetic individuals, namely, 150 minutes of moderate intensity physical activity per week.

In addition to lowering the risk of diabetes, regular physical activity can play a significant role in the management of diabetes for individuals who already have this condition. This fact is recognized by the Physicians' Statement on Physical Activity from the American Diabetes Association[25]

as well as the Lifestyle Management Standards for Medical Care and Diabetes 2018 from the American Diabetes Association.[28]

The Diabetes Prevention Program (DPP) showed that individuals who have pre-diabetes (fasting glucose between 100 and 125 mg/dL) could reduce their risk of progressing to diabetes by 58% by performing regular, moderate physical activity and losing five to seven pounds.[29] Recommendations for physical activity and the metabolic syndrome are similar to those for diabetes and pre-diabetes and recognized by multiple organizations, including the AHA.

It has been estimated that 36–38% of individuals in the United States have metabolic syndrome by National Cholesterol Education Program III and IV (NCEP III and IV) criteria.[30,31] The clustering of risk factors in metabolic syndrome, including elevated fasting glucose, reduced high-density lipoprotein cholesterol (HDLC), elevated triglycerides, increased waist circumference, and elevated blood pressure, makes this a particularly dangerous condition with regard to risk of CVD. In fact, NCEP III recommends that people who have metabolic syndrome be treated as though they already have CVD. The association of regular physical activity represents a proven strategy for lowering the risk of developing MetS as well as assisting in its treatment.[32]

17.6 PHYSICAL ACTIVITY AND WOMEN'S HEALTH

The PAGA 2018 Scientific Report concluded that regular physical activity can play multiple important roles in women's health.[33,34] These benefits include reducing the likelihood of dying from multiple chronic diseases, including CHD, obesity, diabetes, and certain cancers. Regular physical activity also plays important roles in pregnancy and post-partum, including reducing the risk of excessive weight gain and improved fitness and emotional wellbeing.[33–35] (See Chapters 21 and 22 for more details.)

17.7 PHYSICAL ACTIVITY AND YOUTH

The PAGA 2018 Scientific Report lists multiple benefits from physical activity for children between the ages of 3 and 17.[7] In 2008, not enough information was available for children below the age of five, but the PAGA 2018 document reported that numerous studies in the preceding ten years had allowed the recommendations to extend down to the age of three.

The recommendation made by the PAGA 2018 was 60 minutes of moderate to vigorous physical activity (MVPA) on a daily basis and three sessions of musculo-skeletal training weekly for children between the ages of 3 and 17. Unfortunately, only 20% of children achieve these levels.[36,37] It is particularly unfortunate that the levels of physical activity are so small in children. We now know that the roots of many chronic diseases that become manifest in adults have their roots in childhood. For all of these reasons, it is important that physicians counsel both children and families on the importance of the multiple benefits of physical activity for all children over the age of three.

17.8 PHYSICAL ACTIVITY IN OLDER ADULTS

The same recommendations for regular moderate or vigorous intensity physical activity that apply to younger adults also apply to adults over the age of 65, according to the PAGA 2018 Scientific Advisory Report. In 2016, individuals over the age of 65 comprised approximately 13% of the U.S. population and are projected to reach 72.1 million individuals (19%) of the total population by Year 2030.[38] This age group is the most rapidly growing of all population segments in the United States.

Physical activity conveys multiple benefits for people over the age of 65, including decreased risk of chronic disease or as an adjunct to its treatment, increased physical function, and decreased risk of falls.[39] Increased physical activity may be particularly valuable for individuals who are frail or have lower levels of current physical activity. Unfortunately, only 27% of individuals over the age of 65 meet current recommendations for levels of physical activity.[40] For all of these reasons, clinicians should emphasize to individuals over the age of 65 the multiple and important health benefits from continuing to maintain an active lifestyle.

17.9 PHYSICAL ACTIVITY IN INDIVIDUALS WITH CHRONIC CONDITIONS

The PAGA 2018 Scientific Advisory Committee Report recommends that individuals who have chronic conditions try to maintain the same levels of physical activity that are recommended for individuals without chronic conditions. However, individuals with chronic conditions need to be conscious of any limitations that they may have and discuss their current situation and potential modifications of the Physical Activity Guidelines with their personal physicians.

Chronic conditions are very common in the U.S. population. Over half of the American population (51.7%) have at least one chronic condition, and approximately one-third (31.5%) have multiple chronic conditions.[41] About 80% of individuals over the age of 65 have multiple chronic conditions.

The list of the most common chronic conditions in the United States in adults and children is found in Figure 17.2. Physical activity is particularly important in the areas of osteoarthritis[42] and hypertension[43,44] as well as either management or prevention of type 2 diabetes (T2DM).[45] Individuals who have multiple sclerosis,[46] spinal cord injuries,[47,48] or intellectual disabilities[49] may need to make modifications of the physical activity plan in order to meet with the realities of their current condition. However, increased physical activity is important even for these individuals.

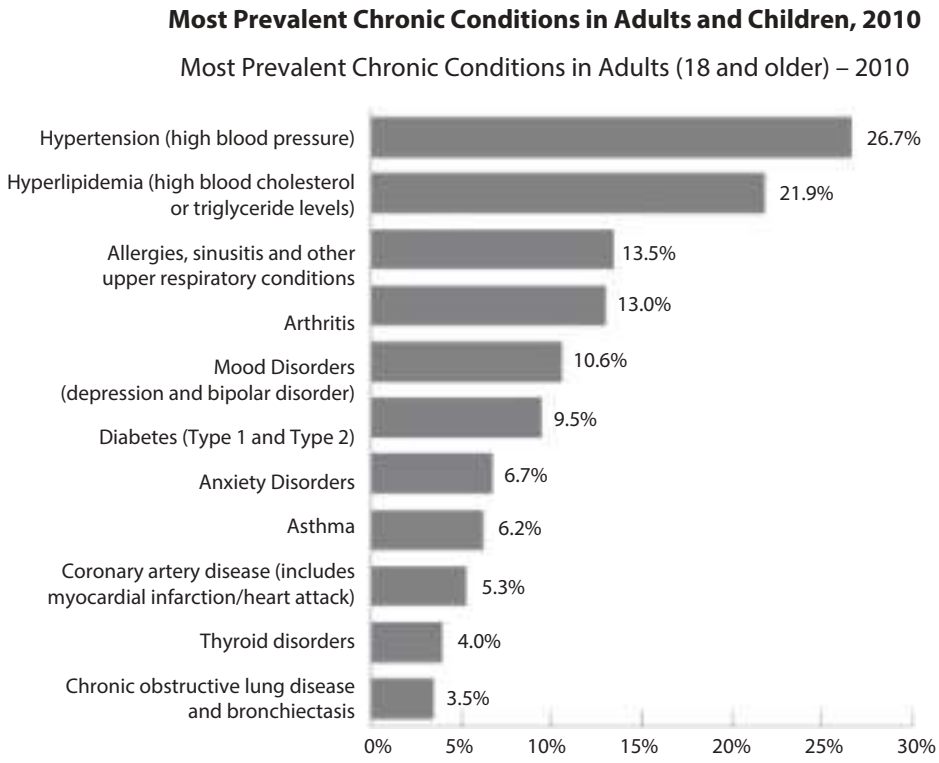

FIGURE 17.2 Most prevalent chronic conditions in adults and children, 2010.

17.10 PHYSICAL ACTIVITY, WEIGHT GAIN, AND OBESITY

The PAGA 2018 states that regular physical activity lowers the risk of weight gain and obesity. In the United States, unfortunately, over 70% of the adult population is either overweight or obese. While physical activity alone is not a powerful modality for acute weight loss, it is critically important to the long term maintenance of weight loss.[50,51] Moreover, physical activity lowers the risk of weight gain, which is also a significant risk factor for a variety of diseases, such as CVD, T2DM, and MetS.[52] Moreover, physical activity in combination with caloric restriction has been demonstrated in multiple trials to increase the likelihood of short-term weight loss.[50–53]

For all of these reasons, it is important for all clinicians to discuss weight, weight gain, and obesity in every clinical encounter. More information concerning obesity and its treatment and relationship to other chronic diseases is found in Chapters 20 and 21.

17.11 PHYSICAL ACTIVITY, COGNITION, AND BRAIN HEALTH

Many clinicians are surprised to learn that physical activity plays a critically important role in brain health.[54,55] This was underscored in the PAGA 2018 as well as a Presidential Advisory issued by the AHA and the American Stroke Association (ASA) on "Optimizing Brain Health."[56] The risk factors for diminished brain health are similar to those for CVD. For this reason the AHA and ASA have recommended that people follow what is called the "Life's Essential 8,"[6] which are the lifestyle related guidelines for reducing the risk of CVD. There is now also accumulating evidence that regular physical activity lowers the risk of dementia and Alzheimer's disease[57,58] (see also Chapter 21). There is a suggestion that inflammation plays a role in the development of dementia and Alzheimer's disease. The recommendation is to begin positive lifestyle measures as early in life as possible and maintain them throughout the lifespan.

17.12 THE ROLE OF PHYSICIANS IN PROMOTING AND PRESCRIBING INCREASED PHYSICAL ACTIVITY

Numerous studies have shown that physician recommendation is a powerful motivational tool for changing behavior. This is particularly true in the area of physical activity. As already indicated, only 25% of the adult population in the United States is active at the level recommended by the

PAGA 2018 and the AHA. Unfortunately, fewer than 40% of physicians routinely counsel people in the area of physical activity.[59–61] This is particularly unfortunate, since over 70% of individuals see their primary care physician at least on an annual basis. Thus, it is important for physicians to recognize the power of physical activity to lower the risk of multiple chronic diseases and counsel every patient on this. The recommendation of 150 minutes of moderate intensity physical activity per week is highly appropriate for virtually every patient and should be referred to by clinicians.

17.13 PRACTICAL APPLICATIONS

Both the American College of Sports Medicine (ACSM) and the PAGA 2018 Guidelines have stated that for the vast majority of individuals, physician evaluation is not necessary before starting a moderate level of physical activity program.[62] Individuals who have been extremely sedentary, however, might benefit from additional workup by their physician.

For the vast majority of people, the goal is to remove any impediment that might occur that prevents individuals from exercising. Thus, following the mantra of "starting low and going slow" is appropriate for virtually every individual. Patients who are either overweight or obese or have been very inactive could benefit from further evaluation from their physician. Also, individuals who have a history of CHD might benefit from procedures such as an exercise tolerance test prior to starting an exercise program.

Most individuals, however (even those with a history of CHD), can simply start and use common sense to be their guidance if they begin at a low level and proceed slowly, working their way up over a period of weeks or months to the 150 minutes of moderate intensity physical activity per week. It should be noted that in 2008, part of the guidance for people deriving multiple benefits from physical activity involved bouts of at least 10 minutes in duration with a total accumulated daily duration of at least 30 minutes. In the PAGA 2018, this recommendation was revised because evidence existed that even much shorter bouts of physical activity could accumulate to generate important health benefits.

17.14 OVERCOMING SEDENTARY BEHAVIOR

The PAGA 2018 Guidelines emphasize for the first time accumulating data that sedentary behavior increases the risk of CVD. Individuals who are sedentary for more than seven hours per day sitting or lying down during waking hours are at particularly high risk for all-cause mortality and mortality from CVD and T2DM and perhaps some cancers.[63,64]

The good news is that individuals who have relatively sedentary occupations can virtually eliminate the increased risk by being active at the level recommended by PAGA 2018. The people who are at the greatest risk of CVD and T2DM are those who are sedentary and also do not engage in any meaningful amount of physical activity. Unfortunately, the average adolescent and adult in the United States spends approximately 7.7 hours a day (55% of monitored time) in sedentary activities.[65,66] Reversing this sedentary behavior trend when advising people who have sedentary occupations involves discussing the danger of this sedentary behavior and the means to ameliorate it by engaging in the recommended levels of physical activity. The relationship between sedentary behavior and levels of physical activity is found in Figure 17.3. This figure depicts that individuals who are sedentary and also have little physical activity in

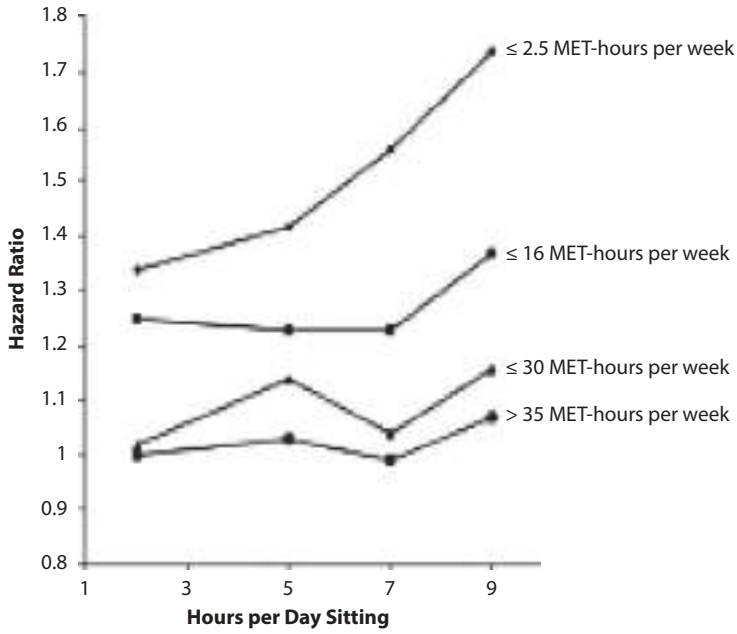

FIGURE 17.3 Relationship between sitting and all-cause mortality, stratified by amount of moderate to vigorous physical activity.

their daily lives are at the greatest risk for CVD and other chronic diseases.

17.15 PUBLIC HEALTH CONSIDERATIONS

The PAGA 2018 Scientific Report focuses attention on activity that can be done from a public health perspective to increase the likelihood of individuals becoming more physically active.[65–71] This involves endeavors such as creating more parks and green space, utilizing school facilities, and mounting campaigns concerning the benefits of physical activity.[72–75] It is clear that lack of physical activity in the United States is both an individual problem and a significant public health problem. In the world, overall, inactive lifestyle is a major component of the World Health Organization's campaign to ameliorate non-communicable diseases (NCDs). The good news is that there is an emerging literature showing that well-designed public health programs that are structured and follow a sound theoretical basis can make a difference in many individuals' lives in terms of their level of physical activity.

17.16 SUMMARY/CONCLUSIONS

There is no longer any serious doubt that regular physical activity yields multiple benefits. Conversely, an inactive lifestyle is hazardous to individuals' health. There is an accumulating literature about the multiple benefits of increasing physical activity. Perhaps most important in this area is the enormous compendium of background information contained in the Physical Activity Guidelines for Americans 2018 Scientific Advisory Report. This is a report that should be in the toolbox of every lifestyle medicine clinician.

Certainly, physical activity is one of the most important of the lifestyle medicine pillars. It is incumbent upon physicians to counsel patients about the importance of regular physical activity on every clinical encounter. Moreover, it has been demonstrated that physicians who are physically active themselves are more likely to counsel patients in this area. For all these reasons, the relationship between lifestyle medicine and physical activity is very important, as summarized and expanded upon in the PAGA 2018 Scientific Report.

CLINICAL APPLICATIONS

- The Physical Activity Guidelines for Americans 2018 contains a vast compendium of scientific literature on the multiple benefits of physical activity.
- The PAGA 2018 Report (at least the Executive Summary) should be in the toolbox of every lifestyle medicine physician.
- Regular physical activity is one of the best strategies that most people can use in their lives to lower their risk of various chronic diseases and improve their daily quality of life, sleep, energy level, and happiness.
- All of these points are made clear with substantial evidence in the PAGA 2018 Scientific Report.

18 Overcoming Sedentary Behavior

James M. Rippe, MD

KEY POINTS

1. Sedentary behavior, particularly at levels higher than seven hours of sitting or lying down during waking or throughout the day, is associated with increased risk of all-cause mortality, mortality from cardiovascular disease, type 2 diabetes, as well as some cancers.
2. Regular, moderate to vigorous physical activity has been shown to offset many of the increased risks associated with sedentary behavior.
3. The benefits of moderate to vigorous physical activity are particularly strong for individuals with high levels of sedentary behavior who are also currently inactive. This information suggests that individuals who spend a considerable amount of time each day in front of computer screens or in other sedentary activities should be particularly counseled about the important need for regular physical activity to offset some of the consequences of sedentary behavior.

18.1 INTRODUCTION

A great deal of research has emerged over the past decade linking sedentary behavior to a variety of adverse health concerns.[1] Good data are now available to suggest that sedentary behavior increases the risk of a variety of conditions, including coronary heart disease (CHD), type 2 diabetes (T2DM), and some cancers. Sedentary behavior has been defined in this research as "any behavior which is characterized by energy expenditure of 1.5 METs or less while in a sitting, reclining or lying position."[2] In addition to the negative association with health outcomes, unfortunately, sedentary behavior is highly prevalent in the United States. Data from the U.S. National Health and Nutrition Examination Survey (NHANES) indicate that children and adults in the United States spend on average approximately 7.7 hours per day (55% of monitored time) being sedentary.[3] Thus, reversing the sedentary behavior trend in the United States can generate significant health improvement. The current chapter examines sedentary behavior and its relationship to various health issues utilizing the framework established by the Physical Activity Guidelines for Americans 2018 (PAGA 2018) Advisory Committee Scientific Report.

18.2 SEDENTARY BEHAVIOR AND ALL-CAUSE MORTALITY

The PAGA 2018 Scientific Report rated the evidence for a relationship between the greater amount of time in sedentary behavior and all-cause mortality as "strong." Based on a total of 9 systematic reviews and meta analyses that consisted of 20 original studies, a significant relationship between sedentary behavior and all-cause mortality was revealed.[4–11] Some of these studies also showed that T.V. viewing or screen time was also related to all-cause mortality.[12,13] Importantly, there appears to be a dose–response relationship between sedentary behavior and all-cause mortality.[7,9] Studies that have reviewed this relationship have revealed that for every one-hour increase in sitting time, or for more than seven hours a day sitting, there were dose–response relationships between increased sedentary behavior and all-cause mortality.[7] A similar response was revealed between T.V. viewing and all-cause mortality, where a dose–response relationship was also found.[9]

An inverse relationship exists between moderate to vigorous physical activity and sedentary behavior when it comes to all-cause mortality.[10,11] The adverse effects of sedentary behavior on all-cause mortality are strongest among people who have low amounts of physical activity. This relationship is illustrated in Figure 18.1.

Individuals who had greater than seven hours of sedentary behavior combined with low levels of moderate or vigorous physical activity substantially increased their risk for all-cause mortality. Conversely, individuals who accumulated between 15 and 30 MET hours per week of moderate intensity physical activity substantially lowered their risk of all-cause mortality, even if they were sedentary for more than seven hours a day.[11] The relationship between MET hours per week exercising and risk based on the number of hours per day sitting showed that individuals who exercise at the recommended level of accumulating 150 minutes per week of moderate intensity physical activity will substantially lower the increased risks caused by sedentary behavior. Thus, it is particularly important for individuals who have sedentary occupations to engage in regular physical activity at levels recommended by PAGA 2018.

To put this in perspective, the PAGA 2018 Scientific Report recommends 10–15 MET hours per week of physical activity. There are additional benefits for individuals who choose greater than 30 MET hours per week (roughly 150

DOI: 10.1201/9781003227793-21

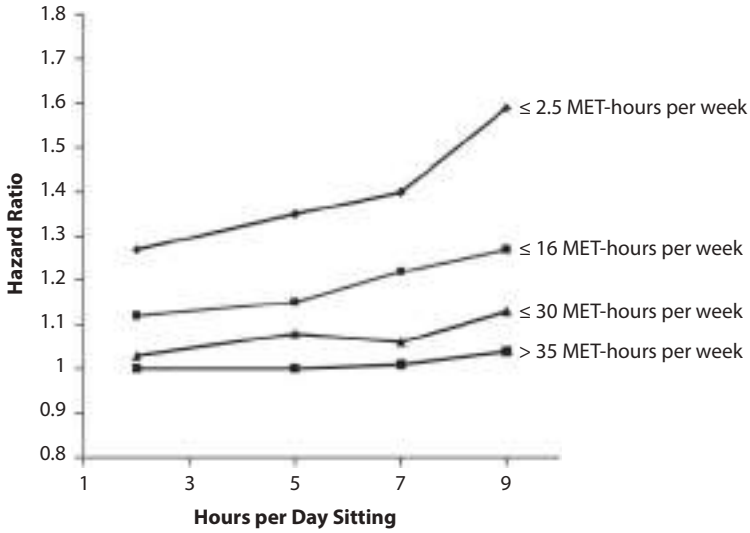

FIGURE 18.1 Relationship between sitting and all-cause mortality, stratified by amount of moderate-to-vigorous physical activity. (Source: Adapted from data found in Ekelund et al, 2016.)

minutes per week of moderate intensity physical activity), although the incremental benefit is small compared with the benefit of achieving the recommended dosage of moderate to vigorous physical activity outlined in the PAGA 2018 document. The important take home point is that individuals who have sedentary occupations (such as office work) will particularly benefit from following the guidelines for moderate to vigorous physical activity on a weekly basis.

In addition, there has been some suggestion that taking breaks in sedentary behavior may reduce the adverse health consequences related to all-cause mortality. Although there is some research in this area, further research is required to determine whether or not periodic breaks to sedentary behavior will ameliorate some of the adverse health effects of this behavior.

The relationship between sedentary time and moderate to vigorous physical activity is depicted graphically in Figure 18.2.

As this figure illustrates, the more sedentary time an individual participates in, the greater the risk of all-cause mortality, unless they are physically active. Physical activity at levels recommended by the PAGA 2018, as shown in this figure, can largely ameliorate the increased risks of sedentary behavior.

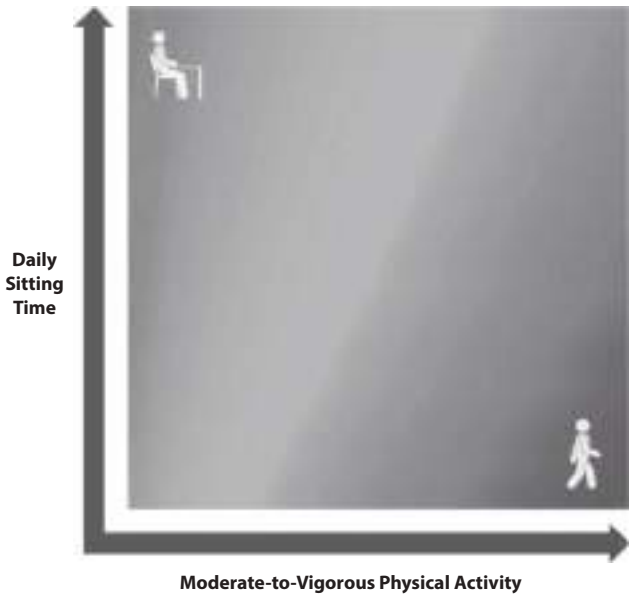

FIGURE 18.2 Relationship among moderate-to-vigorous physical activity, sitting time, and risk of all-cause mortality. (Source: Adapted from data found in Ekelund et al, 2016.)

18.3 SEDENTARY BEHAVIOR AND CARDIOVASCULAR DISEASE (CVD) MORTALITY

The risk of mortality from cardiovascular disease (CVD) and its relationship to sedentary behavior are very similar to the relationship between sedentary behavior and all-cause mortality.[6,10] The PAGA 2018 Scientific Report documented that increased physical activity ameliorated increases in sedentary behavior and also demonstrated that there is strong evidence of a dose–response relationship. Thus, the more physical activity an individual participates in, the more the increased risk of sedentary behavior is reduced. As depicted in Figure 18.3, sedentary behavior of greater than five hours a day starts to significantly increase the risk of cardiovascular disease and is further increased if sedentary behavior is greater than seven hours a day.

18.4 SEDENTARY BEHAVIOR AND CANCER MORTALITY

The PAGA 2018 Scientific Report judged that the evidence of a direct relationship between the amount of time spent

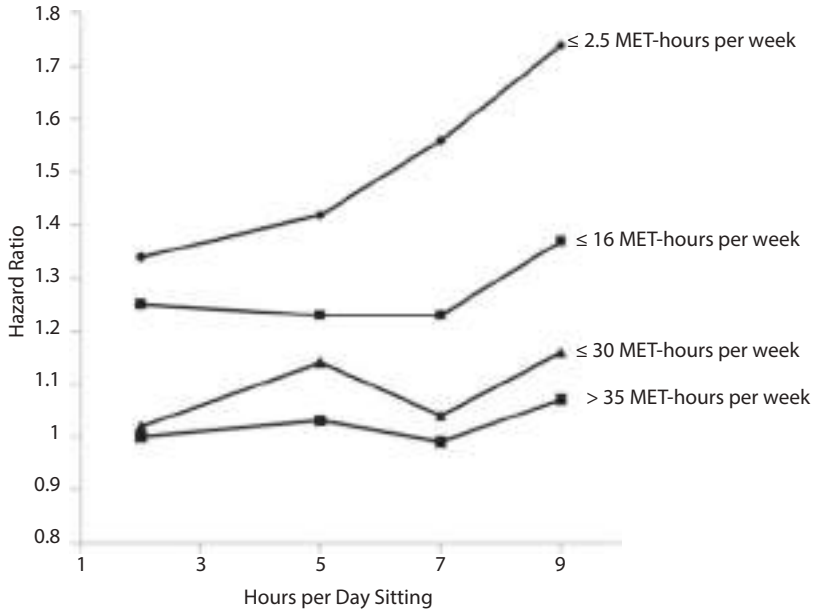

FIGURE 18.3 Relationship between sitting and cardiovascular disease mortality, stratified by amount of moderate-to-vigorous physical activity. (Source: Adapted from data found in Ekelund et al, 2016.)

in sedentary behavior and higher mortality rates from cancer is limited.[10] A number of studies have reported a significant association between sedentary activity and cancer, but the results are inconsistent. Furthermore, cancer is a heterogeneous disease, and many of the risk factors for cancer mortality are clearly affected by such issues as cancer screening, treatment availability, and efficacy. The PAGA 2018 Scientific Report also concluded that there was insufficient evidence available to determine whether or not the relationship between sedentary behavior and cancer mortality was modified by physical activity. Evidence among specific types of cancer judged by the PAGA 2018 was determined to be "moderate."[14] For example, moderate physical activity in sedentary individuals decreased the added risk of sedentary behavior for breast cancer, ovarian cancer, prostate cancer, and lung cancer.

18.5 SEDENTARY BEHAVIOR AND TYPE 2 DIABETES (T2DM)

A strong and significant relationship exists between the amount of time spent in sedentary behavior and the risk of type 2 diabetes (T2DM).[4–6,10,13] The issue of whether or not this is a dose–response relationship is supported by only limited evidence. The issue of T2DM appears to be different between individuals who are active and inactive. Active individuals did not experience elevated risk of T2DM, whereas inactive participants who reported high T.V. viewing were at increased risk of T2DM. The relationship between physical activity and T2DM is outlined in more detail in Chapter 20.

18.6 SEDENTARY BEHAVIOR AND WEIGHT STATUS

There is a limited amount of evidence to support the relationship between sedentary behavior and weight status.[4,5] Studies that are available in this area show a great deal of variation among results with regard to adiposity. Once again, studies are heterogeneous, which allows only limited support for the concepts and their behavior associated with adiposity.

18.7 SEDENTARY BEHAVIOR AND MODERATE TO VIGOROUS PHYSICAL ACTIVITY

Some evidence suggests that moderate to vigorous physical activity lowers the risk of sedentary behavior.[11] It is important to note, however, that the relative reductions in risk are significant only for those who are the most sedentary. In general, the same relationship holds for CVD mortality as for all-cause mortality, with the significant interaction between levels of physical activity and sedentary behavior for both. The most significant benefits come to those who are the most sedentary. When the data concerning sedentary behavior are stratified by levels of sitting while T.V. viewing, the relationships are still quite similar to the amount of sedentary behavior. Thus, sitting or T.V. viewing significantly increases the risk of all-cause mortality, while the level of moderate to vigorous physical activity lowers the added risk in a dose dependent manner.

18.8 PUBLIC HEALTH IMPACT

High levels of sedentary behavior are associated with increase in all-cause mortality and also mortality from

CVD and T2DM. The high levels of sedentary behavior are also associated with moderate increases in certain cancers, such as breast, ovary, prostate, and lung cancer.

There is good evidence that moderate or vigorous physical activity can lower the increased risk of sedentary behavior. This is particularly true for individuals who have the highest level of sedentary behavior. For all of these reasons, it is important for physicians to assess the level of sedentary behavior in every patient and if needed, recommend increased levels of moderate to vigorous physical activity. The public health impact of these changes could be very significant.[1]

18.9 CONCLUSIONS

Both children and adults in the United States have become increasingly sedentary. The average child or adult in the United States spends 7.7 hours per day being sedentary. This includes screen time, watching T.V., and other tasks sitting or lying down. These levels of sedentary behavior have now been clearly associated with an increase in the risks associated with all-cause mortality and mortality from CVD, T2DM, and some cancers. On the other hand, levels of moderate to vigorous physical activity can offset the increase in sedentary behavior. This is particularly true for individuals who have the highest levels of sedentary behavior and are also inactive. For all of these reasons, physicians should assess the level of sedentary behavior in every patient and recommend increased levels of moderate to vigorous physical activity if individuals are quite sedentary to lower the risk that this behavior carries.

CLINICAL APPLICATIONS

- Physicians should assess the level of sedentary behavior in every patient and recommend increased levels of moderate to vigorous physical activity, if needed.
- Sedentary behavior levels of greater than seven hours per day are associated with the increased risk of all-cause mortality.
- Sedentary behavior is also associated with increased risk of mortality from CVD and T2DM as well as some cancers.
- Moderate to vigorous physical activity may offset the adverse consequences of sedentary behavior. This is particularly true for individuals with a high level of sedentary behavior who are also currently inactive.

19 Promoting Regular Physical Activity

James M. Rippe, MD

KEY POINTS

1. Physicians are credible voices in the area of multiple lifestyle decisions and in particular, promoting physical activity.
2. Physicians should take the lead in not only recommending physical activity to their own patients, but also promoting community involvement to increase physical activity and even national strategies for physical activity.
3. Physical activity yields multiple benefits.
4. Currently, a distinct minority of individuals in the United States are physically active at levels that yield health benefits.
5. Multiple factors impact on the likelihood of maintaining a physically active lifestyle. These include individual factors, community, the communication environment (information technology), physical environment, and public policy.
6. These domains provide important mechanisms for exploring what is known about effective ways of promoting physical activity.

19.1 INTRODUCTION

An enormous literature exists demonstrating the positive relationship between regular physical activity and multiple health benefits. This literature underscores and corroborates two key concepts. First, physical activity can play numerous positive roles in lowering the risk of chronic disease and improving daily lives in individuals throughout their lifespan. Second, despite the known benefits of physical activity, the majority of Americans do not participate in enough of it. This chapter will focus attention on ways that physicians can play an important role in promoting physical activity not only for their own patients, but also for the community and for the nation.

As already indicated in previous chapters of this book, physical activity levels for Americans are typically not enough to obtain the full benefit of an active lifestyle, In fact, in 2015, fewer than half of American adults reported levels of aerobic physical activity consistent with federal guidelines as articulated in the Physical Activity Guidelines for Americans 2018 (PAGA 2018),[1] and 30% of adults reported high levels of inactivity during leisure time.[2] Unfortunately, these data also apply to high school students. Only 27% of U.S. high school students report levels of physical activity that are consistent with guidelines recommended by the PAGA 2018 of 60 minutes or more of physical activity a day.[3] For these reasons, and because the input of physicians is critically important to promote physical activity, it is important to explore ways that physicians can be successful to encourage people to exercise and which carry the most promise to elevate the level of physical activity in the future. In addition, since concern has been raised about sedentary behavior, this chapter will also briefly explore ways of reducing this type of behavior. (More detail about reducing a sedentary lifestyle will be found in Chapter 14.)

19.2 CONCEPTUAL FRAMEWORK FOR FACTORS INFLUENCING PHYSICAL ACTIVITY

There are numerous conceptual frameworks that can be utilized to illustrate the factors that impact on physical activity in the United States. The PAGA 2018 uses the conceptual figure found in Figure 19.1.

As indicated in this figure, multiple influences interact in ways that impact on physical activity. This starts at the individual but extends to the community, communication, and environment as well as public policy.[4] This type of framework has also been used in other areas of behavior, such as nutrition, where a similar socio-ecological model was employed in the Dietary Guidelines for Americans (DAGA) 2020–2025 to address factors that need to be addressed when considering more healthful eating in the United States.

19.3 INDIVIDUAL LEVEL

The most robust data that are currently available relating to effective ways of promoting physical activity come from initiatives that are designed to increase physical activity in individuals.[5] This is not only true for the general population[6–8] but also specifically relates to older adults as well as postmenopausal women and youth.

The types of strategies used to promote physical activity typically involve either one on one sessions or group delivered programs involving structured exercise. Educational approaches have also been used to teach individuals how to employ various strategies to increase regular physical activity. Individual interventions for adults typically are the most flexible way of tailoring advice and support to help individuals to meet their physical activity needs and

DOI: 10.1201/9781003227793-22

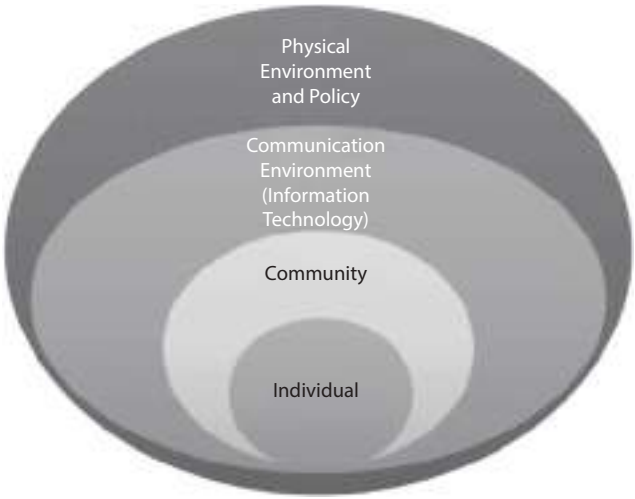

FIGURE 19.1 Conceptual framework for factors that impact on physical activity in the Unites States. (*2018 Physical Activity Guidelines Advisory Committee Scientific Report*. Washington, DC: U.S. Department of Health and Human Services, 2018).

preferences. Unfortunately, the downside of such programs is that they require a high level of staff involvement and can result in significant costs in the long run. Examples of this kind of initiative are personal training and various types of structured exercise classes that have also been employed to target older individuals. These interventions generally demonstrated a small, but positive, effect on physical activity when compared with controls.

The PAGA 2018 rated the evidence for individual approaches to promote physical activity as "strong." These initiatives often focus on not only physical activity but also other health promoting lifestyle measures such as improved diet (more fruits, vegetables, and whole grains) as well as weight loss and other behaviors.

A variety of interventions have also been utilized in postnatal individuals. This is a group of individuals for whom adequate physical activity may be difficult to increase or maintain.[9] The PAGA 2018 viewed evidence in this area as "limited" because there were heterogeneous results from these programs. The most promising of these efforts involved behavior change strategies including goal setting and behavioral self-monitoring. Particularly promising results have occurred in generally healthy, but inactive, women in the postnatal period.

A variety of efforts have also been employed to promote increased physical activity in healthy youth and have been shown to have considerable promise.[10,11] For this reason, PAGA 2018 rated evidence in this area as "strong." The benefits of these approaches were most apparent when incorporating families or delivered in school settings. It is particularly important to focus on lifetime physical activity such as leisure time pursuits in non-competitive sports in youth. Schools have the additional benefit of utilizing facilities that may be available after school hours. Several studies have emphasized improving sidewalk and street design to promote active commuting to and from school.

19.4 THEORY BASED INTERVENTIONS TO INCREASE PHYSICAL ACTIVITY

Most of the interventions involved in various aspects of lifestyle medicine are based on changing behavior. This, of course, is true of efforts to increase physical activity. Many different theory based interventions have been demonstrated to carry some efficacy in helping people make behavior changes in their lives.[12] Education concerning utilizing these theories for behavior change is becoming more common in medical school studies. This area is so important that we have devoted an entire section to behavior change in this textbook as well as the third edition of this book.[13] The behavior change models that are briefly discussed in this chapter are examined in much more detail in Chapters 20, 25, and 29.

19.4.2 Health Belief Model (HBM)[14–16]

This model was initially developed to explain why many individuals back in the 1950s were not participating in preventive health services. The model posits that the likelihood that individuals will participate in a given health behavior largely depends on their perception of the following three issues:

- Severity of illness(es)
- Benefits from engaging in behavior
- Barriers to engaging in behavior

This model suggests that individuals are more prone to adopt a healthy behavior if they believe it is likely to lower their risk of potential illness and that engaging in these actions carries some benefits. Multiple different factors may prompt actions in this area, such as media campaigns, physician reminders, and the experience of friends and colleagues.

The concept of self-efficacy was subsequently added to the Health Belief Model to increase its ability to actively predict health behaviors. This model has been applied to a variety of long-term health behaviors, including physical activity. Some investigators have criticized HBM because of constructs such as "cues to action," which are empirically difficult to test. In addition, some other models have subsequently been demonstrated to exhibit stronger predictive ability to predict health behavior changes. Nonetheless, HBM may be useful in the hands of physicians, particularly if they are counseling patients to initiate programs of increased physical activity.

19.4.3 Theory of Reasoned Action, Planned Behavior, and Integrated Behavior Model

The Theory of Reasoned Action (TRA) starts from premises found in both cognitive and social psychology.[17,18] This

model proposes that an individual's likelihood of engaging in a particular health behavior, such as increased physical activity, can be predicted by the strength of their intention to engage in the behavior. These intentions are a combination of individual's attitudes about the behavior and "social norms." The TRA model is extended to what is called the Theory of Planned Behavior (TPB), which added perceived facilitators and barriers to behavior. The Integrated Behavior Model (IBM) further extended TRA and TPB models by adding the importance of evaluating the intention to engage in behavior.[19] These models have all been demonstrated to be efficacious in various behaviors, including increased physical activity.

19.4.4 Transtheoretical Model

The Transtheoretical Model (TTM)[20,21] is a model developed from many different psychological theories. Prochaska and colleagues first described this model by noting that people vary in terms of motivational readiness to make behavior change. It was initially applied to cessation of smoking. The model is based on people progressing to a series of changes called "stages of change." The model outlines moving from pre-contemplation to contemplation, followed by action, and subsequently followed by maintenance. The TTM model has been widely adopted throughout behavior medicine and is very useful in the area of physical activity.

19.4.5 Social Cognitive Theory[22, 23]

The Social Cognitive Theory (SCT) is a model based on social learning theory. It focuses on individuals' responses to watching others' behavior (this is referred to as "modeling"). Self-efficacy is the main psychological construction for SCT and can be increased through mass experiences, social modeling, improved physical and emotional states, and verbal recommendations.

19.4.6 Positive Psychology[24]

The science of positive psychology has emerged as an area of interest in behavior change. Positive psychology is defined as the scientific study of "conditions and practices that contribute to the flourishing or optimal function of people, groups and institutions." This model is based on the belief that the best way to address behavioral changes is by leveraging psychological strengths. This model has been utilized in a variety of chronic diseases. The typical framework for applying positive psychology includes recommendations to express gratitude to others, recognizing a person's individual strengths, and engaging in acts of kindness as well as mindful meditation.

19.4.7 Overcoming the Intention/Behavior Gap[25]

Recent attention has focused on how to overcome the gap between what individuals intend to do and what they actually accomplish in terms of making behavioral change. Intention alone typically has not been found to be reliable behavior for physical activity changes. To employ this model to increase individuals' likelihood of actually changing their behaviors, physicians should consider such strategies as helping the patient plan specific goals and enhance self-efficacy and positive emotional response.

19.5 COMMUNITY BASED INTERVENTIONS TO INCREASE PHYSICAL ACTIVITY

Physicians can play an important role in leading or supporting community based interventions to increase physical activity.[26] A variety of community-wide efforts have been undertaken to attempt to increase levels of physical activity. These have been divided into a variety of domains, including informational, behavioral/social, and policy/environmental approaches.

These approaches are based on the concept that many adults report barriers to increasing regular physical activity that can be traced to community issues. For example, the most commonly cited factor is lack of access to facilities or safe places to engage in physical activity. Healthcare practitioners can encourage physical activity behavior, but unless individuals have a place in which to be active, they are often unable to follow such recommendations. The goal of community approaches is to make the community more "physically active friendly" and includes both general initiatives and specific recommendations for places. Included in these initiatives and places are the following:

- *Schools*[27–29]—Many physical education and health education curricula are available to provide a framework for promoting physical activity and have been shown to be effective. Unfortunately, there is a paradox in the United States. School buildings and grounds, which are the most widely available public resources and could be used for physical activity, are often underutilized. Studies show that students' engagement in physical activity during leisure time at school suggests that few students use this time to be physically active. Factors associated with increased physical activity at schools include the presence of dedicated spaces for physical activity (e.g., sports fields, gyms, access to sports equipment, interesting and newer playgrounds, and sufficient space for physical activity). Supervision also has been shown to increase participation in physical activity. Unfortunately, many schools have policies to restrict access to school grounds by students and community members outside of school hours. This is a particular problem in low income communities, which often lack other safe spaces for physical activity.
  In addition, active transport by walking or cycling to and from school can yield substantial physical

activity benefit for children and youth. This has been shown by recent evaluation by the Safe Routes to School Program.[30] Some states, such as California, have now dedicated funding to begin to address this issue.

- *Worksites*[31,32]—Many employees spend at least half of their waking hours at work, so worksites are a natural place to try to increase physical activity. Furthermore, physically active jobs have decreased and sedentary jobs have increased in the past few decades. A variety of initiatives have shown some promise in increasing physical activity in the workplace. These include flexible work hours and removing potential barriers to physical activity, such as establishing facilities and a safe place to park bicycles, and providing showers for employees to encourage them to be physically active. One interesting initiative in this area was performed by Dishman et al. in their "Move to Improve" in a multi-site, randomized controlled trial. This study involved putting together specific plans to remove perceived barriers and improve management support for physical activity. At the end of a 12-week intervention, only 2.5% of individuals at control sites engaged in 150 minutes of moderate to vigorous physical activity on a weekly basis, while 51% of the intervention sites met these criteria.[33] This suggests that well-structured worksite programs can make a substantial difference.
- *Community organizations*—Numerous community organizations are available to provide facilities and programs with the goal and potential to increase physical activity. These include health clubs, dance studios, swimming pools, sports leagues, etc. Non-profit organizations such as the YMCA, YWCA, and Boys' and Girls' Clubs can also provide spaces for increased physical activity. In addition, many new housing developments are now including recreational and fitness facilities. This area remains one of active study.
- *Public recreation facilities and built environments*—Public parks and recreational facilities are widely used, with about 80% of the population making some use of municipal facilities. A substantial portion of individuals also utilize parks' programs and services.[34] In fact, in one survey of 114 parks in major U.S. cities, walking and fitness facilities were particularly well utilized. Not surprisingly, parks in low income neighborhoods are utilized less than those in more affluent communities. It should also be noted that parks are eager to have the public use their facilities as venues for increased physical activity. A survey of 144 recreation center directors in San Diego showed that 75% were interested in partnering with health professionals and trained staff on physical activity leadership.[35]

  The Community Preventative Sources Task Force now includes recommendations for making built environments more "activity friendly" along with increasing physical activity.[36] The built environment strategy combines improved pedestrian lanes and environmental design to improve pedestrian bicycling activity, which can facilitate increasing the level of physical activity.

19.6 PROMOTING USE OF PLACE FOR PHYSICAL ACTIVITY

A number of health departments have become involved in analyzing ways of attracting more people to utilize such facilities as part of the initiative to increase physical activity. This initiative includes publicity campaigns and fun walks with refreshments and tee shirts donated by local businesses. These initiatives have often resulted in recommendations from the public to increase the number of trails available for walking.

It should also be recognized that often, environmental policy interventions designed to increase physical activity need to be justified for cost effectiveness. A program such as the CATCH (Coordinated Approach to Child Healthcare) program showed a large economic benefit with regard to quality of life as well as years of life saved (2 ALY).[37] This suggests that an important body of literature may demonstrate that increased physical activity can generate a high rate of return on investment. A number of programs have been developed utilizing the Guide for Preventative Community Services, which rates the effectiveness of various programs.

- *Primary care settings*—A number of different primary care interventions to increase physical activity have been attempted, including counseling sessions with primary care providers of short duration (2–10 minutes) or long duration (e.g., 40 minutes).[38,39] Some of these programs provide physician contact only, while others provide a combination of counseling and printed materials.
  Evidence cited in the PAGA 2018 report showed that primary care initiatives to promote physical activity were effective when compared with "usual care conditions." The primary care setting is particularly appealing, since over 70% of adults see their primary care physician at least once a year. Counseling with written prescriptions has been demonstrated to be more effective than simply a limited amount of counseling.[40]
- *Nurse delivered programs*—A number of studies have also demonstrated some benefit from nurse delivered programs to increase physical activity.[41,42] These programs are particularly attractive, since nurse outreach can be useful given the convenience for some populations, such as frail adults

and those with chronic conditions. Nurses also can provide personal contact and program customization, which may be particularly useful for behavior change in these populations. The ability of nurses to see patients in their home environment can also involve family members and can further facilitate physical activity participation. Continuity of care can be an additional benefit from nurse delivered programs.

19.7 COMMUNICATION/ ENVIRONMENTAL LEVEL

A variety of new Information and Communication Technologies (ICTs) have provided additional modalities with considerable potential for increasing the level of physical activity for a wide variety of individuals. Importantly, these ICTs reach out across to individuals at every stage of lifespan. Approaches to studying ICTs have been divided into domains such as wearable activity monitors, cellphone assisted interventions, web based or internet developed interventions, computer tailored print, multiple, and phone programs, and interactive video games, which are designed to promote activity through player exercise.

- *Wearable activity monitors*—The PAGA 2018 report rated the evidence for wearable activity monitors such as pedometers, accelerometers, etc. used in conjunction with behavior strategies to potentially increase levels of physical activity in the general population of adults as well as those with type 2 diabetes as "strong."[43–45] These monitors, used in conjunction with behavioral strategies, expand and enhance the possibilities for motivation to increase physical activity. Newer activity monitors have been shown to have good reliability and fluidity, which makes them promising intervention tools for population-wide physical activity promotion.
- *Telephone assisted intervention*—A number of interventions have been taken over the last few decades involving telephone reminders.[46,47] These interventions have been shown to generate strong evidence for increased physical activity in the general adult population. Since phone ownership is highly prevalent in the United States, these interventions show great promise for increasing physical activity, because they allow broad dissemination of advice and counseling for adult populations.
- *Web based or internet delivered interventions*[48]—A number of new web based and internet delivered interventions are now available. The PAGA 2018 rated the effects of these interventions as "strong" for increasing physical activity in the general population. PAGA 2018 Guidelines also rated web based or internet delivered programs for individuals with T2DM as "limited" due to the heterogeneity of studies and results. These interventions are particularly attractive because they have such broad dissemination and can allow even small increases in physical activity to generate significant public health impact.
- *Computer tailored print interventions*—These are interventions that collect information through mailed surveys and then are utilized to generate computer tailored mailings containing advice about personal physical activity and support.[49] There are some data to suggest the benefit of these types of interventions when compared with treatment controls. These interventions are particularly useful in populations that have lower computer technology literacy or who live in remote areas.
- *Mobile phone programs*—Programs that utilize text messages appear to have a small to moderate positive effect on physical activity in the general adult population.[50–52] Smartphone applications may be particularly appropriate for children and adolescents. Smartphone applications are particularly appropriate for text-savvy children. Their use with children and adolescents appears to result in a stronger association with increasing physical activity in these populations.
- *Social media*—Physical activity monitors that utilize social media are rapidly developing.[53–55] There is a paucity of long -term trials for these interventions. However, the use of social media with complementary communication channels may improve the likelihood of physical activity messages being beneficial. This is true for population groups that are particularly strong users of social media.
- *Interactive video games promoting active player exercise*—Some evidence exists that this type of intervention can increase levels of physical activity.[56–58] This is particularly true for youths who are actively utilizing video games. This approach may be particularly useful during school times and classroom settings. There is very little research, however, on the efficacy of these programs.
- *Point of decision prompts*—There is good evidence that point of decision prompts such as signage to encourage use of stairs rather than elevators can have a positive impact on levels of physical activity.[59,60] Another advantage of this type of intervention is the ubiquitous presence of stairways in most public accommodations.
- *Access to indoor/outdoor facilities*—Having access to either indoor facilities (e.g., gyms, other recreational facilities, health clubs, swimming pools) or outdoor recreational facilities (e.g., parks, trails, and green space) is associated with

increased levels of physical activity in both children and adults compared with environments that do not have these features.[61–63] A useful summary of these types of interventions can be found at the National Physical Activity Plan (U.S. Report Card on Walking and Walkable Communities 2017).[64]

19.8 INTERVENTIONS TO REDUCE SEDENTARY BEHAVIOR

An accumulating body of information and evidence has emerged that sedentary behavior can have a significant adverse impact on health consequences. This issue is so important that an entire chapter (Chapter 18) has been devoted to this aspect. Strategies to promote physical activity should also address ways of reducing sedentary behavior.

Sedentary behavior in youth can be addressed by such strategies as lowering the amount of television viewing and other screen time. These interventions have been shown to have small, but consistent, results in reducing sedentary behavior.[65–67] This evidence may also be applied to home based interventions, although research in this area is in its infancy. With regard to adult interventions, some data suggest that the educational and behavioral approaches to reduce sedentary behavior may be effective.[68,69] Research in this area has demonstrated small, but consistent, impacts on increasing levels of physical activity.

Work site interventions, such as those that target workers who perform duties primarily while seated, may also have significant short-term impact on reducing sedentary behavior.[70,71] These interventions are appealing because they can be implemented during times when physical activity is generally not feasible.

19.9 CONCLUSIONS

Physicians can and should play a significant role in promoting increased levels of physical activity not only for their own patients but also for the community at large. As already indicated in multiple chapters in this book, lack of physical activity is a significant and pervasive health risk in the United States and other industrialized countries. To solve this problem will require a multifaceted approach.

It has been estimated that less than 25% of the adult population is active enough to attain benefits outlined by the Centers for Disease Control (CDC), the American College of Sports Medicine, and the PAGA 2018. The various modalities discussed in this chapter may help improve this very low participation rate. Since physicians are a trusted source of information, it is incumbent upon physicians to play a role in multiple aspects and initiatives to promote increased physical activity. The good news is that there are multiple opportunities available to help people become more physically active. These opportunities should be discussed by physicians in every office visit.

CLINICAL APPLICATIONS

Physicians are a credible and respected source of information about various health issues. Physical activity should certainly be one of these.

Physicians should routinely recommend increased physical activity not only in their clinical encounters but also in the various venues in the community where options exist to encourage more increased physical activity.

The model proposed by the Physical Activity Guidelines for Americans 2018 Scientific Report 2018 emphasizes that multiple domains, such as individual, community, communication environment, physical environment, and policy domains, exist where physicians can play a significant role.

Behavioral models exist that can contribute to increasing physical activity. Physicians should be aware of and utilize these theoretical constructs, which have been proven to be effective and are outlined in this chapter.

20 Behavior Change

Elizabeth Pegg Frates and James E. Eubanks

KEY POINTS

1. Behavior change is the foundational activity through which Lifestyle Medicine works.
2. Healthcare providers need to be versed in behavior change techniques that foster self-efficacy and cultivate a therapeutic relationship to empower the change process.
3. Four key theories outlining behavior change are the Health Belief Model, the Transtheoretical Model of Change, the Social Cognitive Theory, and the Social Ecological Model of Change.
4. The overall approach to any behavior change includes goal setting, follow-up, self-monitoring, action planning, problem solving, and social support.

"Knowledge is power," said Sir Francis Bacon. However, knowledge alone is not powerful enough to instill lasting change. Patients need more than lectures from healthcare providers to adopt healthy habits. The field of behavior change has been an active one for decades, dominated by psychologists, psychiatrists, social workers, nurses, and others at the front line of counseling patients. The entire field is blossoming as more and more attention is being given to the impact of lifestyle on health. Research in this area is on the rise, and the groundwork has been laid by academics and clinicians dedicated to helping people quit unhealthy behaviors and adopt healthy ones: people like Dr. James Prochaska, who created the Transtheoretical Model of Change, and Drs. Miller and Rollnick, who described and continue to teach the process of motivational interviewing. This Behavioral Medicine section of the textbook is an essential one for all lifestyle medicine practitioners. Patients might know the right amount of exercise they need to improve their health. Also, they might know that they need to eat more vegetables or quit smoking. But, they might not do it without the aid of a healthcare provider who is versed in behavior change techniques that foster self-efficacy, who can tap into intrinsic motivation, and who can cultivate a therapeutic partnership that can serve to empower and fuel the change process.

As physicians and clinicians, we are trained in the expert approach. In the expert approach, we spend a significant amount of time lecturing, informing, and convincing the patient to follow the doctor's orders and advice. This is, at times, a necessary approach, especially when managing acute medical conditions like myocardial infarctions, strokes, sepsis, bacterial pneumonia, and meningitis. However, with lifestyle changes, the best approach is a different approach, the coach approach. With the coach approach, the emphasis is on listening to the patient rather than informing the patient, motivating the patient rather than convincing the patient, and collaborating with the patient rather than directing the patient. It takes some time to adopt the coach approach after years of practicing the expert approach, but it is worth it. In order to adopt this approach, the practitioner needs to be familiar with and understand the process of behavior change. This entire section of the textbook is devoted to this important topic.

There are many behavior change theories and techniques. There is also a plethora of research examining their use. By reviewing the state of the current literature, lifestyle medicine practitioners will be able to better understand which techniques are most powerful and in which situations they are most effective. Learning about the different theories is essential, and practicing the different techniques with patients will enable the practitioner to become proficient with them. The more familiar the practitioners are with the concepts and the research, the more likely they are to adopt these behavior change strategies. Many lifestyle medicine specialists are going through their own process of change in the way they practice medicine and prevention.

Most medical schools did not teach behavior change in the past. Although the research on behavior change is more mainstream, teaching behavior change theories and techniques is not yet a routine part of medical training. The Medical College Admission Test (MCAT) changed a few years ago and added a section on psychology, which includes information on behavior change. When standardized tests like medical school entrance exams and board exams change, the courses and curriculum in pre-med courses, medical school courses, and residencies will have to change as well. There is movement in this direction, and it is gaining momentum.

The National Institutes of Health have been interested in behavior change for years. Karen Glanz, PhD, MPH, from the University of Pennsylvania, has spent her career studying behavior change. Dr. Glanz is Director of the UPenn Prevention Research Center at the University of Pennsylvania and Senior Editor of the textbook *Health Behavior and Health Education: Theory, Research, and Practice*.[1] She has been designated a highly cited author, in the top 0.5% of authors in the field, over a 20-year period.

Four theories that Dr. Glanz highlights in her electronic resource on behavior change include the Health Belief

DOI: 10.1201/9781003227793-24

Model, the Transtheoretical Model of Change, the Social Cognitive Theory, and the Social Ecological Model of Change.[2] These are four theories that every lifestyle medicine practitioner needs to understand. In the Health Belief Model, the theory states that people's beliefs about the risks and benefits of changing behavior influence their readiness to change. If a patient believes that quitting smoking will actually help them to prevent lung cancer, then they are more likely to be interested in quitting. If they believe that since no smokers in their family were diagnosed with lung cancer, they are somehow protected from cancer, that person is less likely to consider quitting. Using the Health Belief Model in practice requires that healthcare practitioners hold conversations with their patients in which they ask open-ended questions that invite patients to talk and share their beliefs. Understanding the beliefs of the patient is key to successful behavior change counseling.

The Transtheoretical Model of Change (reviewed in detail in Chapter 23 by Dr. James Prochaska) describes Five Stages of Change that a patient can transition through for a particular behavior. A patient can be in different stages of change for different behaviors. The stages are:

- Pre-Contemplation
- Contemplation
- Preparation
- Action
- Maintenance

In pre-contemplation, the patient is not even thinking of change, whereas in contemplation, as the name suggests, the patient is contemplating change. They are ambivalent about it. Some people stay in contemplation for years, called Chronic Contemplation. Those in preparation want to change and have an intention to change. They are not ambivalent anymore, but they have yet to take action. Action is the next phase. When the patient makes strides to adopt the new behavior and starts practicing the behavior, they are in action. After action comes maintenance. If the patient has been practicing the new healthy behavior for over six months, they are in maintenance. With each stage comes a set of specific strategies for the healthcare practitioner to use to help the patient move along through the stages. These are outlined in Chapter 23. Patients do not necessarily move through the stages in a stepwise fashion. This is not a straightforward staircase but more of a spiral staircase, where the patient might slip while in action and wind up in contemplation or slip during maintenance and land in preparation. Asking the patient about their readiness to change is key in behavior change counseling.

The Social Cognitive Theory is another behavior change theory that lifestyle medicine practitioners need to know. Albert Bandura, PhD, created this theory, and it explains human behavior using a three-way dynamic, which includes 1) personal factors,2) behaviors, and 3) environmental influences. Dr. Bandura's theory highlights the importance of reciprocity among these three factors. Each one influences the others. When lifestyle medicine practitioners are counseling a patient, they need to account for personal factors, including personality, preferences, beliefs, strengths, and weaknesses. Behaviors that are being reinforced currently and triggers for those behaviors need to be addressed with patients. The environmental influences surrounding the patient are critical and play a role in the behavior change process as well.

Examining the patient's social environments is one of the main points in the Social Ecological Model of Change. In this model, the patient is at the center. Surrounding him is the interpersonal circle, which includes his social network at work, school, home, or on the internet. Around that is the organizational level of influence, including the ethos of his home, work, neighborhood, city, state, and country. Beyond that level is the community influence, which factors in cultural values and norms for the patient. The last level or sphere of influence, the most far-reaching, is the public policy level, where laws impact behavior and require strict guidelines to be followed. This model of change helps practitioners work to set the patient up for success in their daily lives by exploring the world in which the patient lives. It is important to know about the patient, and it is equally important to know about the patient's environment and the external influences on that patient. Taking all these factors into consideration is critical for lasting behavior change.

Looking at the research in the medical literature helps practitioners to share findings from a wide variety of sources about other practitioners helping patients to adopt healthy habits. Specific studies use different patient populations and different behavior change techniques. Review studies collect a number of research articles and examine them for similarities and differences.

In terms of nutrition and diet counseling, a study in the *Journal of the American Dietetic Association* reported that effective counseling techniques were cognitive behavioral therapy (CBT), motivational interviewing, self-monitoring, meal replacement and/or structured meal plans, goal setting, problem solving, and social support. Working with the patient in these areas with these strategies helped them to adopt healthy eating habits. In terms of ineffective strategies, the authors state, "Compelling evidence exists to demonstrate that financial reward strategies are not effective." These extrinsic rewards, like money or gift certificates, might motivate patients, but that motivation rarely lasts after receiving the reward, and it is not compatible with sustainable change.[3]

In a review article that included 22 studies, researchers specifically looked at patients of retirement age to identify the most effective techniques to help this population increase fruit and vegetable consumption. According to the review article, the most useful strategies include barrier identification, problem solving, social support, goal setting, use of follow-up prompts, and providing feedback on performance.[4] There are some consistent messages that are found in different populations and for different behaviors.

Continuing to examine the research will result in highlighting those strategies that are effective across populations and which are best for targeting healthy habits.

Patients with diabetes have been the focus of attention nationally in the public media and in academic institutions with various research studies. In one review article that included research studies from 1975 to 2015, 14 randomized controlled studies were included that examined patients with diabetes and their physical activity levels as well as their dietary patterns. This review identified four behavior change techniques that were repeatedly utilized successfully. They included instruction on how to perform the behavior, behavior rehearsal, demonstration of the behavior, and action planning. Strategies that helped patients to adopt and sustain these two healthy behaviors included supervised physical activity, group sessions, contact with an exercise physiologist, and contact with a dietician. In addition, this review pointed out that the more sessions and the greater the frequency of sessions, the better the results of the trials.[5]

Another diagnosis that has received much attention, from the media as well as from academic researchers, is obesity. In a review article specifically looking at patients with obesity and how to increase their levels of physical activity, the results were split into two areas: 1) how to increase self-efficacy and 2) how to increase the behavior. In order to increase self-efficacy (a belief held by the patient that they could perform the physical activity successfully), the strategies that were most effective included action planning, time management, prompt self-monitoring of behavioral outcome, and planned social support. For increasing the behavior of physical activity, prompt self-monitoring of the behavioral outcome, planned social support, teaching to use prompts, prompt practice, and prompt rewards contingent on effort, not on progress toward behavior, were found to be the most effective.[6]

In another review article that included overweight and obese individuals, there were similar results. Effective behavior change techniques in the short term included goal setting and self-monitoring of behavior. Effective behavior change techniques in the long term included goal setting, self-monitoring, feedback on outcome of behavior, implementing graded tasks, and adding objects to the environment, like a step counter. Using the Social Cognitive Theory and the Social Ecological Model of Change concepts that the individual is influenced by their environment is key for sustaining behavior change. In addition, autonomy-supportive, person-centered counseling, including motivational interviewing, was found to be the most effective counseling strategy to help maintain behavior change over time in this population of patients.[7]

In a review of 35 studies, which included adult patients and focused on weight change as well as physical activity behavior, the results revealed that higher autonomous motivation, higher self-efficacy, and higher self-regulation skills like self-monitoring were the best predictors of beneficial weight and physical activity outcomes. Specifically for weight control, a positive body image and flexible eating restraint were identified as important factors.[8]

Looking at the pediatric population reveals important information for providers. In one review that included 17 studies examining childhood obesity with regard to changing physical activity and eating, the researchers identified several effective techniques and only a few ineffective techniques. The effective techniques included providing information about the consequences of the behavior to that specific individual (personalized information), providing environmental restructuring, giving prompt practice, identifying a role model or position advocate, working on stress management and emotional control training, and focusing on communication training. Ineffective techniques included providing information on the consequences of the behavior in general, providing rewards contingent on successful behavior, and facilitating social comparisons.[9]

Putting this all together, the focus for sensible behavioral change in healthcare must be balanced by a sound scientific base and practical solutions that will reach the intended audience. Behavior change techniques must be effective, and counseling strategies must support specific goals. The general approach to behavior change includes elements of goal setting, follow-up, self-monitoring, action planning, problem solving, and social support. Each of these process components has a vital role in facilitating the development of goal behaviors.

Empathy is an important factor among clinicians, not only for the mutual understanding and respect it engenders among patients but also for the determination of clinical outcomes. Hojat and colleagues found that high empathy scores among physicians supporting patients with diabetes also led to better control of hemoglobin A1c (HbA1c) and low-density lipoprotein cholesterol (LDL-c) in their patients.[10] When physicians take time to connect with their patients and learn more about them on a personal level, patients are also more likely to endorse their medical care as "excellent."[11] Key aspects of empathy include the development of a trusting, caring relationship, self-reflection, listening, and being respectful, supportive, and non-judgmental.

While motivation is a required component for any behavioral change effort, it is the alignment between motivation and goals that allows goals to be achieved. Once initial motivation for a behavior change is identified, motivational interviewing can be employed to support patients as they identify additional reasons for seeking and sustaining change efforts. Central to the skilled use of motivational interviewing is the ability to use open-ended questions that help patients appreciate their priorities in life. Using motivational interviewing in the clinical setting has been shown to improve patient mood and even reduce mortality among stroke patients.[12]

Confidence building empowers behavior change by providing sequentially stronger foundations from which new actions can be carried out. It includes asking about strengths so that patients reflect on moments in their personal lives when they achieved a goal. Relating to a time

when they could carry out the tasks necessary to achieve a goal allows them to appreciate the potential for applying similar behaviors in the present moment.

SMART goals are specific, measurable, action-oriented, realistic, and time-sensitive. This general strategy ensures that behavior change efforts are achievable through each step along the pathway by breaking actions down. Each smaller step in the change pathway should contain an element of accountability, which allows for the follow-through needed to complete the behavior change process. Once an immediate step along the process of change is achieved, the conditions are maintained to proceed to the next. Since behavior change involves incremental changes over time, setting up an accountability structure that includes a positive and motivating support system increases the chance of success and reinforces the confidence needed to continue moving forward. In addition to the strong social support system, it is important for the practitioner to check in with patients and to encourage self-monitoring as well as the use of tracking systems as appropriate to help patients enjoy continued, long-term success with their healthy habits.

As created by one of the authors and first described in 2011 in the *Archives of Physical Medicine and Rehabilitation*,[13] the 5 Step Cycle for Behavior Change uses the key elements of behavior change to enable practitioners to experience success with lifestyle counseling. It is shown here in Figure 20.1. Physicians and clinicians can work through the five-step process with their patients by following these steps: 1) be empathetic, 2) align motivation, 3) build confidence, 4) set SMART goals—those that are specific, measurable, action-oriented, realistic, and time-sensitive—and finally, 5) set accountability. Step 1 is critical. This is a cycle that starts and ends with empathy. With behavior change work, it is important to know the details and idiosyncrasies of the person who has the condition. This will only happen if the person feels they are in an environment that is free of shame, blame, and guilt, also called a judgment free zone. By expressing empathy, the healthcare provider sets the tone for the encounter to be one that is safe and one in which the patient feels comfortable sharing their full experience and their true selves. Without honesty, it is difficult to make progress. Step 2 helps connect the patient to their "why" by aligning motivation. Why change? Motivational interviewing discussed in Chapter 22 will explore this topic in great detail. Step 3 is to build confidence, and this step cannot be skipped. People need to feel that they are capable of change. Everyone has strengths and talents. The healthcare provider can empower patients to embrace these skills, gifts, and strengths that the patient embodies by asking, "What are your strengths?" and then stating, "Tell me about a time when you were at your best." When a patient feels confidence and pride, which is a powerful positive emotion, they are ready for creativity and brainstorming and the next step, Step 4. Step 4 is setting SMART goals. A lofty, vague goal can be inspirational, but it is not practical. Behavior change needs to be practical. SMART goals are just that. They are specific, measurable, action-oriented, realistic, and time-sensitive. Many patients need guidance in setting SMART goals. Guidance is different than telling someone what to do. The healthcare provider is not meant to set the SMART goal, but rather, to collaborate and help the patient to set a SMART goal that aligns with their priorities and their sense of purpose. Lastly, there is Step 5. This is the crucial step of setting accountability. Healthcare providers set accountability so that benchmarks are available to measure success or the need for adjustments in strategies and planning to ensure the goal is achievable. Patients are often motivated by the check-ins and the tracking that comes with accountability. It can be simple logging, data from a wearable device, journaling, or monitoring step counts or number of vegetables consumed. Sharing progress helps keep patients motivated. This 5 Step Cycle has helped healthcare providers by providing a roadmap to behavior change counseling sessions.

FIGURE 20.1 5 Step Collaboration Cycle. (Reprinted with permission from Healthy Learning, publisher of ***Lifestyle Medicine Handbook*** 2nd edition, Chapter 2.)

Central to the process of counseling patients on behavior change is mindfulness. The healthcare provider and the patient both need mindfulness for this process to be successful. The impact of mindfulness on behavior change has been the focus of recent research.[14] Data from an eight-week pilot study on Mindfulness Based Stress Reduction groups tailored to patients with high blood pressure demonstrated significant changes in lifestyle behaviors like physical activity, diet, and alcohol intake for those nonadherent to American Heart Association (AHA) guidelines at baseline, with the changes sustained even after a year.[15] There is some magic to mindfulness that has not yet been fully elucidated, but with the surge in research studies on the topic, it might become clearer soon.

Recent trends in behavior change counseling around nutrition have brought mindfulness about language to the forefront. For example, in an article about reconceptualizing how we speak about eating, the authors, Olstad and

Kirkpatrick, recommend using the terms *eating practices* and *patterns* rather than *behaviors*.[16] They recommend that the focus be shifted away from just will power and individual choices and decisions to including the complex nature of what people eat, which involves their local environment, culture, food industry products, socioecological conditions, and the influence of community on eating patterns. Another important point is to adapt the language of behavior change interventions to suit the literacy level of the patients, using clear language and images that are labeled, and consider color coding for clarity in some cases (green for good and red for bad).[17] Food insecurity has become more and more of an issue with COVID 19 and the Ukraine War. Working on the social determinants of health (SDOH) as part of behavior change counseling around healthy lifestyles is critical. According to the Healthy People 2030, "Social determinants of health (SDOH) are the conditions in the environments where people are born, live, learn, work, play, worship, and age that affect a wide range of health, functioning, and quality-of-life outcomes and risks."[18] Figure 20.2 demonstrates the social determinants of health, including economic stability, education access and quality, healthcare access and quality, neighborhood and built environment, and social and community context. When healthcare providers counsel patients on behavior change, the socioecological model of change needs to be front and center so that providers can meet people where they are and empower them to make strides to a healthier lifestyle.

FIGURE 20.2 Social Determinants of Health from Healthy People 2030. The $ indicates economic stability, the blue graduation cap indicates education access and quality, the red cross indicates healthcare access and quality, the blue house and building represents neighborhood and built environment, and the yellow people represent social and community context. (From https://health.gov/healthypeople/priority-areas/social-determinants-health)

Behavior change counseling takes time. It is usually not accomplished in one visit of 10 or 15 minutes. It takes follow-up and repeated visits. If the practitioners are too busy and do not have the time to do the behavior change counseling themselves, then they can hire a nurse, social worker, health coach, therapist, or behavior change expert to work with the patient. It is important that someone in the office focuses on this behavior change if healthy habits are going to stick. On average, it takes about 60 days or 2 months for a new behavior to become habit. If the patient is in the maintenance stage of change according to the Transtheoretical Model of Change, then the clinician can continue to encourage the healthy habit by asking about it and pointing out all the positive outcomes that are a result of the habit. Keeping on track with healthy habits is the key for patients, and lifestyle medicine practitioners can empower patients to do this by following evidence-based behavior change strategies.

CLINICAL APPLICATIONS

- Use the 5 Step Cycle[13] in your clinical encounters, focusing on making a connection and fostering collaboration.
- Catch yourself using the expert approach when working on behavior change and redirect your efforts to using a more collaborative style of counseling that is consistent with the coach approach.
- Work on making SMART goals with patients that are specific, measurable, action-oriented, realistic, and time-sensitive.
- Make sure there is built-in accountability for the patient; have them check in with you at the next visit, or have them buddy up with a family member or friend.
- If you do not have the interest or time to counsel patients on behavior change, consider hiring someone with this expertise, or consider having someone in your practice trained in motivational interviewing and behavior change so that they can spend the time needed to empower people to change.

21 Applying Psychological Theories to Promote Healthy Lifestyles

Maryam Gholami, PhD, Cassandra Herman, MS, Cole Ainsworth, MPH, Dori Pekmezi, PhD, and Sarah Linke, PhD, MPH

KEY POINTS

- Theories vary based on their focus on the primary force(s) influencing behavior change.
- The primary force(s) influencing behavior change are: individual, interpersonal, and ecological.
- The Socioecological Model is based on the concept that behavior has multiple levels of influences, including intrapersonal, interpersonal, organizational, community, environmental, and policy.
- Health behavior change interventions are most effective when they target the key constructs of behavior change.

21.1 INTRODUCTION

The application of psychological theories and models to health behavior change research, program development, and policy has soared in popularity over the past few decades. Desired outcomes are most likely achieved within the context of health behavior change programs that are based on an objective understanding of the target health behaviors and the variables that influence them; theories and models enable researchers and other program developers to organize these variables to achieve these outcomes.[1]

In this chapter, we focus on select theories and models that have consistently received attention to guide health behavior research: Health Belief Model (HBM), Theory of Reasoned Action (TRA)/Planned Behavior (TBP), Integrated Behavior Model (IBM), Social Cognitive Theory (SCT), Transtheoretical Model (TTM), and Socioecological Model (SEM). Later in this chapter, we discuss theory-based lifestyle interventions that have been broadly used in both research and practice, either by implementing a full model or by using a subset of the most effective constructs.

Many of these theories share some similar or even identical constructs, including the widely adopted concept of self-efficacy, which was coined by the famous psychologist Albert Bandura.[4,5] This construct refers to confidence in one's abilities to successfully perform a particular behavior (i.e., walk 1 mile) despite barriers such as bad weather or a busy schedule. Most incorporate static individual differences (e.g., demographic variables), dynamic individual differences (e.g., mood/affect), and interpersonal factors (e.g., social support), but the degree to which each of these variables is highlighted varies widely from one theory or model to another. Although similarities among the models and theories are clearly apparent, their differences set them apart from one another and make them more or less useful as frameworks through which to understand and/or modify different types of health behaviors. For example, some are more applicable to one-time or short-term health behaviors (e.g., HBM), while others are better suited for longer-term ones (e.g., TTM). An overarching characteristic that differentiates models and theories is their relative focus on the primary force(s) influencing behavior change. Thus, we organize the selected models and theories into three broader levels: individual, interpersonal, and ecological.

21.2 INDIVIDUAL LEVEL

21.2.1 Health Belief Model

The HBM,[6–8] depicted in Figure 21.1, was initially developed in the 1950s in attempt to understand and explain why many individuals were not participating in preventive health services, even when they were offered at no cost. The HBM proposes that the likelihood that individuals will engage in any given health behavior largely depends on their *perceptions* of the following variables: severity of the illness(es) it helps prevent, their susceptibility to the illness(es), benefits of engaging in the behavior, and barriers to engaging in the behavior. According to the HBM, individuals are more likely to adopt the target health behavior if they believe the potential illness is serious, that they are highly susceptible to it, and that the benefits of engaging in the behavior outweigh the associated barriers. The construct "cues to action," which are factors that prompt action (e.g., media campaigns, physician reminders), was later added to the model to increase its explanatory power. Other factors, such as demographic characteristics (e.g., age, race, ethnicity, gender) and psychosocial variables (e.g., peer influence, mood/affect), also exert considerable influence over individuals' decisions to engage in a specific health behavior according to the HBM. Self-efficacy, described as behavior-specific self-confidence,[4,5,9] was also later added to the HBM in attempt to increase its ability to accurately predict health behavior.[9] Self-efficacy was not initially included as

DOI: 10.1201/9781003227793-25

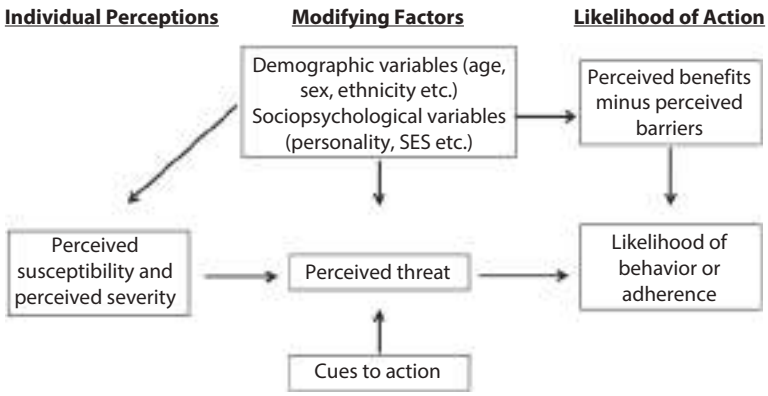

FIGURE 21.1 Health Belief Model.

an HBM construct because the model was primarily used to predict one-time or short-term health behaviors, such as getting a vaccination or health screening, for which self-efficacy is not particularly relevant. Nevertheless, these modified or extended versions of the HBM have been utilized in relatively recent research examining the model's ability to predict short-term behaviors such as breast self-examination among women with a family history of breast cancer[10] and human papillomavirus (HPV) vaccination initiation among adolescent girls in high risk communities.[11]

The HBM has since been applied to longer-term health behaviors and habits, such as exercise, smoking cessation, and dieting, with some success, but it has received significant criticism and has not held up to rigorous scientific examination in these contexts. Indeed, a recent meta-analysis of studies using HBM constructs to longitudinally predict health behavior concluded that utilizing the direct effects model may not be useful, because the two primary constructs (perceived severity and perceived susceptibility) only weakly predicted behavior.[12]

Although the HBM has been one of the most utilized models in health behavior research,[13] many concerns about the model remain. For example, the relationships among the model's constructs are not clearly delineated; measurements of some HBM constructs are not standardized; and some of its constructs (especially "cues to action") are difficult to empirically test.[12,14] Furthermore, other models have exhibited stronger predictive ability of health behavior than the HBM.[15] Thus, although some HBM constructs may be helpful to consider in the prediction of health behavior, the model as a whole may not be particularly useful except in the context of single or short-term behaviors.[12]

21.3 THEORY OF REASONED ACTION, THEORY OF PLANNED BEHAVIOR, INTEGRATED BEHAVIOR MODEL

The TRA, developed by Ajzen and Fishbein,[16,17] stems from premises of cognitive and social psychology. The TRA posits that individuals' likelihood of engaging in a particular health behavior can be predicted by the strength of their *intentions* to engage in that behavior. Intentions represent a combination of their own attitudes toward the behavior and their "social norms." According to the TRA, attitudes are formed by individuals' beliefs about the consequences of the health behavior and the weight they place on those consequences. Likewise, social norms are products of individuals' beliefs about others' expectations of them regarding the behavior and their motivation to comply with those expectations.

Research examining the TRA has demonstrated that it is most useful at predicting behaviors under volitional control. Therefore, Ajzen[18] proposed an extension of the TRA called the TPB in attempt to better predict health behaviors. The TPB incorporates TRA constructs and adds a construct called perceived behavioral control, which is defined as individuals' perceptions of their ability to perform a given behavior.[18] The TPB's perceived behavioral control construct is similar to the concept of self-efficacy[4,5] and is defined in terms of control beliefs (the presence or absence of perceived facilitators and barriers associated with a given behavior) and perceived power (the impact of these facilitators and barriers).

Unlike the HBM, the TRA and TPB models clearly delineate the relationships between their individual constructs. As a result, research examining the predictive abilities of these models has generally supported each of them as a whole.[15] However, a major concern about the models is that they do not incorporate any constructs that allow for affective/emotional or psychosocial variability,[19] which has also been a noted concern with the HBM.[20] Furthermore, the models do not take into account the fact that some behaviors are so habitual that they are not subject to planning or reasoning; in these cases, even the strongest of intentions are not likely powerful enough to overcome the automatic nature of well-established habits.[19]

Although the TRA and TPB have received less attention in health behavior research than some of the newer models in recent years, they consistently rank among the most utilized theories in the field and demonstrate considerable predictive value.[21] The TRA and/or TPB have been used as guiding frameworks for assessing, understanding, and

influencing behavior change in diverse populations with a variety of health behaviors, such as smoking behavior,[126,127] female condom use among Chinese sex workers,[22] safer sex intentions and protected sex among heterosexual, HIV-negative methamphetamine users,[23] family meal frequency among adolescents,[24] healthy nutrition,[25,128] and physical activity,[26,129] among others.

The IBM, developed by Fishbein and colleagues,[27,28] is an extension of the TRA and TPB and similarly posits that the most important determinant of a given behavior is the intention to engage in the behavior. In addition to TRA and TPB, the IBM incorporates variables from other notable theories including HBM[8,29] and SCT.[4,5,30] According to the model (Figure 21.2), a behavior is likely to occur if (1) one has a strong intention to engage in the behavior, (2) one has the required skills and abilities to perform it, (3) the behavior is salient and has occurred before, and (4) there are no environmental constraints to impede behavioral engagement.[31] If, however, intentions to engage in the behavior have not been formed, the model suggests that emphasis may need to be placed on three primary determinants of intention: attitude toward the behavior, perceived norms, and personal agency. The first construct, *attitude toward the behavior*, is further divided into two dimensions in the IBM. Experiential attitude or affect[32] is the emotional response to the idea of engaging in the suggested behavior. Individuals are unlikely to engage in the behavior when strong negative emotional responses are elicited, while individuals with a strong positive response are more likely to engage in it. Instrumental attitude refers to beliefs about the consequences of engaging in the behavior, as is found in the TRA and TPB.

The second construct, *perceived norms*, is a reflection of the social pressure to either engage in or not engage in a certain behavior. Fishbein[32] describes normative influence as being composed of both subjective and descriptive norms. Subjective norms (formerly social norms in TRA/TBA) are one's beliefs about what others think about them engaging in the behavior and their motivation to comply with others' expectations, whereas descriptive norms are one's perceptions of what others in their social network are doing.

The final construct, *personal agency*, has been previously described by Albert Bandura[33] as exerting personal influence to impact one's own functioning and environmental conditions. In the IBM, two constructs make up personal agency—self-efficacy and perceived control. Self-efficacy refers to confidence in one's ability to perform a specific behavior in a given situation. Meanwhile, perceived control (as previously described in TRA/TPB) is one's perceived amount of control over one's ability to engage in a behavior, which is determined by one's perceived degree of difficulty in engaging in the behavior due to various environmental factors.

The IBM indicates that the aforementioned constructs composing attitudes, perceived norms, and self-agency are all functions of underlying beliefs. For instance, experiential attitudes are a function of one's feelings regarding the idea of engaging in a specific behavior. The more positively one feels about the behavior, the more likely a favorable emotional response will be elicited when thinking about engaging in it.

Previous successful applications of the IBM include understanding behavioral intention and behavior for

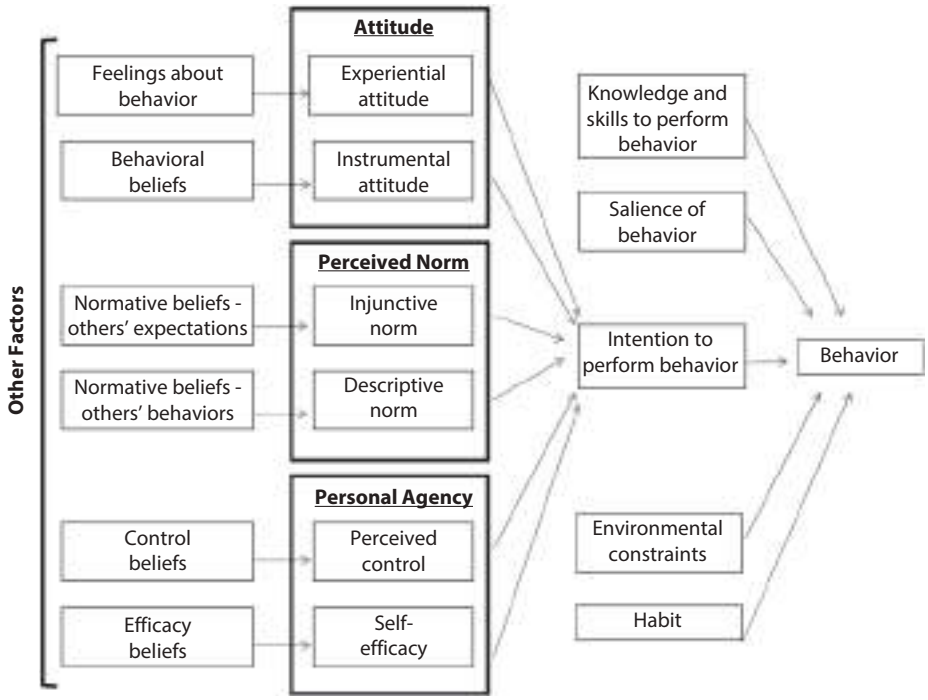

FIGURE 21.2 Integrative Behavior Model.

drinking behavior among university students,[130] condom use among injecting drug users and other HIV risk groups,[34,35] HIV/STD prevention in Zimbabwe,[36,37] adolescent sexual behavior,[38] and road user behaviors in Vietnam.[39] Moreover, IBM has been used as a theoretical framework for Project Respect, a large multisite randomized controlled trial testing HIV/STD risk reduction strategies among participants visiting public health clinics for STDs.[40,41]

21.4 TRANSTHEORETICAL MODEL

The TTM is extensively described in Part IV, Chapter 4, of this book.

Although the TTM originated in the addictions research field, it has since been applied to numerous health behaviors (e.g., fruit and vegetable consumption,[48,131] weight control,[49,132,133] contraceptive use,[50] sun protection,[52,134] medical compliance,[53,135] cervical cancer and mammography screening,[54,55] stress management,[56] intimate partner violence,[57,58] and exercise[59,60]), in diverse populations (e.g., college students,[61] adolescents,[48,136,137] and patients with severe mental illness,[62] tuberculosis,[63] HIV,[64] and multiple sclerosis[53]), and in many countries (e.g., Taiwan,[54] Nepal,[64] Malaysia[63]).

However, several criticisms of this model have been raised.[65,66] For example, the complexity of health behaviors is an issue when considering stage-based behavior change theories. Staging algorithms typically ask about physical activity or diet in general, but motivational readiness for change may vary for subcategories not fully captured by these algorithms (e.g., interested in walking and vegetable consumption but not strength training or reducing fat intake). The TTM also focuses on stage progression as a significant outcome, but this is not always associated with actual behavior change.[67,68] Nevertheless, the TTM has been a highly influential theoretical framework comprised of a number of useful organizing constructs that have been shown to be meaningfully related in empirical data and psychometric studies.

21.5 INTERPERSONAL LEVEL

21.5.1 Social Cognitive Theory

SCT is one of the most robust health behavior change theories.[3,69] It evolved from Social Learning Theory[3,42] and originally focused on observational learning, or learning by watching others' behavior (also called modeling), and the reinforcements (both positive and negative, internal and external) that help determine whether or not one will repeat the behavior. Updated by Bandura and colleagues, SCT posits that behavior change is influenced by internal individual factors (e.g., cognitive, affective, biological) as well as the social and physical environment. The model is reciprocal in that each of these factors affects the others in a continuous, dynamic feedback loop (Figure 21.3).[3]

Self-efficacy is the main construct of SCT[4] and as mentioned previously in this chapter, a powerful predictor of behavior change that has been incorporated into numerous social and behavior science theories.[3,69] Self-efficacy beliefs have been strongly associated with actual performance of a diverse range of health behaviors.[70,71] According to Bandura, self-efficacy can be increased through mastery experiences, social modeling, improving physical and emotional states, and verbal persuasion.[69] Mastery experience is gained through succeeding in attainable, yet increasingly challenging, health behavior change goals and is considered to have the strongest influence on self-efficacy beliefs.[3,69,72] Modeling, as previously discussed, can be accomplished by watching others perform the desired behavior; it is especially effective when relatable peer(s) perform the behavior. Finally, maintaining an optimal level of physiological intensity (i.e., excited but not too anxious) for performing the behavior, which can be accomplished by using relaxation techniques and positive self-talk as well as receiving encouragement from others, can increase self-efficacy.[3,69,72]

Self-regulation strategies are also used to enhance confidence for behavior change and typically begin with self-monitoring, or systematically observing, one's current health behaviors.[69] Overlapping to a degree with the concept of mastery experience, self-regulation can also include

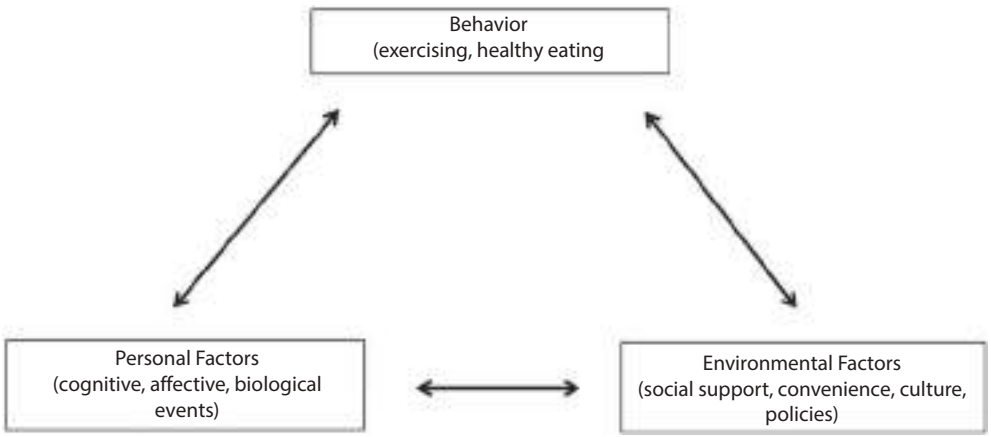

FIGURE 21.3 Social Cognitive Theory.

establishing rewards for meeting behavior change goals and enlisting social support from family and friends for performing target behaviors.[69]

Another important determinant of behavior according to the SCT is outcome expectancies.[3] This construct, defined as the influence that the outcomes anticipated from a health behavior exert on one's willingness to perform this behavior, makes intuitive sense and has been supported in numerous research studies.[73] According to SCT, one's expectations affect both initiation of and persistence of the behavior. Not only can perceived self-efficacy have direct effects on initiating activities, but by means of expectations of eventual success, it can affect continuing efforts once they are initiated. SCT posits that a health behavior is more likely to be performed if positive outcome expectancies are present, whereas negative outcome expectancies reduce the likelihood of the health behavior. For example, individuals will be much more inclined to run a mile if they anticipate that doing so will energize them rather than cause them to feel sore.

SCT offers a comprehensive model of the behavior change process and provides a strong foundation for health promotion research and practice, using numerous strategies to address diverse public health issues. Furthermore, SCT has been successfully applied to a variety of health behaviors (e.g., cardiovascular disease,[74–78] cancer screening,[79] tobacco use,[80–83] alcohol use,[42,84–86] diet,[87,88,138] weight management[139] and obesity,[89] physical activity,[73,87,88,90,91,140,141] diabetes prevention,[92,142] condom use[93,94]), in a wide range of ages (including children,[88] teens,[84] and elderly[90]) and underserved populations (e.g., African Americans,[80] Latinas,[89,92,143] low-income individuals[88,89]), and in several different countries (mostly in the United States, but also in China,[94] Sweden,[88] and Australia[90]).

21.6 ECOLOGICAL LEVEL

21.6.1 Socioecological Model

In more recent years, psychological theories and models have increasingly incorporated the broader contexts that affect health behaviors, recognizing that these external factors are often as influential as internal factors.[95–97] Socioecological models are based on four fundamental principles that are critical to understanding their application to health behavior change:[98–100] (1) the environmental and personal factors that influence health behavior dynamically interact with each other; (2) environments are multidimensional and complex; (3) people are multidimensional and complex, and intervention designs should consider both the individual and the groups with which the individual is affiliated; and (4) people–environment interactions exert multiple levels of influence, such that individuals often modify their settings, and social features of settings influence individuals. Based on these principles, the social ecological framework suggests that health behavior change strategies should consider both person-focused and environment-focused strategies for health behavior change.[99] Since multiple levels of factors influence behavior, interventions for health behavior change should also be multilevel.[101] Individual-focused strategies may include preventive screening programs, individual counseling, or participation in lifestyle interventions. Environmental strategies include both geographic (e.g., mixed-use communities) and sociocultural (e.g., integrating target health behaviors into organizational structures/cultures) aspects.

The SEM has recently grown tremendously in popularity, particularly in the public health realm. As the SEM has gained attention, intervention strategies have extended their target factors to other levels such as delivery of pediatric preventive care[144], physical activity and sedentary behavior during COVID-19[145], community participation,[102] health equity[146], organizational policies for smoking cessation,[103] neighborhood resources for physical activity[104] and healthy food,[105] children's obesity prevention and weight loss programs[147–149], and comprehensive programs for diabetes care.[106] The SEM differs from more traditional psychological models in that it explicitly incorporates not only the individual's immediate external influences (e.g., interpersonal relationships) but also more peripheral factors (e.g., community, environment). Furthermore, rather than predicting a specific order or direction in which influences exert themselves, the SEM depicts the individual in the center of increasingly broader circles of influence, which interact with one another in an ongoing process (see Figure 21.4).

The SEM has been applied in understanding, assessment, and intervention research on a variety of health behaviors and/or in diverse populations, including dietary behaviors in urban food environments in Africa[150], fruit and vegetable consumption among low-income African Americans,[107] church-based health promotion interventions,[108] diabetes prevention and treatment interventions for Native people in the USA and Canada[151], physical activity promotion and fruit and vegetable intake,[109] and physical

FIGURE 21.4 Socioecological Model.

activity assessment within a variety of different populations,[110–112] among others. The SEM has also been used to identify and classify barriers and facilitators individuals face in the adoption of health behaviors[113–115] and to participation of minorities in clinical trials.[116]

As with all of the aforementioned models and theories, some challenges arise in the application of the SEM to health behavior change interventions. Because the model is exceptionally comprehensive, its application is inherently complex. For example, addressing the SEM's multiple levels of influence, including regional (e.g., neighborhoods), structural (e.g., the physical environment), and institutional (e.g., government, worksite, family) factors, on health behaviors is challenging due in large part to limitations on control over these external variables. Despite its complexity, the SEM appears to be a promising model for an increasingly multidisciplinary scientific community.

21.7 THEORY-BASED HEALTHY LIFESTYLE INTERVENTION IN RESEARCH AND PRACTICE

Research and practice are both producers and consumers of theory-based interventions, contributing to the evidence base in lifestyle interventions, understanding the determinants of behaviors, testing behavior change strategies, and implementing and disseminating effective interventions.

In the selection of strategies to change lifestyle in research and practice, some focus on the most effective constructs, such as self-efficacy, intention, planning, and self-regulatory skills, and evaluate their mechanism and effectiveness regarding behavior change. Others follow a defined structure according to a specific theory or model such as HBM or SCT as a rationale for choosing constructs and arranging their relationships and mechanisms in the process of analyzing and assessing outcomes. The recognition of the wide range of health behavior determinants can make the design and evaluation of intervention strategies a complex process.

The use of psychological models or theories to better understand, predict, and change behaviors is widely accepted. Thus, they have been applied in the design of health promotion interventions in both research and practice. In the HBM, each step in the decision-making process is dependent on the previous decision or belief. The SCT is based on the assumption that psychological constructs, namely, self-efficacy and outcome expectancy, serve as predictors of individuals' behavior. The TPB postulates that a central factor to perform a given behavior is an individual's intention.[117] However, not all of those who have the intention would perform a health behavior.[118–120] This so-called *Intention Behavior Gap* is explicitly addressed in Part IV, Chapter 6 of this book.

Several behavioral constructs have been introduced to translate intentions to behavior, among which the most frequently used are goal setting,[121] implementation intention,[122] action and coping planning,[123] and self-monitoring.[124] Goals affect individuals' performance through four mechanisms: specifically, they (1) direct attention and effort toward relevant activities, (2) energize action and elicit greater effort, (3) increase persistence, and (4) affect action indirectly via motivation.[125] Goal-setting is consistent with SCT in the sense that both acknowledge the importance of goals and self-efficacy. The difference is that the emphasis of goal-setting theory is on the process of defining clear properties of an effective goal in order to make it more achievable.[121]

When a person is inclined to adopt a particular health behavior, the intention has to be transformed into detailed action plans of when, where, and how to perform the desired action, and coping plans on how to overcome the barriers.[123] Implementation intention[122] is another form of planning strategy, which typically requires that individuals specify their plans in an "if-then" format that explicitly links the anticipated situation to a specific response, specified in the "then" part of the plan.

After taking up a health behavior, one has to focus on maintaining the behavior for the long -term. This involves continuous self-management, meaning the person needs to monitor his/her adherence to the newly adopted health behavior. Self-monitoring is a concurrent self-management strategy, where the health behavior is continuously evaluated with regard to the person's behavioral goal or standard.

21.8 SUMMARY

In this chapter, we focused on some of the most frequently utilized models and theories that guide health behavior change interventions. Over the past few decades, the fields of behavioral medicine, public health, and medicine (among others) have been gradually shifting from a sole focus on the individual to a progressively greater focus on the local and to a growing extent, global environment in which the individual resides.[1,99] Although this shift recognizes and better accounts for the increasingly globalized world that undoubtedly influences individuals' behavior more than ever before, these new ecological models and theories are quite complex and somewhat generic.[98–100] Their numerous and relatively broadly defined variables are often difficult to measure, rendering these models as a whole difficult to assess. However, they relieve individuals of the responsibility that they should engage in target health behaviors regardless of the external barriers they may face. Moreover, the health problems and challenges for which health behavior change interventions are designed have also shifted from primarily acute and/or short-term illnesses (e.g., deadly viruses and infections) to predominantly chronic diseases (e.g., cardiovascular disease and diabetes). One-time or short-term problems appear to be adequately addressed by the individual-focused theories and models, whereas interventions for longer-term problems are more appropriately designed using interpersonal (and presumably ecological) ones.

We presented the constructs that have been shown to be most effective in translating behavioral intentions into actions. Many other theories not included in this chapter also incorporate key concepts that help explain and predict health behaviors. Perhaps the two biggest challenges in health behavior change are (1) to match health behavior goals with the models and theories that incorporate the most relevant constructs to design and implement effective interventions and (2) to systematically incorporate and account for the wide range of ecological factors that clearly influence health behavior to an increasingly great extent in the modern, global world.

CLINICAL APPLICATIONS

- The behavior change theories and models guide behavioral interventions, including addiction or obesity treatment.
- Self-monitoring intervention components are useful for disease prevention and health behavior promotions.
- For community health initiatives, the socio-economic model is very helpful because it involves all stakeholders in the process.
- Sometimes, it is more effective to focus on one construct, such as intention or self-efficacy, to improve healthy behavior.
- Lifestyle change is a process, and continuous monitoring and support are essential for the maintenance of changes made and encouragement for further changes.

22 Motivational Interviewing and Lifestyle Change

Peter Fifield, EdD LCMHC, MLADC, Joji Suzuki, MD, Samantha Minski, PhD, and Jennifer Carty, PhD

KEY POINTS

- Understand the key components of the Spirit of Motivational Interviewing and how it differs from more directive communication approaches.
- Learn the meaning of and how to use OARS (open-ended questions, affirmations, reflections, and summaries) when engaging with your patients.
- Understand the importance of ambivalence and how to intentionally focus on increasing change talk while minimizing sustain talk.

CLINICAL APPLICATION TAKE HOME POINTS

- MI is a strengths based approach, which maintains that clients have within themselves the capabilities to make lifestyle changes successfully.
- MI recognizes and accepts that patients who need to make changes in their lives approach lifestyle changes at different levels of readiness to change.
- Ambivalence is the patient's ability to see both the reasons for and the reasons against change: a normal behavior that should be expected when anyone considers making a change in their lives.
- Before thinking about increasing change talk and decreasing sustain talk, clinicians should focus their attention on creating therapeutic rapport with the patient.

22.1 INTRODUCTION

The United States spends more money per capita on healthcare than any other country in the world.[1] Considering that three of the top ten causes of death in the world (cardiac and respiratory disease, and stroke) are behaviorally related,[2] lifestyle medicine has the potential to fundamentally change healthcare. Clinicians are thinking outside their typical prescribing habits and writing more prescriptions for exercise and fresh food pharmacies, providing savings in healthcare costs.[3] This change, however, comes with a different kind of cost: the cost of individual effort. Patients are faced with hard decisions about how they live, including potentially changing major components in their lives. Subsequently, clinicians will have to modify the tools they use to treat patients, one of which must be the tool of communication regarding behavior change.

Making changes in our lives is inevitable. However, sometimes changes that appear simple in theory prove to be difficult to implement in practice. Think, for instance, about flossing. How many people floss their teeth as often as recommended; one to two times daily? Is it due to low supply of floss, a lack of knowledge about the importance of flossing, or even lack of time? Perhaps not. Most likely, it is due to a low intrinsic need or perceived importance of flossing. For years, doctors, nurses, teachers, consultants, and others have heavily favored a "directive approach" to change (i.e., telling folks what to do). While a directive approach may be indicated in certain situations (e.g., medical emergencies), this approach tends to backfire when addressing other situations; specifically those involving ambivalent patients. Although not always conscious about being directive, clinicians have often held the view that "I, the expert, have the key to change; which I will impart upon you, *when* and *if* you are ready." If behavior change did not result, patients were deemed to be unmotivated, uncaring, and non-compliant. Motivational Interviewing[4] is one clinical *tool* that allows a shift in how we "see" patients' attempts at making changes. With this change of view comes a change in language. Instead of being non-compliant, a patient is seen as ambivalent about changing, and the role of clinicians is to adopt a "guiding" approach" as opposed to the more directive approach mentioned above. Such a guiding approach provides hope that change is possible. Paradoxically, respecting a patient's autonomy and freedom not to change is sometimes what makes the change possible.

Motivational Interviewing (MI) is a therapeutic approach that targets language of change. Specific attention to the language of change offers an alternative view to addressing treatment readiness. Instead of passively waiting for the motivation and readiness to suddenly appear, or worse yet, aggressively pushing forward with a plan regardless of the individual's stage of change, MI allows an intentional and strategic focus on the client's readiness to change. Many MI practitioners hold the inherent view that they are only responsible for the interaction, not the outcome. This is rooted in the fundamental truism that clinicians can do very little to make a patient implement sustained behavior change unless they themselves want to do so. Clinicians

DOI: 10.1201/9781003227793-26

can, however, assist with increasing and strengthening the patient's internal motivation and preparedness for the change. As Miller and Rollnick explained, MI "involves a collaborative partnership with patients, a respectful evoking of their own motivation and wisdom and a radical acceptance recognizing that ultimately whether change happens is each person's own choice, an autonomy that cannot be taken away no matter how much one might wish to at times."[4] MI offers clinicians an alternative lens through which to view the situation, which is proven to reduce burnout.[5]

Currently, *Motivational Interviewing: Helping People Change* is in its third edition. Numerous other supportive texts describe the use of MI in myriad settings, ranging from treatment of addictions and chronic illness to multiple offender programs and school systems. Since the first edition, MI has been cited in more than 25,000 articles and has been studied in over 200 randomized clinical trials.[4] Furthermore, there have been over 16 different books expounding on MI, ranging from treating addictions and psychological problems to managing classroom behaviors and interactions with dental patients. MI improved outcomes in 63% of the studies examined.[6] A recent review on the effects of MI found it to be effective in improving a wide range of medical outcomes, including blood pressure, cholesterol, HIV viral load, alcohol and marijuana use, abstaining from tobacco, and adhering to medical advice.[6] Impressively, the effects of MI hold regardless of the clinician's background (e.g., nurse, mental health clinician), as long as the clinician has sufficient training and supervision.[7]

22.2 WHAT IS MOTIVATIONAL INTERVIEWING?

To better understand MI, it is helpful to explore its origins. The foundation for MI was set during a clinical trial comparing treatment approaches for individuals with problem drinking.[8] As part of this trial, clinicians' empathic statements toward their patients were recorded by supervisors. It was noted that these empathic statements had a stronger effect on drinking behavior than the interventions being evaluated and that these improvements in drinking behavior were maintained for up to 24 months following the intervention.[9] The importance and utility of empathy were reinforced after Miller participated in a role-play process where he modeled his therapeutic style for a group of psychologists. Although his audience questioned his approach to treating alcohol problems, this led Miller to identify the framework that would later become MI.

Since then, MI has evolved into a clinical approach aimed at increasing an individual's motivation for behavior change.[10,11] This communication method is not the combination of a set of techniques to apply at random. It requires a clinician to purposely listen for two types of language: change talk and sustain talk. Simply put, change talk refers to statements focused on why a person should engage in the desired behavior change, while sustain talk is reasons why a person should continue their current behavior(s). Often, change and sustain talk occur in the same sentence, and the clinician's goal is to strategically evoke change talk while simultaneously minimizing sustain talk.

This natural process of seeing reasons to change, as well as reasons not to, is referred to as *ambivalence*.[4] For example, an obese individual with poorly controlled diabetes may express interest in increasing their consumption of fruits and vegetables to lose weight yet struggle to make healthy choices when presented with junk foods at work. The difficulty implementing behavior change persists despite an individual having the knowledge of why they should act differently. MI allows this ambivalence to be explored and possibly resolved.

Motivational Interviewing encourages clinicians to resist the "righting reflex," or the tendency to argue for the behavior changes they wish to see in the patient.[4] The desired effect of telling someone why they should change is for the patient to align with these reasons. However, what tends to happen is that the patient defends their choices, paradoxically strengthening their rationale for not changing. People, in general, tend to align with their own thoughts and opinions more strongly than those of others. When they verbalize their own reasons for sustaining their behavior, they may align with these beliefs more closely than they previously had.

MI differs from other treatment approaches in that it is necessary to understand and demonstrate the "spirit of MI" to effectively utilize it.[4,11] The spirit of MI differs from the techniques a clinician can employ as part of this approach. It is characterized by four key elements: partnership, compassion, evocation, and acceptance.

Partnership. MI is practiced as a true collaboration, maintaining that there are two experts in the room—the clinician and the patient. While the clinician may be an expert in smoking cessation, for example, the patient is an expert on themselves and on implementing the recommended plan in their own lives. Therefore, the clinician must work alongside the patient to best help them. A visual example of this was created by Jeff Allison,[4] who described MI as an opportunity to "dance with a patient, not wrestle." This metaphor suggests that while the clinician may guide the session in a goal-oriented fashion, they are not in the position to convince or force their patient to make any choices. Another distinction of this partnership is the understanding that the clinician is not responsible for all the answers, and the individual ultimately knows what is best for them. This is in direct contrast to training models emphasizing the role of a professional to have all the answers to problems their patients present to them. It is sometimes hard for clinicians to internalize that they may be more responsible for the intervention than the outcome.

Compassion. Compassion goes beyond having positive regard for another and an understanding of their experiences, to include purposely prioritizing what is in their best interest. The other three aspects of MI's spirit can be employed to serve the interests of the clinician, but with

compassion, the emphasis is placed on doing what is best for the patient. Compassion underscores the importance of being selfless and structuring communication around an individual's personal goals even if they do not align with the clinician's goals.

Evocation. One of MI's goals is to help the patient better understand and recognize their own reasons for behavior change. It suggests that the patient already has their own reasons for changing, and MI's role is to illuminate what these specific reasons are. By evoking and strengthening change talk and suppressing sustain talk, a patient's ambivalence may be resolved, allowing them to focus on the preparation and planning it takes to make and sustain change.

Acceptance. Four key components make up the principle of acceptance and are based on work by Carl Rogers.[12] Together, they explain that the clinician must accept a patient, their choices, and what they have the capacity to do.

Absolute Worth. Rogers identified absolute worth as unconditional positive regard. It communicates the importance of abstaining from judgment. Rogers suggested that when people feel judged, they are less likely to change. They may feel reluctant to attempt change when their environment feels unsafe. Contrasting this, when individuals feel valued, it provides an opportunity for them to explore themselves and the possibility of change.

Affirmation. Affirmations provide a way of communicating to another that you recognize their efforts as well as their positive attributes.[12] In many disciplines, clinicians are trained to evaluate their patients for deficiencies and inadequacies and to identify what is going wrong. However, affirmations intentionally focus on the opposite—the strengths and resilience of the patient. Clinicians are encouraged to share with the patient the characteristics, traits, or behaviors they already possess that will assist them in accomplishing their goals.

Autonomy Support. To fully accept an individual, their own attitudes and decisions must be appreciated and respected. Humans seem to possess a unique need to preserve their sense of autonomy, to maintain an internal locus of control, and to make decisions for themselves. Respecting and supporting autonomy is in direct contrast to convincing someone to act in a certain way. Ultimately, an individual will decide what changes to implement, and if they are maneuvered toward a direction they do not agree with, they will advocate for the opposite behavior as a way of demonstrating their free will.

Accurate Empathy. This is another "critical condition for change," per Rogers. Clinicians need to prioritize their patient's perspective and purposely ask questions to better understand their interests, views, and beliefs. It is important to distinguish our own opinions from our patients so that we can avoid imposing our views on others. Ultimately, it is difficult to respect patient autonomy if the clinician does not understand who they are, what they believe in, and what they hope for.

22.2.1 Research and Evidence

In the 30+ years since MI was described, it has had broad applicability, and the large body of MI research reflects this. MI has been utilized to address a wide variety of behaviors throughout the lifespan, across multiple settings, and by healthcare clinicians across training levels and disciplines. Concerning health behaviors, MI has demonstrated effectiveness for individuals with chronic pain, diabetes, HIV, poor contraceptive use, excess weight, alcohol, and substance use, as well as promotion of positive health behaviors (e.g., physical activity, self-care, treatment adherence).[13–23]

Meta-analyses suggest that MI improves outcomes by 10–20% in a variety of conditions compared with no treatment and is at least as effective as active treatments.[24] These effects hold across severity of problem, patient gender, age, and ethnicity. Motivational Interviewing also appears to be effective when delivered via telehealth.[17] Indeed, research has found that the style of MI might be a more culturally sensitive form of psychotherapy, which might explain the finding that MI is more effective in minority groups.[25] Interestingly, Motivational Interviewing is more effective when clinicians do not rigidly follow a manual, perhaps because sticking closely to a manual encourages clinicians into problem solving too quickly.[25]

Clinicians from a variety of backgrounds and training can attain proficiency in MI through a 2-day intensive training or the equivalent of 12–16 hours of in-person didactic and role-playing opportunities, followed by continued coaching and supervision/consultation.[24,26] Sustained proficiency in MI has been shown with 14–16 hours of training followed by modest yet prolonged (i.e., 4–5 hours over 6 months) supervision and coaching from an expert trainer.[7]

Motivational Interviewing first garnered attention as an effective technique for its use in alcohol use disorder in the early 1980s. Since then, meta-analysis suggests that MI has a small effect size in improving alcohol use[27] Further, it appears that for alcohol use disorder, MI is just as effective as, and in some cases more effective than, other treatments, particularly in the short term.[27] Additionally, MI appears to be an effective treatment for substance use disorders throughout the lifespan.[27,28,29]

The effects of Motivational Interviewing extend to other health behaviors, such as weight loss. Motivational Interviewing research suggests it can be utilized effectively to contribute to improvements in eating, exercise behaviors, and weight loss. In a review of 11 randomized controlled trials evaluating MI for weight loss in overweight and/or obese adults, MI demonstrated a medium effect size of 0.51 standard deviations for weight loss compared with control interventions.[30,31] A similar meta-analysis indicated that MI led to an increase in diet and exercise for overweight adults with an effect size of 0.56.

Motivational Interviewing has also been used to address population health issues, such as vaccine hesitancy, though this research is still in its infancy. One study suggested that MI improved vaccine rates at a large university health care center for some, but not all, vaccines.[32] The American Academy of Family Physicians has suggested that physicians utilize MI to increase rates of COVID-19 vaccination based on the theoretical underpinnings of MI.[33,34]

Although originally utilized for an adult population, the effectiveness of MI extends to children and teenagers. The impact of MI for children and teenagers depends on the target health behavior. A meta-analysis evaluating MI for pediatric health domains (e.g., risky sexual behavior, physical activity, substance use) suggests that MI has a small, but significant, effect across behaviors ($g = 0.16$) compared with alternative interventions and that these improvements are maintained across follow-up evaluations.[35] These findings are encouraging for the use of MI to improve health outcomes for children and teenagers.

22.3 FOUR PROCESSES

22.3.1 Introduction

Clinicians need to be mindful of the four processes of MI: Engaging, Focusing, Evoking, and Planning. The use of a metaphor is helpful in understanding the four processes of MI. First, imagine there is a boat; a vessel to hold both the practitioner and the patient. Through the process of engagement, the patient invites the practitioner into the boat. Together, via the use of MI skills, the practitioner begins rowing the boat. With the utilization of focus, the two occupants decide on a direction to row. As the journey towards the shared destination continues, evocation is utilized to enhance and reinforce the motivation to continue rowing. Once there has been substantial motivation established, the process of planning enables a continued journey in the direction of change behavior. Clinicians should keep in mind that the journey of rowing the boat together can be a linear process. However, most often, it is recursive; navigating and re-navigating the same exacting waters. The process becomes MI when the communication style follows the MI Spirit, there is a focused goal, and the practitioner evokes the patient's motivations for change. In practice, behavior change often requires that the four processes be repeated in an iterative fashion over many weeks, months, and even years.

22.3.2 Engaging

Motivational interviewing first seeks to create an appropriate interpersonal environment that sets the stage for the possibility of change to occur by intentionally working to create a strong and collaborative relationship between the patient and the clinician (e.g., by asking "shall we row together?"). According to Miller and Rollnick,[4] the goals of the engagement in MI are to establish a working relationship with the patient, create agreement on treatment goals, and collaborate on ways to achieve those goals. This contrasts with the medical model, in which the clinician takes on an authoritative, educator, or expert role. It should be noted that there are times when the educator or expert role is not only helpful but necessary in medicine and psychotherapy (e.g., when providing information about a medical procedure or diagnosis; addressing acute and emergent medical or psychiatric problems). An MI approach works best when a patient is in either the contemplative or the planning stage of change.[35] Focusing on engagement in the relationship, as opposed to a fact-finding mission, requires a different set of complex skills. OARS (i.e., open-ended questions, affirmations, reflections, and summaries) are a helpful tool set to develop engagement with the patient. These are described more fully in the following.

Open-ended questions. The difference between open-ended and closed-ended questions is relatively easy to spot, though much harder to change in communication patterns (Table 22.1). Open-ended questions elicit responses that require more than one- or two-word responses, and typically elicit full sentence responses. Open-ended questions encourage patients to give thoughtful and elaborate narrative-like responses to questions, and patients themselves must choose what to disclose. They also allow the patient to engage more collaboratively in the discussion. Closed-ended questions elicit one-to-two-word responses, often a "yes/no" or fact-base response. The use of closed-ended questions is helpful when a specific response is needed; however, relying too much on closed-ended questions can be inefficient, seem disingenuous, and reflect the clinician's agenda, rather than the patient's.

Affirmations. Affirmations are statements or reflections of an individual's strengths or efforts, and can be simple ("Thank you for coming in on time today") or complex ("You are a resourceful person for dealing with this stress for so long"). According to Miller,[9] the goal of making affirmative statements is to enhance the patient's self-esteem and self-efficacy. Increasing an individual's self-efficacy has been shown to improve motivation for change.[36] It is important that affirmations, as with any emphatic statement, are expressed genuinely. As well, it is best to avoid making the statements focused on your approval of a patient's behavior; these are considered compliments and not affirmations.

TABLE 22.1
Examples of Open versus Closed-Ended Questions

Open-ended questions	Closed-ended questions
What brings you in today?	You're here to talk about quitting smoking, right?
What is important to you about changing your diet?	Is your diet important to you?
How do you manage your stress?	Do you mind if I ask you a few questions about your health habits?
If you had to quit smoking, how would you do it?	Do you want to try the nicotine patch?

Where there is approval, there can be disapproval, and this could put undue pressure on the patient to perform for the clinician in the future. At times, it may be difficult to conjure an affirmation. Take, for an example, a patient who has unmanaged diabetes with a high A1C, is overweight, eats poorly, does not exercise, and albeit is late every visit, continues to show up. An affirmation for this individual could be, "You were determined to make it here today."

Additional examples of affirmations:

"You are very good at caring for others."
"It is hard to get you down for long."
"You are resilient."

Reflections. Reflections are one of the most frequently used skills in Motivational Interviewing (Table 22.2). The goal of using reflective statements is twofold. The first is to convey empathy and compassion to the patient. The second, and perhaps more unique, purpose of reflections is to strategically elicit and guide the discussion toward motivation for change. Reflections can range from simple to complex. Those who are just beginning to practice MI may choose to focus on simple reflections until they become more proficient. To best illustrate different types of reflections, let us first look at a case example.

Clinician: "Thank you for coming in today. Your primary care physician told me a little bit about you and that you might be interested in quitting smoking. Why don't you tell me in your own words what brings you in today."

Patient: "Well, I'd like to quit smoking and I've been thinking about it for a while, but I'm not sure I can. My doctor wants me to quit, but between work and being a single parent, smoke breaks are my only time to myself."

Simple: In a simple reflection, the clinician may repeat back what the patient stated, "You'd like to quit smoking and you've been thinking about it for a while." Simple reflections are best used in moderation, for they may become tiresome for both clinician and patient if repeated multiple times. Simple reflections might also involve the clinician reflecting back a statement very close to what the patient said and substituting synonyms or slightly rephrasing what the patient offered. For example, "Your doctor wants you to quit smoking and you don't have a lot of alone time besides smoke breaks." Clinicians might also utilize paraphrasing, which is when the clinician is listening for ways to infer the underlying meaning in what the patient is saying and to reflect that meaning back to the patient. When this is done well, it helps the patient to continue their own thought process, rather than starting a new one. Paraphrasing in this example might look like, "Tackling something like quitting smoking seems difficult as a single parent, and part of you recognizes that this is an important part of your health."

Complex: In complex reflections, clinicians are reflecting the feeling that highlights the emotional aspect of what the patient is discussing. These are often more complex versions of paraphrases. As clinicians become more skilled at this type of reflection, they use both feeling statements ("you are scared") as well as metaphors ("you feel like you are treading water"). In this example, the clinician might reflect back, "You are really stressed and worried about losing the only alone time that you have."

Summaries. The final component of OARS is summary statements. Summary statements are used to tie together everything discussed during the interaction and to ensure that there is clear communication. It is often helpful to let the patient know that a summary is coming by using statements such as, "Let me see if I understand so far," or "To summarize, on the one hand you feel … and on the other hand …" Summaries can also be used to link together statements that they have made in previous encounters or to include information you might have from other sources (e.g., medical chart, PCP, spouse if permission has been given, etc.). Summaries are a helpful device to transition focus to a different topic and to probe the patient's readiness to make a plan. It is helpful to end a summary statement with an invitation such as "Did I miss anything?" or "Anything you want to add or correct?" This encourages the patient to continue collaborating and to have autonomy. A particularly useful way to incorporate summaries is to offer patients a summary of their change talk, referred to as the "change talk bouquet," in which the change talk statements evoked are bundled into a summary. This could function as a transitional summary to move on to the key question or to conclude the interview by highlighting the positives.

Roadblocks for engaging. Despite our best efforts and intentions, barriers to effective patient engagement exist. Often in the form of how we communicate, these

TABLE 22.2
Additional Examples of Reflections

Type of reflection	Example
Amplified	"You were petrified"
Double sided	"Quitting will be hard, and you realize the change will benefit your family"
Affective	"It upsets you to hear yourself say that"
Metaphor	"It feels like you are drowning"
Continuing the sentence	"… and you have been waiting to say that for a long time"
Emphasizing personal choice	"… and you know you are the only one who can make this change"
Siding with the negative	"… and then there is always the choice to change nothing"

"roadblocks" can hinder effective listening and engagement with the patient. Motivational Interviewing is an approach that helps avoid these roadblocks. The following are 12 common roadblocks that hinder effective communication (adapted from Thomas Gordon's 12 Roadblocks): [4]

1. Ordering, directing, or commanding
2. Warning, cautioning, or threatening
3. Giving advice, making suggestions, or providing solutions
4. Persuading with logic, argument, or lecturing
5. Telling people what they should do; moralizing
6. Disagreeing, judging, criticizing, or blaming
7. Agreeing, approving, or praising
8. Shaming, ridiculing, or labeling
9. Interpreting or analyzing
10. Reassuring, sympathizing, or consoling
11. Questioning or probing
12. Withdrawing, distracting, humoring, or changing the subject

The communication styles outlined in this list rely on being directive, educating, or judging, rather than collaborating and supporting autonomy.

A helpful alternative to these roadblocks is the Elicit-Provide with Permission-Elicit (EPPE) model, a conversational structure that allows a clinician to provide education to a patient in an MI-consistent way. First, the clinician will *elicit* what the patient already knows about condition X, if they are interested in learning more, and if they have permission to share more information. This approach respects patient autonomy by asking permission and assessing interest. If permission is given, the next step is to *provide* affirmation, feedback, advice, or information to the patient. If permission is not granted (this may sound strange, but it happens), then do not continue with educating or risk damaging the relationship. Please keep in mind that the patient's presence in the room with you is not necessarily implied consent for providing information. For the last step, the clinician would again *elicit* reactions, questions, and possibly plan for next steps (Figure 22.1).[4]

An additional common trap is spending most of the time during the initial session *only* gathering information, as opposed to spending time connecting to and understanding the patient. This can be a challenging balance for clinicians when certain information is required to be answered in an intake session. When the clinician solely focuses on information gathering, they are more likely to be perceived as the expert in the relationship, which risks prematurely defining the focus of the interview or focusing on the clinician's agenda rather than the patient's.

An approach that can be used to safeguard against this is the MI assessment sandwich.[37] First, the clinician uses OARS to build rapport and engage with the individual (via the elicit-provide-elicit model). This allows the patient to join with the clinician while simultaneously providing an opportunity for the clinician to understand the patient's readiness for change. Then, the clinician leads into the information gathering portion of the session. This could include any number of assessment protocols. Finally, the clinician focuses on eliciting change talk, working with the patient's ambivalence, and ultimately, if appropriate, creating a change plan.

22.3.3 Focusing

The second process in MI is focusing. Clinicians and patients must know the direction toward which they are rowing the boat. Without a clear understanding of the goal or specific behavioral change, it can be difficult for both the patient and the clinician to know where to focus their attention. Learning how to collaboratively set an agenda becomes an important skill in this MI process. The clinician may have some clear ideas on how to proceed based on their own expertise; however, the client, being the expert in themselves, might also have clear ideas about how to proceed. Understanding that there can be two experts in the room is essential to moving forward. The true art of focusing comes in when the patient is less clear about their goal and how to move forward. The clinician should feel comfortable staying in the focusing process until a clear goal can be established. To help move along the process when there is an unclear goal, Miller and Rollnick[4] suggest a tool called agenda mapping, which they describe as being similar to "looking at a map and seeing the places you might go, perhaps like two people on a sailboat slowing down for a moment to agree on a new course (p. 106)." Agenda mapping starts by asking the patient for permission to take a step back to consider all the topics that the patient would like to discuss. This technique guides the patient to where you are going and supports their autonomy. Next, the patient and clinician create a list of possible options to talk about. Once this bird's eye view is created, the clinician guides the patient back toward a narrower, more specific focus.

Another challenge to focusing is when there is a preset goal to the visit (e.g., court ordered therapy). In these cases, it is important to acknowledge that the individual is being mandated to be at the appointment and might be reluctant to engage. It can be helpful for the clinician to acknowledge their dual role of being the patient's clinician while also making an importation recommendation about the patient. This type of honest and open conversation can help create the trust necessary to move forward in the interview. In these cases, the clinician taking a neutral stance regarding

FIGURE 22.1 Elicit-Provide with Permission-Elicit model

any desired outcome (equipoise)[4] is useful. Typically, in MI, the clinician is working toward moving the patient toward a particular goal, which is typically clear (e.g., smoking less; losing weight; going to treatment); in equipoise, the clinician would remain neutral and allow the patient to explore the pros and cons of each side of the potential outcome (e.g., to stay with a job or not; to leave a partner or not). A clinician in this situation might choose to complete a decisional balance with the patient (Figure 22.2).

22.3.4 Evoking

As a patient makes their way toward change (the direction they are rowing in), ambivalence is a natural and common place to get stuck. Concepts such as "change talk" and "sustain talk" help explain the two sides of ambivalence: reasons for changing and reasons for not changing. Miller and Rollnick[4] hypothesized that self-motivational speech (change talk) is one mechanism of action in MI, and there is a strong body of evidence reliably linking change talk to positive health outcomes.[38–40] Furthermore, there is evidence that MI-consistent clinician behaviors lead to change talk.[41–43] Moyers et al. suggests that change talk "[m]ediates the relationship between MI-consistent clinician behaviors and improved client outcomes."[40] Change talk is the verbalization of the patient's internal motivation to change. Statements that represent movement toward change are precisely the language clinicians should be focused on evoking, strengthening, affirming, and validating. Clinicians must first build their awareness and ability to recognize change talk and then work on responding to it.

Recognizing change talk: Although sustain talk is normal, focusing on it is not always helpful. Often, clinicians are habituated, or even trained, to identify the problems in a situation. With MI, it is necessary to shift the lens from a problem-centric approach (which may elicit sustain talk) to a solution-focused approach with hopes to elicit change talk. According to Miller and Rollnick,[4] change talk is divided into two categories: preparatory change talk and mobilizing change talk.

Preparatory Change Talk:

Desires: "I really want to" … "I'm hoping that if" … "I really wish life was different."

Ability: "I know I can do this if" … "I have changed like this in the past."

Reason: "If I could just lose ten pounds, I know I would feel better" … "I know what I'm doing is not healthy" … "If I could just get started, I would feel more confident in other ways."

Need: "The doctor said I need to quit" … "I need to do this for me and my family" … "I'm always so exhausted and I know it is affecting my work."

Mobilizing Change Talk:

Commitment: "I am willing to hear your advice on what to do next" … "I'm going to start tracking daily step count."

Activation: "I've been considering how to tackle this bad habit" … "I'm ready to start."

Taking Steps: "I have already bought a gym membership" … "I called the smoking cessation phone line and left a message" … "I talked to my wife about what she thinks."

It is important to remember that sustain talk is not fundamentally bad or non-therapeutic. In fact, it is completely normal. The clinician's goal, however, is to strategically evoke and respond to change talk when they hear it. Miller and Rollnick[4] state that "[s]killful MI significantly strengthens client change talk, which in turn predicts subsequent change (p. 155)." When responding to change talk, it is helpful to identify the type of change talk to facilitate movement forward. If the patient is providing preparatory change talk, the clinician targets increasing the change talk and moving toward a plan. If the patient is providing mobilizing change talk, the clinician then works on increasing the change talk toward next steps.

FIGURE 22.2 Decisional balance.

Evoking change talk is an essential part of MI, and scaling type questions are often used to facilitate this. To do this, use an imaginary scale ranging from 0 to 10. This *importance ruler* is integrated into conversations about change by inquiring how important it is to the patient to change the target behavior. For example, the clinician could ask:

> "On a scale from 0 to 10, where 0 is "not important at all" and 10 is "extremely important," how important is it to you to _____?"

This offers a baseline level of importance. From here, the clinician could begin eliciting change talk. Proceed by asking:

> "Tell me a bit about why you are at a (reported number) and not a (lower number)?"

Keep in mind to offer the patient-reported number first, followed by a lower number. When the clinician approaches in this manner, the patient will provide change talk by offering up reasons why it is important. If asked in reverse, this question elicits sustain talk and road blocks, as they would be rationalizing reasons to stay the same. This last question can be followed up by:

"What would it take to get you from (lower number) to (a number slightly higher)?"

The response will likely provide more change talk and support the efforts and/or successes in the past. The abovementioned ruler in Table 22.3 can also be used to investigate the patient's level of confidence. To do this, simply replace *importance* with *confidence.* The result will be the patient's confidence talk. Be sure to offer the patient's stated number first once again, followed by the lower number. When done in this manner, the patient will offer up reasons for their confidence, including wants, needs, and even past successes. Other provocative questions that could elicit change talk are:

- What is there about you that would help you do this?
- How might you go about it to succeed?
- How would you go about this change?
- What have you done successfully in the past that was like this in some way?
- What are the reasons for changing?

Responding to Change Talk is a critical component of MI. Given that change talk represents internal motivation for change, it can be further strengthened by strategically responding with OARS. Strategies for Evoking Change Talk[4] fall into a commonly used and easy to remember mnemonic: EARS.

- *Elaborate* by asking open-ended questions such as, "Why do you want to make this change or how might you go about it," or use the importance/confidence ruler. Clinicians can also inquire about what was successful in the past or what the patient hopes to achieve by this change in the future.
- *Affirmations* are given to agree with, encourage, or support the patient.
- *Reflect* on what the patient has already said. If possible, offer a complex reflection; one that elaborates on the change talk or emotional content.
- *Summarize:* Here, the clinician attempts to collect the "bouquets" of change talk and provide it back to the patient in summary form.

As mentioned earlier, sustain talk is the patient's argument to maintain the status quo. This is a normal behavior that should be expected during the change process. Sustain talk occurs when the patient has intrapersonal conflict (ambivalence) with changing a target behavior. Discord, however, is very different. Discord occurs when there is an interpersonal conflict between the patient and the clinician. Said otherwise, discord is behavior that reflects an issue or disharmony within the relationship. Discord shows up in numerous ways, including:

- Defensiveness
- Arguing
- Interrupting
- Ignoring

Discord can occur in any of the four processes of MI, be it discord in engaging, focusing, evoking, or planning. Discord is best addressed by returning to the first process of MI—engaging. There are numerous ways to approach the amelioration of discord. First, it can be done by simply apologizing for the disconnect. A simple "sorry" can go a long way in repairing the collaborative relationship. A statement such as "I'm sorry I overstepped my bounds. I should not be telling you what to do," can easily reduce the tension of discord. Affirming the patient is also an effective technique. A clinician who observes discord could offer, "You are very sure of what has worked in the past." Lastly, there is shifting focus. This technique is an implicit way for the clinician and patient to agree to disagree by shifting the conversation away from the contentious topic. An example of shifting focus is, "You are right, my opinion is not important here, tell me what is important about this to you."

TABLE 22.3
Importance Ruler

0<----------10
Not important at all — **Extremely important**

22.3.5 Planning

Once a significant amount of change talk is present, it may now be appropriate to investigate a plan, keeping in mind not to get ahead of the patient's level of readiness. The planning is an ongoing, ever-changing process that requires the clinician to assess potential approaches to addressing the target behavior. First, the clinician offers a summary in the form of a "change talk bouquet"—a collection of "flowers" (change talk statements) the clinician has collected and offered back to the patient like a bouquet. This can be followed by a simple question, such as "Where should we go from here?" This can transition the clinician and patient from processing to planning. This question may result in either a clear step forward, a multitude of options forward, or a step forward with no clear path. When there is a clear path to change, it is helpful to focus on clarifying the goal and summarizing your current understanding of the progress. From here, you begin troubleshooting hurdles and speed bumps impeding progress and narrowing down the details to attain more specific details regarding the plan. Although not MI specific, the acronym SMART is often helpful when creating goals:

Specific: Define the goal as much as possible, including interrogatives such as what, where, and when will this occur?

Measurable: Ensure the goal/behavior can be tracked. For example, "I will exercise for 30 minutes 3 days a week."

Attainable: Ensure that the goal can be accomplished. Try to make the goal not too high or too low below their standard performance.

Relevant: Is the goal in line with other goals they have?

Timely: Goals should have a start time, as well as a time limit to accommodate for evaluation. After a certain amount of time, such as one week, one month, or one year, the goal will be evaluated for success.

Sometimes, the path forward has many branches; the motivation is present, but there could be a multitude of options for the patient to choose from. After you have provided a summary and list of the different options, it is important to confirm the goal. Then, try to investigate the patient's preference and intuitions regarding next steps, asking questions such as, "If you could imagine being most successful in this task, what three options seem most likely to move you forward?" or simply, "Which one appeals to you most?" From here, continue evoking change talk and troubleshooting further tasks. Lastly, there is the scenario where there is no clear plan at all. As with the clear plan and the plan with many options, first, the practitioner clarifies the plan after offering a summary. From here, you engage in a brainstorming session with the patient, offering up any option that is plausible. At this point, you want to work with the patient's ideas from general to specific. The CATS mnemonic, under "Mobilizing Change Talk," can guide you as you continue working on the patient's change talk regarding commitment, action, and taking steps.

22.4 SUMMARY

Motivational Interviewing is a "collaborative conversation style for strengthening a person's own motivation and commitment to change."[4] In this chapter. we discussed the four processes of MI and basic MI skills such as OARS and how to respond to change talk, sustain talk, and discord. Proficiency in MI is attainable with training, coaching, and a lot of practice. As seen in research, using MI is typically better at improving outcomes than offering education alone, wait-listing, or treatment-as-usual interventions[6] and often better than using a directive style.[44] Clinicians are encouraged to explore how MI can influence change behaviors and how cultivating the relationship alone may positively influence outcomes. Keep in mind, you are often more responsible for the interaction than you are for the outcome.

23 Transtheoretical Model

James O. Prochaska and Janice M. Prochaska

KEY POINTS

- The importance of a healthy lifestyle
- Characteristics of people in each stage of change
- The principles and processes to apply at each stage
- Increasing impacts with multiple behavior change
- Challenges to the Transtheoretical Model (TTM)
- How TTM can increase well-being
- Multiple benefits of integrating TTM into practice

23.1 INTRODUCTION

Health risk behaviors, like smoking, inactivity, unhealthy diets, alcohol abuse, and ineffectively managed stress, account for about 70% of a population's morbidity, disability, mortality, reduced functioning and productivity, and escalating health care costs. In contrast, a healthy lifestyle, including abstinence from smoking, eating 5 servings of fruits and vegetables each day, adequate physical activity (e.g., walking 10,000 steps a day or doing 150 minutes of moderate exercise a week), and striving to maintain a body mass index (BMI) of less than 25, is being shown to increase life expectancy by up to 14 years.[1–3] However, having a healthy lifestyle of 0 (smoking), 1–2 alcoholic drinks per day, 5 (fruits and vegetables), 10 (10,000 steps), 20 (20 minutes of stress management), and 25 (<25 BMI) (0–1-5–10, 20, 25) has been an elusive goal for 97% of the population.[4] Why are these health risk behaviors so critical to health and well-being? They represent fundamental functions of life: breathing, drinking, eating, moving, and feeling. If we breathe toxins, we threaten our bodies. If we drink alcohol to toxic levels, we do damage to our minds and bodies. If we don't move enough, we don't remove enough toxins from our bodies.

To have a significant and sustainable impact on attaining these healthy behaviors, a model of behavior change is needed to address the needs of entire populations, not just the minority who are motivated to take immediate action for better health. The Transtheoretical Model of Behavior Change (TTM) is founded on stages of change that categorize segments of populations based on where they are in the process of change. Principles and processes are applied to initiate movement through the stages of change. Interventions based on TTM principles can produce programs that are interactive and broadly applicable for the treatment of entire populations. The programs include computer-tailored interventions (CTIs) delivered through various modalities, such as counselor guidance, telephonic coaching, the Internet, and texting.

23.2 STAGES OF CHANGE

The TTM postulates that change is a process that unfolds over time through a series of stages: Precontemplation, Contemplation, Preparation, Action, Maintenance, and Termination.

Precontemplation is a stage in which the individual does not intend to take action in the foreseeable future (usually measured as the next six months). Individuals may be at this stage because they are uninformed or underinformed about the consequences of a given behavior, or they may have tried to change a number of times and have become demoralized about their ability to do so. Individuals in both categories tend to avoid reading, talking, or thinking about their high-risk behaviors. In other theories, such individuals are characterized as "resistant" or "unmotivated" or "not ready" for health promotion programs. In fact, traditional programs were not ready for such individuals and were not motivated to match their needs.

Individuals who are in the Precontemplation stage typically underestimate the benefits of change and overestimate its costs but are unaware that they are making such mistakes. If they are not conscious of making such mistakes, it is difficult for them to change. As a result, many remain stuck in the Precontemplation stage, with considerable resulting harm to their bodies, themselves, and others. There appears to be no inherent motivation for people to progress from one stage to the next. The stages are not like stages of human development, in which children have inherent motivation to progress from crawling to walking, even though crawling works very well and even though learning to walk can be painful and embarrassing. Instead, two major forces can move people to progress.

The first is *developmental events.* In the authors' research, the mean age of smokers who reach the long-term Maintenance stage is 39 years. Those who have passed 39 recognize it as an age to reevaluate how one has been living and whether one wants to die from that lifestyle or whether one wants to enhance the quality and quantity of the second half of life. The other naturally occurring force is *environmental events.* A favorite example is a couple

DOI: 10.1201/9781003227793-27

who were both heavy smokers. Their dog of many years died of lung cancer. This death eventually moved the wife to quit smoking. The husband bought a new dog. So, even the same events can be processed differently by different people.

A common belief is that people with health risks must "hit bottom" before they are motivated to change. So family, friends, and physicians wait helplessly for a crisis to occur. But, how often do people turn 39 or have a dog die? When individuals show the first signs of a serious physical illness, such as cancer or cardiovascular disease, those around them usually become mobilized to help them seek early intervention. Evidence shows that early interventions often are lifesaving, and so it would not be acceptable to wait for such a patient to "hit bottom." In opposition to such a passive stance, a third force that has been created to help individuals progress beyond the Precontemplation stage is called *planned interventions.*

Contemplation is a stage in which an individual intends to take action within the ensuing six months. Such a person is more aware of the benefits of changing but also is acutely aware of the costs. When a smoker begins to seriously contemplate giving up smoking, their awareness of the costs of changing can increase. There is no free change. This balance between the costs and benefits of change can produce profound ambivalence, which may reflect a type of love–hate relationship with risks and thus can keep an individual stuck at the Contemplation stage for long periods of time. This phenomenon often is characterized as "chronic Contemplation" or "behavioral procrastination." Such individuals are not ready for traditional action-oriented programs.

Preparation is a stage in which individuals intend to take action in the immediate future (usually measured as the ensuing month). Such persons typically have taken some significant action within the preceding year. They generally have a plan of action, such as participating in a weight-loss group, consulting a counselor, talking to a physician, buying a self-help book, or relying on a self-help approach. It is these individuals who should be recruited for action-oriented treatment programs.

Action is a stage in which individuals have made specific, overt modifications in their lifestyle within the preceding six months. Because action is observable, behavior change often has been equated with action. But in TTM, Action is only one of six stages. In this model, not all modifications of behavior count as action. An individual must attain a criterion that scientists and professionals agree is sufficient to reduce the risk of disease. With smoking, for example, only total abstinence counts. With alcoholism and alcohol abuse, many believe that only total abstinence can be effective, whereas others accept controlled drinking as an effective action.

Maintenance is a stage in which individuals are working to prevent relapse but do not need to apply change processes as frequently as one would in the Action stage. Such persons are less tempted to relapse and are increasingly confident that they can sustain the changes made. Temptation and self-efficacy data suggest that Maintenance lasts from six months to about five years. One of the common reasons for early relapse is that the individual is not well prepared for the prolonged effort needed to progress to Maintenance. Many persons think the worst will be over in a few weeks or a few months. If, as a result, they ease up on their efforts too early, they are at great risk of relapse.

To prepare such individuals for what is to come, they should be encouraged to think of overcoming a bad habit as running a marathon rather than a sprint. They may have wanted to enter the Boston Marathon, but they know they would not succeed without preparation and so would not enter the race. With some preparation, they might compete for several miles but still would fail to finish the race. Only those who are well prepared could maintain their efforts mile after mile. Using the Boston Marathon metaphor, people know they have to be well prepared if they are to survive Heartbreak Hill, which runners encounter at about mile 20. What is the behavioral equivalent of Heartbreak Hill? The best evidence available suggests that most relapses occur at times of emotional distress. It is in the presence of depression, anxiety, anger, boredom, loneliness, stress, and distress that humans are at their emotional and psychological weak point.

How does the average person cope with troubling times? He or she drinks more, eats more, smokes more, and takes more drugs to cope with distress. It is not surprising, therefore, that persons struggling to overcome risky behaviors will be at greatest risk of relapse when they face distress. Although emotional distress cannot be prevented, relapse can be prevented if individuals have been prepared to cope with distress.

If so many Americans rely on oral consumptive behavior as a way to manage their emotions, what is the healthiest oral behavior they could use? Talking with others about one's distress is a means of seeking support that can help prevent relapse. Another healthy alternative is exercise. Physical activity helps manage moods, stress, and distress. Also, 150 minutes per week of exercise can provide a person with more than 70 health and mental health benefits.[5] Exercise thus should be prescribed to all sedentary individuals. A third healthy alternative is some form of deep relaxation, such as meditation, yoga, prayer, massage, or deep muscle relaxation. Letting the stress and distress drift away from one's muscles and one's mind helps the individual move forward at the most tempting of times.

Termination is a stage in which individuals have zero temptation and 100% self-efficacy. Whether they are depressed, anxious, bored, lonely, or stressed, such persons are certain they will not return to their old unhealthy habits as a method of coping. It is as if they had never acquired the habit in the first place. In a study of former smokers and people with alcohol use disorders who were abstinent for less than five years, about 20% of each group had reached the stage of no temptation and total self-efficacy. This is an ideal stage that only a minority might reach.[6]

23.3 PRINCIPLES AND PROCESSES OF CHANGE

To help motivate patients to progress from one stage to the next, it is necessary to know the principles and processes of change that can produce such progress.

23.3.1 Principle 1

The benefits of changing must increase if clients are to progress beyond Precontemplation. In a review of 12 studies, all showed that the perceived benefits were higher in the Contemplation than in the Precontemplation stage.[7] This pattern held true across 12 problem behaviors: use of cocaine, smoking, delinquency, obesity, inconsistent condom use, unsafe sex, sedentary lifestyles, high-fat diets, sun exposure, radon testing, mammography screening, and physicians practicing behavioral medicine.

A technique that can be used involves asking a client in the Precontemplation stage to describe all the benefits of a change such as quitting smoking or starting to exercise. Most persons can list four or five. The coach can let the client know that there are eight to ten times that number and challenge the patient to double or triple the list for their next meeting. If the client's list of benefits of exercise begins to indicate many more motives, such as a healthier heart, healthier lungs, more energy, healthier immune system, better moods, less stress, better sex life, and enhanced self-esteem, he or she will be more motivated to begin to seriously contemplate such a change.

23.3.2 Principle 2

The "cons" of changing must decrease if clients are to progress from Contemplation to Action. In 12 of 12 studies, the authors and colleagues found that the perceived costs of changing were lower in the Action stage than in the Contemplation stage.[8]

23.3.3 Principle 3

The relative weight assigned to benefits and costs must cross over before a client will be prepared to take action. In 12 of 12 studies, the costs of changing were assessed as higher than the rewards in the Precontemplation stage, but in 11 of 12, the rewards were assessed as higher than the costs in the Action stage. It should be noted that if raw scores are used to assess these patterns, it would appear that the rewards for changing are seen as greater than the costs, even by persons in the Precontemplation stage. It is only when standardized scores are used that clear patterns emerge, with the costs of changing always perceived as greater than the rewards. This suggests that compared with their peers at other stages of change, persons in the Precontemplation stage underestimate the rewards and overestimate the costs of change.

23.3.4 Principle 4

The strong principle of progress holds that to progress from Precontemplation to effective Action, the rewards for changing must increase by one standard deviation (SD).[8]

23.3.5 Principle 5

The weak principle of progress holds that to progress from Contemplation to effective Action, the perceived costs of changing must decrease by one-half an SD.

Because the perceived benefits for changing must increase twice as much as the perceived costs decrease, twice as much emphasis must be placed on the benefits as on the costs of changing. What is striking here is that the authors and colleagues believe they have discovered mathematical principles for the degree to which positive motivations must increase and negative motivations must decrease. In a recent meta-analysis of nearly 140 studies on 48 behaviors, the pros of changing increased by exactly 1.00 SD, whereas the cons decreased by 0.54 SD.[9] Such principles can produce much more sensitive assessments to guide interventions, giving coaches and clients feedback for when coaches' efforts are producing progress and when they are failing. Together, they can modify methods if movement is needed for the client to become adequately prepared for the Action stage.

23.3.6 Principle 6

It is important to match particular processes of change with specific stages of change. Table 23.1 presents the empirical integration found between stages and the principles and processes of change. Guided by this integration, the following processes would be applied to clients across the stages of change:

1. *Consciousness raising* (get the facts) involves increased awareness of the causes, consequences, and responses to a particular problem. Interventions that can increase awareness include observations, confrontations, interpretations, feedback, and education. Some techniques, such as confrontation, pose considerable risk in terms of retention and are not recommended as highly as motivational enhancement methods such as personal feedback about the current and long-term consequences of continuing the unhealthy behavior. Increasing the costs of not changing is the corollary of raising the benefits of changing. So, consciousness raising should be designed to increase the perceived gains from changing.
2. *Dramatic relief* (pay attention to feelings) involves emotional arousal about one's current behavior and the relief that can come from changing. Fear, inspiration, guilt, and hope are some of the emotions that can move persons to contemplate

TABLE 23.1
Integration of the Stages, Principles, and Processes of Change

Precontemplation	Contemplation	Preparation	Action	Maintenance
Consciousness raising				
Dramatic relief

			Counter conditioning	
			Stimulus control	
Pros of changing increasing				
	Cons of changing decreasing			
		Self-efficacy increasing		

Note: Social liberation has been found not to have differentiated emphasis across all five stages.

changing. Psychodrama, role playing, grieving, and personal testimonies are examples of techniques that can move people emotionally. It should be noted that earlier literature on behavior change concluded that interventions such as education and fear arousal did not motivate behavior change. Unfortunately, many interventions were evaluated in terms of their ability to move people to immediate action. However, processes such as consciousness raising and dramatic relief are intended to move people to the Contemplation stage rather than the Action stage. Therefore, their effectiveness should be assessed according to whether they lead to the expected progress.

3. *Environmental reevaluation* (notice your effect on others) combines both affective and cognitive assessments of how an unhealthy behavior affects one's social environment and how changing would affect that environment. Empathy training, values clarification, and family or network interventions can facilitate such reevaluation. For example, a brief media intervention aimed at a smoker in the Precontemplation stage might involve an image of a man clearly in grief saying, "I always feared that my smoking would lead to an early death. I always worried that my smoking would cause lung cancer. But I never imagined my wife would die from lung cancer." Beneath his grieving face appears this statistic: "50,000 deaths per year are caused by passive smoking." In 30 seconds, this message achieves consciousness raising, dramatic relief, and environmental reevaluation.
4. *Self-reevaluation* (create a new self-image) combines both cognitive and affective assessments of an image of one's self free from an unhealthy behavior. Imagery, healthier role models, and values clarification are techniques that can move individuals in this type of intervention. Individuals first look back and reevaluate how they have lived as unhealthy individuals. As they progress into the Preparation stage, they begin to develop a focus on the future as they imagine how life could be if they were free of the unhealthy habit.
5. *Self-liberation* (make a commitment) involves both the belief that one can change and the commitment and recommitment to act on that belief. Techniques that can enhance such willpower include public rather than private commitments. Motivational research also suggests that individuals who have only one choice are not as motivated as they could be when they have two choices.[10] Three choices are even better, but four choices do not seem to enhance motivation. Wherever possible, then, clients should be given three of the best choices for applying each process. With smoking cessation, for example, there are at least three good choices: quitting "cold turkey," using nicotine replacement therapy, and using nicotine fading. Asking clients to choose which alternative they believe would be most effective for them and to which they would be most committed can enhance their motivation and their self-liberation.
6. *Counter conditioning* (use substitutes) requires the learning of healthier behaviors that can substitute for the unhealthy behavior. Counter conditioning techniques tend to be quite specific to a particular behavior. They include desensitization, assertion, and cognitive counters to irrational self-statements that can elicit distress.
7. *Reinforcement management* (use rewards) involves the systematic use of reinforcements and punishments for taking steps in a particular

direction. Because successful self-changers rely much more on reinforcement than on punishment, it is useful to emphasize reinforcements for progressing rather than punishments for regressing. Contingency contracts, overt and covert reinforcements, and group recognition are methods of reinforcement and incentives that increase the probability that healthier responses will be repeated. To prepare clients for the longer term, they should be taught to rely more on self-reinforcements than on social reinforcements. Clinical experience shows that many individuals expect much more reinforcement and recognition from others than they actually receive. Relatives and friends may take the Action stage for granted. They typically generate only a few positive consequences. Self-reinforcements, obviously, are much more under self-control and can be given more quickly and consistently when temptations to lapse or relapse are resisted.

8. *Stimulus control* (manage your environment) involves modifying the environment to increase cues that prompt healthy responses and decrease cues that lead to relapse. Avoidance, environmental re-engineering (such as removing addictive substances and paraphernalia), and attending self-help groups can provide stimuli that elicit healthy responses and reduce the risk of relapse.
9. *Helping relationships* (get support) combine caring, openness, trust, and acceptance, as well as support for changing. Rapport building, a therapeutic alliance, coach calls, buddy systems, sponsors, and self-help groups can be excellent resources for social support. If clients become dependent on such support to maintain change, the support will need to be carefully faded, lest termination of coaching becomes a condition for relapse.
10. *Social liberation* (notice public support) is the process by which changes in society increase the options and opportunities to have healthier and happier lives freer from risky behaviors. Social networks are examples of a dramatic increase in being able to participate in positive interactions free from pressures to rely on unhealthy habits.

23.3.7 Principle 7

Self-efficacy is the situation-specific confidence that people have while coping with high-risk situations without relapsing to their unhealthy behavior. Self-efficacy increases as people move through the stages of change.

What is the result when all of these principles and processes of change are combined to help clients and entire populations move toward the Action stage to reduce their health risks? A series of clinical trials applying stage-matched interventions offers lessons about the future of behavioral health care generally and treatment of the bad habits specifically. In a large-scale clinical trial, the authors and colleagues compared four treatments: (a) a home-based action-oriented smoking cessation program (standardized), (b) stage-matched manuals (individualized), (c) a CTI plus manuals (interactive), and (d) counselors plus CTI (personalized). Clients (739 smokers) were randomly assigned by stage to one of the four treatments.[11]

In the CTI treatment, participants completed 40 questions by mail or telephone. Their responses were entered into a central computer, from which tailored feedback reports were generated. These reports informed participants about their stage of change, the pros and cons of changing, and change processes appropriate to their stages of change. At baseline, participants were given positive feedback on what they were doing correctly and guidance on which principles and processes they needed to apply to progress. In two progress reports delivered over the following six months, participants also received positive feedback on any improvement in any of the variables relevant to progress. Thus, demoralized and defensive smokers could begin to progress without having to quit and without having to work too hard. Smokers in the Contemplation stage could begin to take small steps, such as delaying their first cigarette in the morning for an additional 30 minutes. They could choose small steps that would increase their self-efficacy and help them become better prepared for quitting.

In the personalized treatment, smokers received four proactive counselor calls over the six-month intervention period. Three of the calls were based on the CTI reports. When they didn't have a CTI report, counselors reported much more difficulty in interacting with participants without any progress data. Without scientific assessments, it was more difficult for both clients and counselors to know whether any significant progress had occurred since their last interaction.

Figure 23.1 presents point prevalence abstinence rates for each of the 4 treatment groups over 18 months, with treatment ending at 6 months. Results with the 2 self-help manual conditions were parallel for 12 months, but the individualized stage-matched manuals achieved better results at 18 months. This is an example of a *delayed action effect*, which often is observed with stage-matched programs. It takes time for participants in early stages to progress all the way to Action. Therefore, some treatment effects as measured by action will be observed only after considerable time has elapsed. But, it is encouraging to find treatments producing therapeutic effects months and even years after active treatment has ended. The CTI alone and personalized counselor calls plus CTI treatments produced comparable results for six months. The CTI alone produced delayed action effects through 18 months. The effects of CTI plus counselors leveled off. One hypothesis is that clients can become dependent on counselors. Counselors may need to phase out treatment gradually to reduce such dependence and enhance the self-efficacy of clients.

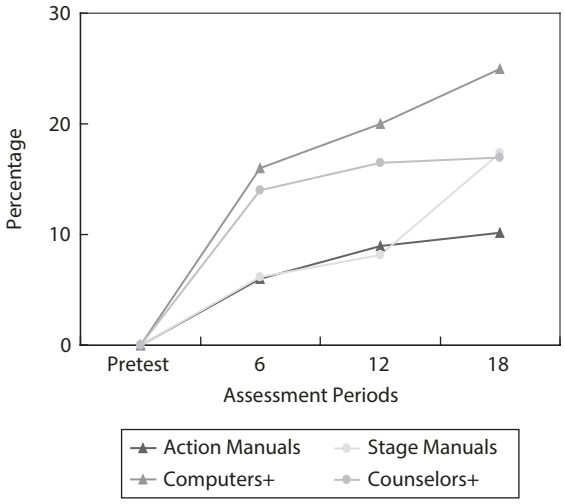

FIGURE 23.1 Point prevalence abstinence (%) for treatment groups pretest and at 6, 12, and 18 months.

23.4 CRITICAL ASSUMPTIONS OF THE TTM

The TTM is also based on critical assumptions about the nature of behavior change and population health interventions that can best facilitate such change. The following are a set of assumptions that drive transtheoretical theory, research, and practice:

1 Behavior change is a process that unfolds over time through a sequence of stages. Effective health promotion interventions need to match their help to individuals' stages as they progress over time.
2 Stages can be both stable and subject to change, just as chronic behavioral risk factors are both stable and subject to change. Health initiatives can motivate change by enhancing the understanding of the pros and diminishing the value of the cons.
3 The majority of at-risk populations are not prepared for action and will not be served by traditional action-oriented prevention programs. Helping individuals set realistic goals, like progressing to the next stage, will facilitate the change process.
4 Specific principles and processes of change need to be emphasized at specific stages for progress through the stages to occur.

These critical assumptions need to be taken into consideration when developing health promotion interventions for behavior change that can facilitate progress through the stages.

23.5 INCREASING IMPACTS WITH MULTIPLE BEHAVIOR CHANGE PROGRAMS

One of the greatest challenges for the application of any theory is to keep raising the bar, that is, to be able to increase the theory's impact on enhancing health. One potential is for TTM to treat multiple behaviors in a population, since most populations have multiple behavior risks and are at risk for both chronic disease and premature death. Those multiple-comorbid populations also account for a disproportionate percentage of health care costs. One estimate is that about 60% of health care costs are generated by about 15% of populations who have multiple behavior risks and medical conditions.[12]

Historically, studies conducted on multiple behavior changes have been limited by reliance on the action-oriented treatment and the lack of applying the most promising interventions, such as interactive and individualized TTM-tailored interventions.[13] From a TTM perspective, applying an action paradigm to multiple behaviors would indeed risk overwhelming populations, since Action is the most demanding stage, and taking action on two or more behaviors at once could be overwhelming. Furthermore, among individuals with four health behavior risks, like smoking, diet, sun exposure, and sedentary lifestyles, fewer than 10% of the population were ready to take action on two or more behaviors.[14] The same was true of populations with diabetes who needed to change four behaviors.[15]

With a population of 1,277 overweight and obese patients proactively recruited in the United States, we applied our first strategy for multiple behavior change. We call this the modular approach, where participants receive a separate TTM CTI module for each of their risk behaviors related to healthy weight management. The treatment groups had significant changes at 24 months on healthy eating, exercise, and emotional eating. This study was the first to report results showing significant coaction in the TTM CTI group and significant changes in fruit and vegetable intake that were not treated. Also, this study reported a mean of about 0.8 behaviors changed per participant in the TTM group, which was 60% greater than the 0.5 behaviors in the control group.[16]

One of the most exciting developments in our knowledge of simultaneously changing multiple behaviors is the phenomena of coaction. Coaction is the increased probability that if individuals take effective action on one behavior (like exercise), they are more likely to take action on a secondary behavior (like diet). We have found that significant coaction typically occurs only in our TTM treatment groups and not in control groups, suggesting it is likely to be treatment-induced.[16–18]

With a population of 1,400 employees in a major medical setting, the authors and colleagues made available online modular TTM CTIs for each of four behaviors (smoking, inactivity, BMI >25, and stress) and three Motivational Interviewing (MI) telephonic or in-person sessions. Employees chose which behaviors to target and how much time and effort would be spent on any behavior. At six months, both treatments outperformed the Health Risk Intervention (HRI), which included feedback on the person's stage for each risk and guidance on how they could progress to the next stage.[19]

With a population of 1,800 students recruited from 8 high schools in 4 states, Mauriello et al. applied a second-generation strategy with exercise as the primary behavior receiving three online sessions of fully tailored CTIs.[20] The secondary behaviors of fruit and vegetable (F&V) intake and limited TV watching alternated between moderate and minimal (stage only) tailoring. Over the course of the 6-month treatment, there were significant treatment effects in each of the three behaviors, but only changes in F&V were sustained at 12 months. Significant coaction was found for each pair of behaviors in the treatment group but not in the control group.

23.6 STUDIES CHALLENGING THE TRANSTHEORETICAL MODEL

Critics of the TTM have several core concerns. These include how well TTM constructs predict outcomes compared with non-TTM variables and whether TTM constructs (like processes of change) predict progress across stages of change in the way that TTM should predict. Their concerns are supported by some empirical studies, but some of the negative results in these studies can be explained by inappropriate methodology. Others have stronger methodology and provide useful detail that can be used to refine the TTM.

Farkas et al. and then Abrams et al. compared addiction variables with TTM variables as effective predictors of cessation over 12 to 24 months.[21,22] Addiction variables, including the number of cigarettes smoked and duration of prior quits (e.g., more than 100 days), were more effective than TTM variables in predicting cessation rates, suggesting that addiction models were preferable to TTM. Responses to these comparative studies have included concerns that Farkas et al. compared 14 addiction-type variables with just the single-stage variable from TTM.[23,24] The Abrams et al. study included self-efficacy and the Contemplation Ladder—an alternative measure of readiness or stage—as part of their addiction model but failed to acknowledge that both of these constructs are part of TTM.[22] Also, from an intervention perspective, the amount of variance accounted for by predictor variables is less important than the amount of variance that can be controlled or changed through an intervention. For example, duration of previous quits (e.g., more than 100 days) may be more predictive than stage; little can be done to change this historical variable, while a dynamic variable like stage is responsive to interventions.

In the first of a series of studies, Herzog and colleagues found that six processes of change were not adequate predictors of stage progress over a 12-month period.[25] In a second report, processes predicted stage progress but only when the Contemplation Ladder was used.[26] In the third report, TTM measures predicted 12-month outcomes, but self-efficacy and the Contemplation Ladder were not counted as TTM variables.[22] These findings conflict with other research that has found change processes and other TTM variables predict stage progress.[27–34] Johnson, J. L. et al. in their study explained some of the inconsistencies in previous research by demonstrating better predictions over 6 months versus 12 months, and better predictions using all ten processes of change instead of just a subset.[33]

One of the productive responses to studies critical of the TTM is to conduct further research. In response to the criticism that addiction severity levels are better predictors of long-term outcomes than stage of change, a series of studies was conducted to determine which types of effects predict long-term outcomes across multiple behaviors. To date, four such effects have been found.[35] The first is **severity effect**, in which individuals with less severe behavior risks at baseline are more likely to progress to the Action or Maintenance stages at 24-month follow-up for smoking, diet, and sun exposure. This effect includes the severity of addiction that Farkas et al. and Abrams et al. preferred.[21,22] The second is **stage effect**, in which participants in the Preparation stage at baseline have better 24-month outcomes for smoking, diet, and sun exposure than those in the Contemplation stage, who do better than those in the Precontemplation stage. This effect is what Farkas et al. and Abrams et al. criticized. The third is **treatment effect**, in which participants in treatment do better at 24 months than those randomly assigned to control groups for smoking, diet, and sun exposure. The fourth is **effort effects**, in which participants in both treatment and control groups who progressed to the Action and Maintenance stages at 24 months were making better efforts by using the TTM variables like pros and cons, self-efficacy, and processes at baseline. There were no consistent demographic effects across the three behaviors, indicating that no single demographic group did better across these multiple behaviors. What these results indicate is that either/or thinking (such as either severity or stage) is not as helpful as a more inclusive approach that seeks to identify the most important effects, whether they are based on TTM or on an addiction or severity model. These four effects are now being applied in TTM-tailored interventions for employees and other populations.

23.7 MULTIPLE DOMAINS OF WELL-BEING: FROM SUFFERING OR STRUGGLING TO THRIVING

Motivated by a risky test philosophy of science, we keep raising the bar to have increasing impacts with vulnerable populations, such as moving from changing a single behavior to a riskier goal of changing multiple risk behaviors.[36] One of our most recent challenges has been to simultaneously enhance multiple domains of well-being, e.g., physical, emotional, social, and work well-being. Prochaska et al. conducted a project with 3,391 participants from 39 states who had an average of almost 4 chronic conditions and almost 4 risk behaviors, with 40% obese, 35% overweight, and 0% exercising adequately or managing stress

effectively. A majority had poor diets, were or had been smokers, and had problems with depression.[37]

Compared with national norms, this population, with 59% women, a mean age of 48, and 48% unemployment, had much lower scores on each domain of well-being. Most striking was that a majority were suffering or struggling, and only a minority were thriving. The only time this pattern had been seen in the United States as a whole was during the economic crash of 2008.[38]

Random assignment to treatment groups and one control group was made. One group had telephonic TTM CTI coaching with exercise as the primary target and stress management as secondary. The second group received CTI coaching with stress as the primary target and exercise as secondary. Compared with controls, both treatment groups produced more multiple behavior change than controls and more improvement on multiple domains of well-being. In all comparisons, the telephonic coaching, which spent most of the time on exercise, produced more positive changes than the CTI coaching, which treated stress primarily and exercise secondarily.[37]

What was most rewarding was that the majority of both treatment groups, but not the control groups, had progressed from suffering or struggling to thriving. These results led us to produce a follow-up book to *Changing for Good*, which for over 20 years has been a guide for many health coaches.[39] Our new book, *Changing to Thrive*, is designed to help professionals, their clients, and other populations to reduce multiple risk behaviors, enhance multiple domains of well-being, and progress from suffering or struggling to thriving.[5]

23.8 CONCLUSIONS

It seems clear that the future of health promotion programs lies in stage-matched, proactive, interactive interventions. Much greater effects can be generated through the use of proactive programs because participation rates are increased, even if efficacy rates are lower. But, proactive programs also can produce outcomes comparable to those of traditional reactive programs. Although it is counterintuitive to suggest that outcomes for groups that are proactively recruited can match those of individuals who reach out for help, that is what informal comparisons strongly suggest. For example, in a comparison of results at 18-month follow-ups for all subjects who received three CTIs in a study of reactive intervention and a study of proactive intervention, the abstinence curves were remarkably similar.[40] The results with the counseling plus CTIs were even more impressive. Proactively recruited smokers, working with both coaches and the CTI, achieved higher rates of abstinence at each follow-up than did the smokers who had called for help. These results are partially attributable to the fact that the proactive coaching protocol has been revised and, it is to be hoped, improved on the basis of previous data and experience. But, the point is that if it is possible to reach out and offer people improved behavior change programs that are appropriate for their stage of readiness to change, it ought to be possible to produce efficacy or abstinence rates at least equal to those seen with individuals who reach out for help. Unfortunately, there is no experimental design that would make it possible to assign study subjects randomly to proactive versus reactive recruitment programs. Thus, one is left with informal but provocative comparisons. Results with multiple behavior interventions using some type of TTM tailoring and proactive recruitment have found effects as good as when smoking alone is treated. The results with the other treated behaviors were even better.

If these results continue to be replicated, programs will be able to produce unprecedented effects on entire populations. To do so will require scientific and professional shifts: (a) from an Action paradigm to a stage paradigm, (b) from reactive to proactive recruitment, (c) from expecting participants to match the needs of programs to having programs match the needs of clients, (d) from single- to multiple-behavior interventions, (e) from clinic-based to population-based programs that apply individualized and interactive intervention strategies, and (f) reducing multiple problem behaviors to enhance multiple domains of well-being to help vulnerable populations to progress from suffering or struggling to thriving.

With the knowledge and tools needed to move forward, we end with a final question for your consideration.

How ready are you to integrate a stage approach in your work?

1. I don't intend to integrate a stage approach in my work in the next six months (Precontemplation).
2. I intend to integrate a stage approach in my work in the next six months (Contemplation).
3. I intend to integrate a stage approach in my work in the next month (Preparation).
4. I have been integrating a stage approach in my work for less than six months (Action).
5. I have been integrating a stage approach in my work for more than six months (Maintenance).

Some ideas to guide your next steps:

1. If you are in Precontemplation, look for more information on using a stage approach and consider how your work, your client interactions, and your colleagues might benefit by your adopting a stage approach. (See Table 23.2 regarding some of the benefits.)
2. If you are in Contemplation, learn more about using a stage approach by talking with others who use it and seeking additional training in the approach at www.prochange.com/elearning. Identify what barriers might be in your way and consider ways to overcome them. Feel inspired by how the stage approach has helped others to engage patients more successfully.

TABLE 23.2
There are Many Benefits of Integrating TTM into Your Practice

TTM:

- Prepares you to work with entire populations wherever they are in the stages of change
- Helps you reduce resistance among your clients
- Allows you to see and appreciate how your clients are making progress in stages
- Enables you to set stage-matched goals with clients
- Gets you to offer and prescribe behavior change programs that are stage-appropriate
- Teaches you the principles and processes of change that are applicable across all health behaviors
- Shows you an approach that's successful at increasing engagement, increasing healthy behaviors, reducing multiple risks, and enhancing multiple domains of well-being and productivity

3. If you are in Preparation, make a commitment to begin using a stage approach, and share that commitment with others. Build your confidence by role playing or practicing the approach with clients. Ask colleagues to support and assist your efforts, and notice the benefit.
4. If you are in Action or Maintenance, keep this chapter and other training materials visible to make it easy to use a stage approach. Appreciate the benefits TTM offers you and your clients. Boost your confidence by using the approach even with resistant clients.[41] See a demo of a CTI at www.prochange.com/demo. The authors cofounded Pro-Change Behavior Systems, Inc., in 1997 and sold it to the two lead staff in 2015. They now act as consultants from time to time.

TTM has a broad range of clinical applications:

- Multiple behavior change for the prevention and management of chronic diseases, like type 2 diabetes
- Medication adherence for lipids, changing diet, and increasing exercise to prevent and manage cardiovascular disease
- Prevention and management of clinical depression
- Changing multiple behaviors and enhancing multiple domains of well-being in populations with multiple chronic conditions
- Changing multiple behaviors to prevent severe types of cancer

24 The Impact of Positive Psychology on Behavioral Change and Healthy Lifestyle Choices

Shelley Carson, Andrea Cook, Stephanie Peabody, Sandra Scheinbaum, and Leslie Williamson

KEY POINTS

- The goal of positive psychology, a science that focuses on human strengths, is to increase well-being and flourishing in individuals and groups. Psychological well-being is a "health asset," protecting against risk of physical illness.
- A substantial and growing body of evidence connects positive emotions, optimism, and subjective well-being with better health and longevity outcomes, even in the context of adversity.
- Positive psychology practices can influence health and wellness by encouraging patients' use of their strengths to manage stress and emotions, and to work toward healthy habits and lifestyle changes.
- Positive psychology interventions (PPIs), which can be prescribed, have been developed and tested in randomized controlled trials. PPIs have been demonstrated to be effective in improving positive emotions and well-being, and reducing depressive symptoms.

"Treatment is not just fixing what is broken; it is nurturing what is best."[1]

24.1 INTRODUCTION

Positive psychology is defined as the scientific study of the "conditions and processes that contribute to the flourishing or optimal functioning of people, groups, and institutions."[2] Patients who seek healthcare services, from yearly check-ups to treatment for serious illnesses such as diabetes and cancer, can benefit from incorporating positive psychology principles into their lives. As healthcare professionals, we can assist patients in improving their overall well-being by promoting positive psychology tenets during office visits and throughout treatment protocols. We can inquire about what is going right for them and point out personal strengths that we observe in them. There is a growing body of evidence indicating that positive psychology practices can influence health and wellness by encouraging patients' use of their strengths to manage stress and emotions, and to work toward healthy habits and lifestyle changes. We can assist patients to tap into these practices to improve their comfort, treatment compliance, and resilience.

In this chapter, we will examine the major tenets of positive psychology, review the evidence-based research on how positive psychology factors impact a variety of physical health issues, and offer suggestions on how positive psychology principles and interventions can be incorporated into any lifestyle medicine practice.

24.2 POSITIVE PSYCHOLOGY: A BRIEF OVERVIEW

The term "positive psychology" was first used by Abraham Maslow in his 1954 book *Motivation and Personality*.[3] Maslow and other psychologists of the humanist tradition, who believed in the self-actualization tendencies of humans and the nobility of the human spirit, deeply influenced the field of positive psychology as it exists today. However, as a structured discipline, positive psychology is very young; most scholars trace its beginnings to Martin Seligman's presidential address to the 1998 American Psychological Convention in San Francisco. In that address, Seligman argued that psychology had become a science focused primarily on improving symptoms of mental illness while neglecting research into what constitutes human flourishing and "what makes life worth living."[4] Although reducing suffering is a worthy goal, Seligman suggested it was incomplete; he called for an additional new psychological science, one that would focus on human strengths and the prevention of symptoms, rather than just the repair of human weaknesses.

Since 1998, scientific centers for the study of positive psychology have investigated factors leading to optimal self-regulation, well-being, flourishing individuals, and thriving communities. To counter criticism that positive psychology focuses too much on the positive and fails to recognize the negative realities of individual situations, a movement dubbed Second Wave Positive Psychology has sought to situate the original positive psychology principles within contextual and cultural concerns, and relate

DOI: 10.1201/9781003227793-28

positivity to real-world negative circumstances and suffering.[5,6] The application of these principles has resulted in the development of rigorously tested interventions to promote human strengths, realistic optimism, and competencies, thus improving well-being and self-regulation, and buffering against disease.

24.2.1 The PERMA Model

The main goal of positive psychology, according to Seligman,[7] has been to increase well-being and flourishing in individuals and groups. The major elements of well-being can be summed up in the PERMA model (see Table 24.1).

Each of the five elements of the PERMA model not only contributes to overall well-being but is sought after for its own sake.[7] As we shall see throughout this chapter, not only do these elements contribute to well-being, but they measurably contribute to lifestyle medicine outcome goals as well.

Positive Emotions. Positive emotions include, but are not limited to, joy, hope, pride, love, and gratitude. In addition to increasing levels of happiness and overall well-being, positive emotions have been found to predict emotion regulation skills and to help individuals find meaning in personal struggles.[8] Positive emotions have also been shown to facilitate the physiological components of recovery from stress, a major contributor to long-term health.[9]

Engagement. Much of the work on the importance of engagement for human flourishing centers on Mihaly Csikszentmihalyi's work on the psychological state of flow.[10] In the flow state, a person is fully immersed in, energized by, and focused on a current challenging activity. Relative to health, the flow state is associated with overall well-being, reduced symptomatology, and positive changes in both therapeutic and rehabilitation processes.[11]

Relationships. Having healthy, positive relationships with other people is one of the best predictors of well-being. A robust body of research indicates that close relationships contribute to stress reduction, health, and longevity.[12–14]

Meaning. In his iconic book *Man's Search for Meaning*, Victor Frankl[15] argued that our ability to find meaning in our lives is central to our ability to survive and thrive as human beings. Since the publication of Frankl's book, a growing body of research has found meaning in life to be associated with greater physical health[16] and longevity.[17]

Accomplishments. Setting goals and accomplishing them, even when they are small goals, provides us with a sense of fulfillment, satisfaction, and confidence in our ability to meet life's challenges. Accomplishment, measured as progress toward goals that are important to the individual, is also correlated with subjective well-being in a meta-analysis of 85 studies.[18] Self-efficacy, our belief in our ability to accomplish the tasks we have before us, is associated with stress reduction and lower vulnerability to stress, including stress associated with the COVID-19 pandemic.[19]

TABLE 24.1
Seligman's PERMA Model of Well-Being

Positive Emotions	Experiencing emotions such as love, joy, gratitude, serenity, hope
Engagement	Being completely absorbed in an activity (state of flow)
Relationships	Developing positive connections with others
Meaning	Believing in and serving something that is bigger than yourself
Accomplishment	Achieving incremental steps toward identified goals

Source: Adapted from Seligman, M., *Flourish: A visionary new understanding of happiness and well-being*, Free Press, New York, NY, 2011.

24.3 POSITIVE PSYCHOLOGY AND POSITIVE HEALTH

The Constitution of the World Health Organization encourages us to consider health as a "state of complete physical, mental and social well-being, and not merely the absence of disease or infirmity."[20] Positive health, as an aspect of positive psychology, describes a state beyond the mere absence of illness, and focuses on three independent health variables: subjective, biological, and functional.[21] Positive subjective health describes the state when an individual feels great and frequently experiences vigor, hardiness, an internal health-related locus of control, optimism, positive emotion, and high life satisfaction. The state of positive biological health looks at variables relevant to health, such as optimum heart rate variability, high levels of high-density lipoprotein (HDL), and cardiorespiratory fitness. Positive functional health includes both physical functionality (e.g., fitness and flexibility) and personal functionality (e.g., close friends and family, meaningful work, and the ability to meet the demands of one's chosen activities).

Positive health works to empirically identify and enhance *health assets* that predict health and illness over and above conventional risk factors. According to Seligman et al.,[22] a health asset is "an individual factor that produces longer life, lower morbidity, lower health care expenditure, better prognosis when illness does strike, and/or higher quality of life." Positive health adds to the preventive medicine model by fostering health assets, such as psychological well-being and the five aspects of the PERMA model, that contribute to health promotion and protect against the risk of physical illness.

In recent years, there has indeed been an increasing pool of research evidence supporting a correlation between such health assets and physical health outcomes. For example, psychological well-being[23, 24] and positive social relationships[13] have been shown to predict positive health outcomes in both cross-sectional and longitudinal studies.

24.3.1 Positive Psychology Factors and Cardiovascular Disease

A number of chronic disease studies have demonstrated associations between psychological well-being and

improved health outcomes for patients with cardiovascular disease. Three recent reviews of the literature, including one from the American Heart Association, found that elements of subjective well-being consistently protect against cardiovascular disease (CVD), even after controlling for traditional risk factors.[25–27] In addition, a prospective study of almost 7,000 participants found that higher optimism was associated with a lower risk of heart failure after adjusting for sociodemographic, behavioral, biological, and psychological covariates,[28] while another study of over 5,000 Hispanic/Latino participants found that dispositional optimism predicted better overall cardiovascular health.[29]

An additional study that examined cardiometabolic measures (including diastolic and systolic blood pressure, HDL and low-density lipoprotein (LDL) cholesterol, triglycerides, glycosylated hemoglobin, waist circumference, and C-reactive protein) in 800 adults over an 8–11-year time period found that both positive emotions and life satisfaction at Time 1 predicted lower cardiometabolic risk at Time 2, with life satisfaction possibly being the more robust predictor.[30] Finally, a review of 11 experimental studies concluded that gratitude, a positive psychology factor, positively impacts biomarkers of cardiovascular health, including endothelial dysfunction and prognostic inflammatory markers, as well as improving adherence to health behaviors.[31]

24.3.2 Positive Psychology Factors and Diabetes

Positive health outcomes related to diabetes have also been reported. A meta-analysis of 80 studies that looked across diverse populations of age, race, geography, and diabetes type concluded that across the lifespan, positive psychology characteristics (e.g., self-efficacy, self-esteem, adaptive coping, social support) were associated with improved diabetes management and glycemic control.[32] An additional study that focused on preadolescent youth with Type I diabetes found that psychological well-being was associated with lower depressive symptoms and better glycemic control.[33] In a prospective study of 7,800 middle-aged British citizens (562 of whom developed diabetes over the course of the study), life satisfaction and emotional vitality, but not optimism, were associated with reduced risk of physician-diagnosed diabetes.[34]

24.3.3 Positive Psychology Factors and Mortality

Ultimately, subjective well-being has been found to be associated with health, longevity, and reduced mortality.[35–37] An important review and meta-analysis of 62 studies examining over one million participants found that subjective well-being was associated with a decreased risk of mortality, and that the decreased risk was slightly more protective for men.[36]

A French study[38] that examined the influence of positive affect, negative affect, and life satisfaction on mortality in a cohort of 3,777 older adults found that positive affect predicted longevity. A British observational study obtained subjective well-being measures from a sample of over 9,000 men and women aged 50 and older at three time periods over a decade.[39] Individuals in the group with the highest well-being at Time 1 had the fewest deaths at Time 3, while the group with the lowest well-being at Time 1 had the greatest number of deaths at Time 3. While no claims of causality can be derived from this observational study, it contributes to the growing body of evidence that links well-being and life satisfaction with longevity.

A large prospective study[40] analyzed the incidence of stroke over a mean of 16 years in over 6,000 individuals. This study found that higher emotional vitality (a subscale of general well-being including optimism, mastery, and positive emotions) was associated with lower stroke incidence.

Two sytematic reviews looked specifically at the effect of optimism on mortality, one including 15 studies and over 200,000 participants and the other including 25 studies encompassing over 200,000 participants. Both concluded that optimism was associated with lower risk of all-cause mortality.[41, 42]

Not all studies, however, support the association between well-being and longevity. The UK Million Women Study, which followed over 700,000 women in a prospective study over a 12–16-year period, reported no connection between mortality and positive affect.[43] Four percent of the sample died during the study period. The authors reported that unhappiness was associated with self-rated poor health, but when this relationship was controlled for, happiness and well-being did not directly predict mortality.

In summary, however, the preponderance of research indicates that factors associated with positive psychology and well-being have a beneficial effect on a variety of health conditions, including cardiovascular health, diabetes, general mortality, and risk for stroke. Many major reviews within the past decade have examined the topic.[25–27, 36, 41, 42] All have shown that positive affect and subjective well-being have a beneficial effect for healthy populations or those who are mildly ill, suggesting that these factors should be promoted as protective factors for public health. While the evidence associating these well-being factors with positive health is impressive, we must be mindful that many of the studies are correlational, and reverse causation (that is, that better health is leading to psychological well-being rather than vice versa) is a concern.[44]

24.3.4 Positive Psychology Factors and COVID-19

The COVID-19 pandemic was a major public health crisis, resulting in over 770 million confirmed cases and 7 million deaths worldwide as of this writing.[45] Although there is currently no direct evidence that psychological well-being impacts the incidence of COVID, there is indirect evidence that aspects of psychological well-being can ameliorate negative physiological and psychological factors of the

disease and the pandemic. First, the risk for both hospitalization and mortality related to COVID-19 is elevated in persons suffering from mental health issues such as depression and stress disorders.[46–48] Psychological well-being is negatively associated with mental health issues related to the COVID pandemic,[49,50], and PPIs demonstrate reduction in mental health symptoms.[51]

Two factors, gratitude and social support, have been shown to be particularly salient in the face of COVID-related negative mental health. A diary study conducted by Chinese researchers reported that perceived positive health and reduced COVID-related stress were predicted by experiences of gratitude.[52] And, a large British study of over 70,000 participants reported that those individuals who had more positive social relations and support, as indicated by social contact during the pandemic, displayed fewer depressive symptoms.[53]

Finally, research indicates that as factors of psychological well-being increased during the pandemic, so did health behaviors, such as getting adequate exercise.[54,55] Another study of over 1,500 Korean citizens found that the factors of self-efficacy and social support were associated with positive health behaviors during the pandemic.[56] In general, the body of research associating positive psychological factors with positive outcomes from COVID is primarily correlational but appears to be growing in scope.

24.3.5 Positive Psychology Factors and Additional Health Considerations

In addition to the direct effects on health reviewed so far, positive psychology factors appear to confer other health benefits, including pain modulation and higher reported quality of life in persons with chronic illness. A number of studies have found that positive affect can reduce the experience of chronic pain. In a longitudinal study of over 9,000 adults, researchers found that positive well-being at Time 1 predicted lower levels of severe pain distress at Time 2 in persons with and without chronic pain. Less severe pain at Time 2 was also predicted by Time 1 life satisfaction in the group with chronic pain.[57] A study of 96 patients with severe pain indicated that subjective well-being had a beneficial effect on pain control, pain catastrophizing, and pain interference.[58]

A rather large body of research has now investigated the effect of positive psychology factors on increasing the quality of life in patients with chronic diseases. The results are fairly consistent in finding that positive emotions, well-being, and meaning-making decrease negative emotions, reduce the risk for depression, increase functionality, help maintain positive relationships, and help maintain compliance with medical regimens.[59–61]

While a positive attitude and positive emotions have been shown to help patients maintain a higher quality of life while dealing with severe health issues, other voices within the research field have suggested caution in interpreting or promoting positive psychology factors as "cures" for serious illness.[62] The research supporting positive psychology factors as health assets is strong. However, patients who are facing difficult health issues may feel frustrated, misunderstood, or even hopeless if confronted with what Aspinwall and Tedeschi have called the "tyranny of optimism."[62] This argument has been heeded and addressed by second wave positive psychology.[5,6] The goal of the field is to help patients raise their level of positive emotions within the bounds of the reality of their current situation. The next section describes PPIs that have been empirically tested, many in randomized controlled trials.

24.4 POSITIVE PSYCHOLOGY INTERVENTIONS

We have seen that factors related to positive psychology do in fact predict positive health conditions. However, can these positive psychology factors be purposely enhanced to benefit health? To date, a number of positive psychology interventions (PPIs) have been identified and tested. The field of positive psychology thus provides both a theoretic framework within which to approach patient health and a wide range of interventions that can be effective in the enhancement of psychological well-being.

Several meta-analyses indicate that PPIs have demonstrated small to moderate improvements in well-being, increased optimism and happiness, as well as decreased depressive symptoms. Results have been maintained for follow-up periods of up to six months.[63–68] Mental health and well-being factors are generally assessed with validated self-report tools (see Table 24.2 for a list of commonly used measures in PPIs).

PPIs can be delivered through a variety of modalities: web-based self-help programs, apps delivered on various technology devices, group training, or individual therapy/face-to-face meetings. The majority of interventions are delivered in a self-help format. While all formats have demonstrated effectiveness, interventions that are more intensive and include face-to-face interactions have been shown to generate larger positive effects.[63,64,66,67]. Further, PPI interventions have beneficial effects in both children and adults.[69]

In the following, we describe the most widely used evidence-based PPIs:

Gratitude. Two types of gratitude interventions have been widely studied. These include the *Gratitude visit*, in which individuals have one week to write and then deliver a letter of gratitude in person to someone who has been especially kind to them but whom they have never properly thanked,[78] and the *Gratitude list (Counting blessings)*, in which individuals are instructed to write down between three and five things in their lives, large or small, that they are grateful for, either each night for a period of two weeks or every week for a period of ten weeks.[81] Individual studies indicate that these short interventions increase positive emotions and mood extensively enough to be noticed by others, and also improve sleep quality.[78,81,82] Meta-analyses

TABLE 24.2
Self-Report Measures Commonly Used to Test Positive Psychology Interventions

Measure and Reference	Category	Description
Center for Epidemiological Studies–Depression Scale (CES-D)[70]	Depression	20 items on 4-point scale
Flourishing Scale[71]	Well-Being	8 items on 7-point scale
Gratitude Questionnaire (GQ-6)[72]	Gratitude	6 items on 7-point scale
Mindful Attention Awareness Scale (MAAS)[73]	Mindfulness	15 items on 6-point scale
Life Orientation Test-Revised (LOT-R)[74]	Optimism	10 items on 5-point scale
Positive and Negative Affect Schedule (PANAS)[75]	Emotions	20 items on 5-point scale
Psychological Well-Being Scales[76]	Well-Being	18 items on 6-point scale
Satisfaction with Life Scale (SwLS)[77]	Well-Being	5 items on 7-point scale
Authentic Happiness Inventory (AHI)[78]	Emotions	24 items on 5-point scale
Subjective Happiness Scale[79]	Emotions	4 items on 7-point scale
Values in Action Inventory of Strengths (VIA-IS)[80]	Personal Strengths	240 items on 7-point scale

that capture the cumulative results of multiple studies suggest that gratitude interventions are modestly effective in improving positive affect and psychological well-being in the short term, but more evidence needs to accrue before long-term effects of these interventions can be established.[83–85]

Three good things. Individuals are instructed to write down three things that went well each day for one week. They are also asked to explain why each good thing happened.[78] Both the original test of this intervention[78] and a later replication showed long-lasting increases in positive emotions.[86]

Using signature strengths. Individuals take an online inventory of 24 character strengths that was developed by Christopher Peterson and colleagues[80] and receive feedback about their top 5 "signature" strengths. They are then instructed to use one of these signature strengths in a new and different way each day for one week. A meta-analysis of 14 studies indicated that this intervention improved positive emotions and life satisfaction, as well as decreasing depression.[87]

Best possible self. Individuals are instructed to think about their life in the future and imagine that everything has gone as well as it possibly could. They are to imagine that they have worked hard and been successful at accomplishing their life goals. They are then instructed to write about what they have imagined for 20 minutes a day for 4 consecutive days.[78] A meta-analysis of 29 studies indicated that this intervention improved positive emotions, optimism, and well-being.[88] A second meta-analysis of 34 studies found small but important effect sizes for improvements in positive emotions and optimism.[89]

Acts of kindness. Individuals are instructed to perform five acts of kindness—all within one day of the week—for six weeks. The acts can be anything that makes others happy or that benefits others (such as donating blood, visiting an elderly relative, etc.)[79] This intervention is associated with increased positive emotions immediately following the acts as well as sustained increases in subjective well-being.[79,90]

Mindfulness meditation. Some reviews also include mindfulness interventions in their list of PPIs.[64] Mindfulness interventions cultivate nonjudgmental awareness of the present moment through daily or weekly meditation. Individuals are generally instructed to relax and focus on the flow of their breath or some other aspect of their current environment for a period of 20 minutes, nonjudgmentally acknowledging any passing thoughts and then letting them go.[91] While the topic of mindfulness is often associated with positive psychology,[92] it is too extensive to review in this chapter and is covered elsewhere in this volume. Numerous reviews have shown that mindfulness interventions can improve well-being in both patients and healthcare providers;[93–95] therefore, mindfulness meditations, along with PPIs, are recommended additions to any lifestyle medicine practice.

24.4.1 PPIs and Moderating Factors

Several factors impact the effectiveness of PPIs, including the patient's level of depression at the beginning of the intervention, age, motivation to improve, the format of the intervention, and the appropriate patient/intervention match. Sin and Lyubomirsky[64] found that patients who had symptoms of depression at the start of the intervention benefitted more from PPIs than those who were not depressed, and that PPIs were effective in preventing relapse in previously depressed patients. These same researchers found that patients who were older benefitted more than those who were younger, and that patients who demonstrated a greater motivation to improve benefitted more from the interventions than those who were less motivated. A German study found that those individuals who believed in the malleability of well-being benefitted more from PPIs than those who did not believe that well-being could be changed.[96] Finally, research suggests that patient characteristics such as personality and cultural background may impact the effectiveness of interventions.[64,97] However, there is a continuing need for research that better addresses racial, ethnic, and

gender differences in the implementation and effectiveness of PPIs.[98]

24.4.2 Positive Psychology Technological Devices

The delivery of health-related information and tools through apps that are available on a wide variety of technological devices provides healthcare and support that are not always geographically, financially, or socially accessible. There are many types of positive psychology assessment and intervention tools offered through mobile device apps. Most health-based assessment and intervention tools fall under two broad categories: *active* or *passive*. Active apps require direct participation, such as completing mood logs or recording subjective experiences. Passive apps do not require active participation and can automatically gather data (e.g., calories burned, heart rate, steps taken) through a smartphone's GPS, accelerometer, or other sensors.[99] Most positive psychology tools tend to fall in the active category of tools.

As of 2021, the American Psychological Association estimated there were betweeen 10,000 and 20,000 mental health apps,[100] with the number skyrocketing since COVID began. While not all of these apps are associated with positive psychology, few of them have been vetted. According to Torous and Powell,[99] any assessment or intervention tool should be empirically validated, be widely used, focus on some aspect of positive human functioning, be appropriate to the setting, and be easy to interpret/administer. While the current wide variety of positive psychology apps may enhance motivation, promote positive affect and well-being, or improve compliance with intervention protocols, practitioners should be cautious when deciding which intervention tools to recommend for their patients. Many apps have not been validated through empirical research, and most of the validation for these apps that does exist was completed by the app developer rather than an independent source.[101]

In summary, a number of PPIs have been developed and tested, and have been shown to be effective in improving positive emotions and well-being, and reducing depressive symptoms. Several moderating factors that impact effectiveness have also been identified, including the method of delivery. While the most effective method is one-on-one therapy, other methods (including web-based self-help), although less effective, are still beneficial. New delivery methods, including mobile apps, are being developed and with adequate testing, may also offer a beneficial form of positive psychology intervention delivery.

24.5 Incorporating Positive Psychology into Lifestyle Medicine Practice

There are several methods for incorporating positive psychology into the practice of lifestyle medicine. We discuss four methods here: 1) modeling positive psychology principles in your practice; 2) having positive health conversations with patients; 3) prescribing PPIs; and 4) incorporating a health coach trained in positive psychology principles into your practice or clinic.

24.5.1 Modeling Positive Psychology Principles

Since Albert Bandura first introduced social learning theory over a half-century ago, research has supported the concept that people learn through observing and modeling other people's behavior, attitudes, and emotional reactions.[102] In a healthcare setting, modeling health behaviors is a valuable method of promoting behavior change in others. Effective ways to model positive psychology principles in your practice include:

- Displaying *positive emotions* during interactions with patients and with other staff (contentment, hope, serenity, interest, amusement, inspiration) unless inappropriate to the situation
- Expressing *gratitude* to staff within earshot of patients for their positive work
- Determining your own signature *character strengths* and using them on a regular basis in your work

24.5.2 Having Positive Health Conversations with Patients

One method of introducing positive psychology principles into a lifestyle medicine practice is through both incidental and more focused conversations that occur throughout the patient visit. Here are some examples:

- During examinations, ask open-ended questions that focus on the patient's strengths:
  - What aspects of their health do they feel good about?
  - What is their overall level of well-being?
  - What capacities—strengths, interests, and resources—can they bring to the table if need be to help improve their health?
  - What are their situational benefactors (e.g., supportive family, friends, good job)?
- Here are a few good questions to ask patients in order to encourage them to explore and share their positive health attitudes and behaviors:
  - "When was the last time you felt well?"
  - "What have you done in the past that made you feel better?"
  - "Can you tell me about a time when you were at your best? What strengths were you using at that time?"
  - "It seems like this is very important to you. How do you imagine your life would be different if you [lost weight]?"
  - "What would be possible for you if you [quit smoking]?"

- When patients speak, employ *active* listening:
  - Face your patients and put down any papers, pencils, or equipment while they speak to you. Make eye contact and nod to express that you hear them. Reflect back to them in your own words what you heard them say (e.g., "If I understand you correctly …," "It sounds like you're feeling …," "What I hear you saying is …," "Is this correct?").
  - Active listening allows patients to feel heard and often helps them to understand their own symptoms, condition, and potential for habit change more clearly.
- Encourage patients to avoid social comparisons (including comparisons with themselves as they used to be when they were younger) and to focus on their own current strengths.
- Remind patients that they can make *mindful* choices: every step we take, every bite we eat, every activity we perform, every reaction to an event we have, is a choice. Sometimes we forget that. It's liberating to know we can mindfully *choose* so much about our lives!
- Engage in a short realistic optimism process with patients:
  - First, help them to see their current health situation objectively rather than catastrophically.
  - Second, help them brainstorm the best possible outcomes given their current situation.
  - Third, help them plan to move confidently and positively toward those best possible outcomes.

24.5.3 Prescribing Positive Psychology Interventions

Just as exercise can be prescribed for its health-enhancing and disease-preventing effects,[103] PPIs can be prescribed for the same reasons.[104] Table 24.3 presents sample prescriptions for evidence-based PPIs mentioned in the previous section. These PPIs have been shown to increase positive emotions, decrease negative emotions, and increase overall well-being.

When prescribing a PPI, as research indicates, it is important to consider patient characteristics such as personality and cultural background.[64,105] For example, Nelson and Lyubomirsky[105] have pointed out that introverts may benefit more from reflective activities such as counting blessings or meditation, while extraverts may prefer more outgoing activities, such as acts of kindness. Likewise, patients from a collectivist cultural background (e.g., some Asian cultures), where group happiness is emphasized, may benefit more from one of the prosocial interventions, such as acts of kindness or writing a gratitude letter, than from an intervention targeting the individual, such as best possible self.[64,97] Some research suggests that patients may have better results when matched with a self-selected intervention with which they feel comfortable.[106]

It is also important to consider the modality of the prescription. Self-motivated patients may benefit from a prescription to simply perform an action, such as those listed in Table 24.3. However, less motivated patients may derive more benefit from a prescription to work one-on-one with a trained positive psychology health coach.

24.5.4 Incorporating a Health Coach Trained in Positive Psychology Principles into Your Practice

As an important part of an effective collaborative care team model, health coaches in primary care practices offer positive psychology skill building for patients who would benefit from lifestyle changes to improve their health condition. Health coach job tasks include assessing readiness for change, collaboratively establishing client goals, evaluating successful steps and self-limiting patterns, re-assessing and modifying goals, articulating insights gained, and

TABLE 24.3
Examples of Prescriptions for Positive Psychology Interventions

Name	Rx	Evidence for Effectiveness
Gratitude Letter and Visit	Write and deliver in person a letter of appreciation to someone who has been kind to you but whom you have never properly thanked.	76, 78, 82
Three Good Things	Write down three good things that happen each day for one week, together with an explanation for why each good thing happened.	78, 86
Use Your Signature Strengths	Take the survey at viacharacter.org. Use one of your five signature strengths in a new and different way for a week.	78, 87
Gratitude List	Write down three new things (small or large) you are grateful for each night for two weeks. At the end of each week, read your entire list.	76, 83–85
Best Possible Self	Imagine as vividly as possible that you have worked hard and been successful at accomplishing your life goals. Write about what you have imagined for 20 minutes a day for 4 consecutive days.	78, 79
Acts of Kindness	Pick one day of the week for the next six weeks, and on that day each week, perform *five* acts of kindness (large or small) for other people that you would not have otherwise performed.	90

formulating a post-coaching plan to sustain changes that promote health and wellness.[107]

Research has shown that patients who received coaching services demonstrated significant improvements in both physical and mental health, with reductions in chronic disease markers (HbA1c, blood pressure, LDL cholesterol) that persisted one year after completion of the health coaching intervention.[108] Health coaching with a positive psychology emphasis has been found to improve overall patient health, with a 19% decrease in patient-reported medical symptoms and enhanced mental health strengths, including improved quality of life and increased mastery of areas of well-being, such as maintaining trusting relationships and realizing one's potential.[109] In addition, primary care clinicians reported that patients who received health coaching were more empowered and less demanding.[110] Health and wellness coaches are becoming fixtures in hospitals, clinics, private practices, and health clubs.

24.6 CONCLUSION

The advancement of positive emotions and well-being is synergistic with the advancement of physical health. In this chapter, we have reviewed the evidence for a connection of positive emotions, optimism, and well-being with better health and longevity outcomes. In particular, there are growing bodies of research that connect positive emotions, optimism, and well-being with better cardiovascular health, better diabetes management and glycemic control, lower pain levels, and lower mortality among healthy persons.

While individual levels of optimism and well-being are, to an extent, trait-like factors, research has provided evidence that these factors can be enhanced through PPIs. These interventions have centered on increasing positive emotions, self-efficacy, and life satisfaction while decreasing negative emotions and stress. Some of the mechanisms employed in these interventions include expressing gratitude, understanding and using one's strengths to achieve goals and solve problems, focusing on and savoring positive events, and completing small acts of kindness.

We have suggested several methods for implementing positive psychology principles and interventions in a lifestyle medicine practice, including modeling these principles in yourself and your practice, incorporating the principles in discussions with patients, prescribing PPIs as part of preventive or palliative care, and adding positive psychology coaching to your practice or clinic. There is growing evidence for the physical health benefits of positive psychology practices for both physical and mental well-being. Practitioners of lifestyle medicine are in an excellent position to promote overall well-being as an important part of comprehensive healthcare.

SUMMARY OF CLINICAL APPLICATION POINTS

1. Have Positive Health Conversations with Patients	• During examinations, ask open-ended questions that focus on the patient's strengths. • When patients speak, employ *active* listening. • Encourage patients to avoid social comparisons (including comparisons with themselves as they used to be when they were younger) and to focus on their own current strengths. • Remind patients to make *mindful* choices: every bite we eat, every activity we perform, every reaction to an event we have, is a choice. It's liberating to know we can mindfully *choose* so much about our lives! • Engage in a short realistic optimism process with patients.
2. Model Positive Psychology Principles	• Display *positive emotions* during interactions with patients and with other staff (contentment, hope, serenity, interest, amusement, inspiration) unless inappropriate to the situation. • Express *gratitude* (for example, to staff) within earshot of patients for their positive work. • Determine your own signature *character strengths* and use them on a regular basis in your work. • Discuss the personal *meaning* of health in your own life (e.g., lifestyle challenges you may have struggled with in the past and how you may have used positive psychology principles to help effect positive lifestyle changes).
3. Prescribe Positive Psychology Interventions	Just as exercise can be prescribed for its health-enhancing and disease-preventing effects, positive psychology interventions (PPIs) can be prescribed for the same reasons (e.g., gratitude letter, three good things journal, acts of kindness).

25 The Intention–Behavior Gap

Mark D. Faries, PhD, Wesley C. Kephart, PhD, and Devin Graham, MS

KEY POINTS

- Intention indicates how hard a patient is willing to try, or how much effort they are willing to put toward any given behavior.
- Intention, alone, is generally found to not be a reliable predictor of physical activity or dietary behavior—even if intention is high (the intention–behavior gap).
- Thus, the practitioner should consider the factors that have been shown to moderate or affect the strength of the intention–behavior relationship, which include:
- Action and Coping Planning: Forms of planning that specify a critical condition linked to goal-directed responses (e.g., "if-then" statements), and when an individual imagines a scenario that might hinder them from performing an intended behavior (e.g., barriers), respectively
- Self-Efficacy: A personal expectation or judgment regarding one's competence to accomplish a specific task in a particular context
- Capacity (Executive Function): A concept that describes the neurocognitive faculties of higher-order supervisory abilities to direct cognitive functions toward a goal
- Emotional Response: The affective reaction to some type of internal or external stimuli
- The practitioner and healthcare team can play a key role in helping to bridge the intention–behavior gap with their patients by improving the utilization of action and coping planning, building self-efficacy, or identifying anticipated affective responses (e.g., regret).
- Understanding of the intention–behavior gap allows modification of lifestyle prescriptions and development of practice models that maximize lifestyle adherence when lifestyle is the medicine.

25.1 INTRODUCTION

Two common scenarios are experienced by practitioners with lifestyle prescriptions:

1. The patient has *no* intention to adopt the lifestyle prescription, or
2. The patient has intention to adopt the lifestyle prescription but does not follow through with it.

Both scenarios of non-compliance can be frustrating to the patients and the practitioners, who truly desire the best for their patients. This chapter hinges on the realization that lifestyle medicine only works if patients take their medicine. As a result, practitioners are very interested in medication adherence, especially the aspects of evidence-based factors that might contribute to increasing adherence to the prescription.

Thus, the purpose of this chapter is to introduce and elucidate the intention–behavior gap (IBG). In addition, we aim to investigate the efficacy of current proposed solutions to the IBG to provide the practitioner with options to increase medication adherence when lifestyle is the medicine.

25.1.1 What Is the Intention–Behavior Gap?

Traditionally, intention has been conceptualized as the immediate antecedent to behavior. In other words, we have intention to do something, then we do it (behave). However, early examinations of behavior highlighted that intention did not always translate to behavior. Early theories to explain this phenomenon were the predecessor of the more widely utilized Theory of Planned Behavior (TPB) by Drs. Ajzen and Fishbein, which shed light on potential factors that either moderated or mediated the relationship of intention with behavior (e.g., habit, facilitating or constraining conditions, or social and affective factors). However, the intention–behavior gap remains enigmatic as it relates to physical activity (PA) or healthy eating.

After observing the IBG in practice, researchers uncovered that intention, even if it was high, was not a reliable predictor of PA or dietary behavior. [1] Clearly, there is variation in behavior—with some doing more, some doing less, and some not changing over time. In an ideal scenario, intention would explain all (100%) of this variation, accounting for why some people increase, some decrease, and some do not change their behavior. We would be able to measure intention level and predict, perfectly, how much their behavior would change. However, the TPB, which includes intention, was found to predict only 24% and 21% of the variation in physical activity and dietary behavior, respectively.[2] In other words, somewhere between 75% and 80% of the variation in behavior is not explained by intention and its related predictors.

In response, Rhodes and de Bruijn set out to explain how big the IBG gap was with leisure-time, moderate-to-vigorous physical activity that met current public health

DOI: 10.1201/9781003227793-29

guidelines.[3] They discovered that across ten studies presented, on average, approximately:

- 21% were non-intenders and were *unsuccessful* in performing the behavior,
- 2% were non-intenders but were *successful* in performing the behavior,
- 36% were intenders but were *unsuccessful* in performing the behavior, and
- 42% were intenders and were *successful* in performing the behavior.

If these results translate to practice, we can assume that about seven out of ten patients will have intention to be more physically active, while the rest (three out of ten) will not have intention: "The results suggest that, while some people still require interventions changing intentions, much of the inactive population has positive intentions."[3] However, of those who did have intention to get more physical activity, only 54% were successful in performing the behavior, which would translate to about one out of every two patients who intend to be more physically active following through with their intention. The rest, 46% of the intenders who did not follow through with their intention, epitomize the IBG.

We find similar IBGs with fruit and/or vegetable (FV) consumption. For example, the authors of a systematic review found that intention only predicted or explained 34%, 43%, and 31% of the variation in total FV intake, fruit intake, and vegetable intake, respectively. Other studies have examined the relationships or correlations (r) between intention and FV behavior, such as achieving previous public health recommendations of consuming 5 FV per day. Generally, on average, these correlations are weak: $r_+ = 0.27$ in children/adolescents,[4–8] $r_+ = 0.36$ in college students,[9–11] $r_+ = 0.41$ in adults,[12, 13] and $r = 0.40$ in older adults.[14] As a reminder, strong correlations typically surpass $r \geq 0.50$ on the 0 to 1 scale.

A more recent review of studies of healthy eating found that on average across all studies, intention and behavior were only moderately correlated ($r_+ = 0.45$).[15] Also, studies were separated into those that directed participants to consume health-promoting foods versus avoiding health-compromising foods. Interestingly, the intention–behavior relationship was weaker for *avoiding unhealthy* food ($r = 0.28$) than *promoting healthy* food ($r = 0.43$). These findings suggest that patients could have a higher probability of overcoming the IBG with healthy food–promoting prescriptions (e.g., add another vegetable to your day) than with prescriptions aimed at avoiding unhealthy foods (e.g., eat less sugar). Clearly, both prescriptions are important in lifestyle medicine practice, but the nuances of the IBG can help explain variation in medication adherence within patients.

The IBG remains large, as intentions only get translated into action about half of the time, [1] which equates to the fact that 1 in 2 patients will succeed. In response, additional theories have been utilized to help explain the IBG, such as the Action Control Theory, the Precaution Adoption Process Model, the Temporal Self-Regulation Theory, and the Volitional Model of Goal-Directed Behavior. Rhodes and Yao have provided an excellent review of 16 models, hoping to better explain the IBG in physical activity, concluding: "Whether these models will serve to improve our interventions and/or explain [physical activity] better than the current state of research is unknown."[16] In other words, we have several models and factors that can help us, but the future is bright with opportunity to innovate and properly evaluate old and new models to further our understanding of the IBG. Until then, we can begin to put the known concepts into practice, reducing the probability of IBG occurrence in our patients. Many of the leading concepts are summarized later in this chapter, alongside practical applications for you to implement—if you have intention to do so.

25.2 INTENTION IN PRACTICE

25.2.1 What Is Intention?

As it relates to the IBG, intention indicates how hard a patient is willing to try, or how much effort they are willing to put toward any given behavior.[17] The assumption is that "[t]he stronger a person's intention, the more the person is expected to try, and hence the greater the likelihood that the behavior will actually be performed."[18] Also, with such desire and willingness, intention to do a behavior indicates a more proximal time frame. They intend to behave very soon, not later or in the coming months/years.

25.2.2 Intention in Practice

In practice, patients might relay that they "intend" to be more active or start eating more healthily. However, this might resemble a statement of hope for some time in the future rather than an actual dedication to change. In this case, they are not indicating that they are willing and ready to put forth vast amounts of effort to be more active and eat more healthily in the immediate future. So by definition, they do not have true intention to change. In a way, they are saying, "I intend to," but really mean "I would like to," or "I hope to." This is supported by Rhodes and Rebar's 2017 study, in which they advise investigators to be cautious, noting that "intention" can be interpreted both as a decision taken toward performing a certain behavior and/or the commitment to enact a behavior. [19] They found that these two concepts are not equal predictors of physical activity. Instead, the authors recommend using the terms *decisional intention* to denote the direction meaning of intention and *intention strength* to denote the intensity of commitment. The semantics here are important, as this gives insight into intention strength and the IBG in practice.

For example, Dr. Ajzen has provided instructions for developing questionnaires to assess intention with the context of the TPB; these instructions are accessible online at http://people.umass.edu/aizen/pdf/tpb.measurement.pdf. First, the behavior must be clearly defined in its target,

action, context, and time elements. In other words, we cannot simply ask patients about their intention be more physically active. That is too general. We would need to more specifically define physical activity, such as "at least 30 minutes per day, 5 days per week for the next 4 weeks." Since intention is assuming a level of likelihood of effort toward performing the behavior, "likely" or "unlikely" anchors are applied. Here is a final item that a patient could be asked to answer.

"*I intend to exercise for at least 30 minutes per day, 5 days per week for the next 4 weeks.*"

Unlikely : 1 : 2 : 3 : 4 : 5 : 6 : 7 : Likely

As you can see, the specifics of the behavior, including the type of behavior, the amount of the behavior, and the time frame could greatly impact a patient's level of intention. Although not of direct focus within this chapter, it is important to note that lifestyle prescriptions can and should be modified to accommodate an inadequate level of important factors, such as intention or self-efficacy (discussed later in the chapter).

25.2.3 Intention Stability

Intention strength has also been conceptualized as *intention stability*, which refers to the fluctuations in intention across time.[20,21] In those with high intention to engage in more physical activity, for example, having more intention stability could help.[21] Those with high intention–high stability achieved twice the amount of physical activity as those with high intention–low stability. In other words, if a patient has high intention, ensuring that the intention remains stable over time can be beneficial for behavior. If intention slips over time, then behavior could be negatively impacted—even if the patient initially had high intention to follow the lifestyle prescription.

The largest effect, however, was seen in those with low intention. Low intention—high stability participants did not increase physical activity from baseline, as expected. They did not have much intention to change and were stable with their low intention over time. Yet, low intention–low stability participants were more willing to change as their physical activity behavior increased. In this case, their instability of intention was beneficial. These findings highlight individual differences in intentional response, as well as the complexities of self-regulatory factors that could influence intention and subsequent behavioral success.[22–24] Thus, there is the need for the practitioner to better understand what other factors or concepts could moderate or affect the strength of the intention–behavior relationship.

25.3 SOLUTIONS FOR THE IBG

25.3.1 Action and Coping Planning

25.3.1.1 Introduction

The health action process approach (HAPA; Figure 25.1) model is a behavior change framework that allows for additional explanatory variables beyond the TPB. More specifically, it is a model "that explicitly includes post-intentional mediators to overcome the intention-behavior gap."[25] The motivation phase includes factors that lead up to intention, while the volition phase describes the variables helping connect intention to behavior. A generic model example is shown in Figure 25.1.

When a patient has intention to adopt a particular health behavior, the action must be initiated and subsequently maintained. As previously mentioned, the ensuring process of connecting intention and behavior requires multiple factors and skills that facilitate successful self-regulation of one's own behavior. The HAPA could allow an open architecture for multiple factors but emphasizes self-efficacy (discussed in the next section) and planning. The hypothesis

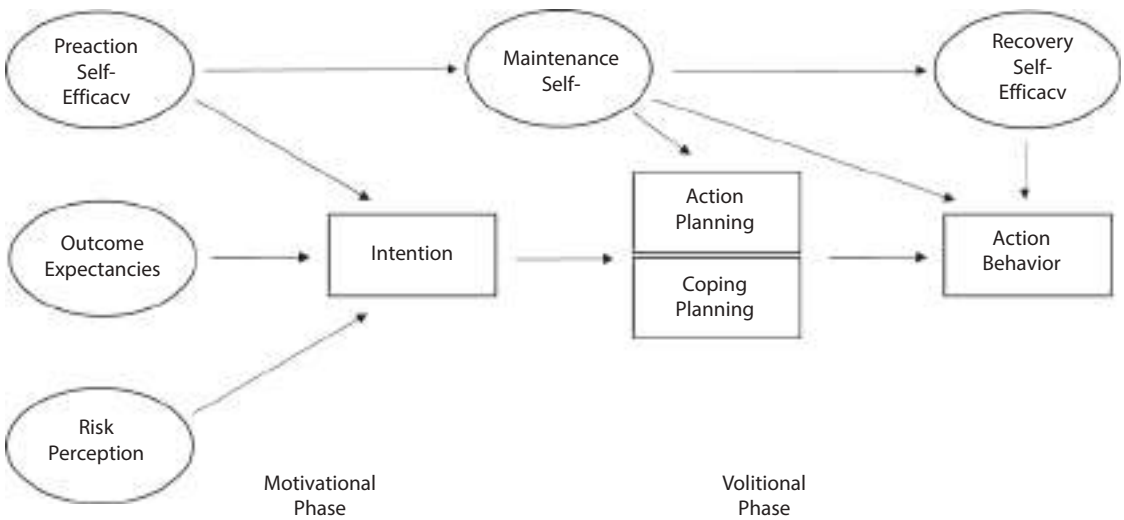

FIGURE 25.1 Health Action Process Approach Model. (From Schwarzer, R., ***Appl. Psychol.***, 57(1), 1–29, 2008)

relays that "good intentions are more likely to be translated into action when people develop success scenarios and preparatory strategies for approaching a difficult task."[25] Such planning is accomplished through action planning and coping planning.

Action planning, or implementation intentions, is "a form of planning that specifies a critical condition linked to goal-directed responses."[26] Such plans provide "if-then" statements to help connect a patient's intention to following through with the behavior. For example, "*If I wake up at 6:00 am tomorrow morning, then I will get ready and immediately go jogging in the neighborhood*."

However, as with any plan, problems will be encountered, and strategies are needed to invest conscious effort for the purpose of solving problems or responding to perceived discrepancies in behavior. So, in relation to HAPA and implementation-intention strategies, *coping planning* takes place when an individual imagines a scenario that may hinder them in performing an intended behavior. Coping planning is making a plan that anticipates difficulties or barriers that might hinder the patient's implementation of their intentions to live a healthy lifestyle.[27,28] A coping planning statement might look like, "*If it is raining or too cold in the morning, then I will go to the gym instead of jogging in the neighborhood*."

25.3.1.2 Review

Of all the potential moderators of the IBG, implementation-intention (action planning) research is perhaps the most robust. For PA, a 2013 review examined 26 independent studies and concluded that action planning could help promote PA, but the effect size was relatively small (d = 0.31) for measures of PA post intervention and even smaller for longer-term follow-up measures (d = 0.24).[29] The authors conclude that

> although implementation intentions are viewed as a powerful strategy to overcome the above self-regulation problems, individuals might have to formulate specific plans not only for their [behavioral] resolution (e.g., if it is Sunday morning, then I will go to the gym) but also for the management of barriers. Thus, this aspect can lower the efficacy of implementation intentions for complex [behaviors], particularly if the manipulation of implementation intentions is less elaborate (i.e., only planning when, where and how).[29]

A 2011 review and meta-analysis on healthy eating and implementation intentions highlighted 14 studies that investigated the efficacy of implementation intentions in increasing healthy eating behaviors, while 8 studies were designed to reduce unhealthy eating behaviors.[30] For healthy eating patterns, implementation intentions appear to be more effective in promoting the inclusion of healthy food items (d = 0.51) than they are for diminishing unhealthy eating patterns (d = 0.29). However, the authors note that the overall effect sizes of the results were small, perhaps due to poor control groups or weak outcome measures. A 2017 review and meta-analysis of 12 empirical studies examining the effect of implementation intentions on reducing fat intake found a moderate effect size (d = 0.49),[31] which fared better than the effects found by Adriaanse and colleagues[30] on reducing unhealthy eating behaviors (d = 0.29).

Coping planning, on the other hand, could help account for the weak effect sizes found with action planning's effect on PA and healthy dietary behavior, since the coping plan anticipates personal challenges or barriers to completing the action plan. In this way, the patient can create a sense of control over unwanted concerns or distractions to their behavior. Also, coping planning implies action planning.[32] Research in physical activity suggests that both action and coping planning could be used to help individuals connect intention to behavior in the short term; however, coping planning appears to have a larger effect on behavior over time.[28]

25.3.1.3 Practical Application

The practitioner can help the patient develop action and coping plans. From this section, the main actionable ideas are that action control and action planning are related to exercise.[33] A beneficial way to employ this strategy would be, for example, to instruct the patient to write down how they plan to exercise, where they plan to exercise, and when they plan to exercise. Similarly, this formula could be followed for planning how they will prepare vegetables, where they plan to obtain them, and when they plan to consume them (meal time). Next, they can form coping plans to help clarify, specifically, how they will deal/cope with upcoming problems. Doing so is clearly beneficial. If a patient likes to walk outside, ask them what they will do if it is a rainy day. If they go to a restaurant with friends, what will they order to be the healthiest? In this vein, conversations are somewhat endless; however, having a few discussions to plan and set up some contingencies could help the patient stay on their journey toward health.

Here is a sample template for use in practice.[34]

---

1. My Goal _____

"To eat 2 more fruit and vegetables per day this week."
"To walk 3 afternoons this week."

2. My Plan

If/When I _____ I will _____

"When I have lunch at work, I will have a piece of fruit."
"When I get off work, I will walk around the block."

3. My Backup Plan

If I _____ I will _____

"If I go out to eat for lunch, I will eat the piece of fruit before I leave."
"If it is raining or too cold outside, I will walk on the treadmill in the office gym."

25.3.2 Self-Efficacy

25.3.2.1 Introduction

Self-efficacy is a mixture of value and personal belief in one's ability (i.e., confidence) to achieve intended results.

Put another way, it is a personal expectation or judgment regarding one's competence to accomplish a specific task in a particular context. In relation to the IBG, the HAPA provides three separate self-efficacy constructs:[25]

1. *Pre-action or Action Self-Efficacy*: This type of efficacy occurs before individuals have yet acted and helps develop a motivation to do so. Individuals who are high in pre-action self-efficacy imagine success, anticipate potential outcomes of diverse strategies, and are more likely to initiate a new behavior.
2. *Maintenance or Coping Self-Efficacy*: Represents optimistic beliefs about one's capability to deal with barriers that arise during the maintenance period.
3. *Recovery Self-Efficacy*: Addresses the experience of failure, lapses, and setbacks.

25.3.2.2 Review

The HAPA model (Figure 25.1), with the various self-efficacy constructs, is generally able to account for additional variance of behavior beyond intention. For example, in adults classified as obese, self-efficacy was found to be the main direct and indirect predictor of both intention and physical activity.[35] Pre-action self-efficacy had a direct effect on intention, and in combination with outcome expectations, predicted 30% of the variance in intention. Consistently with the model, maintenance/coping self-efficacy predicted coping planning, which did not predict physical activity behavior. However, recovery self-efficacy did, and in combination with social support, accounted for 18% of the variation in physical activity. In other words, approximately 82% of the variation in physical activity is unaccounted for by this model despite self-efficacy being a leading determinant.

The HAPA model was also applied to patients classified as overweight and obese regarding intention to eat high-fat foods and their subsequent consumption two months later.[25] Recovery self-efficacy was the main predictor of consumption, with contribution from planning. This overall model accounted for 46% of the variation in high-fat food consumption, which is a more substantial predictive model than we saw with the previous physical activity example at 18%.

Additional studies have investigated self-efficacy in regard to PA and the IBG.[36–39] Only two of the four have shown higher self-efficacy to be related to greater intention for PA.[36, 37] Rhodes and colleagues[31] did show that self-efficacy varied across various intention–behavior profiles. Because self-efficacy is context specific, one's confidence in being physically active was wisely assessed with these contexts in mind (e.g., when a little tired, in a bad mood, when it becomes boring).[36] When measured in this way, "successful maintainers" of PA have a mean self-efficacy of 3.68 (on the 1 to 5 scale), indicating moderate–high confidence in their abilities. The "non-intenders" and the "unsuccessful adopters" had low–moderate self-efficacy ratings of 2.45 and 2.54, respectively.

Self-efficacy also has an effect on planning, which mediates the intention–behavior relationship. For example, Luszczynska and colleagues showed that a six-month intervention to boost self-efficacy or self-efficacy combined with action planning (i.e., specific plans outlining actions to meet particular goals) led to similar increases in FV consumption.[40] Interestingly, Richert and colleagues investigated the outcome of FV intake following a planning intervention in 411 employees.[41] The effectiveness of the planning intervention was found to be contingent on self-efficacy. In other words, those with low self-efficacy did not benefit from the planning. Similarly, Luszczynska and Schwarzer examined the influence of self-efficacy on intention and subsequent breast self-examination.[42] They first found that planning mediated the relationship between intention and behavior. Pre-actional self-efficacy had a positive effect on both their intention to conduct and their planning for conducting a breast self-examination, but not the actual behavior. However, their maintenance self-efficacy, which was assessed 12–15 weeks later, had a weak but positive effect on actual breast self-examination behavior.

25.3.2.3 Practical Application

Currently, the evidence for self-efficacy to bridge the IBG is generally supportive, yet still somewhat speculative, despite the growing literature in support of the importance of self-efficacy in health behavior. Interventions to reduce the IBG continue to arise, some of which lend potential support to the importance of self-efficacy. For example, when brief text messages were sent to participants to remind them of their action plans in addition to a standard psychoeducational intervention, self-efficacy increased slightly, while the psychoeducational intervention alone resulted in a significant decrease in self-efficacy.[43] The authors conclude with considerations for application, suggesting that

> individuals in the standard intervention group became discouraged by the experience that they could not fully transform their intentions into action. On the contrary, the text message reminders in the augmented intervention group might have assisted sedentary individuals to strengthen the confidence to become more active. Importantly, there is robust evidence that self-efficacy is a prerequisite for successful behavior change throughout a variety of health-related domains, including physical activity.[43]

Thus, the practitioner should consider the common determinants of perceived self-efficacy in their patients[44] as well as novel methods or technology to enhance patient self-efficacy.

Planning is also another key factor that can be facilitated in practice, but it hinges, at least in part, on self-efficacy. In other words, proper planning can help patients connect intention to behavior *if* they feel confident in their abilities to be physically active or eat healthfully across various contexts, especially when faced with certain barriers or when

resuming healthy behavior following a break from it. In summary,

> self-efficacious individuals are optimistic about their capability to resume an exercise regimen after a break, which might help them enact their plans. Therefore, self-efficacious people might be more likely to translate their intentions into action. In other words, action plans do not convert intentions into behavior if a person harbors self-doubts.[45]

These findings also highlight (1) the need to ensure each type of self-efficacy in patients and (2) the importance of understanding predictors in theoretically based path models (e.g., working left to right in the HAPA model).

25.3.3 Capacity (Executive Function)

25.3.3.1 Introduction

Self-regulation of behaviors, especially those behaviors that have been ingrained over time, can be quite difficult—even for those who might have the utmost intent to follow a prescription. This paradox highlights an important need for an adequate capacity of our brains to control and manage our thoughts, attitudes, and behaviors. This capacity, which is a foundation for self-regulatory abilities, is collectively known as the executive functions (EF). EF is a concept that describes the neurocognitive faculties of higher-order supervisory abilities to direct cognitive functions toward a goal.[46] When disassembled, the aspects of EF generally include attentional control, response inhibition, planning and problem solving, working memory, and cognitive flexibility (see Table 25.1). Put simply, EF appears to be the capacity for an individual to control their actions and thus, is a theoretically pertinent attribute to help bridge the IBG.

25.3.3.2 Review

First, the EF capacity of an individual might determine the strength of the connection between intention and behavior. For example, Hall and colleagues investigated the relationship of attentional/inhibitory control and intention for vigorous PA and FV intake.[52] Such measures, (e.g., Go/No-Go task), "predominantly tap one facet of executive function that may be particularly pertinent to behavioral self-regulation: the ability to suspend prepotent responses to external cues."[52] Clinically, such suspension of cues, thoughts, or actions that have been ingrained over time could be very helpful when overriding unhealthy habits to allow healthier choices.

Based on results from the Go/No-Go task, participants were classified as having either strong or weak EF (i.e., attention/inhibitory control). Those with low intention to increase PA or FV intake did not augment behavior regardless of their EF categorization. In other words, when someone has low intention to change, whether they have strong or weak attention/inhibition, there was no increased consumption of FV or minutes of PA. Only those with both high intention strength and strong EF scores bridged the IBG with an increase in PA and FV intake.

In another study, Hall and colleagues[53] investigated the role of EF with a sample of postmenopausal women undergoing a self-regulation enhancement intervention of implementation intentions (discussed earlier). They found that higher EF capacity in areas of inhibitory control, working memory, and task switching (i.e., subconscious ability to shift attention between one task and another) was associated with an increased ability to employ the self-regulatory strategy, which led to higher self-reported PA. In corroboration of these findings, poorer inhibitory control is associated with higher saturated fat intake, whereas higher working memory was found to be associated with greater FV consumption.[54]

However, inhibitory control has not been consistently associated with health behaviors. For example, Wong and Mullan reported that inhibitory control was not related to breakfast consumption.[55] Wong and Mullan did report, however, that abilities to plan and problem solve, as measured with the Tower of Hanoi task, moderated the IBG for those with low intention. Thus, breakfast consumption was not shown to be due to a deficit in inhibitory control; it is, instead, related to an individual's capacity to plan. However, these data on breakfast consumption indicate that some behaviors might be pliable through some aspects of EF rather than others, even within the same category of behaviors, such as healthy eating (i.e., breakfast consumption vs. increasing FV).

Like inhibitory control, planning and problem solving have proposed implications for healthy behaviors in that

TABLE 25.1
Common Executive Functions and Their Definitions (with Citations)

Executive Function	Definition
Attentional Control[47]	The ability to willfully direct one's focus on a given topic/subject
Response Inhibition/Inhibitory Control[48]	The ability to stop dominant or prepotent responses
Planning[49]	The formulation, evaluation, and selection of a sequence of actions to achieve a desired outcome
Problem Solving[50]	The procedure of deriving solutions to complex issues
Working Memory[48]	A limited capacity system that is responsible for manipulating and holding temporary information, especially when new information is presented
Cognitive Flexibility[51]	Ability to adapt to face new and unexpected conditions in the environment

greater inhibitory control and/or greater capacity for planning and problem solving should lead to a higher probability of follow-through of health behaviors. "The ability to plan efficiently may be especially useful in health-protective [behaviors], for example setting aside time to prepare meals, and making plans to exercise."[55] Norman and Conner reported that one's self-reported ability to plan was positively associated with exercise frequency in younger and older men and women.[56] Reuter and colleagues used a volitional planning intervention within an ongoing employee health promotion program.[57] Participants were asked to plan by simply writing down "when, where, and how you will eat five portions of fruit and vegetables a day," which led to increased FV intake one month later.

However, the results of planning as a moderator are rather ambiguous, with other investigations reporting null findings regarding PA.[58,59] Luckily, the research is relatively nascent regarding the different facets of EF as they relate to healthy behaviors. More investigation is warranted to further clarify the relationship of some aspects of EF with certain health behaviors. One could hypothesize that some EFs are more intuitively related to certain endeavors than others. For example, the ability to pass on donuts at the office could be related to inhibitory control. Planning/problem solving could be related to scheduling a week with sufficient time to attain 150 minutes of moderate exercise. However, there could be overlap. Proper planning/problem solving could mitigate the desire to even eat a donut, as in the case when an individual eats a breakfast filled with numerous fibrous fruits and vegetables, which helps control their blood sugar, subsequently leading to an attenuated hunger response.

25.3.3.3 Practical Application

For the practitioner, it is important to have a sense of a patient's EF capacity. If a practitioner was so inclined, they could download a free software that offers numerous EF-related tests from http://pebl.sourceforge.net/. Many of the tests only take a few minutes to administer, the software is relatively user-friendly, and the results are generally simple to interpret. However, computerized tests are not compulsory to assess EF capacity. There are a few questionnaires that can provide a quick assessment concerning where an individual lies on the EF capacity spectrum, such as the Web-Ex[60] and the EF index.[61]

Also, it is possible for EF to be improved. Computerized, home-based interventions have been successful for improving EF in long-term breast cancer survivors.[62] Acute exercise, chronic exercise, and plant-based diets also improve EF in a host of ages.[63–66] Researchers have also found that prayer,[67] tai chi and meditation,[68] positive feelings,[69] self-affirmation,[70] and even a short visit with nature[71] can provide acute enhancement of various aspects of EF and self-control. Alternatively, more Westernized diets and inactivity can negatively affect EF.[72–74] Since unhealthy behaviors can decrease EF, there is concern for a cycle whereby unhealthy actions decrease one's capacity to implement healthy actions, which in turn, can make self-regulation of healthy behavior more difficult.

These ideas are focused on improving EF, which will likely take an extended period of time. Rather, the practitioner should consider how prescriptions could be modified. For example, the Maintain IT model poses that it is essential to link desired health behavior changes to an individual's identity, beliefs, or personal values to achieve success, a process known as *centered identity*.[75] Over time, this process can reduce the patient's reliance upon EF, as enacting the health behavior becomes increasingly routine. However, individuals with lower EF might require more guidance and planning than those with higher EF scores. If EF is a constraint, then it is imperative to configure an individualized plan where EF is not a limiting factor: for example, providing a patient who is weak in planning and problem solving with a simpler food log to self-monitor food intake, as a more complex version might be too difficult. However, if a patient is quite strong in planning, then a more detailed logging plan might be suitable. At this time, such individualized prescriptions are speculative. Nevertheless, as the research continues to provide insight into EF and its role in the IBG, the practitioner can incorporate EF into clinical practice when appropriate.

25.3.4 Emotional Response

25.3.4.1 Introduction

Consider doing a behavior that you believe will produce negative or adverse feelings. Would this anticipation affect your intention? Intention does not predict behavior as well when a strong affective component (i.e., feelings) is present.[76] Theoretically, an anticipation of the feelings that a behavior might produce could influence one's intention to perform that behavior. This assumption is behind "anticipated affective reactions" (AAR) or the positive affect (e.g., exhilaration) or negative affect (e.g., regret) that is anticipated to follow performance or non-performance of a behavior.[77, 78] AAR is considered an emotional dimension of attitude (see TPB)[79] but is proposed here with a possible role in moderating the IBG.

25.3.4.2 Review

Conner and colleagues put this possibility to the test. They found that when intentions to perform various health behaviors (e.g., eat five fruits/vegetables a day, exercise regularly, use sunscreen) were based on anticipated affective reactions to those behaviors,[77] "[i]n other words, the stronger the correlation between the feeling of regret associated with performing the behavior and intention, the more likely that intention was to predict health behaviors."[77] These findings corroborated an earlier review, which found that the anticipation of negative affect following a behavior (or not performing a behavior), such as regret, worry, tension, and anxiety, was a significant correlate ($r_+ = 0.43$) with intention and predictor of an additional 7% of the variation in intention beyond TPB variables ($R^2\Delta = 0.07$).

Regret, in particular, has similar support for other health-related behaviors.[80,81] A more recent study found that anticipated regret was a significant correlate of COVID-19 vaccination intention.[82] This study analyzed both *inaction regret*, regret for *not* getting the COVID-19 vaccine, and *action regret*, regret *for* getting the vaccine. Inaction regret was positively correlated with intention ($r = 0.82$), and action regret was negatively correlated with intention ($r = -0.42$). It is currently unknown whether action or inaction regret might better moderate the IBG. Although a wealth of research has been conducted over the IBG within PA and dietary behaviors, there is still much to be learned about the IBG and vaccination. Brewer and colleagues have provided a clear overview of the hypothesized relationships between anticipated regret and health behavior (Table 25.2).[80]

Abraham and Sheeran manipulated anticipated regret by having participants in an experimental condition focus on it through answering an anticipated regret item, "Would you regret it if you did not exercise in the next two weeks?"[83] Participants were then asked about their intention to exercise over the following two weeks. A control group was asked their exercise intention and then their anticipated regret. Those in the experimental condition had nearly double the intention ($M = 6.18$ on an 8-point scale) as the control group ($M = 3.67$). In this way, anticipating regret, a negative feeling, had a positive effect on intention when made salient before exercise intentions were considered. The authors conclude that highlighting anticipated regret in relation to not exercising could enhance future interventions.

Similar results could be achieved in the FV domain, as a brief, leaflet-based motivational intervention of implementation intentions with anticipated regret (of not meeting daily recommended intake of FV) was able to predict intention to meet the intake of FV but was not related to FV intake.[84] However, Godin and colleagues found that anticipated regret was positively correlated with FV consumption ($r = 0.34$) and intention ($r = 0.59$) in a sample of adult men and women classified as obese.[13]

Although receiving little attention in the literature, negative anticipated affect or negative affective responses to healthy behaviors could theoretically reduce intention. For example, I have heard negative anticipatory response with both whole food, plant-based diets (e.g., "It will taste like cardboard and grass") and exercise (e.g., "It will hurt me," or "It will be boring"). Also, if I try the healthy meal, and I do not enjoy it, then my intention might be lower to try another healthy meal in the future. Similarly, if I respond to a bout of exercise in a negative way, then I might have less or no intention to try it again. Such responses are very feasible, as the affective and exercise relationship has been examined for decades,[85] and the affective response using the single-item Feeling Scale (very bad to very good)[86] to a single bout of exercise in sedentary adults was able to predict their physical activity level 12 months later.[87]

The exercise–affect relationship might help explain how exercise intensity could moderate the IBG. For example, Rebar and colleagues found that it takes more intention to follow through with vigorous-intensity physical activity than with moderate-intensity activity or walking.[88] This could be due to numerous reasons, one of which could be the physical demands of and affective responses to more vigorous forms of physical activity. However, for the practitioner, this distinction could be helpful. As the authors state, "The results of this study suggest that focusing on activities of lesser intensity may help bridge the intention-behavior gap, thereby potentially enhancing the effectiveness of intention-enhancing physical activity intervention."[88]

25.3.4.3 Practical Application

In summary, anticipated affective responses to performing (or not performing) a behavior have been shown to predict intention across multiple health behaviors, including PA and FV. Practitioners, then, should consider assessing and highlighting perceived regret, in particular, within their patient interventions. As previous authors suggested, "[I]f we want to help individuals act on their intentions then promoting greater correspondence between intentions and underlying anticipated affective reactions to the target behavior, may be a useful approach."[77] In support, Brewer and colleagues conclude that anticipated regret should be a standard variable assessed in studies of health behaviors.[80] They also offer that anticipated regret should be measured with the following guidelines:

TABLE 25.2
Hypothesized Relationships between Anticipated Regret and Health Behavior

Anticipated regret of	
Action	**Inaction**
Discourages health behavior *Example*: anticipated regret of vaccination (if it led to side effects) discourages vaccination.	Encourages health behavior *Example*: anticipated regret of not getting the flu vaccine (if the person later got the flu) encourages vaccination.
Discourages risk behavior *Example*: anticipated regret of smoking (if it caused cancer) discourages smoking.	Encourages risk behavior *Example*: anticipated regret of not trying cigarettes (if it led to being shunned by friends) encourages trying cigarettes.

Source: Recreated from Brewer, N.T., et al., *Health Psychol.*, 35(11), 1264–1275, 2016.

1. Specify a negative consequence of the action or inaction.
2. Assess regret of the action or inaction but not the health consequence.
3. Examine only anticipated regret without also assessing other expected negative emotions.
4. Have separate subscales for action and inaction.
5. Include multiple items in each subscale, if possible.

They also provide an example item that would meet the first three criteria: "Imagine that you had an abnormal Pap test, but the HPV vaccine might have prevented it. How much would you regret that you did not get the HPV vaccine?"[80]

It is also important to manage emotional states so that a patient will stick with a prescription. The practitioner might ask the patient about their anticipated expectancies and feelings surrounding the lifestyle prescription. The prescription can then be modified to encourage positive feelings, feelings of self-efficacy, or even anticipated regret, depending on the specific behavior. Making prescriptions without consideration of the anticipated feelings of the patients, for both new behaviors and past behaviors they are being asked to do again, could be detrimental and ineffective in increasing intention and bridging the IBG.

25.4 SUMMARY

A phenomenon exists where intention to perform healthy behaviors does not translate into behavior, called the "intention–behavior gap." Patients are faced with a challenge of (1) building intention to initiate healthy lifestyle behaviors and (2) acquiring the self-regulatory abilities to follow through with their intention. Unfortunately, left alone, most patients will succumb to the intention–behavior gap, frustrating themselves and the practitioners who desire to help them succeed with lifestyle medicine prescriptions. This chapter provided initial insight into how the practitioner and the healthcare team can play a key role in helping bridge the intention–behavior gap with their patients, such as the use of action and coping planning, building self-efficacy, or identifying anticipated affective responses (e.g., regret). An awareness and better understanding of the intention–behavior gap allows modification of lifestyle prescriptions and development of practice models that maximize lifestyle adherence when lifestyle is the medicine.

CLINICAL APPLICATIONS

- Action and Coping Planning
  - Instruct the patient to write down how they plan to exercise, where they plan to exercise, and when they plan to exercise. This can also be done in regard to more healthful dietary choices.
  - Assist the patient in formulating coping plans to help clarify, specifically, how they will deal/cope with upcoming problems, such as how to still exercise on a rainy day.
- Self-Efficacy
  - The practitioner should consider the common determinants of perceived self-efficacy in their patients. This can be done by using peer models, giving frequent and focused feedback, and also encouraging accurate attributions.
- Capacity
  - Test the individual's EF and determine where they fall on the spectrum. Individuals with lower EF may require more guidance and planning than those with higher EF scores. If EF is a constraint, then it is imperative to configure an individualized plan where EF is not a limiting factor.
- Emotional Response
  - Practitioners should consider assessing and highlighting perceived regret, in particular, within their patient interventions.
  - The practitioner might ask the patient about their anticipated expectancies and feelings surrounding the lifestyle prescription. The prescription can then be modified to encourage positive feelings, feelings of self-efficacy, or even anticipated regret, depending on the specific behavior.

26 Cognitive-Behavioral Change Approaches to Enhancing Physical Activity Participation and Decreasing Sedentary Behavior in Adults

Barbara A. Stetson, PhD and Patricia M. Dubbert, PhD

KEY POINTS

- Systematic evaluations of the use and effectiveness of behavior change techniques in physical activity interventions support the value of basic cognitive and behavioral strategies for promoting and maintaining physical activity.
- Wearable activity trackers are popular and effective interventions and are likely enhanced with goal-setting and self-monitoring strategies.
- High quality internet-based physical activity information and motivational materials have the potential to reach high-risk groups previously underrepresented in health promotion efforts. Online and social media physical activity interventions using cognitive-behavioral strategies may not be sufficient on their own to sustain activity gains over time.
- Structured telephone contacts and smartphone apps providing activity prompts can be effective, particularly when the content and timing of messaging are personalized to address individual preferences and other factors such as physical and emotional status.
- Sedentary behavior is distinct from moderate and vigorous activity, and assessment benefits from objective measurements. Interventions have been most successful when specifically targeting sedentary behavior rather than combining this with efforts to also target physical activity increases.
- Physical activity interventions can have a wider and more representative reach by planning recruitment and interventions across gender, income, and racial/ethnic groups, considering barriers to engagement, community access, and neighborhood settings along with behavior change approaches.

26.1 INTRODUCTION

Numerous reviews and meta-analyses of the research literature have now confirmed the results of many individual clinical trials demonstrating that interventions can increase physical activity (PA). In recent years, evidence has also begun to accumulate on interventions designed to decrease sedentary behavior (SB) as a related but separate and significant health concern. These reviews of PA and SB interventions have contributed to increasingly specific understanding of optimal approaches for promotion of PA and SB behavior change and maintenance, including which techniques and conditions might be effective,[1,2] by whom,[3] and for whom,[4,5] as well as identifying key areas in need of future research.[6, 7]

In this chapter, we will provide an overview of frequently used cognitive-behavioral interventions for increasing PA and decreasing SB at the individual level. Our purpose is to identify intervention approaches that have consistently shown efficacy in promoting PA and in attempts to reduce SB. We also include discussion of the influence of emerging technologies on PA assessment and interventions and recent attempts to increase the diversity of participants and to enhance community outreach in this area of scientific inquiry. We do not attempt to provide another critical review of the literature, since timely reviews are already available for the interested reader.

26.2 OVERVIEW OF EFFECTIVE COGNITIVE-BEHAVIORAL CHANGE APPROACHES TO PHYSICAL ACTIVITY INTERVENTIONS

The "behavioral" and "cognitive" interventions we use today for promoting physical activity (PA) and decreasing sedentary behavior (SB) are derived from experimental psychology and theories of behavior change. Behavioral intervention methods are characterized by a focus on specific observable behavior and factors that can be manipulated to influence the behavior that is the target of change. Cognitive interventions focus on changing the cognitions that are thought to facilitate or hinder behavior and rely on verbal or written reports to assess the otherwise unobservable events. Different cognitive-behavioral theories, such as Social-Cognitive Theory, the Transtheoretical Model, and

DOI: 10.1201/9781003227793-30

the Theory of Planned Behavior, attempt to explain how cognitions influence behavior and how factors from different levels (such as individual biology and learning experience as well as physical and social environments) influence cognitions and behavior. Most successful health promotion behavior change intervention programs today are based on one or more cognitive-behavioral theories and use a combination of behavioral and cognitive change methods.[8] Table 26.1 shows examples of some frequently used methods in PA promotion. While early studies of behavioral and cognitive interventions to promote healthy PA often focused on only one or two methods, many interventions used today have several components designed to complement each other and produce stronger and more sustainable effects.

Reviewers have used different approaches to attempt to identify which cognitive-behavioral interventions and combinations of methods produce the best results. A systematic review of 129 analyses of intervention components for diet and PA found that specific goal-setting, feedback on performance, use of prompts to be active, and individual tailoring via provision of information or counseling were all associated with greater PA intervention effectiveness.[9] Another study used a meta-analysis of PA interventions, including more than 100,000 healthy adult participants,[10] with a wide variety of interventions and experimental designs in both published and nonpublished studies. Findings were similar to the previous review: goal-setting, contracting, self-monitoring, and using cues or rewards were effective interventions; they also revealed demographic limitations of the literature, as the vast majority of participants were middle aged, female, and only rarely ethnic minority. Conclusions from the expert review of PA intervention research for the 2018 PA public health guidelines[7,11] were also consistent with previous reviews, i.e., that commonly used theory-based intervention components such as self-monitoring, forming intentions or goal-setting, demonstrating or modeling PA, changing the environment to facilitate PA, and rewards for behavior change are effective for increasing PA. The expert reviewers also emphasized that PA interventions can be effectively delivered using a variety of methods, including face-to-face individual and group sessions, by phone, and through internet programs, as well as in a wide variety of settings.

The recent development of taxonomies and coding systems related to behavior change techniques has facilitated comparison of intervention components[12] across studies of PA and SB interventions.[13] A recent large-scale systematic review and meta-analysis examined PA and SB interventions for behavior change *and maintenance*[14] in randomized controlled trials and made use of these state-of-the-art methods, including the Behavior Change Technique (BCT) Taxonomy,[12] for evaluating active intervention ingredients using standardized definitions and descriptions. Additionally, to evaluate aspects of the interventions such as delivery mode, treatment delivery (and fidelity), duration, and frequency, the researchers used the Template for Intervention Description and Replication (TIDieR), a checklist detailing the intervention delivery approaches.[15] Also of note, studies included in the review were conducted in a diverse representation of countries, and intervention providers were mixed, most frequently an instructor or student interventionist. The most common intervention settings were primary care, exercise facility, or mail delivery. Theoretical approaches varied, with the Transtheoretical Model used the most. A wide range of contact frequency and duration was observed, ranging from 1 print contact to 33 sessions over 14 months (mean length 21 weeks). Unfortunately, only 12 of the 26 studies reported ethnicity, with three-quarters of those reporting a majority of White participants.[13] The most frequently reported behavior change techniques were goal-setting behavior and social support. Immediate post-intervention PA data suggested that participants randomized to intervention conditions had significantly more PA compared with control participants, with interventions yielding improvements ranging from 606 to 1,849 steps per day and from 31 to 247 minutes of PA per week. Evaluation of follow-up data indicated that participants randomized to interventions continued to engage in more PA, but the effect was smaller, with follow-up improvements ranging from 421 to 1,370 steps per day and from 5 to 95 minutes of PA per week. Intervention effectiveness for PA maintenance was associated with the presence of BCT Taxonomy–indicated use of action planning, specific performance instruction, use of prompts/cues, behavior practice and rehearsal, graded tasks, and self-rewards.[13] Only one of the studies reported intervention treatment fidelity; the authors accordingly highlighted this as an important need in future examinations of PA intervention approach effectiveness.

The reviews mentioned in this section are only a few among many supporting the value of basic cognitive-behavioral strategies in promoting PA. Emerging standardized taxonomies for comparing and summarizing evidence across studies will facilitate future reviews and meta-analyses. Improvements in future clinical trials of PA and SB interventions are likely if they include evaluation of adherence to intervention protocols (fidelity), adequate sample sizes, representation of diverse ethnicities and racial groups, complete sets of findings, and testing of different theoretical frameworks and cognitive approaches.

26.3 TECHNOLOGY IN PHYSICAL ACTIVITY MONITORING AND INTERVENTIONS

26.3.1 Activity Monitoring

Accurate information about performance is an essential component of many theory-based cognitive-behavioral change strategies, and the rapidly expanding access to technology for physical activity monitoring is now a major influence on current cognitive-behavioral PA intervention programs and research. Widespread adoption of wearable devices and mobile apps to promote PA is extending our knowledge of the benefits of self-monitoring on PA and

TABLE 26.1
Examples of Cognitive-Behavioral Methods in PA Promotion

METHOD	DEFINITION (excerpted/adapted from BCT Taxonomy[12])	EXAMPLE
Goal-setting	Set or agree on a goal defined in terms of the behavior to be achieved	Set a goal to walk in the neighborhood for 30 minutes
Action planning and intention formation	Detailed planning of performance of the behavior (must include at least one of context, frequency, duration, and intensity)	Plan to walk at a moderate pace in a nearby park for 30 minutes at lunchtime 4 days a week
Monitoring	Observe or record behavior with the person's knowledge as part of a behavior change strategy	Record attendance at a cardiac rehabilitation program group exercise classKeep a daily paper and pencil diary of exercise completedReview step count data displayed by a fitness smartwatch
Self-monitoring	Establish a method for the person to monitor and record their own behavior(s) as part of a behavior change strategy	
Feedback	Monitor and provide informative or evaluative feedback on performance of the behavior *(e.g., form, frequency, duration, intensity)*	Personal trainer reviews with client details of how performance has changed during past monthReceive notifications on a mobile phone or other device when specific activity goals have been accomplished
Biofeedback	Provide feedback about the body *(e.g., physiological or biochemical state)* using an external monitoring device as part of a behavior change strategy	Wearable device vibrates to indicate a target activity heart rate has been reached
Prompts or cues	Introduce or define environmental or social stimulus with the purpose of prompting or cueing the behavior. The prompt or cue would normally occur at the time or place of performance	Leave exercise shoes in front of the door as reminder to walkDog barks and looks expectantly at the door at usual walking timeSign near stairs encourages walking upstairs rather than taking the elevator
Behavioral practice/ rehearsal	Prompt practice or rehearsal of the performance of the behavior one or more times in a context or at a time when the performance may not be necessary, in order to increase habit and skill	Practice a yoga pose guided by instructor
Graded tasks	Set easy-to-perform tasks, making them increasingly difficult, but achievable, until behavior is performed	Weight training program begins with light weights and gradually progresses over time to heavier weights and/or more repetitions
Social support	Advise on, arrange, or provide social support *(e.g., from friends, relatives, colleagues, buddies, or staff)* or non-contingent praise or reward for performance of the behavior. It includes encouragement and counseling, but only when it is directed at the **behavior**	Arrange to meet a friend to exercise togetherForm a group of work colleagues who will encourage each other to interrupt sedentary work with brief activity
Instruction on how to perform the behavior	Advise or agree on how to perform the behavior	Recommendations for exercising safely and effectively are provided on a government website for persons with osteoarthritis
Demonstration of behavior/modeling	Provide an observable sample of the performance of the behavior, directly in person or indirectly, e.g., via film or pictures, for the person to aspire to or imitate	Fitness instructor bikes with class
Rewards, material reinforcement	Arrange for the delivery of money, vouchers or other valued objects if and only if there ***has been*** effort and/or progress in performing the behavior	Fitness program gives participants a tee shirt upon completion of a specified goalHealth insurance program offers monetary incentives for participants who report regular exercise for a specified period of time
Social reward	Arrange verbal or non-verbal reward if and only if there ***has been*** effort and/or progress in performing the behavior	Fitness instructor praises class members who bring their exercise diaries to the class
Self-rewards	Plan to reward self in future if and only if there has been effort and/or progress in performing the behavior	Purchase a new workout outfit after completing a workout at the fitness center
Problem-solving	Analyze, or prompt the person to analyze, factors influencing the behavior, and generate or select strategies that include overcoming barriers and/or increasing facilitators	Examine activity data for patterns that may help understand successes and failures to meet goals

creating opportunities for novel and highly individualized interventions.[16]

Modern pedometers, with their electromechanically based systems, are easy to use, still relatively inexpensive, and can produce objective, reliable, and valid estimates of normal gait walking–related PA.[17]. More technologically sophisticated activity trackers now available for research and commercially to the public offer many advantages and features that are engaging for wearers and valuable for researchers, including the ability to detect both PA and SB and activity intensity from light to vigorous, assess lateral and vertical movement, accumulate data over time, and provide in-the-moment as well as cumulative feedback.[2] Some trackers also have a GPS location capability built in or when linked to a smartphone. Validation studies consistently indicate that most commercially available trackers compare well for accuracy with research-level activity monitors and direct observation.[16]

A carefully conducted study with research-quality accelerometers found that total activity counts (TAC) as well as activity meeting criteria for moderate and vigorous intensity PA (MVPA) correlated significantly with more favorable levels of a variety of cardiometabolic and endocrine biomarkers in a sample of more than 500 women.[18] The correlations were attenuated but not eliminated by including self-reported PA in the statistical models. This result is what is expected if accelerometer data are a more accurate assessment of the activity that influences the biomarkers. Importantly, several more recent studies and a meta-analysis have found significant linear associations between higher daily step counts and all-cause mortality in a variety of populations. [19,20] In the meta-analysis, the association of steps per day with mortality was observed to vary by age: for those under 60, the association was attenuated after 8,000–10,000 steps per day, and for those 60 and older attenuated at 6,000–8,000 steps per day. Analyses of activity intensity measured by steps per minute showed association with mortality in some, but not all, studies.[20]

A 2022 study that followed 4,838 older women (average age 78.9 years) for 7 years to assess their walking PA and health risks[21] found that for every 1,000 steps per day added, there was a 6% lower incidence of developing diabetes; the relationship was stronger for MVPA steps than for light intensity steps per day. Interestingly, body mass index (BMI) was not a significant mediator of the association between steps and diabetes.

Another recently published meta-analysis examined the important question of the effects of interventions using accelerometers on PA and weight loss.[2] Data from 14 clinical trials were analyzed for PA and from 11 trials for weight loss; both sets of analyses showed small but significant positive effects. The authors noted that there was substantial variation among studies; qualitative findings suggested that effects were greater when the interventions included stronger emphasis on using device-driven feedback. The results suggested diminishing effects of accelerometer use over time, which would be consistent with other types of self-monitoring research. Another finding of note was that the results did not suggest accelerometers produced better effects than simple pedometers; this finding is encouraging for interventionists concerned about using the simplest and least expensive tracking devices.

Commercially available activity trackers are generally well liked by users, despite some technical issues,[22] but the accuracy of their data varies among models and is affected by where they are worn on the body and the gait of the user.[23,24] One validation study[25] found that although daily counts between a commercially available and a research tracker did not agree, over seven days, the results for active minutes were comparable. Another[26] found strong correlations between a commercial tracker and a research-quality tracker, but the commercial tracker tended to overestimate step counts. Health and fitness professionals who are evaluating activity using commercially available trackers should not rely on only a single day's data; users should consider at least one week's data and be aware that actual activity may be less than that indicated by a commercial tracker for healthy people and greater for those with slow or impaired gaits. Reviewers[9,27] agree that the use of activity trackers is an effective intervention for increasing physical activity but have noted that many of the interventions also included goals related to steps and/or diaries, highlighting the self-monitoring aspects of activity tracker use and the likely importance of coupling monitoring devices with goal-setting strategies in order to achieve optimal results.

26.4 COMPUTER AND WEB-BASED INTERVENTIONS

The rapid increase in the use of web-based interventions for PA promotion during the past two decades is not surprising given the many potential advantages, including the convenience of access at almost any place and time by large numbers of participants who may live far away from the original source, opportunities to utilize multimedia components, cost savings when interventions are based on interaction with computer algorithms rather than paid professionals, and the anonymity and self-paced nature of websites. A review of early studies (published before 2010[28]) concluded that web-based formats were feasible and engaging and yielded success rates similar to those of more traditional methods such as print and telephone outreach, although some studies noted greater satisfaction with some face-to-face content.[29] Examples of free, high-quality PA promotion intervention materials that utilize cognitive-behavioral approaches can be found on the websites of the United States Centers for Disease Control and Prevention and the National Institutes on Aging. Browsing these websites, any interested consumer can read and print PA information and motivational materials, watch videos of age-appropriate exercise, and use interactive PA tracking tools. It should be noted that these websites are now attempting to be more inclusive of at-risk groups that have often been underrepresented in health promotion efforts;

for example, most materials are available in Spanish as well as English, and the National Center on Health, Physical Activity, and Disability has a YouTube channel dedicated to exercise at home videos.[30]

Much of the research on web-based interventions is now focused on trying to answer more specific questions of how to reach and optimize PA interventions for population groups differing in characteristics such as age, culture, and health conditions. These research directions should in the future provide helpful guides to building acceptable and effective intervention programs for diverse groups, but at the present time, there are too few studies within specific groups to allow more than preliminary conclusions. For example, a review and meta-analysis including 11 studies[31] examined the use of web-based distance physical rehabilitation interventions on PA and walking in persons with multiple sclerosis. The analyses showed large positive effects for interventions using the internet, telephone, exergaming, and pedometers compared with no treatment, but the amount of data was too small to determine whether there were differences in effectiveness between these methods.

As noted earlier, cognitive-behavioral theories highlight the importance of goal-setting and some type of monitoring and performance feedback. Many web-based interventions depend only on self-reported data from users, but a group of Australian researchers[32] conducted a study to determine whether the effects of a web-based PA promotion intervention with no face-to-face contact would be improved by adding objective performance data using Fitbit trackers. After 3 months, the Fitbit users had greater increases in MVPA (163 vs. 77 minutes/week). They also completed more of the web modules and gave the website higher ratings than the control users. Other researchers have reported similar findings of stronger results when objective PA measures are used to evaluate performance.

26.5 MOBILE PHONES AND DEVICES

With even greater accessibility than computers, mobile phone messaging and apps are now increasingly used for interventions across a variety of preventive behaviors. Careful reviews of clinical trials using texts and/or apps indicate that texting can increase activity in adults in the short term,[33,34] but the effects in some projects have been disappointing. For example, a large, randomized control trial that offered free text messaging to deliver health-related information to pregnant women (Txt4baby) included an evaluation of the effectiveness of PA promotion messaging.[35] Inactive pregnant women were randomly assigned to one of four groups differing in dose and timing of messaging, and PA was measured using Fitbits. Unexpectedly, no increases in PA were observed regardless of message frequency or time, and participants who received the highest number of messages (six per week) unexpectedly had greater decreases in PA and increases in sedentary time. The authors concluded that "more is not better," that the frequency of messaging might have been aversive, and suggested that future interventions may need to incorporate more choice, utilize more behavioral strategies, and focus more on self-efficacy and beliefs.

A review of nine studies of smartphone apps that used steps or minutes of MVPA per day as outcomes[36] reported that the experimental interventions ranged from six weeks to six months in duration and included features such as PA performance summaries, goal achievement, and motivational prompts; some also included social comparisons and text messages. Steps per day increased in six studies, but the two studies looking at MVPA did not find significant differences favoring the app. Sensitivity analyses suggested the best results were for the short term (less than three months) and for interventions that targeted PA alone. Another review and meta-analysis of 11 studies[37] that compared a PA intervention app with no treatment or a more traditional intervention also found that the apps helped produce better short-term results in steps per day, but the authors noted that the quality of the research was generally low.

According to cognitive-behavioral theories, prompts or cues should increase behaviors, so researchers are exploring how both the content and timing of mobile messaging may need to be personalized for better results. One recent study[38] tested three kinds of messages (prompt to move more, prompt to sit less, or an inspirational quote) and different message frequencies from zero to six per day. Responses, measured by step counts, were quite varied between individuals, differed on weekdays versus weekends, and there was no "average" best combination. "Move more" and "sit less" messages generally had a greater effect on warm than on cold days, but this was not true for all participants. Optimal tailoring of messaging for individuals may be very complex, but as technology and understanding of key factors advance, might in the future not only include personal variation in the timing and content of mobile interventions, but also take into consideration factors that vary from day to day and from time to time, such as pain level, emotional state, and reactions to meeting or failing to meet exercise goals.[39]

Health professionals and interventionists desiring to use smartphone apps to promote PA should keep the limitations noted by researchers in mind and also be aware that the quality of apps is highly variable.

26.6 SOCIAL MEDIA

Online social networks offer a unique vehicle for PA intervention, and interventionists have utilized Facebook, Twitter, WeChat, and other programs widely available to consumers as well as study-specific platforms.

To date, reviews of attempts to use social media for increasing PA indicate that additional studies are needed to improve the effectiveness of the interventions. One review of 53 intervention studies using social media[40] found that only one-third reported positive effects on PA; two more critical reviews also found limited success for these interventions when compared with controls.[41, 42] These results

are consistent with other studies suggesting that the online and social aspects of social media PA interventions in tandem with known tools of self-monitoring and goal-setting can be engaging and effective for increasing activity, but that effects of PA interventions using social media that have been tested thus far are typically small and are not sustained over time.

26.7 EXPANDING THE TARGETS OF ACTIVITY PROMOTION: ASSESSING AND TARGETING SB

Accumulating evidence suggests that SB is distinct from a lack of MVPA, and studies increasingly examine MVPA, inactivity, and SB separately.[43] Examples of SB often examined in the research literature include screen time (e.g., computer use, television viewing), video games, time spent in transportation, and reading;[44] SB measurement has yet to catch up with the rapid growth in use of tablet and mobile devices with screens.[45, 46] There are also a number of components of SB that require separate examination in relation to health impact and intervention potential, including total sedentary time, durations of sedentary bouts, and frequency and duration of interruptions. Self-report measures of SB have been used in assessment and interventions studies[47] and may provide useful information, but objective measures such as accelerometers and inclinometers are probably necessary to accurately capture time spent engaging in. and patterns of, SB.[43]

Some intervention studies have attempted to focus on both decreasing SB as well as increasing PA. Overall, those focused specifically on SB seem to have been more successful in reducing SB relative to those that have included both foci.[48,49] Studies also differ in whether the intervention aimed to reduce time spent in sedentary activities or targeted breaking up periods of sedentary time, such as by providing prompts to stand up or and move after periods of sedentary time. A systematic review of *non*-worksite interventions to reduce SB (targeting sitting time and/or breaks in prolonged inactivity[50]) found that a combination of self-monitoring and technological feedback may be useful SB reduction strategies; however, providing real-time SB feedback using technology without other interventions may not be enough to change SB patterns.[51,52]

The majority of interventions for SBs in adults have targeted the workplace. A meta-analysis[53] found successful reductions in both self-reported and objectively measured workplace SB, with an average difference of 91 minutes per day spent in sedentary activities between intervention and control groups.[43] A more recent review of SB interventions and their impact on sitting time and screen time utilized an umbrella review of systematic reviews with both children and adults.[49] All of the reviews of SB interventions in workplaces showed reductions in sitting at work time (39.6- to 100-minute reductions per 8-hour workday). Individual components associated with effective SB changes were environmental changes such as use of sit-to-stand desks and active workstations. The use of active workstations such as sit-to-stand desks, treadmills, and portable pedal machines has been evaluated in a wide range of settings; a recent meta-analysis found that 14 of 15 studies reported significant changes in SBs.[54] Point of choice prompting technology to take standing breaks or get up and move (via prompting wristwatches or computer prompting software installed onto desktops) has also been reported.[54] Most of the interventions were shorter than 90 days in duration, so the maintenance of reductions in SBs in the workplace over time is unclear. The degrees to which roles of employer or coworker support or internal versus external factors influenced behavior change in these worksite settings are also unknown and important areas for further exploration, since social support and monitoring have independently been shown to influence PA.

Gardner and colleagues reviewed behavior change strategies used in published SB reduction interventions with adults.[55] Twenty-six studies and 38 interventions (53% worksite-based) were coded for use of discrete behavior change techniques in the interventions, using a BCT Coding Taxonomy.[56] The most commonly used behavior change techniques were goal-setting, provision of social support, adding objects to the environment, and action planning. Intervention approaches were categorized as very promising, quite promising, or non-promising according to the level of SB changes observed. Very or quite promising interventions were more likely to directly target SB rather than PA. The greatest degree of behavior change was noted for approaches that used environmental restructuring education or persuasion techniques. More information is needed regarding effective SB intervention strategies in older adult populations and how to best achieve maintenance of changes in SB over time.

26.8 PHYSICAL ACTIVITY INTERVENTIONS IN RACIAL/ETHNIC UNDERSERVED SAMPLES

Reviews of both PA and SB interventions continue to highlight the need for additional studies that are more representative of the population and extend the evidence base. While lower levels of MVPA are often observed in low socioeconomic status (SES) populations and in individuals from minority racial/ethnic backgrounds, these groups are still underrepresented in PA interventions and evaluations due to inadequate planning and conceptualization of recruitment approaches, barriers to engagement and intervention response, and limited interventions that have been specifically developed for minorities or culturally adapted.[57] Whitt-Glover and colleagues conducted one of the first systematic reviews of interventions to increase activity and fitness in African Americans.[58] The majority of studies were conducted with women. Interventions included community-based approaches such

as delivering the intervention in community settings such as the YMCA, community centers, church, worksites, and public housing projects. Cultural adaptations were included in many of these studies, for example, a church setting, activity instructors from the African American community, gospel, soul and hip-hop music and dancing, and incorporated prayer. The culturally adaptive methods of intervention were frequently paired with familiar behavior change approaches, including monitoring, use of pedometers, peer phone contacts, supervised exercise sessions, and social support via group walks in the local neighborhood. The multiple approaches and study design limitations made it difficult to evaluate the specific influences of these culturally tailored approaches. However, examination of findings from individual studies indicates that common factors associated with the effectiveness of individual studies of PA interventions in African Americans are similar to those noted in previous reviews of PA interventions, such as using a randomized controlled trial design, assessing PA using an objective measure, providing specific PA goals to participants, and including structured activity programs.

A recent systematic review and meta-analysis reviewed randomized controlled trials of behavior change interventions targeting men's PA, considering both pre-post intervention changes in PA and sustained change at a year or longer.[59] This review considered 24 eligible studies with men only and those in which the data was disaggregated by sex. Findings indicated a PA intervention effect size that is consistent with approximately 980 steps per day and an increase of 97 minutes of total PA per week. The review found that the moderating factors associated with greater increases in PA included having a gender-tailored design, using a theoretical framework, using four or more behavior change techniques, frequent contact with participants, and a program of ≤12 weeks' duration.

A small adaptation of the Diabetes Prevention Program lifestyle change intervention was developed to target PA in men from underserved communities in New York City.[60] This men-only program, Power Up for Health, integrated individual and community-level approaches. Five New York Park and Recreation sites across Bronx, Harlem, and Brooklyn were randomized to intervention arms, and coaches, participants, and community advisors provided input on programming. The outcome of this pilot program indicated increases in PA, particularly when PA sessions were added to the end of face-to-face education sessions. Stakeholders recommended phone sessions as an option to reduce participant burden.

Family-based PA interventions may also be beneficial for enhancing engagement and benefits for ethnic minority and underserved populations. Project SHINE, a family-based intervention with African American families, originally targeted adolescents using family-based, interactive sessions with PA goal-setting and self-monitoring with session content addressing lifestyle change motivation, sense of belonging, and family communication about maintenance of changes. Community speakers also presented information about norms for African American families.[61] The program had a beneficial impact on adolescent PA behavior. Subsequent follow-up analyses with participating caregivers indicated that they also improved MVPA, while control group caregivers showed decreases in PA.[61]

Promotion of PA in racial and ethnic minority populations has also successfully incorporated cultural values and models by employing ethnically matched health educators and interventionists.[57] Community-based outreach and bridging neighborhood and community approaches with the use of community health workers who are from the target population has also been successful; these *promatoras* have been widely used in culturally sensitive health interventions in U.S. Latina PA promotion efforts.[57,62] Carefully controlled intervention studies are needed to examine the specific influences of culturally adapted PA intervention approaches more thoroughly.

A six-month, culturally adapted, individually tailored, internet-based PA intervention with sedentary, Spanish-speaking U.S. Latinas was successful in increasing MVPA and achievement of national guidelines for PA.[63] Increased MVPA was maintained at a 6-month follow-up, 12 months following the baseline.[64] Acculturation and health literacy were not significant moderators of the impact of the intervention,[64] highlighting the range of participants benefiting from this web-based intervention approach.

An e-health intervention aimed at preventing weight gain in a sample of low-income African American women in a primary care setting used telephone-based interactive voice technology (IVT) for self-monitoring behavior change goals, including walking 10,000 steps/day.[65] This monitoring technology entailed listening to a voice prompt and responding with a simple numerical answer and had the advantage of brief duration, low cognitive demand, and dynamic and immediate feedback messages, without the need for internet connectivity.[65]. Participants' engagement in calls and adherence to weekly IVR monitoring was high and associated with positive study outcomes.

While studies have shown that technology-based PA interventions and different kinds of settings may be helpful in delivery of PA interventions with low-income, minority populations, care must be taken to understand which approaches might provide the best reach and acceptability. In some demographic groups, omnipresent internet access and mobile phone usage makes these modes of intervention delivery ideal; however, technology adoption gaps remain for many lower-income groups. Pew Research data from 2021[66] showed that the percentages of Americans in each tier of income who have broadband at home or own a smartphone did not significantly change between 2019 and 2021. Approximately one-quarter of adults with household incomes below $30,000 reported that they did not own a smartphone, 40% of adults in lower-income groups did not have home broadband, and 43% did not have a home computer or laptop. In contrast, adults living in homes with income above $100,000 owned nearly all of those devices

and were much more likely to have multiple devices. Pew data from 2021 indicated that 27% of adults in low-income households are smartphone-only internet users and used the phone for activities that are intended to be done on larger screens, such as applying for jobs or completing schoolwork.[66] This technology gap has important implications for the development of PA and SB interventions aiming to reach underserved, low-income participants.

The potential reach of home-based resources and community-centered approaches to further impact public health across a wide range of individuals, including those from disadvantaged groups, has led to efforts to translate what is known about effective components and delivery approaches of PA interventions into accessible community settings and dissemination formats. Strategies that appear to be effective for PA promotion in underserved populations include those that are delivered through home, church, or community-based channels, utilize technologies appropriate to the population, include cultural adaptations, incorporate staff or peer interventionists who reflect the community, and take advantage of opportunities for environmental interventions.[57]

26.9 COMMUNITY-WIDE PA INTERVENTIONS

As described in the preceding sections, print, telephone, internet, mobile device, and peer delivery modalities all offer opportunities for reaching a wide variety of individuals who may benefit from dissemination of these supported intervention approaches. A 2015 Cochrane review examined 33 studies of community-wide interventions aimed at increasing PA to evaluate their influence on population-level health;[67] 25 were conducted in high-income countries and 8 in low-income countries. The authors concluded that methodological issues precluded reaching clear conclusions regarding the effectiveness of community interventions; however the methodological review offered instructive information about the types of community interventions that have been conducted and suggestions for future intervention programs and research. A major concern identified in the community-wide PA intervention literature was selection bias, particularly limited use of community comparisons and randomization, and the quality and validity of assessments used to measure outcomes. Despite these limitations, it is encouraging to see that the majority of interventions included establishing partnerships with local government or non-government local organizations. Community strategies generally involved planning initiatives with the aim of producing long-lasting benefits for the community. They also operated at a series of levels to attempt to influence activity, such as environmental changes, policy changes, and use of the media. Some studies found significant increases in the use of community resources such as trails and pathways, indicating that programs reached some segments of the targeted population, but the effects did not translate to changes in the population levels of PA. The review also provides a description of community-level strategies for outreach to many types of disadvantaged groups. Many of the studies included some form of individual behavior change counseling delivered by a health professional, social marketing through local mass media, other communication outreach (posters, flyers, information booklets, websites, maps) to raise awareness of the intervention program and provide specific information, and working within specific settings that might facilitate contact with individuals who have social disadvantages such as lack of transportation and might otherwise be missed by traditional outreach, for example, schools, senior centers, workplaces, community centers, homeless shelters, and shopping malls. Environmental change strategies such as creation of walking trails and partnering with legislative and fiscal leaders to promote planning for outreach to the broader population were also undertaken.

The Cochrane Review[67] also provides a useful overview of the types of recent community approaches and highlights the challenges inherent in attempting to identify key components of effective community-based PA interventions that broadly impact population-level PA. The conclusions noted that many authors of the studies included in the review identified reasons for lack of efficacy as due to being unable to penetrate the community as well as a relatively short intervention duration, limited methodologies, and limited resources. Considering the recognized need for studies of adult PA promotion representing diverse population groups, these types of community-wide intervention approaches offer tremendous potential to promote activity, especially if advances in PA assessment methodologies and in technology use for outreach allow researchers to improve upon study designs and recruitment. More well-controlled evaluations of these approaches are needed and offer challenges for future community-wide PA intervention evaluations. Additionally, careful consideration of the method of outreach to and communication with community stakeholders is needed to ensure that the intended audience has been reached by the intervention and is able to maintain changes in PA over time.

Since the publication of the Cochrane Review,[67] several large-scale community intervention studies have provided information about adoption and maintenance of PA changes over time. A large community study conducted in Japan that showed significant increases in walking across all categories of age, sex, and market segments found that those who had higher cumulative awareness had greater uptake of the intervention.[68] Follow-up evaluations two and five years post a city-wide community PA intervention with 3 independent samples of 3,000 adults found that continued participation over time was challenging and that while PA knowledge was maintained at two years, that did not translate to maintained PA behavior.[69] Moving from a broad approach to targeting a specific population of older adults, and adding specific, manageable goals and self-monitoring tools, improved participation and engagement.[69]

26.10 ENVIRONMENTAL FACTORS IN PA

An additional approach to addressing the needs of the broader community when developing successful cognitive-behavioral PA interventions is to consider the role of the built environment and neighborhood, which has the potential to facilitate or create barriers to behavior change and maintenance. The last decade has produced a body of studies documenting that the physical environment and neighborhood factors play an influential role in PA.[70,71] Reviews have found that neighborhoods that are characterized as walkable (those with mixed land use, such as having homes, schools, workplaces, and areas to shops accessible) can encourage walking to multiple destinations.[70] King and colleagues evaluated both social and built environment influences in the context of PA interventions across five intervention trials.[72] Features of the built environment were assessed with a Neighborhood Walkability Scale. Activity guidelines were more likely to be met by participants living in neighborhoods with more attractive scenery and ease of walking, and traffic safety was related to both facilitating and impeding activity. The role of environment and neighborhood in PA may be a particularly important consideration when developing individual or group interventions for low-income or underserved populations and minority racial/ethnic groups.[73] A multilevel *promatora*-led intervention, aimed at promoting PA in a sample of 319 Latina women recruited from 16 churches, examined the influence of neighborhood environment variables on intervention effectiveness,[74] Participants' perception of their neighborhood esthetics moderated intervention effects on both self-reported leisure time PA and accelerometer-derived moderate to vigorous activity, with those reporting more favorable esthetics benefiting more. The authors of this study noted that less satisfying neighborhood esthetics could be associated with greater poverty and disorder and hinder motivation for PA in this context.

Other studies have reported what may seem to be an unexpected finding, that PA interventions were more likely to help those who perceived more environmental *barriers* to increase their activity. In an examination of two randomized activity trials conducted with similar methodologies and recruitment, Kerr et al. explored the interactions between changes in walking over time, lifestyle PA intervention conditions, and the walkability of participants' neighborhoods.[70] Examination of the interactions between the built environment and interventions revealed that men who resided in less walkable neighborhoods (as assessed with a walkability index) who were in the intervention group significantly increased their walking time, while men who resided in highly walkable neighborhoods decreased their walking over the course of the study. Men in the control condition did not increase their walking time. For women, results showed similar trends, with women living in low walkable neighborhoods who were in the intervention group increasing their walking the most, although results did not reach statistical significance. Women who perceived an unsafe volume or speed of traffic had decreased walking time (22-minute daily decrease), while women who perceived that the traffic in their neighborhood was safer had increased walking time (increased by 17 minutes) over the course of the study. The findings of this study may reflect a ceiling effect of living in a highly walkable neighborhood.

These mixed findings on interactions between built and neighborhood environment highlight the need for additional research to understand these results. Differences in use of self-reported perceptions of neighborhood factors and structured environmental space ratings and noted gender differences in interactions between built environment issues and activity outcomes are intriguing and suggest that personal appraisals of the neighborhood environment are important to consider. Men and women may have different perceptions of, and responses to, changes at the built environment level. The authors observed that one encouraging implication of the study findings is that the pattern of results shows that behavior change interventions can encourage walking even in less supportive environments.

One aspect of the built environment that has been studied for the potential for low-cost PA intervention is the use of stairs in community and workplace settings. The presence of stairs across a variety of settings has offered researchers the opportunity to assess the viability of using simple prompts to promote PA in public settings. A Norwegian intervention study, "Romsas in Motion," used theoretically developed, comprehensive approaches to addressing individuals, groups, and the environment, with tailored strategies accounting for readiness for change in PA in a low-income, ethnically diverse population.[75] PA levels increased, particularly in those with the greatest needs, and simple exposure to low-cost, poster prompts to use stairs and walk an available path was highly effective. A recent systematic review of 50 eligible studies examined the effectiveness of stair-use interventions[76] and found that they increased PA in 64% of worksite and 75% of public settings. Combining directional and motivational signs in worksite settings increased stair climbing by 83%, and conducting a second phase in public settings increased stair climbing by 86%. A quasi-experimental study comparing the use of general and specific stair messages to promote PA found that specific messages were more effective.[69] Future evaluations of this cost-effective approach in tandem with other known influences on PA may further assist efforts to increase PA adoption and maintenance across community settings using low-cost and practical approaches.

Programs that move beyond examining associations between built environment and PA to consider how and when and for whom behavior change intervention techniques promote PA or reduce SB in the environmental context will further our understanding of how to best promote neighborhood and physical environment climates that are conducive to the adoption and maintenance of consistent PA.

26.11 MAINTENANCE OF PA OVER TIME

Several recent studies and reviews have addressed the ongoing question of how to best promote consistent and sustained PA.[7] A systematic review and meta-analysis evaluated the effect of randomized clinical trial PA interventions and the trial strategies on at least six months of PA maintenance in community-dwelling older adults.[77] This review found that while some strategies to enhance PA maintenance were discussed in the individual studies, most were not designed with a focus on PA sustainability. Overall, PA interventions improved time spent in PA relative to control conditions at six months but not at one- or two-year follow ups, with heterogeneous findings regarding specific cognitive and behavioral strategies.[77]

Another recent systematic review and meta-analysis approached understanding PA behavior change and maintenance by focusing on intervention impact on self-efficacy for PA and the maintenance of PA self-efficacy post intervention.[78] The review encompassed 180 randomized trials that reported data on changes in and maintenance of PA self-efficacy. Behavior changes techniques used in the studies were coded using the BCT Taxonomy, and their associations with PA self-efficacy were evaluated. Significant associations were found between the number of behavior change techniques used and PA self-efficacy at the end of the intervention but not for maintained changes in PA self-efficacy. Examination of specific behavior change techniques found that behavioral practice was associated with larger effects for maintenance of PA self-efficacy, while practical social support was associated with lower maintenance of PA, and interventions delivered in person and within church/community settings led to higher effect sizes in maintenance of changes in PA self-efficacy. This pattern of findings highlights the complexity of the relationships between behavioral techniques and PA self-efficacy. The authors note that this pattern supports other reviews suggesting that planning social support and social change are associated with lower effect sizes for PA self-efficacy and may be related to social comparisons and relative personal judgements about PA abilities.[78] This emphasizes the need for ongoing evaluations of the optimal approaches to integrating social support elements within interventions and suggests that interventionists should not assume that increased social support will always be helpful.

26.12 CONCLUSION

Promotion of healthy PA and SB behavior change and maintenance is a popular topic for cognitive-behavioral researchers. Early studies aimed at understanding the utility of behavior change approaches to enhancing exercise participation have been extended by exciting and creative developments in research approaches. Advances in behavioral science taxonomies for evaluating specific cognitive-behavioral behavior change techniques used in interventions have led to greater ability to evaluate effective mechanisms of action in PA interventions. Cognitive-behavioral interventions such as self-monitoring, social support, goal-setting, and feedback with individual tailoring of content appear to be effective techniques across PA intervention studies and populations. Technology has greatly enhanced the methods available for PA monitoring and communications between interventionists and program participants. The use of written diaries and logs is now often accompanied or replaced by accelerometers, step counters, and a variety of wearable devices. Activity program participants may access interventions through peers, the internet, mobile phones, and various types of structured telephone contact approaches in addition to—or instead of—face-to-face contacts and printed materials. Efforts to improve intervention approaches to encourage adoption of exercise are now enhanced by a renewed emphasis on the importance of interventions that promote maintenance of activity once it has been established. Recent advances in ecological momentary analysis have allowed longitudinal examination of the usefulness of specific aspects of theoretically based intervention approaches, aiding in efforts to longitudinally examine the process of activity maintenance, cognitions and affect, and relationships to intervention components. Recent intervention studies have also addressed not only activity per se but also changes in the SBs that are encouraged, if not enforced, by our modern lifestyles.

Technological changes continue to introduce new ways of replacing active living with SB and suppress opportunities for PA in almost every domain of modern life. The obesity epidemic now threatens almost all population subgroups and even less technologically advanced cultures. Although these public health challenges are undoubtedly powerful adversaries, new discoveries of the benefits of PA are a continuing source of inspiration to researchers, healthcare providers, and others committed to finding more effective ways of encouraging all people to be physically active and healthy. Interventionists may employ effective PA counseling techniques in a variety of settings and take advantage of a variety of free and commercial materials based on empirical evidence.

The advances and limitations highlighted in this review of behavioral and cognitive interventions for promoting PA suggest some of the important directions for future work. In particular, we expect to see more studies that translate findings of efficacious interventions into a wide variety of settings and populations. New technologies are likely to make monitoring of the spectrum of activity, from complete rest to the most vigorous exertion, more accurate and less expensive. Telecommunications, internet, and mobile communications will continue to provide new opportunities to connect people to PA promotion interventions, and we need to learn how to effectively and efficiently combine the technology with the personal contacts that many people still desire. Consideration of how to best extend the evidence base to a wider range of adults, including older adults and representation of diverse racial and ethnic minorities and underserved communities, will further our understanding

of effective intervention approaches for larger segments of the population. Additionally, much remains to be learned about how to promote sustained activity over time and how to consistently reduce SB. Best practices for integrating across individual and community levels of intervention are still unknown, and the range of approaches now available offer exciting opportunities for the development of multicomponent intervention programs. There will also be unexpected challenges, but the scientific and creative advances of the past decade suggest that there will be exciting new progress to report in future years.

CLINICAL APPLICATIONS

- The use of established cognitive-behavioral approaches, such as self-monitoring, goal-setting and feedback, individual tailoring of content, and social support, appears to enhance PA interventions and should be incorporated when promoting PA change.
- PA assessment and promotion can be enhanced with widely available technology such as wearable activity trackers, websites, structured telephone contacts, social media, and mobile apps. These may also be used to promote communication between interventionists and program participants and used in addition to or instead of face-to-face contacts and printed materials.
- SB poses health risks independent of MVPA and is a useful target for intervention. Approaches specifically targeting SB, rather than simply including SB as a component of broader PA interventions, may be most successful in reducing SB.
- PA interventions may be more acceptable and effective when tailored to specific populations, such as different gender and age groups, different cultures, and different neighborhood environments.
- Home-based and community settings can provide greater reach to at-risk and underserved populations and help to translate evidence-based intervention approaches for promoting PA and decreasing SB in real-world settings.

27 Enhancing the Nutrition Prescription Using Behavioral Approaches

Jonas Sokolof, DO, Margaret Loeper Vasquez, MS, RD, LDN, Jenny Sunghyun Lee, PhD, MPH, MA, DipIBLM/ACLM, FACLM, Elizabeth Pegg Frates, MD, FACLM, DipABLM, Sam Morley, MS, MPH, Daniel B. Clarke, MBA, and P. Michael Stone, MD, MS, IFMCP

KEY POINTS

- The nutrition prescription is one of the most important components of lifestyle intervention.
- Empowering patients with basic nutrition knowledge can help with nutrition prescription adherence.
- When prescribing nutritional lifestyle interventions, it is important for the practitioner to take into account the various cultural and social factors involved in the individual's or group's dietary habits.
- A coaching approach built on a solid coach–client relationship can promote positive behavioral change as it relates to nutrition.
- Group medical visits can be a cost efficient and productive tool to implement nutritional prescription within a lifestyle medicine program.
- In order to effectively comply with a nutrition prescription, it is vital for patients to possess fundamental culinary skills so they can prepare health promoting meals at home.

27.1 OVERVIEW

Recent studies have shown that most patients suffering from chronic medical conditions do not follow lifestyle recommendations (i.e. tobacco cessation, healthy eating, exercise, etc.) despite the fact that doing so could significantly alter the underlying disease process in a positive manner.[1] Adopting healthy behaviors centered on optimal diet, sufficient physical activity, and reduction or elimination of substance use thus becomes vital in the overall treatment of many chronic diseases. Therefore, when considering the lifestyle medicine prescription, emphasis on changing a patient's behavior becomes a key component in the treatment plan. This chapter will focus on nutrition. It will review nutrition prescription and its importance, the art and science of coaching for behavior change in nutrition, as well as culinary skills and strategies to use for optimal nutrition.

27.2 THE IMPORTANCE OF NUTRITION PRESCRIPTION

Perhaps the most important modifiable lifestyle factor involved in the overall maintenance of health and prevention of disease is diet. It is clear that sub-optimal nutrition plays a direct role in the development and propagation of chronic diseases such as obesity, diabetes, hypertension, cancer, and cardiovascular disease.[2] The most recent U.S. Dietary Guidelines, made available to the American public in 2020, emphasize a dietary pattern rich in a variety of whole grains, fruits, and vegetables while simultaneously limiting consumption of added sugars, saturated fat, and sodium.[3] These guidelines were derived from scientific data that support a whole-food, mostly plant-based diet as the overall pattern of eating involved in health promotion and disease prevention. These efforts remain consistent and are evolving into primary prevention practices in order to reduce the incidence of overweight and obesity, Type II diabetes, cardiovascular disease, and cancer.[3] The evidence continues to accumulate on how a diet that is lower on the food chain can dictate the health of a population.[4] The United States Preventive Services Task Force (USPTSF) recommends that nutrition counseling be intensive and focused on behavioral interventions. A good nutrition prescription increases both the intensity and the ability to apply a focused behavioral intervention. Based on the latest U.S. Dietary Guidelines and scientific evidence, most would agree that the overall dietary pattern recommended for health promotion would be one that is plant centric—including half of a plate of a colorful variety of vegetables. Furthermore, emphasis should be placed on eating whole foods in the "pure" form as opposed to foods that have been processed. However, possessing knowledge on the most health promoting dietary pattern is meaningless without tools in place or a mechanism to put this knowledge into action. Dietary habits are largely controlled by the complex interaction of human behavior, cultural practices, and societal norms. Therefore, for clinicians to effectively intervene from a nutritional perspective, they must also know how to help change human behavior. Such behavior can be both

DOI: 10.1201/9781003227793-31

learned or acquired and reinforced by the interplay of social interactions, cultural norms, and or societal factors, making it difficult to change over a short-term period.

Since it is now widely accepted that dietary pattern has a profound effect on overall health, the necessity of incorporating behavioral strategies to promote health and healing becomes even more vital to the lifestyle medicine practitioner. Among the major barriers to implementing such strategies are lack of confidence in behavior change counseling, inadequate provider training in behavioral counseling, and lack of time and or reimbursement for counseling services. Lack of confidence in behavioral counseling abilities seems to rank highest among healthcare providers as the reason for not implementing behavioral change strategies into their practice.[5] This lack of confidence is not surprising when one considers that physicians are offered little to no training in counseling techniques and most medical schools do not incorporate behavioral modification into their curricula. There is an entire chapter on health coaching, which can serve to amplify the behavior change information in this chapter.

Another barrier is the lack of standardization of behavioral counseling techniques. Currently, rigorously tested behavioral change strategies do not exist. One reason for this could be that it is challenging to design and conduct randomized controlled trials that can effectively evaluate the efficacy of behavioral techniques. The lack of concrete evidence supporting specific behavioral tools designed to improve lifestyle habits leads to inadequate advice given by providers, long counseling sessions, inappropriate methods of behavioral advice delivery, and poor follow-up.[6] Furthermore, most behavioral programs fail to incorporate specific guidance based on an individual's unique ethnic, cultural, and socioeconomic status. This lack of a personalized approach makes adherence to behavioral change much more difficult to sustain.

As healthcare continues to change from an economic standpoint, more physicians are finding themselves under more pressure to produce viable bottom-line numbers to meet growing healthcare costs and overhead, and to earn a living. Therefore, many clinicians feel that the time they have with patients, already limited, must be spent addressing symptoms rather than focusing on root causes such as sub-optimal lifestyle habits. Additionally, reimbursement for lifestyle counseling is either non-existent in many healthcare plans or simply not sustainable for most physicians when considering "bottom lines."

Influences that help shape decisions made on health behavior occur within an individual's personal life. Many of these decisions are directly influenced by relatives, friends, co-workers, and community members.[5,6] Thus, all these influences must be considered when constructing a nutrition prescription with motivation for behavior change as its foundation.

The nutrition prescription must be goal oriented for it to be successful. The acronym SMART has been used in helping physicians to set such goals for their patients. It is categorized as follows: S, specific; M, measurable; A, action oriented; R, realistic; and T, time sensitive. It has been found that when these SMART goals are aligned with an individual's life goals, the individual will be more motivated to change behavior.[5,6]

This chapter covers the key aspects of achieving a successful nutritional prescription to achieve lasting behavior change. Effective nutrition prescription implementation can only occur when patients are motivated to change. Various strategies to achieve optimal motivation will be discussed. Behavioral change theories for the lifestyle medicine practitioner are reviewed. Strategies for incorporating these principles, along with effective behavioral counseling techniques within the clinic setting, are highlighted throughout the chapter. Since health behavior is dynamic and dependent upon various cultural, social, and community factors, content related on how to integrate these aspects into a behavioral plan to facilitate nutrition goals is included. This chapter is unique as it includes information from a professional chef. Daniel Clarke shares his practical strategies to implement culinary skills. Empowering patients to adopt healthy eating patterns involves empowering them to cook at home. This chapter will help clinicians guide their patients on real life, hands-on cooking techniques and recipe planning while helping to promote positive behavioral changes.

27.3 EDUCATING PATIENTS ON NUTRITION BASICS: LAYING THE FOUNDATION

27.3.1 Nutrition, a Snapshot

The challenge of teaching nutrition is that the message is somewhat dull. Balance and moderation is certainly not as exciting or enticing as the new mocha-choco-pumpkin flavored iced coffee, or the influencer promoting just these 5 easy steps that promise to have you looking like you did at 17, complete with carefully curated photos. Herein lies possibly the most important lesson: ignore the marketing and outside influences, and listen to your body. This is a difficult lesson, particularly in America, but for most, knowledge is power.

Macronutrients, or the large building blocks of our nutritional intake, are Carbohydrates, Protein, Fat, and Water. Carbohydrates come in two forms, complex and simple; they are an extremely important source of energy for our bodies and our brains.[7] The vast majority of carbohydrates we consume should be complex for maximum nutrient density, slower digestion/energy absorption, and feelings of satiety.[7] Protein is found in many foods, from grains to meats. Protein is important for building and repairing tissues as well as a building block of hormones and enzymes.[7]. When educating about protein, encourage plant proteins. If people choose to eat fish, warn them of the high mercury levels in large fish like swordfish, tuna, mackerel, marlin, and others. If people do eat meat, warn them about processed meats and their link to cancer. If they desire meat,

recommend poultry or lean meats in limited quantities, such as one serving a week, maximum. Saturated fats in red meat can lead to high cholesterol. Fats have gotten a bad reputation in recent history, but fats are important for providing energy, transporting vitamins, and helping you feel satisfied after meals. Some fats are better than others for health; unsaturated fats and fats found in plants should be included in a healthy diet where saturated and "man-made" fats such as trans fats should be avoided.[7,8] Lastly, water is not always included as a macronutrient, but it is at that level of importance. One cannot survive without water for longer than a few days.[8] The human body needs proper hydration for cells to work properly, maintain temperature, and lubricate joints. When discussing fluids, unsweetened beverages should be encouraged.

Micronutrients, or the small building blocks of our nutrition intake, are all the vitamins and minerals. These nutrients, along with phytonutrients, work together to ensure that numerous body functions do not just work properly, but thrive.[7,8]

These basics of nutrition barely scratch the surface. Research is exploring the various avenues of how healthful nutrition is so much more than just nutrients and calories. Behaviors like sleep patterns, the gut flora, and when an individual eats can impact their mental health, physical health, and other lifestyle factors, such as quality of sleep.[9–11]

27.3.2 Whole Foods You Recognize

When thinking about changing nutrition behavior, a good first step is to take a look at the refrigerator and the pantry. Is there food in there, or food-like substances? Are there whole foods that were picked, plucked, pulled, and harvested? If there are mostly processed foods in someone's house, then there is a great deal of work to be done.

What is something that the majority of Americans have in their freezer and is the biggest contributor to sodium intake? The answer is frozen pizza. The dough comes from wheat, sauce from tomatoes, and cheese from milk. Doesn't sound too terrible, right? However, to turn it into a long-term stable frozen food, the wheat has been stripped of the nutrients, the sauce has lots of salt, fat, and sugar added, and the cheese has been processed from cow's milk. So, how does someone turn that frozen pizza into a "whole food" that is easy to prepare? Starting with the dough, most people do not have time to make their own wholewheat dough from scratch, but it is easy to purchase it. Or, someone could use a wholewheat English muffin or try a cauliflower crust. Another option is to hollow out a zucchini for a pizza base. Thinking about the sauce, the closest one can get to the whole food is slicing the tomato up, or try crushed tomatoes, or look at the nutrition label for the tomato sauce and select one with the smallest ingredient list, lowest amount of salt, and lowest amount of sugar. Lastly, the cheese can be added sparingly. A sprinkle of mozzarella and a sprinkle of a strong cheese like parmesan will deliver the flavor while limiting the extra calories and saturated fat that cheese adds. One can also use plant-based cheeses to keep the pizza plant based.

A good start is to recommend that people evaluate their food buying patterns. Think about how they can change their purchases and migrate them toward the original source of the food (see Table 27.1).

Thinking about the progression of these foods, from most processed on the left to least processed on the right, it is easy to notice that what is removed is the "extra" that's not needed. So with the "juice," when one moves to 100% juice, one loses the added sugar, and when one moves to whole fruit, one loses the concentrated source of natural sugar and adds fiber, vitamins, and minerals. The other thing that happens when one moves from left to right on this chart is that food preparation tends to increase. If food preparation is a hurdle, pick and choose where to make the changes. There are some convenience foods that still maintain the whole food and its nutrient composition. Examples include ready to microwave brown rice, canned beans (rinse to decrease sodium), plain frozen veggies, plain frozen fruit, baby carrots, cherry tomatoes, pre-sliced grilled chicken, and individual frozen pieces of fish. These items take only slightly longer to prepare than popping a frozen meal into the microwave.

When there is a patient or client who does like to cook, a provider can encourage them to purchase a Community Supported Agriculture (CSA) share or go to a farmer's market. Some simple exercises for patients can include trying a new vegetable (kohlrabi, jicama, celery root, golden beets, arugula, eggplant, and so many more choices); look

TABLE 27.1
Sample Progression toward Whole Foods

Current example	Step toward	Whole food
"Juice" or soda	100% Juice	Piece of fruit
Box cereal	Low-sugar wholewheat cereal	Oatmeal or quinoa
Frozen chicken wings	Low-ingredient whole meat chicken tender	Homemade breaded chicken breast
Frozen stir fry veggies	Frozen stir fry veggies no sauce packet	Raw sliced veggies
Hydrogenated nut butters	Natural nut butters	Raw nuts
Ramen style noodles	Rice noodles with soy sauce	Rice or wholewheat noodles with veggies and edamame

up recipes for the new items. This can be fun and exciting for patients.

27.3.2.1 Portion Control

Probably one of the most important things to stress with patients who are moving from a Standard American Diet (SAD) to a whole-food plant predominant one is portion control. Once people are enjoying a whole-food plant-based pattern of eating, portion control is less of an issue, because the fiber in plants like whole grains, vegetables, and fruits is satisfying and satiating. For those making small changes and reducing their amount of fast foods and processed foods, as well as simple carbohydrates and red meats, portion is key. A portion of meat is a deck of cards. Most restaurants supply at least four times that portion.

As the message of balance and moderation is not complicated, it does allow some wiggle room both for treats and for increasing nutrient-dense intake. The challenging part about portion control is that our baseline is all out of whack. Many think and have the perception that a foot long sub, a bag of chips, and 20 oz of soda is a normal lunch. The reality is, for most people, half of that sub, a piece of fruit, and water is the correct portion. No one has the exact same calorie and nutrition needs. To evaluate and provide a close estimate of a patient's calorie needs, a dietitian should be consulted. However, there are many guides to offer a patient to keep portion sizes appropriate. Some helpful tips for portion control include:

- Size of the plate—This matters! People tend to fill the plate. Choose a dessert plate rather than a dinner plate for meals.
- Divide the plate—Half of the plate should be filled with vegetables and/or fruits, a quarter with healthy protein, mostly plants, and a quarter with whole grains.
- Measure—Use measuring cups/spoons for a week. See how much you are actually serving yourself. Can you decrease it by one tablespoon? A quarter of a cup? After a week, you will have an idea of what serving sizes look like on your plates and in your bowls, etc.
- Serve and put away—Serve yourself the appropriate portion, and put the rest back into the pantry. You will be less likely to serve yourself seconds when it is not in front of you.
- Pre-portioned items—Purchase items already portioned (fruit cups, yogurts, string cheese) so you can grab and go!
- Eat at the table—Turn off the screens and pay attention to what you are eating, who you are eating with, and how you are feeling.
- Cook!—When you are in charge (vs. eating out), you know what the ingredients are, and you know how much you've served yourself. Tips for this will follow later in the chapter.
- Split it!—When you do eat out, ask the server to package half the entrée before bringing it to the table, or split an entrée with your friend.

27.3.2.2 Nutrients for Health

When one embarks on changing one's behavior related to nutrition in a more healthful direction, there are some nutrients that can help. Most Americans are juggling not only their weight but also the comorbidities that accompany obesity, as more than one-third of U.S. adults are obese.[12] The bottom line when thinking about healthful eating, modifying behaviors to increase health, or taking small steps in that direction is that the food has to taste good. Processed foods do this largely by adding salt, fat, and sugar.[10] There are ways to make food not only taste good without this formula but also provide some potentially beneficial influence on those obesity-specific comorbidities.

One of the obvious ways to improve the healthful qualities as well as add flavor and nutrient composition to a dish is to remove or drastically reduce the salt added and replace with herbs and spices. Basil, oregano, and rosemary are all wonderful spices that can jazz up a dish. A paste can be made with herbs and olive oil that can be used as a spread instead of butter, margarine, or mayonnaise. Turmeric has been shown to have anti-inflammatory effects, and a pinch can be added to egg white scramble, roasted veggies, rice, and soup, and blended into a smoothie.[13–15] Cinnamon is a wonderful addition to warm cereal, added to smoothies, and added to baking, and has been shown to have antioxidant properties as well as wound healing properties.[16] More studies are needed on these spices' effects in humans, as often, these spices are eaten in small quantities.[17] This leads back to the moderation and balance message, that no one item is the answer. No one item is going to be the quick fix for a strong, healthy body. The only way is to work toward a diet of balanced fruits, vegetables, plant proteins, complex carbohydrates, also called whole grains, a variety of colorful herbs and spices for additional flavor, and hydration.

27.3.2.3 Cultural Sensitivity and Nutrition

Health is not simply the biochemical state of an absence of disease or illness, but also embodies quality of life, including meaningfulness, joy, connection with others, and well-being. Health also includes a person's goals and circumstances as well as cultural values, traditions, and practice.[18,19] Similarly, eating foods does not only provide the nutrient chemicals and energy to sustain life and promote therapeutic efficacies at a biochemical level; food intake encompasses and entails emotional, social, and cultural relevance as well. What, why, and how individuals, families, and groups eat are developed and determined by cultural and religious traditions, social status, preferences, power, and more.[20]

Today, there exists a plethora of cultures and people with different eating habits, steps in food preparation, and identities in food. Eating is an intimate act one chooses, performs, and practices based on various factors (e.g. beliefs,

attitudes, needs, preferences, traditions, circumstances, environment) to sustain, promote, and celebrate life. The food a person chooses to eat reflects their identity. That is, the food choices an individual makes may reveal their social class, educational background, knowledge of food, as well as health and fitness goals. For instance, the person eating a low-fat and high-protein diet has different physique goals or preferences than the person eating a vegan diet or fast food diet. While these people may have different fitness goals or understanding of what foods are healthy and nutritious, there may be other health and cultural disparities present. These individuals, for example, may have access to different food items due to living in a health desert or due to their own financial burdens. Similarly, food is linked with power. In general, the cost of purchasing or acquiring healthy and safe foods (e.g. organic plant-based foods) is expensive, and those eating less food or unhealthy foods may have less power and be of lower socioeconomic status. Making sure that people understand that frozen vegetables and fruits or even canned vegetables and fruits (which must be rinsed) are better alternatives to fast food is essential. There are nutrients in these frozen and canned vegetables and fruits. The cost may be the same as a fast food meal. They are both cheaper, but one option offers vitamins, minerals, and antioxidants. This is an important part of education.

Another area to address is gender. Gender disparities in cooking also exist in food preparation. The traditional gender role of the female counterpart preparing and serving meals is a historically common practice. Reality TV cooking and chef shows also have popularized the art of cooking, adding prestige to the profession, which has also shaped the perceptions behind cooking. Cultural traditions additionally shape methods of cooking, what foods a person consumes, as well as how they eat. This may include family recipes passed through generations, weekly family dinners, eating a turkey for Thanksgiving in the United States, a kosher diet observed by many in the Jewish community, going to a restaurant for a meal to celebrate a special occasion, and more. Also, the foods consumed by individuals are those considered edible by a culture. Escargot is a well-known French delicacy uncommonly found on menus in American restaurants. Further, sushi has become quite popular in the Western world, but raw fish has not always been a staple of the American diet. Understanding a person's culture give you a new lens into their dietary patterns.

Furthermore, eating plays a role in relationship dynamics. Food is fundamental to culture and serves to potentiate social relationships. People dine together as a family, going out on a date for romantic pursuits, grabbing coffee to become better acquainted, or invite friends and neighbors to break bread together. These experiences promote closeness among diners as well as the sharing of cultural practices around food and nutrition. Moreover, people choose food based on their personal taste preferences. However, those foods deemed tastier are not always healthy and nutritious, so individuals selecting foods according to their taste preferences may be at an increased risk for disease. In French culture, the hedonistic value of food is held in high regard. Interestingly, French consumers rank foods displaying nutritional information more negatively and anticipate these foods to be less enjoyable to eat as well.[21] This portrays the concern that emphasizing healthy food choices may result in a utilitarian view of food as a necessity over the pleasure and comfort of food. This could make food enjoyment incongruent with health practices of eating nutritious foods.

There exists a tension between the science of food for health and how people relate to food physically, culturally, socially, and sensually.[19] According to the 2016 Food and Health Survey on Americans' food choices, taste continues to have the greatest impact on the decision to buy foods and beverages, followed by price, healthfulness, convenience, and sustainability for a decade between 2006 and 2016. Also, it has been shown that scientific understanding and use of the nutrition facts label can prompt food purchases and choices.[22] For example, a person with hypertension attempting to lower their sodium levels may opt for sodium-free or low-sodium food options. Diabetics may opt for sugar-free or sugar replacements to maintain lower blood sugars. However, the frequency of use of nutritional labels in choosing food was in general low among low-income women in Women Infants and Children food program (WIC) or other risky populations. While the use of food labels has increased in recent years, from 32% in 2004 to 52% in 2008, consumers still make their dietary decisions through various determinants of food choices including biological, psychosocial, cultural, economic, and environmental factors.[23]

In past decades, healthcare professionals have focused on and endorsed the importance of nutritional intake when promoting healthful diets and lifestyles for their patients. Meantime, the advent of genome sequencing has resulted in personalized medicine based on a person's genotype.[24] This includes the field of nutrigenomics, which encompasses the epigenetic effects of food or how nutrients trigger changes in genome expression.[25] Thus, one's genotype could be used to determine a unique diet regimen for optimal health, disease prevention, and therapy. Further, studies have shown that individuals have reported dietary recommendations based on genetics to be more understandable and useful compared with general dietary advice from their primary care providers (PCPs).[26] This novel field may be useful to improve patient compliance with provider recommendations and subsequently, health maintenance. However, despite the intrigue of nutrigenomics, the relationship of a person's environment and culture with their diet cannot be forgotten by PCPs. Providers need to inquire about the intricacies of patients' eating habits, schedule, and lifestyle to help counsel them on best lifestyle practices.[27] This also includes not just how food is prepared as a basic, but also finances for food budgets, troubles with mastication, swallowing, digestion, allergies or food intolerances, and dietary needs and preferences.

It remains clear that food is ultimately inseparable as both a biological necessity and a cultural conduit; cultural differences in diet and eating impart different disease outcomes in patients. For instance, minorities have an increased risk of obesity and comorbidities compared with Caucasians.[15] Weight loss interventions are less effective in these groups as well.[27] Cultures that consume higher amounts of processed foods and animal products have increased incidence of hyperlipidemia as well.[6] This indicates that the role of culture in food consumption needs to be addressed for effective weight management for minority patients. A focus solely on nutrition prevents a holistic approach to food that encompasses cultural sensitivity and considerations. Personalized nutrition with a holistic regard for cultural competencies includes providers well versed in the culture and language of their patients, family-oriented interventions, instructive materials in their native language, and social support within their cultural community.[18,25,27] Encompassing these individualities optimizes personalized nutrition as a tool for a healthy diet. Thus, a holistic, culturally sensitive, and individualized health approach may reinforce the effectiveness of personalized nutrition in the primary care setting.

27.3.2.4 Effective Counseling Techniques for the Nutritional Prescription

The coaching mindset is the art and heart of behavior change. It is a co-creative process that engages the patient in their own healing by illuminating a self-directed path. In this model, the patient is the expert, and the coach is the guide. This patient-centered way of engaging with clients is a fundamental shift from the current model of care, where the clinician dictates and directs. The coaching model is a theory-based practice that emphasizes collaboration and facilitation of the client's desire for change. Emerging studies show that behavior changes are enhanced when this self-directed partnership approach is utilized.

The coach–client relationship is a dynamic force that is pivotal to the change process. This relationship is built on trust, mutual respect, and partnership. At the core of this relationship is a deep understanding that clients have the ability to emerge their own answers and meaning. The pace and path toward wellness are created by the client and facilitated by the coach. It's a shift away from advising to illuminating. As listed in Table 27.2, there are *five main domains* to consider when moving from the Expert Approach to the Coach Approach.[28] "Focusing on 5 specific domains of communication enables practitioners to successfully switch from the expert approach to the coach approach when they are counseling on lifestyle medicine issues. The five domains include sharing knowledge, listening, asking questions, addressing problems, and taking responsibility."[2,27,28]

The first is *Sharing Knowledge*. The coach asks permission before launching into a lecture about a topic. The client can choose how and when information is distributed. This puts the locus of control back on the client and fosters participation. The second domain is *Active Listening.*

TABLE 27.2
Frates' Five Specific Domains of Communication for Coaching[28]

1. Sharing Knowledge
2. Listening
3. Asking Questions
4. Addressing Problems
5. Taking Responsibility

Source: Frates, E.P. and Bonnet, J., *Am. J. Lifestyle Med.*, U.S. National Library of Medicine, 2016, September. https://pubmed.ncbi.nlm.nih.gov/30202286/.

The coach listens without an agenda. It's a mindful state of listening that creates empathy and fluidness for the client. The third domain is *Asking Questions.* Open-ended, profound questions emerge from the active state of mindful listening. These deeper questions asked by the coach provoke insight and self-awareness in the client. The fourth domain is *Addressing Problems.* Problems and blocks are viewed as opportunities for growth. The focus is on the learning and not the problem. Solutions are discussed in partnership with the client, and the client makes the final call on which path to choose. The fifth domain is *Taking Responsibility.* Client participation is essential to successful behavior change. Goals and agreements are created based on the client's agenda, thus fostering follow through and self-responsibility.

Fostering self-awareness and insight is pivotal to the change process. The coach strives to assist clients in discovering their own answers by cultivating more meaningful questions. The coach moves away from interpreting and imposing meaning to asking questions such as: *"What does that mean to you?"*, *"What would that look like for you?"*, *"What did you mean by that?"* These types of exploratory open-ended questions assist the client in developing the self-awareness and insights necessary to make permanent changes in behavior.

27.3.2.5 Frates' Five-Step Model for Behavior Change

The five-step model for behavior change and motivation is a framework for successful coaching encounters.[29] This model was originally described in 2011 and has been easily adopted by healthcare providers of all types. It is currently being taught in medical schools to help future clinicians gain confidence and comfort in counseling patients about adopting and sustaining healthy lifestyles. Figure 27.1 describes the process.

This process is also described in the Introduction to Behavior Change chapter of this textbook. It is important and an essential foundational model for counseling on nutrition, exercise, stress resilience, substance use, sleep, social connections, and other behaviors associated with health.

FIGURE 27.1 The Five-Step Cycle of Collaboration. (From Frates, E.P., et al., ***Am. J. Phys. Med. Rehabil.***, U.S. National Library of Medicine, 2011, December. https://pubmed.ncbi.nlm.nih.gov/22019966/)

This model demonstrates five steps to follow when counseling patients on behavior change. It is a cycle that begins and ends with empathy. The following three paragraphs are reprinted with permission from the *Lifestyle Medicine Handbook* 2nd Edition:

The first[t] step is to *Be Empathetic*. There are two key components to empathy: *listening with intention* and *accurately reflecting* back narrative. Empathy helps to foster a connection between patient and provider. The second step is *Align Motivation*. This is based on Miller and Rollick's book *Motivation Interviewing* (*MI*). MI is a goal-oriented style of motivating that focuses on the *language of change*. The communication with MI is designed to strengthen personal motivation for a specific goal by eliciting and exploring the person's reasons for change in an environment of acceptance and compassion. The core MI skills are *OARS*. *O: open-ended questions* which allow the client to go deeper into exploring and expressing feelings and desires for change. "What makes you want to change your diet now?" *Affirmations*, finding the positives, the strengths, or as Miller and Rollick like to call it, *change talk*, and acknowledging it to enhance motivation. Change talk invites the client to give their own reasons for changing. Questions that evoke change talk are things like *"what would your life be like if you were eating less fast food daily?" "How would losing 10 lb enhance your current situation?" or "I heard you mentioned you wanted to give up gluten—what makes you say that?" R: Reflective listening*, which is demonstrating understanding by repeating or paraphrasing what you hear. *S: Summarizing* or reflecting back main points to establish rapport, connection, and facilitate the co-creation of client centered goals.

The third step in the five-step model for behavior change and motivation is *Building confidence* by identifying core strengths. The coach explores a client's core strengths by asking open-ended questions about past success and having the client identify which strengths they used and how these strengths could be applied to their current health goals. The fourth step is co-creating SMART goals with the client. SMART goals are *S*pecific, *M*easurable, *A*ction oriented, *R*ealistic and *T*ime sensitive. SMART goals take a large goal such as, *"I want to lose weight",* and break it down into smaller measurable chunks. *"How much weight? What is the first step towards doing this? When will you start this new behavior?"* are the kinds of questions used by the coach to facilitate the creation of SMART goals by the client? The fifth step is *Set Accountability*. The coach and client mutually decided on the best method of tracking and the frequency of communication and appointments. Having a very specific tracking system motivates and enhances behavior change. With the evolution of technology, it has become very convenient to measure and track in the moment. This immediate feedback keeps clients engaged with their goals and enhances behavior change. Frequent follow-up appointments allow the client to celebrate successes and explore blocks to setbacks.

For behavior change to be positive and permanent, the client's participation in the change process is required. This essential truth is shifting the landscape of medicine and health. This tried and true coaching model of collaboration and co-creation of client-center goals in an environment of empathy and compassion has the potential to transform health and facilitates deeper engagement with life.

27.3.2.6 Nutrition Counseling and Education in the Group Medical Visit Model

Nutrition counseling in the medical model acts as a perfect fusion in the patient-centered medical home for empowering the patient. In 2005, a review of the daily clinical responsibilities and demands placed on physicians estimated that it would require primary care physicians 18 hours a day to deliver evidence-based preventive and chronic disease management care.[27] Additionally, estimates vary; there is a nutrition related reason for at least 25% of all visits to primary care providers.[30] Medical students and residents receive, on average, 19.6 hours of nutrition education during their training.[31] Additionally, only 20% (3.9 hours) of the contact hours is formally nutrition science and application. The rest of the education focuses on integrated curriculum, clinical practice, biochemistry, physiology, and biochemistry.[29] American physicians are deficient in nutrition education.[32] A model for primary care clinics to empower patients to help intervene in their chronic health conditions through changing modifiable lifestyle factors has emerged. It is the group or shared medical visits, where the clinician and the nutritionist or health education specialist educate and provide a clinical evaluation experience to help address the many issues of chronic illness.[33] The fusion of nutrition counseling and

education with the clinician in primary care is the future of healthcare delivery for chronic conditions.[34]

27.3.2.7 Nutrition and the Group (Shared) Medical Visits: Application to the Primary Care Clinic

In the patient-centered medical home model of clinics in the United States, educators are being used alone or in conjunction with the clinician to allow more complete lifestyle education in nutrition to modulate chronic disease. The five major modifiable lifestyle factors include diet and nutrition, sleep, exercise and movement, thoughts and emotions, and relationships.

Maintenance of health and improvement in chronic illness are modulated by addressing these modifiable factors. This is a reimbursable model that has been used successfully in a wide range of clinical settings. Nutrition is key in the management of most chronic conditions, and group visits are an effective strategy to help encourage and empower patients to eat more nutritious foods on a regular basis.

When compared with the one-on-one session with clinicians, the group medical visit model has shown efficacy by improving tracked outcomes measures of compliance, biomarkers, follow-up, and lasting changes so that patients can meet more nutrition benchmarks.

There are many different structures to the shared medical visit session. Different monographs are available to help the clinician and clinic institute programs.[35,36]The main focus of the groups is to improve access, educate, and promote behavioral change. When a form of medical visits were incorporated into patient care in the VA, the focus was on diabetes self-management education using nurses or health coaching and also in psychotherapy and patient peer-to-peer support groups. Outcomes, time to treatment change, empowerment of the patient, and the satisfaction with their care improved. Nutrition is a key component of managing diabetes.

27.3.2.8 Using the COACH Approach™ and Group Visits in Therapeutic Programs for Chronic Disease with a Focus on Nutrition

There is an art and science to running group visits.[37] Joseph Pratt, MD was one of the first physicians to use group visits early in the 20th century, and he used them with tuberculosis patients at Mass General Hospital to improve education and treatment.[38] This model has been used to improve treatment in diabetes, metabolic syndrome, hypertension, cardiac disease, asthma, arthritis, chronic pain, and chronic headaches, to help manage stress and sleep disorders, and in the geriatric and the obstetric population.[33] A Cochrane collaboration systemic review in 2005 reviewed group-based training for self-management strategies in people with Type 2 diabetes mellitus, and it showed improvement in biomarkers: improved decreased hemoglobin A1C at 6, 12, and 24 months, lower average fasting glucose at 1 year, improved weight loss at 1 year, lower systolic blood pressure at 6 months, decreased diabetic prescription use, and improved diabetic knowledge at 1 year.

The health benefits of groups for the medically ill included decreased symptoms, improved compliance and adaptation to illness, and decreased use of emergency room visits and inpatient admissions. Blood pressure, blood glucose levels, and access to care improved. And most importantly, there was behavioral change. The benefits of this type of education and visit for the patient, clinic staff, nutrition educator or counselor, and provider are many. (See Table 27.3.)

27.3.2.8.1 Experience and Modeling

From the physicians' perspective, there is increased face-to-face time with patients. It is a more efficient patient education model than one-on-one office visits, and it allows increased integration of lifestyle change. There are a few models that have been recorded in the literature: the Scott model, which has an interdisciplinary team coordinating the group together, and the Noffsinger model, which has the physician leading the group. There are many variations.[39–42] The model needs to adjust to the location, physical plant, clinic and education personnel, and the client base. All group medical visits are local, with their own characteristics.

27.3.2.9 What Is the Focus of the Group Medical Visit?

There is a marked variety of focal points for the group medical visit. It can focus and concentrate on test results, general system issues, disease process, or a healthy process. As an example, at a primary care clinic in Ashland, Oregon, they have been using nutritionists, registered dieticians, physician assistants, nurse practitioners, and physicians for group medical visits. There are ten visits per month with three main topics: functional nutrition trimester by trimester obstetric care (healthy process), a cardiometabolic syndrome series (disease condition process), and test reviews of carotid intimal medial thickness results, or advanced

TABLE 27.3
Benefits of the Shared Medical Visit

1. Enhanced patient care experience with more education and empowerment
2. Improved patient satisfaction with the care they receive
3. Improved clinician efficiency and job do-ability
4. Improved morale and job satisfaction of the clinical and non-clinical support staff
5. Enhanced access to care for the patients
6. Physician ability to increase panel size and reopen closed practices to new patients
7. Cost effectiveness of care improved
8. Improved quality and safety of medical care delivered to patients
9. Helps providers avoid "burnout"

Adapted from [39–42]

lipids or inflammatory panels. Nutrition and its effects on lifestyle, health, and chronic illness is incorporated into all the groups.

The format and implementation are straightforward (Table 27.3), and the benefits previously outlined in Table 27.2 continue. The results have improved nutrition education, biomarkers, and therapeutic lifestyle changes. The programs have increased the frequency of delegated nutrition education and nutritionist evaluation visits for all the chronic conditions frequently seen in the clinic (Table 27.4).

The topics or focus of the groups can range from review of underlying general issues (inflammation) to specific laboratory or imaging related to a chronic process (lipids, advanced lipids, or carotid ultrasound-carotid intima media thickness). The groups can be diagnosis specific (hypertension, high cholesterol, rheumatoid arthritis), or they can form a series about the same topic (pain, cardiometabolic syndrome) (Table 27.4)

The introduction of the nutrition educator, nutritionist, nutrition counselor, or health education specialist into the primary care clinic is essential for the patient-centered medical home, the primary care clinician, and the desire for improved health and chronic disease outcome. It is important to evaluate your clinic population, demographic, level of desire, and the extent of using this tool.[43] But at the end of the day, this addition empowers all involved, generating hope and expectation because of the positive changes that occur.[44] This is a reimbursable process that is geared to the strength of all members of the clinic and health caring team with positive results.

27.3.2.10 Practical Culinary Skills to Ease Behavioral Change

In clinical encounters, whether they be in groups or in one-on-one settings, it is important to share basic culinary skills with patients whenever possible. Empowering patients to cook at home can help them save money, lower

TABLE 27.4
Examples of Topics for the Group Medical Visit and Nutrition Intervention Possibilities

Topic or Focus	Nutrition Education/Modifiable Lifestyle Factor
Test specific: Lipids, or advanced lipids, coagulation—INR, blood sugars …	Foods and diet changes that improve lipids and blood sugars, or affect coagulation. The addition of herbs/spices that impact the process underlying the abnormalities in the laboratory (co-decided by the clinician and the nutritionists)
Imaging or procedure specific: Carotid intima media thickness, colonoscopy	Ways to impact inflammation and plaque. Helping people understand root cause of the inflammation and how to keep your vessels healthyWays to help restore the bowel flora balance with food and fermented foods and how to help your bowel be healthy
Process specific: Inflammation, detoxification, malabsorption, autoimmunity, one-carbon metabolism, or methylation	Discuss/inform the role of macronutrients, micronutrients, and food choice and preparation that improves:-Inflammation (EFA, fermented foods, limiting simple carbohydrates, adequacy of antioxidant rich foods)-Detoxification or biotransformation (adequacy of color rich vegetables rich in antioxidants, minerals, vitamins for phase 1 biotransformation and adequacy of protein and sulfur amino acid containing foods for phase 2 biotransformation)-Malabsorption: discuss timing, volume, combination of foods and preparation that influences absorption. The effect of over the counter medications on absorption-Autoimmunity or allergies: foods and nutrients that help balance immunity; foods rich in vitamins D and A, and the minerals zinc and iron-One-carbon metabolism can focus on the interplay of adequacy of B vitamins, essential fatty acids, and mineral rich foods that form the foundation of adequate one-carbon metabolism balance in a person with any of the chronic illnesses associated with an imbalanced one-carbon metabolism common in primary care
Condition specific: Cardiometabolic syndrome or any of its components: hyperglycemia, hyperlipidemia, hypertension, high body fatObesityArthritisAsthmaChronic Obstructive Pulmonary Disease	A single class or a series of four or more, which helps provide a consistent group membersDetermine the many aspects of food, diet, nutrition, and lifestyle that are focused on during the session or series. All the examples of condition-specific chronic illnesses can be improved by changing the diet in a person-specific fashion
Modifiable lifestyle components: sleep, movement and exercise, emotions—stress, relationship with yourself, others, and food, diet and nutrition	All the modifiable lifestyle factors are influenced by food choice and lifestyle balance. Sleep and exercise or movements are more successful with adjustment of diet and food choice. Emotions are affected by caffeine and alcohol intake, which change nutrient requirements. Relationships with food and others are affected by the habits of food choice and consumption patterns. Disordered eating influences all chronic disease conditions
Specialty specific: Promoting healthy balanceExample:Obstetric group medical visits: preconception, first, second, third trimester, followed by lactation and introduction of foods to the newborn and infant	Each of the different stages of pregnancy can have different foods and nutrients emphasized. This is a very empowering opportunity for clinician, nutritionist, and patient alike, impacting pregnancy outcome and transgenerational health (Stone)

EFA, essential fatty acids.

their consumption of processed foods, manage their weight, reduce their intake of sodium, increase their intake of potassium, and increase their intake of vitamins, minerals, antioxidants, and other anti-inflammatory agents in a whole-food plant-based eating pattern.

The following is a list of tips and tricks to empower providers and patients to do more cooking at home.

Basic Tools and Kitchen Set Up

The pantry of a healthy kitchen should include good vinegars, spices, fresh herbs, olive oil, and other healthy oils. No-salt or reduced-salt canned products, real food salt substitutes, and assorted whole grains are also suggested. When using salt, use it as a finisher, preferably a flake sea salt (fleur de sel), so you do not have to use as much. Basic culinary skills include how to hold a knife and sharpen it and proper cooking of vegetables.

Cooking techniques include braising, roasting, grilling, steaming, and sautéing.

Braising is searing (usually meat) in some form of fat, corn oil, or olive oil, then simmering at a low temperature in a small amount of liquid or stock. Submerge the protein halfway in a covered vessel. The cooking liquid is reduced throughout the cooking process and is used as a base for the sauce for the item. Roasting is cooking by dry heat, such as an oven, convection oven, or open fire. Grilling is cooking food items by a radiant heat source below the food item. The equipment can be gas, electric, charcoal, or wood. Steaming is cooking an item with a vapor bath created by boiling water or stock. Sautéing is cooking in a small amount of fat quickly in a sauté pan on the stove top or range.

Useful ratios are given in the following subsections.

Stocks and Sauces

Vegetable Stock Basic Formula—Yield: 1 Gallon

- Assorted non-starchy vegetables: 3 lbs. to 5 quarts water, bring to a boil, and simmer for one hour. (Do not use broccoli and asparagus.)

Tomato Sauce—Yield: 1 Gallon

- 1 fl. oz. of olive oil
- 3 tbsp. of fresh minced garlic
- 2 oz. of fresh basil or 1 oz. dried basil
- 13 lbs. of fresh tomatoes or 6 quarts of w/ canned liquids
- Salt and black pepper as needed

Basic Vinaigrette

- 1.5 quarts of oil (favorite extra virgin olive oil)
- 16 fl. oz. of vinegar (whatever vinegar you prefer)
- 1 tsp. of Dijon mustard (aids in emulsifying process)
- Salt, pepper, other seasonings such as fresh herbs

1. Combine the vinegar and desired seasonings.
2. Slowly whisk in all oil until an emulsification is formed. (If too thick, slowly add cold water to adjust.)
3. Serve immediately or store up to seven days.

Note: a blender or hand mixer can also be used, using the same steps and ingredients.

Grains

Method—combine with 1 part rice (rinse, drain well before cooking)

- Par-boiled or Carolina rice—basic formula (by volume)
- Stock, seasoned 1.75 or 2 parts
- Jasmine rice: Rinse, drain well, use 1.5 parts water or stock
- Brown rice basic formula (by volume): Stock, seasoned 2.25 or 2.5 parts
- Wild rice basic formula (by volume): Stock, seasoned 3 parts
- Risotto (by volume): Stock, seasoned 3 parts. Add risotto in three stages
- Cous Cous (by volume): Stock 1.25–1.5 parts

1. Coat grains with olive oil.
2. Pour hot stock over grains, cover, let sit five minutes.
3. Fork through to separate grains.

- Firm polenta or farina grits (by volume): Stock 5 parts; polenta or grits 1 part

1. Add 0.5 part more stock for softer polenta or grits.

- Hominy grits (by weight) to hold shape: Stock 4 parts; hominy grits 1 part

Pasta Dough Basic Formula

- Durum Flour 0.5 lb.
- Semolina Flour 0.5 lb.
- Eggs, whole 4 ea.
- Oil 1–2 tbsp.
- Water 1–2 tbsp.
- Salt pinch

Healthy Substitutions

- 1 whole egg = 2 egg whites
- 1 cup of heavy cream = 1 cup of evaporated milk
- 1 cup of mayonnaise = 0.5 cup of mayonnaise and 0.5 cup of low-fat yogurt
- 1 cup of sour cream = 1 cup of low-fat yogurt plus 2 tbsp. buttermilk or fresh lemon juice

Meal/Menu Planning

1. Map out a menu weekly, before grocery shopping.
2. Try to incorporate local CSA/Farmers markets if accessible by location or monetarily feasible.
3. Use these incomplete protein combinations as substitutes for animal proteins: grains and legumes, lentils and brown rice, wholewheat pasta and beans, tortillas and beans, tofu and brown rice, hummus and wholewheat pita. These can be used for snacks, sides, or entrées.

Some guidelines for developing principles of healthy cooking should include sourcing and selecting nutrient-dense ingredients; always incorporating a variety of plant-based ingredients into every meal; and trying to always make your own stocks, sauces, and vinaigrette dressings. Following these guidelines allows you to control all ingredients that you consume.

Easy Recipes for the Hesitant Cook / Tips

1. Incorporate under-30-minute meals that are healthy and good for you.
2. Cooking in batches allows you to have enough for another meal.
3. Learn how to cook with alternate ingredients that are healthy yet have lots of flavor.
4. Experiment with different spices, seasonings, and herbs.
5. The use of "good" condiments that add flavor and not salt or sugar is important.

In conclusion, more and more doctors are using the kitchen as the first defense for someone to become healthier. Many doctors are starting with this remedy rather than medication. Dr. Walter Willet and Dr. David Eisenberg, both members of the Harvard School of Public Health, have been bridging the gap between schools of medicine and the culinary profession to create awareness for the younger up-and-coming doctors to be more aware of the correlation between medicine and healthy eating.

27.4 SUMMARY

Food plays a significant role in everyone's lives, and different practices and behaviors of eating psychology can be bound to different cultures. The nutrition prescription and using behavioral techniques to guide patients to adopt and sustain nutritious and delicious eating patterns require education for the patient and the provider. Learning about the kitchen, cooking, cultural norms, family values, motivation, obstacles to change, strategies around obstacles, patients' strengths, and the power of plants; recognizing whole foods; knowing about healthy portions; and using the COACH Approach ™ allow clinicians to successfully counsel patients on adopting and sustaining healthy nutritional practices throughout their lives. Nutritional counseling can be done one on one or in group visits. The important factors are to educate both provider and patient on the basics of a healthy diet that is focused on whole foods and is predominantly plant based. Behavioral approaches in enhancing nutrition practices are crucial for all groups in order to mitigate the nutrition gap and enhance health promotion.

Once people understand the guidelines for healthy eating, then coaching them to create SMART goals and keep on track with vegetables, fruits, whole grains, nuts, seeds, legumes, and other healthy sources of protein is the key to maintaining a healthy eating pattern for a lifetime. Using psychology and evidence-based approaches from a practitioner and patient perspective creates self-efficacy, which is critical for long-lasting behavior changes. As chronic disease is on the rise, nutritional needs must be met as a therapeutic lifestyle intervention. Through updating health professionals on evidence-based nutrition practices and the evolving Dietary Guidelines, dietary misinformation will be mitigated, and health promotion will be enhanced.

CLINICAL APPLICATIONS

- Optimal nutrition intervention is the cornerstone of an effective lifestyle medicine prescription.
- By taking into consideration the various cultural factors involved in nutritional practices, the clinician will be able to better design a lifestyle medicine program that patients will find easier to adhere to.
- Implementation of effective health coaching can promote patient compliance with dietary change.
- One way to provide efficient, cost-effective nutritional counseling is through group medical visits.
- Dietary excellence first starts in the kitchen. Therefore, a working knowledge of basic culinary skills is key to building healthy lifestyle habits.

28 Behavioral Approaches to Manage Stress

Shirly Ramchandani, MD, Darshan Mehta, MD, MPH, Elise Loiselle, RN, MSN, FNP-C, and Jacqueline Proszynski BS

KEY POINTS

- The stress response and the relaxation response are innate protective and adaptive responses that initiate physiological and biochemical reactions in the body. The stress response can become harmful with prolonged exposure, but the relaxation response can help reverse the effects of allostatic load.
- Building resilience, practicing Mind–Body Therapies (MBTs), and making positive behavioral modifications can all help counteract the stress response, elicit the benefits of the relaxation response, and improve coping with perceived stress.
- Teaching patients to implement MBTs can help improve their adaptation to stress and is an essential treatment option for patients of all ages and health states.

28.1 THE STRESS RESPONSE AND RELAXATION RESPONSES

Stress is defined as "the non-specific response of the body to any demand for change."[1] Stress can be acute or chronic. The stress response is the physiological response, through activation of changes from the molecular to the behavioral domains.[2] A person's perception of stress is influenced by their genetic predispositions, life experiences, and environmental factors.[2] Over time, the brain initiates a cascade of both physiological and behavioral responses, leading to an increase in allostatic load (Figure 28.1).[3]

This is characterized by a cascade of immune, endocrine, and neural mediators, leading to systemic effects on organ systems.[4, 5] Chronic activation of the stress response is related to numerous chronic diseases and diminished quality of life. These non-communicable diseases (NCDs) are further fueled by damaging health behaviors under chronic stress. NCDs represent the most important global health challenge of the 21st century in terms of disease burden and mortality.[6] Stress is modifiable and is a desirable target for health interventions.

The relaxation response is a wakeful hypometabolic physiologic state that can be voluntarily elicited by many mind–body practices and counteracts the negative effects of the stress response. Figure 28.2 summarizes the physiological correlates of both the stress and relaxation response processes.[5]

28.1.1 Physiological Responses

The stress response is characterized by increased oxygen utilization, increased glucose uptake, and increased respiratory rate.[5] Through activation of the body's sympathetic nervous system, there is bronchodilation and vasoconstriction, leading to increased cardiac output, blood pressure, heart rate, and total peripheral resistance.[3,5,7–11] Oxygen-rich blood is shunted to essential organs[3,5,7–11] by the vascular system.

The relaxation response is characterized by predominance of the parasympathetic nervous system, resulting in decreased respiratory rate, oxygen consumption, and carbon dioxide elimination.[3,5,7–11] In addition, there is a reduction in cardiac output, with lower heart rates and blood pressure, as well as increased heart rate variability.[10,12–16]

28.1.2 Neurohormonal Pathways

The stress response is characterized by a cascade of biochemical changes, which are characterized by two pathways—the sympatho-adreno-medullary axis (SAM) and the hypothalamic-pituitary-adrenal axis (HPA).[3,5,7, 17] The SAM axis is rapid-acting, causing the adrenal medulla to distribute the powerful catecholamines epinephrine and norepinephrine, which activate the "fight or flight" response. This in turn, triggers the organ systems to respond by increasing heart rate, respiratory rate, oxygen consumption, and blood pressure.[3,5,7,17] In the other pathway, the anterior pituitary gland secretes adrenocorticotropic hormone (ACTH). This signals the adrenal cortex to release the hormone cortisol. The flow of cortisol initiates glucose production in the liver, elevating the body's glucose levels, which is necessary to yield adenosine triphosphate (ATP)[3,5,7,17] for utilization by cells.[16] The stress response also triggers the immune system to release pro-inflammatory cytokines, including interleukin (IL)-1 and tumor necrosis factor (TNF)-α.

Chronic stress is significantly associated with higher oxidative stress, lower telomerase activity, and shorter

DOI: 10.1201/9781003227793-32

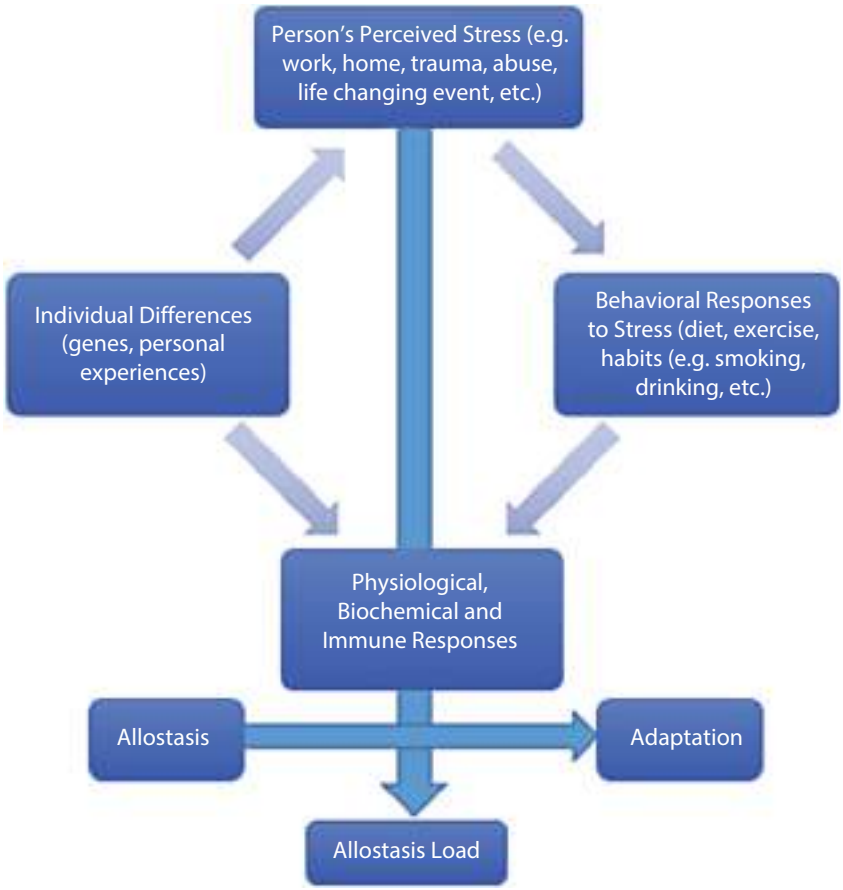

FIGURE 28.1 Moving from allostasis to allostatic load. (Adapted from McEwen, B.S., ***N. Engl. J. Med***., 338(3), 171–179, 1998.)

telomere length, which are known determinants of cell senescence and longevity. Telomere shortening is a risk factor for numerous diseases and may be a general biomarker of aging. Recent research points to the crucial roles of telomeres and telomerase in cellular aging and potentially in disease.[18]

The relaxation response elicits HPA changes, impacting the release of cortisol from the adrenal cortex.[13,20–24] It also increases nitric oxide in the vasculature.[4,22] Nitric oxide is an important biomarker that plays a role in vasodilatation and decreasing blood pressure.[4,5] The relaxation response also has immune benefits, showing an increase in lymphocyte[25] and natural killer cell activity and proliferation,[26–28] and an increase in nitric oxide[5,29] and serum IgA levels.[30] Elicitation of the relaxation response has demonstrated changes in the expression of more than 1500 genes.[4]

28.2 BUILDING RESILIENCE

Resilience is a dynamic trait that reflects an individual's ability to cultivate adaptive behaviors, thereby counteracting the negative effects of stress and returning to a state of well-being.[31,32]

Resilience is built by decreasing the stress response, promoting the relaxation response, and fostering growth enhancement. This model is summarized in Figure 28.3.

Mind–body therapies (MBTs) are essential in decreasing the stress response and activating the relaxation response. MBTs include practices from different cultural traditions. They are believed to share a common physiology as described by the relaxation response. MBTs have been shown to produce measurable reductions in levels of perceived stress,[33–47] increase positive emotions, and decrease levels of anxiety and depression.[15,22,48–58]

Table 28.1 summarizes research using MBTs in disease treatment. Helping build resilience through growth enhancement is another essential component to managing chronic stress.

The effects of stress are relative to individual experience and perception. Therefore, when patients are helped to develop stress awareness, this personal awareness allows an individual to better identify the negative effect of stress and antidote it with positive coping strategies, positive perspectives, and positive behaviors. Evidence suggests that higher positivity longitudinally predicts trait resilience[60] and is in turn associated with a sixfold decreased risk of depressive symptoms[61] and reduced stress.[62] Effective coping, alongside the regular practice of elicitation of the relaxation response, leads to more resilience.

As patients become secure in their awareness of the stress response, MBT practice, and positive coping strategies, recognition is important. Growth enhancement

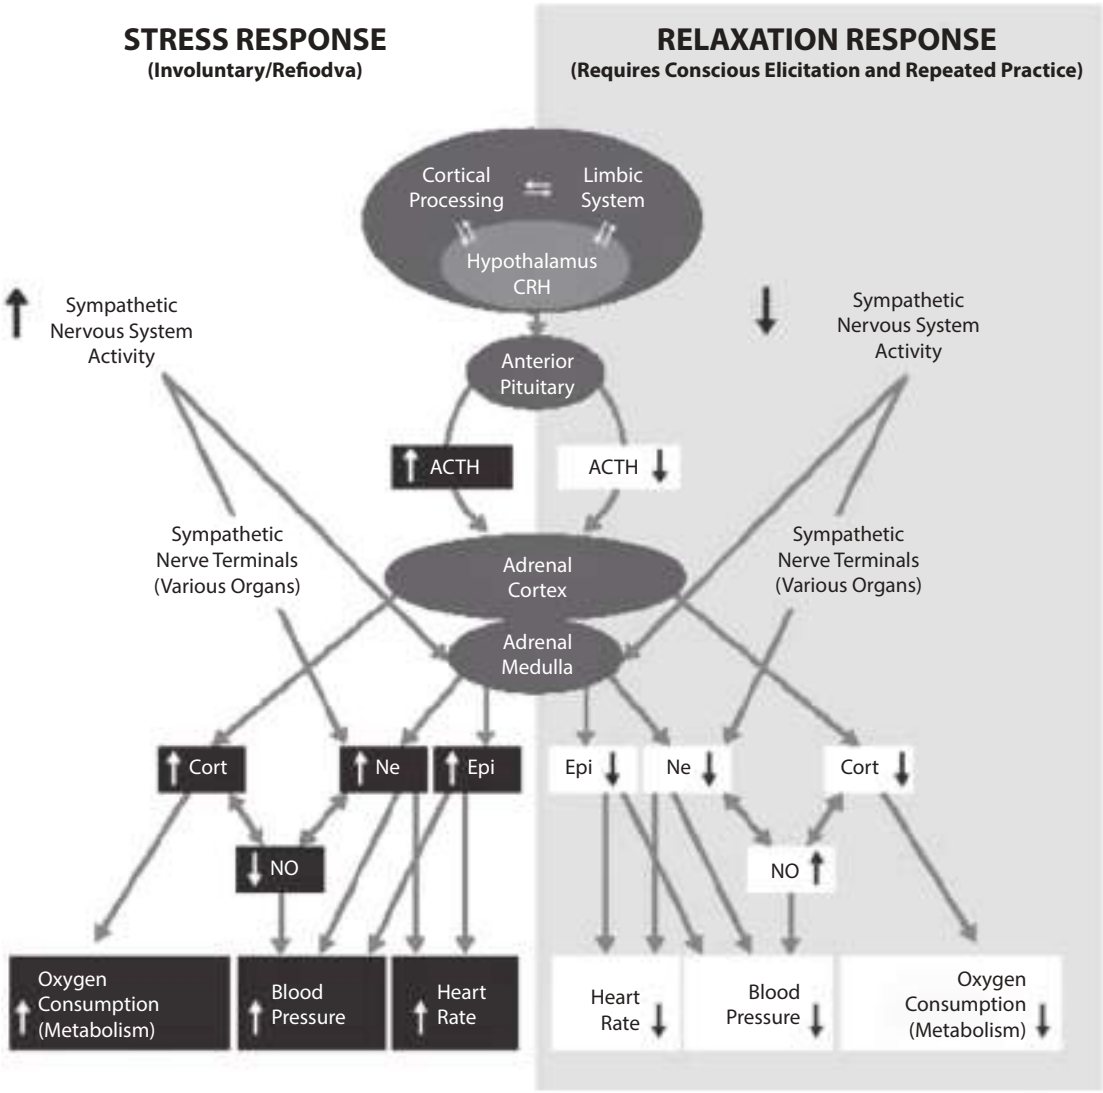

FIGURE 28.2 Comparative impact of the acute stress and relaxation responses: central and peripheral nervous system activities. (From Dusek, J.A. and Benson, H., ***Minn. Med.***, 92(5), 47, 2009.)

should be praised and reinforced by providers. This builds resilience.[33]

28.3 MIND–BODY THERAPIES

MBTs are found across many cultures (Figure 28.4)[17] Clinicians can provide prescriptions for these MBTs. Patients should be encouraged to explore different MBTs to determine which practice(s) they are comfortable with. The patients should also be encouraged to develop a regular practice. Figure 28.5 gives a general overview of tips to help patients develop a regular practice.

28.3.1 Meditation

Herbert Benson originally coined the term *relaxation response* and advised that it can be invoked by two steps:[1] repetition of a word, sound, phrase, or movement, and[2] disregarding other thoughts when they come during the practice. Meditation has been practiced for millennia across many cultures. It has been shown to have health benefits, including decreased blood pressure,[63,64] improved sleep,[62] and reduced anxiety and stress.[66–69]

28.3.1.1 Breath Awareness

Breath awareness is a single-pointed focus meditation. It is the practice of maintaining focused awareness of the breath. This is one of the easiest and most widely used meditation practices. This is exemplified in Figure 28.6.

28.3.1.2 Body Scan

The body scan is a great tool to notice any areas of tension, tightness, and discomfort within the physical body. Chronic pain patients noticed significant reduction in pain with a ten-minute body scan intervention.[73] Progressive muscle relaxation is another tool to help identify the difference

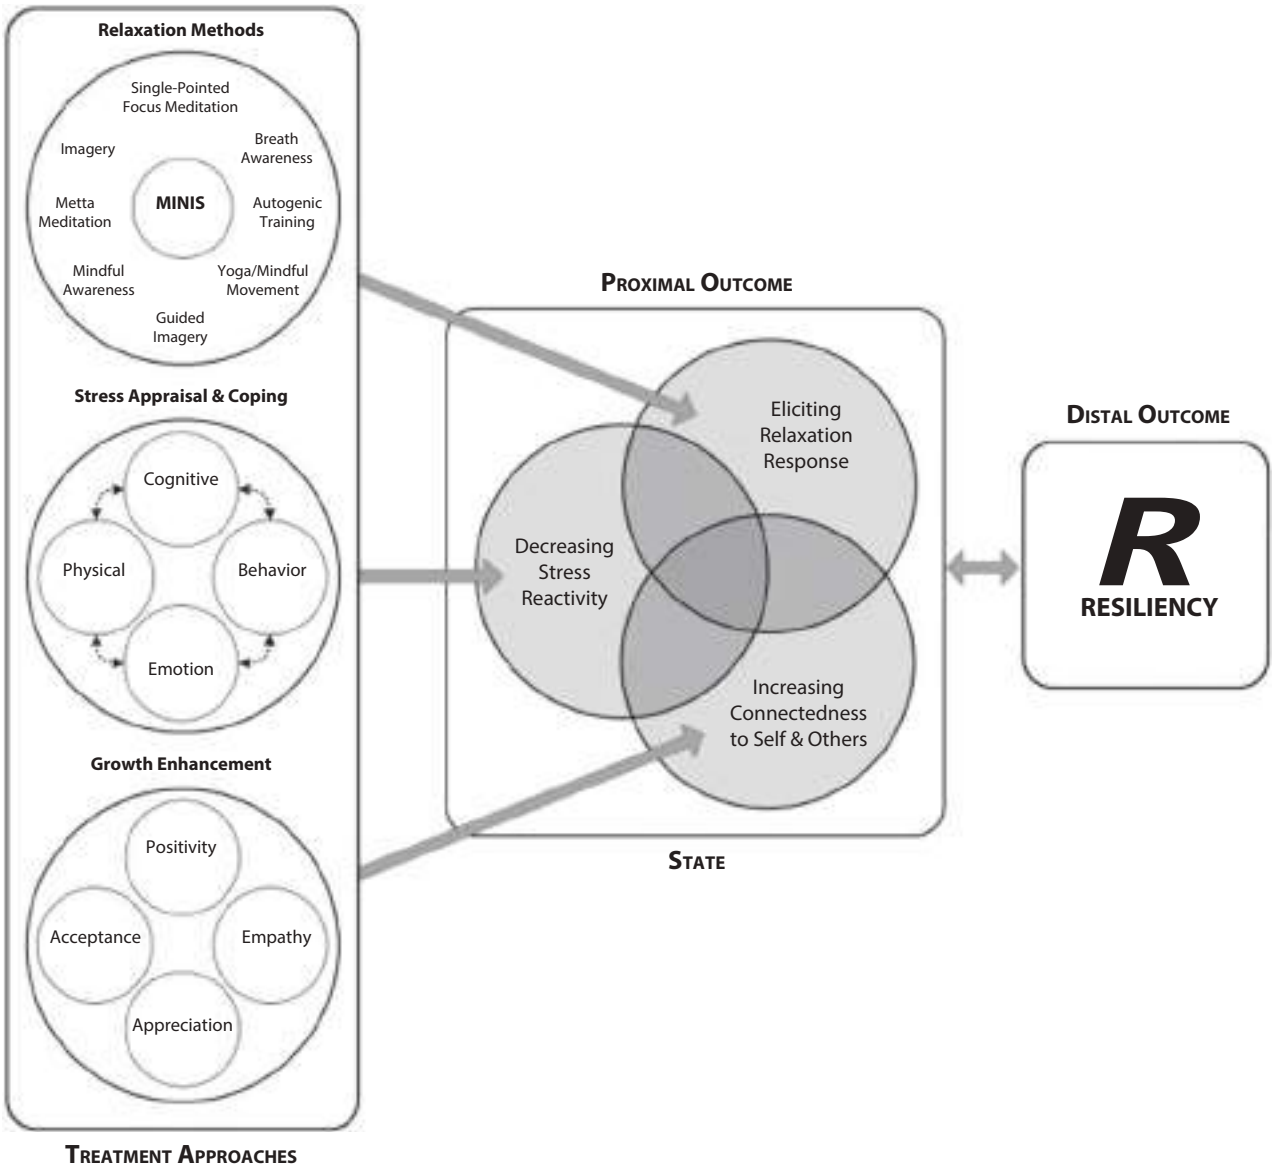

FIGURE 28.3 The relaxation response: the Relaxation Response Resiliency Program (3RP).

between tension and relaxation throughout the body. These practice techniques are described in Figures 28.7 and 28.8.

28.3.1.3 Guided Imagery

This MBT allows the use of imagination. Patients who use this while having surgery have shown higher pain tolerance, less pain and pain medication use, as well as less anxiety and lower heart rates.[72] The patient participating in imagery can sustain focus on an experience but change it in their imagination to reflect a more positive perspective or experience. The patient's own imagination can be a stress management tool by transforming negative memories and mental images[74] through visualizing growth in personal and/or social domains.[75] Imagery can reframe emotional responses to visual depictions of stress, help overcome negative memories of the past and stressful situations in the present, and prepare for anticipated stressful events in the future. A memory can be revised to reflect a more pleasant experience, which deactivates the stress response related to the experience. Figure 28.9 provides a script for guided imagery.

28.3.1.4 Contemplation and Prayer

Another way to elicit the relaxation response is contemplation and prayer. The major health benefits associated with prayer are increased sensation of relaxation and feelings of peace.[76] Many patients may resonate more with the idea of prayer, as it has been practiced throughout almost every religious tradition. There is sustained focus on an intention or positive outcome, and it requires stillness and attention on the intention. Figure 28.10 provides an example activity to guide patients through this practice.

TABLE 28.1
Conditions Treated with Mind–Body Therapies

Health Condition	Types of Practice	Intervention Effects	Research Quotation
Hypertension	YogaMeditation	The mindfulness group had lower clinically measured systolic blood pressure (SBP), 24-h SBP, at-rest SBP, and diastolic BP values.[8]	Ponte Márquez PH, Feliu-Soler A, Solé-Villa MJ, et al. Benefits of mindfulness meditation in reducing blood pressure and stress in patients with arterial hypertension. *Journal of Human Hypertension* 2019; 33(3): 237–247. doi:10.1038/s41371-018-0130-6
Surgical Pain	Qigong	Improvements were observed at 12 weeks in physical well-being and emotional well-being in BCS	Osypiuk K, Ligibel J, Giobbie-Hurder A, et al. Anxiety	MBSR	Mindfulness-based stress reduction could decrease anxiety and depression symptoms	Samira Masumian, Shahrbanoo Ghahari, Zeinab Bahram Beigi, Ali Asghar Asgharnejadfarid, Hooman Yaghmaeezadeh. The Effectiveness of Mindfulness-based Stress Reduction (MBSR) in Reducing of Depression, Anxiety and Quality of Life in Women with Generalized Anxiety Disorder. *Journal of Research in Medical and Dental Science* 2019; 7(1): 71–76. Accessed April 17, 2022

28.3.1.5 Loving Kindness

Loving-kindness meditation is a practice that helps bring more peace into the mindset and life of the individual. Patients who use this technique showed more positive emotions, decreased depression, more social supports, and decreased symptoms.[77] The practice allows individuals to bring more compassion, empathy, and kindness into their daily lives. By teaching the individual to sit in quiet stillness and send out feelings of love, kindness, compassion, and well-being toward others, it deactivates the stress response. When done toward themselves and others, it promotes positive emotions, which increases a sense of personal well-being and overall compassion for others.

28.3.2 Movement

Yoga and tai chi are two modalities that are highly associated with well-being, reduced perceived stress, increased physical fitness, and many positive health outcomes.[75–79] There are some safety concerns for practicing yoga and tai chi, but these are minimized when taught by a certified instructor.[80,81] As with all movement-based practices, it is advised that women who are pregnant, and people with certain medical conditions, such as high blood pressure, glaucoma, and sciatica, should modify or avoid certain postures, especially when starting a yoga or tai chi routine.

28.3.2.1 Yoga

Yoga is a moving meditation, coupling the breath with various body postures, that elicits the relaxation response. Evidence has shown it may be particularly helpful for those suffering from back pain, migraine, mental health concerns, and some gastrointestinal and cardiovascular conditions.[79] Yoga may help alleviate symptom intensity and severity directly through physical movement as well as indirectly through psychological mechanisms.[72] There are many styles of yoga, ranging from low-intensity restorative and Hatha practices to high-intensity vinyasa or ashtanga, each with its benefits and limitations.[85,86] It is important to review the differences between styles to make a recommendation best suited for the patient's health status and treatment goals.

28.3.2.2 Tai Chi

Tai chi is another moving meditation that connects controlled movements of the body with the breathing of the practitioner. It is a Chinese martial art that focuses on the balance of contrasting movements to create physical and

TABLE 1. Example Techniques for Eliciting the Relaxation Response

Technique	Concept	Mechanism
Breath awareness	Shift from shallow breathing to abdominal breathing. Draw air deep into lungs using even breath.	Improve ability of respiratory system to produce energy from oxygen and remove waste.
Self-hypnosis	Narrow consciousness without completely losing awareness, to allow suspension of disbelief and experience of thoughts and images as real.	Facilitates both focused, intense mental activity and state of relaxation simultaneously.
Guided imagery	Use imagination to refocus mind on positive, healing images.	Negative thoughts influence feelings and behavior, and exacerbate physical symptoms. Thoughts become reality (i.e.. you are what you think you are). Therefore, use imagination to reduce subjective stress and to treat physical symptoms.
Autogenic training	Use verbal commands that suggest bodily warmth and heaviness in limbs.	Word phrases suggest relaxation to the unconscious mind, which manifests the desired responses in the body. Aims to reverse "flight or flight" response during physical or emotional stress by promoting relaxation of the voluntary arm and leg muscles, inducing peripheral vasodilation, and normalizing cardiac activity.
Progressive muscle relaxation	Alternately tense and relax different muscle groups, to better distinguish between these two states.	Based on premise that the body responds to anxiety-provoking phenomena with muscle tension that increases subjective anxiety. Muscle relaxation reduces physiologic tension and, therefore, blocks the subjective anxious response.
Transcendental meditation	Engage in attempting to anchor attention nonjudgmentally on a silent mantra.	Negative emotion cannot persist when focusing on something other than the target of the emotion. Habitual thought patterns lose influence when brought to conscious awareness. Present focus reduces emotional extremes. Meditation also slows sympathetic nervous system activity.
Mindful awareness	Observation or attention to phenomena in the moment nonjudgmentally as they enter awareness	Strong emotions become manageable by focusing on sensations rather than the content of emotional thoughts.
Yoga	Movement meditation correlated with the breath.	Yoga is a comprehensive system of practices for physical and psychological health and well-being, and incorporates multiple techniques including physical postures/exercises, breathing exercises, and meditation/concentration techniques. As an integrative discipline, yoga takes advantage of the simultaneous application of its component techniques, all of which contribute to eliciting the relaxation response.

FIGURE 28.4 Example techniques for eliciting the relaxation response.

mental harmony. Like yoga, there are many styles of tai chi that differ slightly in technique and methodology, but all may help to manage pain and arthritis, mental health, cardiovascular disease, and neurological conditions.[78, 79] Individuals with Parkinson's disease, fibromyalgia, rheumatoid arthritis, and osteoarthritis may benefit from practicing tai chi, as it been shown to ease symptom severity and disease-specific pain, and increase balance, stability, and overall quality of life.[87–92] Reports indicate long-term efficacy of tai chi, with benefits persisting at three years' follow-up.[93]. Though it is well suited for all ages, the low-impact, slow-paced qualities of tai chi make it an attractive option for elderly patients (Figure 28.11).

28.3.3 Gratitude

Gratitude is also shown to build resilience. It is the practice of showing appreciation for the present moment, people, experiences, and opportunities in our lives. When a patient is stressed, the foundation of appreciation is lost, and thoughts can become ruminating, worrisome, and negative.[94–96]

Gratitude has many physiological benefits, including a decreased heart rate.[94] Gratitude practice has also shown changes in the brain, including those associated with emotion self-regulation and self-motivation.[97] Another study found that those who practiced gratitude had decreases in symptoms of anxiety and depression, with effects lasting three months beyond the interventions.[98] Expressing gratitude has been shown to reduce levels of perceived stress, anger, and burnout,[50,94–96,99–108] and increase feelings of well-being[95] and happiness. Practicing gratitude has been associated with an overall sense of gratefulness for loved ones, life, and social supports,[100,108] as well as leading to a more positive affect,[109] positive reframing, acceptance, humor, and better coping.[102]

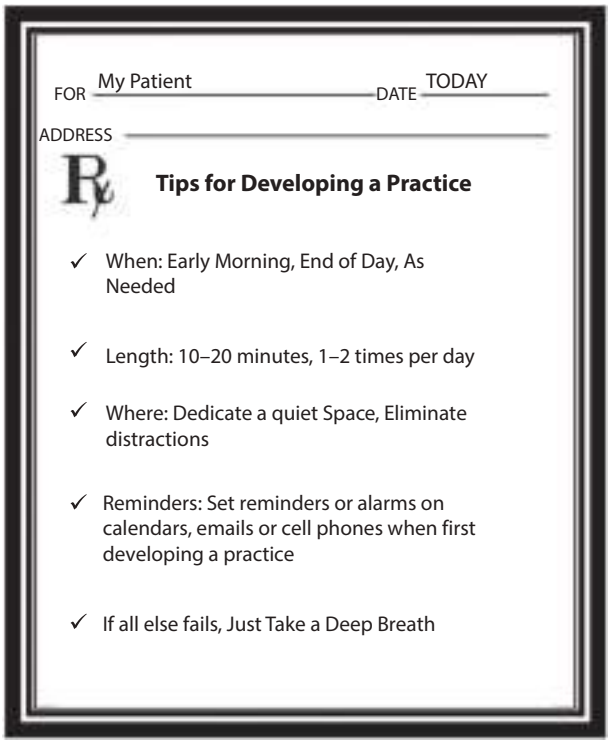

FIGURE 28.5 Tips for developing a meditation practice.

28.3.3.1 Practicing Gratitude

People who express gratitude regularly are more likely to respond to stressors with appreciation instead of negative emotions. It helps build a more positive perspective in those who have a regular practice.[94–96] Some clinicians are using gratitude as a part of treatment for anxiety, depression, and anger.[99–103,105–107,110]

Building a practice of gratitude requires expressing appreciation consistently and intentionally. The practice can be done through journaling, writing letters, talking to family and friends, and even sharing on social media. The more specific one is regarding the appreciation, the easier it is to practice. See Figure 28.12 for tips to develop a practice of gratitude.

28.3.4 Building a Positive Perspective

Building a positive perspective is a critical process in the management of stress. By building a positive perspective, individuals may better manage stress in the moment and subsequently withstand stress in the long term by using positive coping strategies and enhancing resilience.

Barbara Fredrickson (2004) developed the broaden-and-build theory of positive emotions.[111] Positive emotions are essential for optimal functioning, including building resilience, improving attention, fostering creativity, disengaging persistent negativity, improving interpersonal relationships, becoming more resourceful, increasing overall well-being, and ultimately, allowing the person to move beyond survival and into a state of thriving. Positivity also helps with emotional regulation and the ability to be more adaptive when coping with negativity and stress.[112]

Humor is essential to building a positive perspective, helping to combat and manage stress. Laughter and humor are some of the most commonly used and easily accessible self-care practices.[113] Individuals with a high sense of humor report less anxiety, view stimuli as less stressful, and are more likely to use cognitive reappraisal and problem-solving coping strategies.[114] Humor catalyzes the process of appreciation and acceptance, especially self-enhancing (laughing at oneself or making light of stress) and affiliative (making light of relatable experiences with others) humor. It is important to understand both your own and the patient's style of humor. Encourage adaptive humor and reframe any maladaptive humor, such as self-defeating and aggressive/sarcastic styles.

28.3.5 Adaptive Coping Strategies

Patients who experience stress often reach for maladaptive coping strategies that may be harmful to them. Helping patients develop more adaptive patterns will also help them secure high trait resilience, measured by self-efficacy, optimism, humor, and coherence (Table 28.2). Adaptive copers have longer, happier, and less stressful lives.[115] An important component of developing more positive and beneficial coping strategies involves cognitively reframing the patient's response to stress. Cognitive reappraisal is an adaptive strategy that aims to regulate emotions in times of stress by adjusting thought, interpretations, and responses to the stimuli.[117] It is a tool to help edit negative thoughts to shift thinking from a stress reaction to adaptive coping (Table 28.2 gives a few examples of positive coping traits, and Table 28.3 gives adaptive and maladaptive examples of problem-focused and emotion-focused coping strategies for managing stress). Using reappraisal has positive biological and physiological outcomes as well. Patients who practice cognitive reappraisal and change their perception of negative events can reduce stress by reframing psychological and physiological responses elicited by the stress response.[119]

28.3.5.1 Teaching Patients to Change Their Mind

Cognitive reappraisal is a mechanism of change used many in psychotherapeutic interventions, including cognitive-behavioral therapy (CBT), mindfulness-based stress reduction (MBSR), Stress Management and Resiliency Training (SMART), and mindfulness-based cognitive therapy (MBCT). Healthcare providers can introduce cognitive reappraisal skills to patients, and the patients can use these in their daily life. Patients who use cognitive reappraisal skills report improvements in well-being, reduced stress, and improved health outcomes.[120]

The first step in using cognitive reappraisal is thinking of a situation or experience the patient deems "stressful." Then, help them identify the emotions that they feel related to the stressor. Every negative emotion is linked to an underlying belief that the patient feels is true. For example,

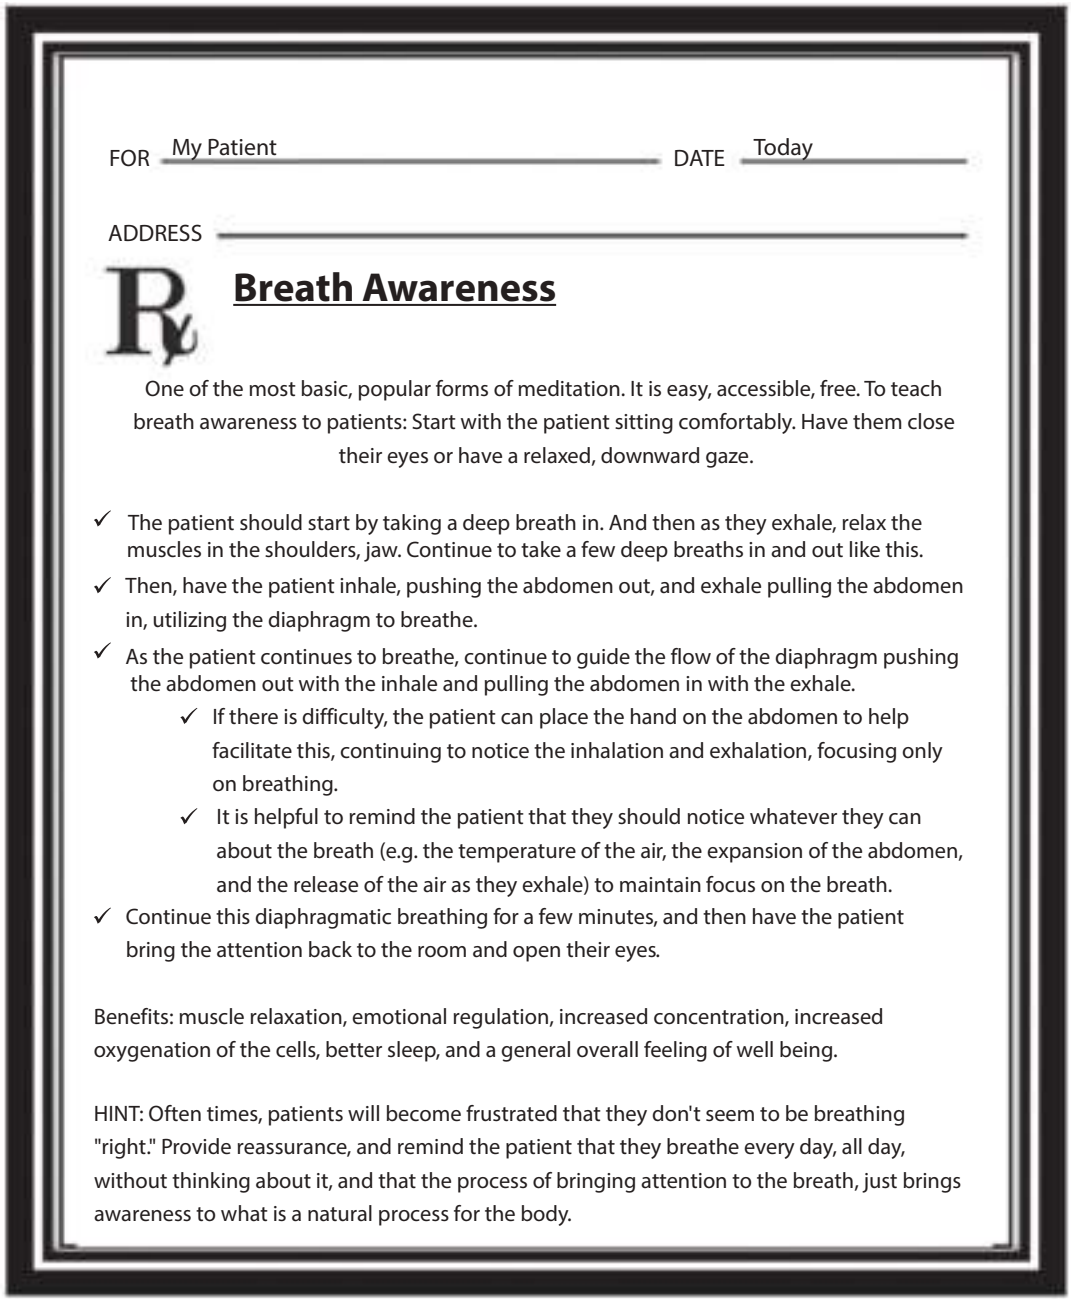

FIGURE 28.6 Tips for developing breath awareness.

the underlying belief of anxiety is "I am not safe, I am not in control." Once the emotions and underlying beliefs are identified, a reappraisal of the stressor can begin by recognizing the maladaptive, negative emotions and beliefs, and working to antidote them with positive emotion. An example could be helping a patient feel acceptance or forgiveness or surrender to the stressor. This helps them establish positive emotions with the stressor and in turn, reinforces the positive underlying belief of that emotion, releasing the negative emotion and thought patterns related to the belief. This allows the patient to move forward, reframing their thoughts to be more positive, beneficial, or motivational. Understanding this basic structure can help providers to clearly explain this process to patients and ensure its benefit (examples provided in Table 28.4). It is important to educate patients that changes take time and practicing these skills regularly will help them develop resilience over time. Tips to prescribe cognitive reappraisal to your patients can be found in Figure 28.13.

28.3.6 Other Lifestyle Modifications

Adjusting lifestyle behavior is the most basic method of making positive, lasting changes in stress levels. Healthy choices in nutrition, exercise, sleep, and habits can not only help to manage stress but also prevent and/or ease symptoms

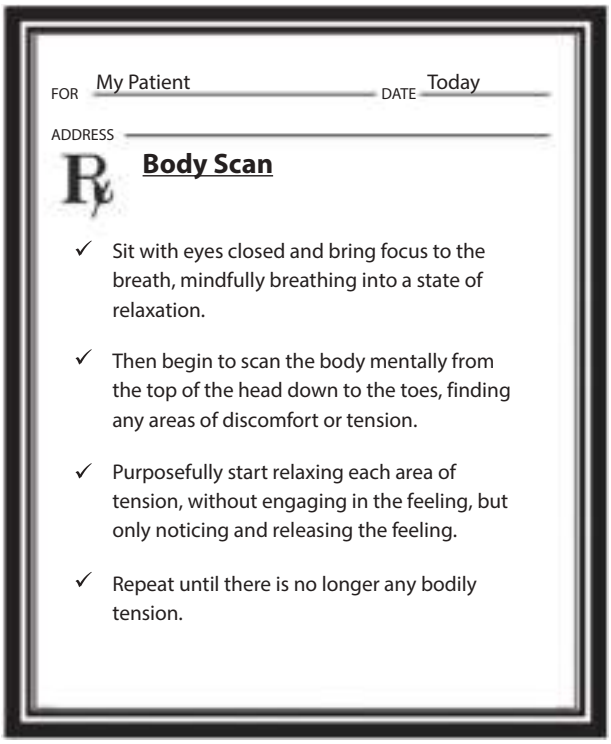

FIGURE 28.7 Tips for doing a body scan.

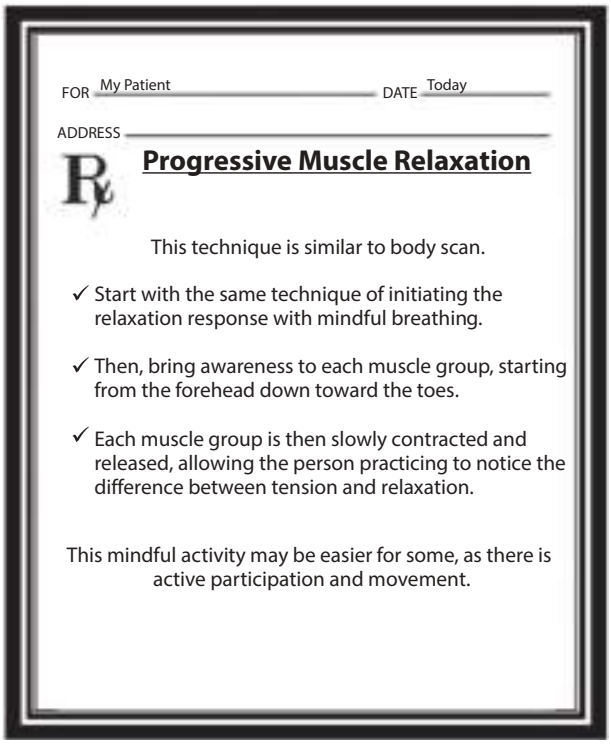

FIGURE 28.8 Tips for doing progressive muscle relaxation.

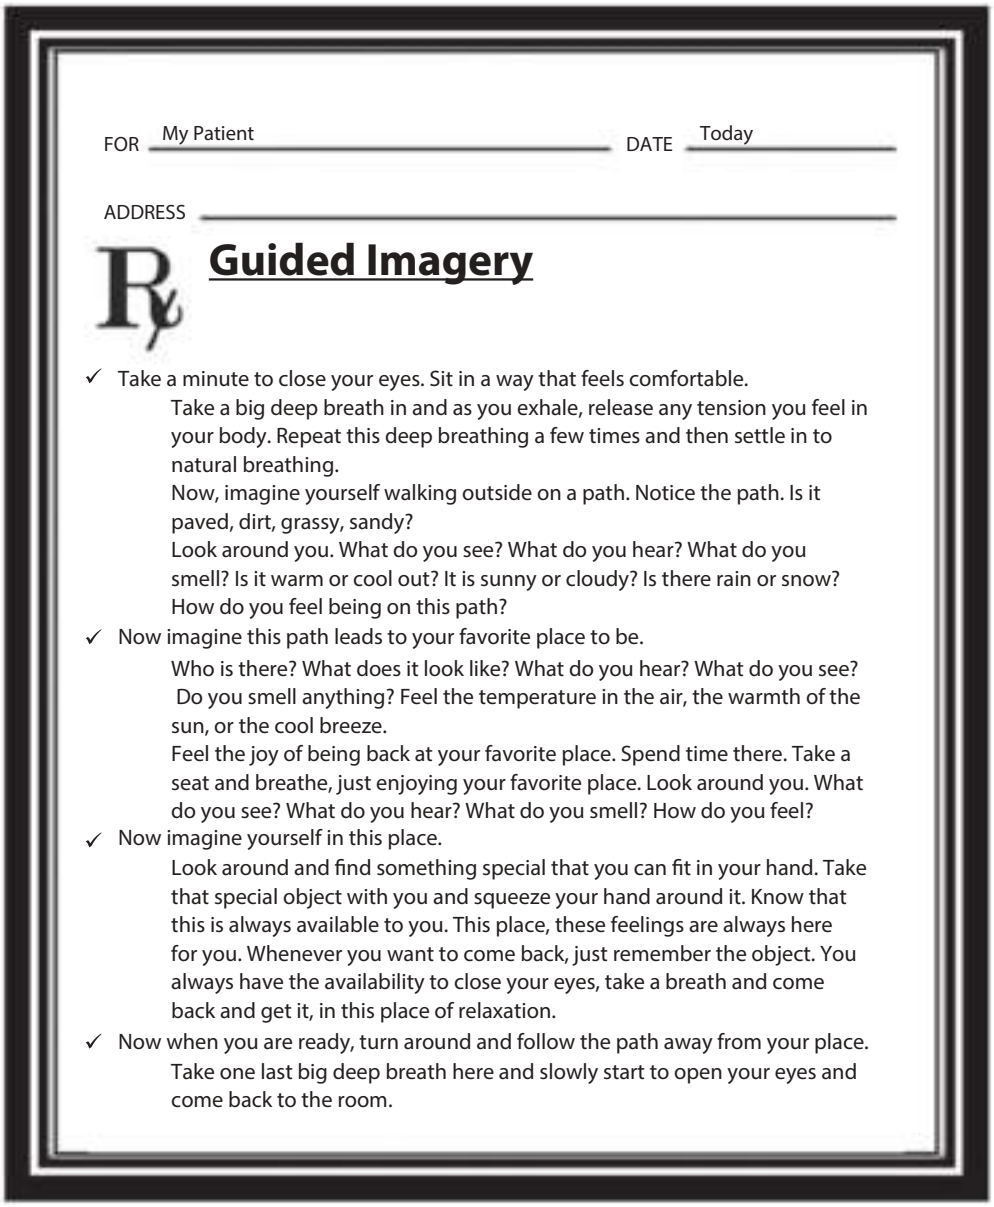
of chronic diseases.[121] These modifications are discussed in depth in other chapters of this book, but it is important to recognize that perceived stress can affect a patient's lifestyle choices. Personalized lifestyle changes can be prescribed as individualized self-care tools, as in Figure 28.14.

28.3.6.1 Nutrition and Stress



Proper nutrition is an important pillar of well-being; however, stressful stimuli can cause healthy eating habits to crumble. Stress impacts eating behaviors at physiological and neurobiological levels to such an extent that it can trigger the body's reward system to seek foods containing large amounts of sugar and fat, mirroring the response of an addiction.[122] This reward-seeking behavior is accompanied by potentially harmful alterations in glucose metabolism, insulin sensitivity, and other hormones related to energy balance.[123] Eating mindfully can ease the stress-related effects on eating behaviors. To eat mindfully is to fully engage the senses in the preparation and consumption of a meal or snack.[124] Taking the time to fully enjoy a meal reduces impulsive eating, increases enjoyment of food, and is related to preference for healthier food choices, especially for stressed individuals.[125,126] Figure 28.15 provides an example of prescribing mindful eating.

28.3.6.2 Sleep and Stress

Sleep is often sacrificed when schedules become overwhelming. Yet, this creates a harmful cycle: lack of sleep may contribute to a rise in stress, while a rise in stress can affect sleep. Stress may alter sleep patterns by increasing or decreasing the number of hours a person sleeps or feels that they need, resulting in negative consequences for cognitive and physical functioning. Sleep disturbance and deprivation are associated with inflammation, increased levels of cortisol, metabolic disruptions, and all-cause mortality.[127,128] Practicing good sleep hygiene promotes getting the necessary amount of sleep for mental and physical restoration. Sleep deprivation may lead to mood abnormalities, decreased cognitive functioning, weight gain, suppressed immune system, and exacerbation of pre-existing conditions.[129,130] According to the Centers for Disease Control and Prevention (CDC), adults are encouraged to sleep at least 7 hours, while teens need 8–10, and school-aged children need 9–12 hours per night. Toddlers and infants required the most, at 11–16 hours per 24-hour period.[131,132] Working with your patient to establish a consistent sleep schedule will improve the quality of their sleep and subsequent health.[130,128] See Sleep Tips (Figure 28.16).

28.4 THE ROLE OF TECHNOLOGY IN STRESS MANAGEMENT

Technology can be a great tool to help patients elicit the relaxation response. There are many smartphone applications, online websites, computer programs, audio recordings, and videos that can help patients develop a practice. Self-guided, online, asynchronous computer courses showed a significant decrease in stress and anxiety, as well as increasing cognitive attention.[57] Researchers are studying mobile apps and video conferencing for the treatment of stress, anxiety and depression,[42,57,133,134] and chronic pain.[135] Virtual reality programs are also being utilized as an educational

FOR My Patient DATE Today

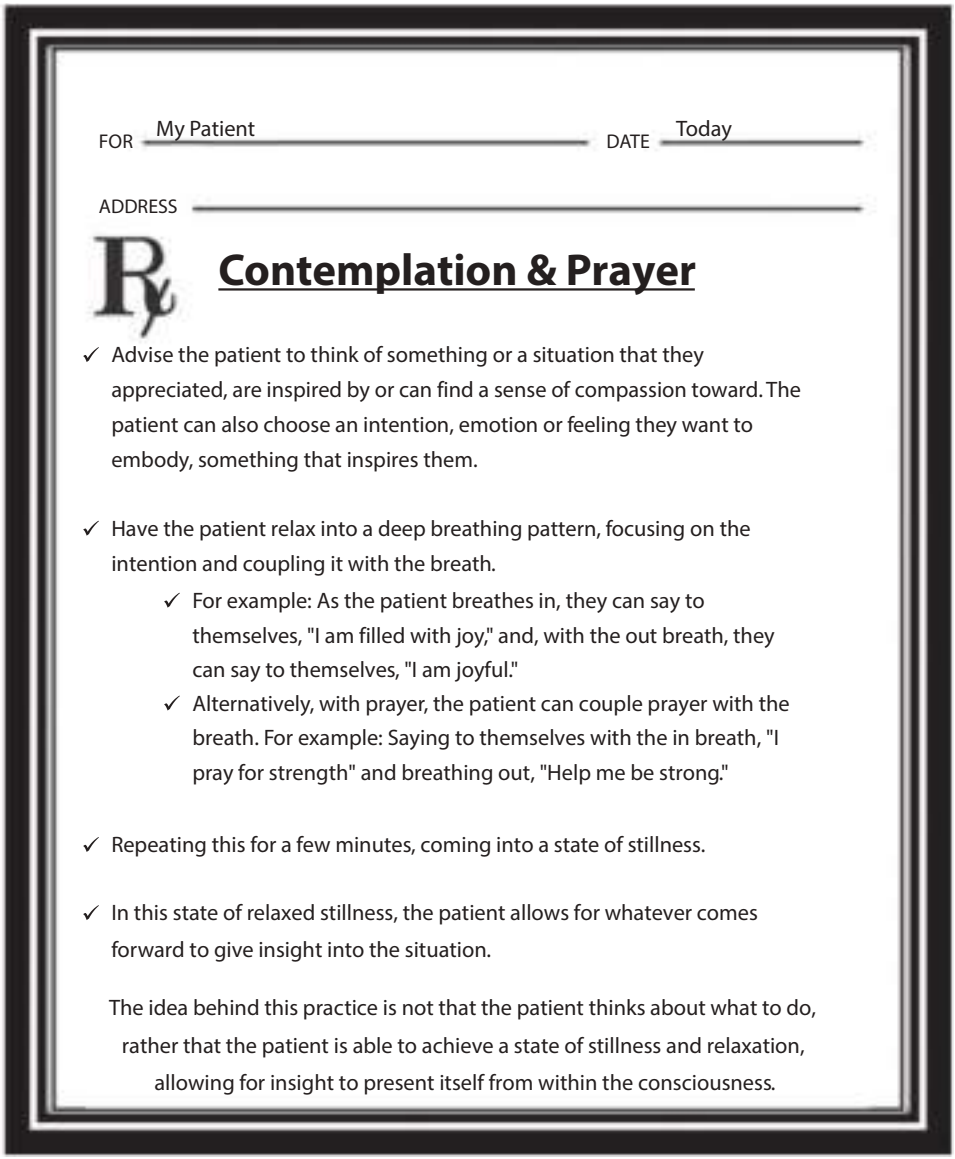
ADDRESS

℞ **Guided Imagery**

✓ Take a minute to close your eyes. Sit in a way that feels comfortable.
Take a big deep breath in and as you exhale, release any tension you feel in your body. Repeat this deep breathing a few times and then settle in to natural breathing.
Now, imagine yourself walking outside on a path. Notice the path. Is it paved, dirt, grassy, sandy?
Look around you. What do you see? What do you hear? What do you smell? Is it warm or cool out? It is sunny or cloudy? Is there rain or snow? How do you feel being on this path?

✓ Now imagine this path leads to your favorite place to be.
Who is there? What does it look like? What do you hear? What do you see? Do you smell anything? Feel the temperature in the air, the warmth of the sun, or the cool breeze.
Feel the joy of being back at your favorite place. Spend time there. Take a seat and breathe, just enjoying your favorite place. Look around you. What do you see? What do you hear? What do you smell? How do you feel?

✓ Now imagine yourself in this place.
Look around and find something special that you can fit in your hand. Take that special object with you and squeeze your hand around it. Know that this is always available to you. This place, these feelings are always here for you. Whenever you want to come back, just remember the object. You always have the availability to close your eyes, take a breath and come back and get it, in this place of relaxation.



✓ Now when you are ready, turn around and follow the path away from your place.
Take one last big deep breath here and slowly start to open your eyes and come back to the room.

FIGURE 28.9 Tips for doing guided imagery.

TABLE 28.2
Protective Positive Coping Traits for Stress Management

Positive Coping Traits for Stress Management	
Self-efficacy	Confidence that one can do what is required to cope and that one's efforts will work
Optimism	Having positive expectations about the future
Humor	Being able to laugh at oneself or situations in a good-natured, light-hearted way
Coherence	Having a general orientation that sees life as meaningful and manageable

tool to elicit the relaxation response. These programs have a significant psychological benefit of lowered depression, anxiety, and perceived stress, as well as changes in physiologic markers.[55] A systematic review found considerable backing for the usefulness of online and virtual delivery of MBTs in decreasing perceived stress.[136] In addition, subjects responded positively, and with significant benefit, to an e-mail based gratitude intervention on increasing sleep

FOR My Patient DATE Today

ADDRESS

℞ **Contemplation & Prayer**

- ✓ Advise the patient to think of something or a situation that they appreciated, are inspired by or can find a sense of compassion toward. The patient can also choose an intention, emotion or feeling they want to embody, something that inspires them.
- ✓ Have the patient relax into a deep breathing pattern, focusing on the intention and coupling it with the breath.
  - ✓ For example: As the patient breathes in, they can say to themselves, "I am filled with joy," and, with the out breath, they can say to themselves, "I am joyful."
  - ✓ Alternatively, with prayer, the patient can couple prayer with the breath. For example: Saying to themselves with the in breath, "I pray for strength" and breathing out, "Help me be strong."
- ✓ Repeating this for a few minutes, coming into a state of stillness.
- ✓ In this state of relaxed stillness, the patient allows for whatever comes forward to give insight into the situation.

The idea behind this practice is not that the patient thinks about what to do, rather that the patient is able to achieve a state of stillness and relaxation, allowing for insight to present itself from within the consciousness.

FIGURE 28.10 Tips for doing contemplation and prayer.

TABLE 28.3
Problem-focused and Emotion-focused Coping Strategies for Managing Stress

	Problem-focused Coping	Emotion-focused Coping
Aim	Action taken to reduce or remove stressor	Action taken to reduce distress caused by stressor
Example	A company is beginning a round of layoffs in the department	
Adaptive Use	Individual starts to save money and refine resume	Individual uses relaxation techniques such as meditation to reduce stress
Maladaptive Use	Individual uses substances to remove the reality of possibly losing a job	Individual denies or mentally blocks the possibility that they will lose their job

Source: Adapted from Carver, C.S. and Connor-Smith, J., *Annu. Rev. Psychol.*, 61, 679–704, 2010.

and decreasing sleep worry.[137] These resources are both practical and appealing to patients and clinicians, as they are often convenient to use and widely available, and still show significant effects on stress reduction. Another important role of technology-based interventions is that they allow increased touch points between providers and patients.

FOR My Patient DATE Today

ADDRESS

℞ **Cognitive Reappraisal**

- ✓ Identify stressor/stressful situation.
- ✓ Identify emotions felt related to that stressor.
- ✓ Identify underlying belief related to that emotion.
- ✓ Find positive emotion to reframe stressor.
- ✓ Reinforce underlying belief related to positive emotion.
- ✓ Reframe thoughts about stressor with new, positive, adaptive thoughts.

FIGURE 28.13 Cognitive reappraisal.

FIGURE 28.14 Tips for self-care.

28.5 SUMMARY

MBTs are beneficial on a physiological, biochemical, and immune response level to patients, and have many positive psychological and behavioral outcomes. There are many health benefits, both preventive and managerial in nature. Prescribing MBTs can become a useful tool in routine practice. Utilizing the techniques described in this chapter, building resilience, and unleashing the mind's capacity to affect health, is an essential treatment option for patients of all ages and health states. The more MBTs are integrated into practice as the standard of treatment and prevention, the more acceptable they will become, and the more positive impact there will be on our patients' health. This will also lead to more research, further confirming the benefits of MBM and paving the way for discoveries about the interconnectedness of the mind, brain, and body.

CLINICAL APPLICATIONS

- Mind–body medicine and many MBTs are beneficial to patients on a physiological, biochemical, psychological, and behavioral level.

TABLE 28.4
Reappraising Negative Automatic Thoughts

Identifying Negative Thoughts		Building an Adaptive Response	
Negative Emotion	Cognitive Distortion	Adaptive Feeling	Cognitive Reappraisal
Anger	My circumstances are unfair or unjust	Tolerance, Clarity, and Sacrifice	I allow what is and make compromises
Hopelessness	Nothing will help me, I am a lost cause	Power and Perseverance	I can have a positive influence
Sadness	I am experiencing a loss in my life	Appreciation and Detachment	I cherish and value what I have or will work with what is
Guilt	I am not living up to my own morals	Newness and Process	I value potential for growth and change, one step at a time
Shame	I've done something wrong or at risk of being found out	Courage and Choice	How can I act in the face of fear to fix the problem and prevent it for next time?
Resentment	They don't deserve my forgiveness	Forgiveness and Compassion	Focus on healing my own suffering and understanding others, not blaming them

What Does Sleeping Do?

Restorative sleep supports your body's natural healing in many ways including:

- Healthy metabolism
- Normal appetite drives
- Flushes inflammation from the brain
- Regulates the immune system

5 hours of sleep is considered core sleep and allows us to function reasonably well. A nice efficiency for those of us who can't always get a good night's sleep. However, to reap the full benefit of sleep, getting all the sleep you need often, let's your body and brain recharge by clearing out the day's accumulated by-products of stress and rebuild new resources. You feel more tolerant, more stress-hardy, more alert, more engaged, have better memory and general sense of positivity and well-being. With a good night's sleep your brain and body are more equipped to handle stress.

Sleep requirements vary from person to person varying from 7 to 9 hours. Waking refreshed is a good sign you've gotten what your body requires.

Normal sleep onset typically occurs within 20 minutes, and even if you waken during the night, you can easily resume sleep without missing your daily requirements

Positive Sleep Thoughts

- My sleep will improve as I learn these new techniques.
- Even with little sleep, I make it through the day just fine.
- Since I had poor sleep, I'll be easy on myself and aim for a little self-nurturance.
- My performance will still be fine, even if I just get core sleep.
- Like most people, I'm probably getting more sleep than I think.
- My daytime function is not just affected by my sleep.
- My daytime function is due in part to my negative, stress-related thoughts.
- Sleeping 6-7 hours per night is associated with the longest life expectance.
- I'm more likely to fall asleep as my body temperature falls throughout the night.
- My functioning will improve during the day as my body temperature rises.
- It is normal to initially feel alert if I awaken at the beginning or end of a dream - drowsiness will soon follow if I keep my mind quiet.
- These techniques have worked for others, they'll work for me.
- Lack of sleep increases my body's sleep drive, so I'll sleep much deeper next time.
- Meditation can counter some of what my body missed out on from lack of sleep.
- If I exercise today, it'll help me sleep tonight.

- Providers should use the tools provided in this chapter as prescriptive for wellness promotion, disease prevention, and illness management by prescribing MBTs as routine practice.
- Prescribing these essential skills to patients, as well as developing a powerful self-practice, has the potential to increase positive interactions and interpersonal provider–patient relationships as well as to provide protective and adaptive resilience in everyone.

29 Health Coaching and Behavior Change

Karen L. Lawson, Margaret Moore, Matthew M. Clark, Sara Link, Samantha Morley, MPH, MS, and Ruth Q. Wolever

KEY POINTS

- Despite awareness that lifestyle behaviors—such as a nutritional diet and regular exercise—play a critically important role in achieving health, individuals struggle to achieve these things on their own. Supporting clients in this effort is not consistently done by any other healthcare provider than a health coach.
- Information alone does not readily result in significant or sustainable health behavior changes. People need reliable support, encouragement, empowerment, and accountability—which health and wellness coaches can provide.
- An individual's beliefs and perspectives about their health challenges and capacity to heal impact their quality of life and clinical course. Health and wellness coaching (HWC) can be a path to more empowered and positive beliefs.

29.1 INTRODUCTION

Stories. They may be our sanctuaries or our prisons—providing hope and guidance or fostering despair. We have the power to choose whether we are author, editor, or witness to these narratives. While the choice is ours, most of us need companionship along the way to create healthy and productive lives, especially when our health and well-being are threatened or disrupted. Health and wellness coaches provide the opportunity and support for individuals to actively choose—and change—their health narratives.

Our contemporary healthcare system is built around diagnosis—what is wrong and how to "fix" it or minimize the suffering. Care is prescriptive, diagnosis-driven, and often depersonalizing. Prevention is a secondary process, screening for asymptomatic existing problems. As healthcare consumers, we receive expert advice and therapeutic procedures, are prescribed pharmaceuticals, and are informed of statistical prognoses. If fortunate, we may receive education about the illness or intervention, or have help navigating the complexities of the disease-care system. However, true prevention through supporting positive health habits—such as eating well, not smoking, exercising, managing stress, cultivating positive relationships, or having quality sleep—is rarely part of our financed medical system. This is true even though such practices are responsible for at least 40% of our health outcomes, and research shows that sustaining four primary health behaviors—not using tobacco, being physically active, moderating alcohol intake, and consuming five servings a day of fruit and vegetables—predicts a fourfold difference in total mortality.[1,2] Patient-centered care endeavors to empower the individual and acknowledge the importance of the relationship between patient and provider. These relationships, however, are filtered through reductionistic frameworks within systems that allow neither time nor reimbursement for counseling for positive lifestyle change. This situation creates stories of disempowered, injured, or ill persons being told what to do and when to do it, while only rarely being engaged on why and how they may achieve these changes given their own unique life circumstances, values, and beliefs.

Health and wellness coaches partner with clients to help them recognize their own narratives of illness and healing; reveal beliefs and choose those they wish to change; reinforce their engagement and empowerment; identify their values and priorities; chart their plan for lifestyle changes within reasonable time frames; recognize resources and address barriers; set, track, and attain self-selected goals; and establish accountability and social support. They hold the vision of the wholeness within an individual—especially when the patients are unable to see it for themselves. While all healthcare providers would ideally provide some of these services, it does not routinely occur. Even in integrative practices aligned with a holistic model of healing, practitioners are the experts being sought for advice, information, or intervention rather than supporting the patient as the expert in their own life. Indeed, the health and wellness coach has been the "missing provider" from our healthcare system. The recognition of that need, and the training and employment of health and wellness coaches to fill this gap, increases our likelihood of success in improving overall health through individuals achieving sustainable lifestyle changes and creating new narratives for well-being.

29.2 HEALTH AND WELLNESS COACHING (HWC)—AS A FIELD AND A PROFESSION

Given the growing burden of chronic disease, the importance of adopting a Lifestyle Medicine approach to health and wellness has been well established elsewhere in this book. The largest malleable factor in the development and course of many chronic illnesses is lifestyle. In the 1990s, despite the recognition of the importance of personal and

DOI: 10.1201/9781003227793-33

TABLE 29.1
Health Coaching is Not Counseling or Therapy

Counseling in Medicine	Health Coaching
Medical model	Learning/Development Model
Diagnosable illness in paradigm of pathology	Desirable goals and achievement in paradigm of possibility
Focus on fixing a problem	Focus on optimal performance
Professional as expert	Coach as non-judgmental partner supporting exploration of health priorities
"Why" questions with present/past focus	"How" questions with present/future focus
Restore client's level of functioning	Move to optimal behavior

TABLE 29.2

Element	% of those studies with adequate detail to code
Patient centered (Institute of Medicine 2001)	86% of 228 trials partially or completely aligned
Patient-determined goals	71% of 217 trials
Self-discovery	63% of 188 trials
Accountability	81% of 159 trials
Content education	91% of 233 trials
Relationship-based	78% of 154 trials

Full-text articles (284 total articles) were identified for the quantitative synthesis to define the key aspects of HWC, as operationalized in the literature. Six particular definitional elements were evaluated using all articles that provided adequate detail to code for each key element, of which 11 to 23% did not.

community health behavior choices, the medical system was still not successfully impacting most individuals' behavior choices.[1] Early efforts in disease and case management, patient education, and other population-based interventions showed some benefit in utilization reduction and medication compliance.[3] As established decades earlier, successfully making positive lifestyle changes requires self-efficacy (Bandura)—an individual's confidence in successfully engaging in specific behaviors. However, self-efficacy was still not readily addressed in mainstream medical care. Multiple educational initiatives were implemented both in public health forums and within physicians' practices, yet the prevalence statistics in health areas that are most significantly impacted by lifestyle choices—diabetes, obesity, and heart disease—continued to worsen. The only negative health behavior among Americans that has diminished has been smoking.[4] A comprehensive approach to tobacco usage, combining public health policies (e.g.. no smoking in restaurants), innovative treatment approaches, and increased awareness of smoking hazards, led to this success. It seems readily apparent that while having accurate information about health behaviors is critical, knowledge alone does not change behaviors. Indeed, in the field of management, it had been established that knowledge alone does not lead to action, but that attitudes, subjective norms, and perceived behavioral control were major determinants of behavior change.[5] These thoughts had not yet been extrapolated to shifting health behaviors.

29.2.1 Theoretical Platform and Historical Underpinnings

The roots of health and wellness coaching (HWC) pull heavily from different branches of psychology, beginning a century ago with Adler and Jung. Adler described our need to achieve personal goals that have value for society and how these goals stem from the unique creative power of an individual (even if unconscious). He further noted that adults use planning to create their future, emphasizing how individuals, when encouraged, feel capable and appreciated, and act in connected and cooperative ways.[6] Similarly, Jung proposed that individuals continued learning throughout life as they moved toward living authentically and "on purpose." He emphasized choosing the values by which they live rather than reflexively conforming to social norms.[7] Mid-century theorists supplemented these core tenets with important findings on how humans find personal meaning on top of meeting basic needs by striving toward self-actualization.[8,9] Humanistic psychology enhanced the study of motivation by emphasizing the role of interpersonal connectedness and sense of purpose.[10] More recent work further articulates the underpinnings of HWC through self-determination theory and self-concordance theory.[11–13] In these theories, individuals strive toward goal attainment when perceiving their goals as aligned with their core values rather than external forces. Later, developmental psychologists added a constructivist element and discerned the precedents for "vital engagement" in one's life.[14,15] Taken together, these theorists consider individuals as *lifelong learners whose individual values and sense of purpose facilitate their potential for positive change.* HWC is founded on the framework that humans strive toward self-actualization, have strong intrinsic resources, and best access their ability for positive change in a safe, confidential alliance wherein they are treated with deep respect and unconditional positive regard.

Paralleling this evolution in psychology, the social phenomenon of wholeness was reemerging in healthcare

through the holistic and complementary medicine, and well-being movements. While HWC and integrative HWC share the theoretical and applied grounding in change theory, behavioral health principles, and techniques for coaching practice, integrative HWC is informed by holistic and complementary healthcare. Apart from the following description of its evolution, and occasional differentiation in research studies, for the purposes of this chapter, we will use the term HWC to be inclusive of all health and wellness coaching practice, recognizing that integrative HWC has a deeper commitment to a mind/body/spirit perspectives and awareness of a broader range of available integrative healthcare practitioners and therapeutic approaches. Leaders in HWC and integrative HWC have joined together to advance the commonality of minimal standards setting for knowledge, skills competency, and educational requirements, acknowledging that integrative HWC requires an additional level of skill and training above this minimum.

The first U.S. holistic retreat center was created by Evarts Loomis, MD, in 1958, bringing the perspective of whole-person healing through the application of lifestyle modification, including nutrition, exercise, mind/body practices, and time in nature. In the 1970s, Dr. Loomis went on to be a co-founder of the American Holistic Medical Association. The emerging human potential movement, cultivating wellness and personal transformation, laid the groundwork for coaching in the personal development area. Tim Gallwey brought the Inner Game approach to coaching, emphasizing the process of how to get out of your own way to let your best emerge.[16] John Travis, MD, self-published *The Wellness Inventory*, launching the wellness movement and introducing the illness–wellness continuum, expanding our horizons beyond a treatment paradigm (Figure 29.1).[17]

In the 1980s, Thomas Leonard began life coaching as a practice, working to codify, popularize, and globalize the discipline of coaching outside the sporting world.[18]

Anthony Grant's work in coaching psychology advanced the legitimacy of life coaching as a platform for applying positive psychology for enhanced mental health, quality of life, and goal attainment.[19] William Miller introduced motivational interviewing (MI) for use with problem drinkers.[20] As a style of communication, it laid a foundation for HWC that deeply respected the autonomy of the individual.[21] MI is now highly evidence-based and used with multiple health issues to assess clients' present motivation to change behaviors that are inconsistent with personal values or goals.[22] In 1982, the Transtheoretical Model (TTM) was initially proposed and then further developed collaboratively by an international group of researchers, theorists, and therapists to provide a more comprehensive model of intentional change than was currently in use for the treatment of addictive behaviors.[23] Popularized in *Changing for Good*, the model posits that individuals undertaking an intentional change go non-linearly through particular stages in considering, approaching, enacting, and maintaining change. The model has continued to evolve, and as of 2016, in *Changing to Thrive*, it provides increased focus on working with individuals who are not yet ready to prepare or take action and are in need of change in a health-related area.[24]

In the 1990s, companies, beginning with IBM, began taking "coaching from being a personal development vehicle for individuals to a way of developing people in business."[25] Thomas Leonard in 1995 started the nonprofit International Coach Federation (ICF), which began to define coaching competencies and offer standardized coach credentials. By 1999, ICF implemented coach training standards and began to accredit individual life coach training programs (https://coachingfederation.org/).

29.2.2 Coaching versus Therapy

A significant proportion of patients/clients in healthcare and community health settings are also dealing with mental health conditions, including depression, anxiety, and addiction.[26] The theoretical framework described earlier has been further augmented with myriad techniques derived from over five decades of outcomes data in psychotherapy and the development of brief solution-focused therapies.[27–29] These techniques enable providers, especially coaches, to focus not on pathology but on behavior change. National standards in mental health literacy for health and wellness coaches have not yet been established but are an important gap to fill in the future. While there are important areas of overlap between HWC and psychotherapy, there are critical distinctions. One is that health and wellness coaches do not diagnose or treat, and they focus not on the diagnosis but on a goal. HWC doesn't seek to provide direction but to create a safe opportunity that allows clients to discover their own insights.[30] Clarity on HWC scope-of-practice is important. At times, individuals experiencing a psychiatric disorder,

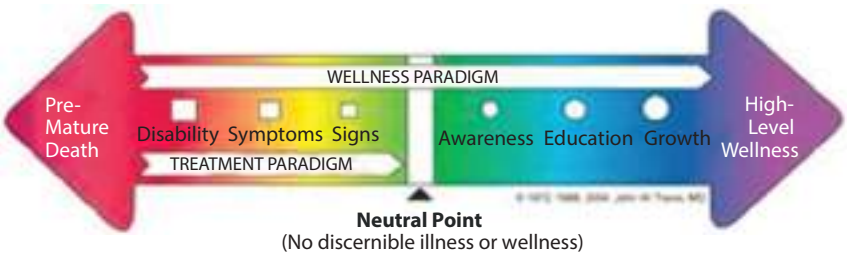

FIGURE 29.1 Illness–wellness continuum.

for example, a major depressive disorder or severe anxiety, may seek HWC as their treatment. Health and wellness coaches should be trained to know how and when to refer these individuals for appropriate treatment with licensed mental health professionals. HWC can be a safe portal into needed mental health services for some individuals who are avoiding needed therapy because of fears or misperceptions. In many situations, a client may benefit from receiving therapy and coaching at the same time—with therapy working at elucidating past events leading to current dysfunction and HWC focusing on present and future goal achievement and mind/body skill acquisition for improved self-regulation. Clients with active addictions or eating disorders are also likely to require connection to a licensed mental health provider, although HWC may sometimes work synergistically.

29.2.3 Coaching versus Health Education and Case Management

All educational approaches focus on conveying information or the teaching of skills. While health and wellness coaches do at times provide information or resources, education is never their dominant function. A "coaching approach" to teaching occurs through "elicit, provide, elicit," a technique from MI that involves exploring the client's current knowledge or understanding, asking for permission to share, offering information, and then asking how clients understood or may apply it.[31] The second philosophical difference arises from the goal setting process. The HWC agenda, always, is client-driven—not dictated by the goals or priorities of the disease management company, insurer, employer, or healthcare provider—and confirms the "clients' values, sense of purpose and personal vision for their lives."[32]

29.2.4 Standardizing the Field of Health and Wellness Coaching (HWC)

In 2008, it became clear to leaders in this field that growing numbers in four domains had created a climate of confusion and erratic quality:

(1) Widely diverse practitioners self-identifying as health and/or wellness coaches
(2) Organizations professing to offer health and/or wellness coaching as a service line
(3) HWC training programs varying widely in approach, content, skills training, format, assessment, and length
(4) Research studies with unclear or inconsistent interventions, all titled HWC

(See Section 29.4, "Evaluation and Research in Health and Wellness Coaching," for more details.)

In order to nurture the professional advancement of HWC, national standards for terms and minimal criteria for basic education needed to be established. Clear definitions and standards were also needed in order to create a consistent basis for rigorous and meaningful evaluation studies. Therefore, in 2010, the National Consortium for Credentialing Health and Wellness Coaching (NCCHWC) was born out of a national summit that brought together over 70 stakeholders from widely diverse fields of healthcare (grant support generously provided by the Institute for Integrative Health; https://tiih.org/). Those stakeholders represented professional associations in health promotion, coaching psychology, nursing, and medicine; researchers, experienced coaches, and subject matter experts; and commercial training organizations and experienced university educators in the field. With nonprofit 501(c)(3) status gained in 2013, the NCCHWC's goal was to professionalize the expanding field of HWC with an evidence-informed foundation.

Wolever, Simmons, Sforzo et al. (2013) systematically reviewed the English and Spanish HWC literature through January 2013, using the international guidelines established by PRISMA (Preferred Reporting Items for Systematic Review and Meta-Analyses).[30] The Pico-derived primary research question was: *"How are interventions described as health or wellness coaching defined and operationalized in the peer-reviewed medical literature?"* Specifically, the review sought to clarify what approaches, practices, strategies, and methodologies constitute HWC in the peer-reviewed literature. A standardized definition of HWC would allow a more rigorous evaluation of HWC. In addition, the professional skills needed to appropriately train HWC could be better identified.

Overall, the literature described HWC as:

> A relationship-based (78%) process that is fully or partially patient-centered (86% of articles), included patient-determined goals (71%), incorporated self-discovery and active learning processes (63%) (vs. more passive receipt of advice), encouraged accountability for behaviors (86%), and provided some type of education to patients along with using coaching processes (91%).

The summative results of the first six years of NCCHWC work were published in 2015[33] and proposed this working definition of HWC:

> Health and Wellness Coaches are professionals from diverse backgrounds and education who work with individuals and groups in a client-centered process to facilitate and empower the client to achieve self-determined goals related to health and wellness. Successful coaching takes place when coaches apply clearly defined knowledge and skills so that clients mobilize internal strengths and external resources for sustainable change.[33]

In 2016, the NCCHWC moved into a formal collaboration with the National Board of Medical Examiners (NBME), in 2017 evolving into a 501(c)(6), the ICHWC—the International Consortium for Health and Wellness Coaching (www.ICHWC.org). This continuing work has

resulted in exacting processes for approval of educational programs and national board certification of individual coaches. In 2018, ICHWC was renamed the National Board for Health and Wellness Coaching (NBHWC) and became a nonprofit affiliate of the NBME.

29.2.5 Health and Wellness Coach Training and Education

Historically, formal training in life and executive coaching began with ICF in the mid-1990s. As of 2020, more than 30,000 coaches held one of the ICF coach credentials: Associate Certified Coach, Professional Certified Coach, and Master Certified Coach. ICF has accredited more than ~500 coach training programs worldwide (at least 125 hours of coaching competency training) (ICF website, accessed 8 June, 2022). The ICF core competencies and ethical guidelines are widely applied and respected as the foundation for professional coaching in leadership, business, and life.[34] ICF standards are mostly focused on the executive and business domains, not on health and wellness coaching.

In the 1990s, pioneering, self-identified health, wellness, and integrative health coaches began practicing. The first independent HWC training and certification program launched in 2002, and the first academic program in 2005. A best practice, collaborative process by NCCHWC from 2010 to 2016, including a Job Task Analysis and national validation survey, led to national training and educational standards to support coaches in acquiring the requisite knowledge and skills.[35] Program standards include synchronous training and mentoring in health and wellness coaching competencies confirmed by a pass/fail assessment of practical skills. By 2022, more than 110 diverse U.S. programs had been approved by the NBHWC, having met the most recent national standards from 2018. Coach graduates of NBHWC-approved training programs are eligible to sit for the national board certification for HWC, an exam of applied coaching knowledge launched nationally in September 2017 and offered triennially as of 2023. As of the time of this writing, there are ~7,400 national board-certified health and wellness coaches.[36]

This examination and process were developed jointly by NBHWC and NBME, the latter of which has implemented physician-credentialing examinations since 1915. The training and education of health and wellness coaches is supported by ten textbooks authored by thought leaders on coaching competencies, MI, and TTM, plus a growing, peer-reviewed literature base. In 2018, national HWC training and education program standards advanced to require a minimum of 60 hours of training in coaching competencies (40 hours must be synchronous, interactive training) and 15 hours of healthy lifestyle education, plus mentor coach feedback on a minimum of three full coaching sessions, and a pass/fail evaluation of a coach's demonstrated practical skills.

Health and wellness coach training and education programs approved by NBHWC are currently diverse in setting, structure, and cost, including academic non-degree; academic degree (at bachelor's degree, graduate certificate, and master's levels); private sector; government (e.g., U.S. Department of Veterans Affairs); and internal programs of large organizations, which include employee benefits vendors, wellness vendors, health systems, and health plans. Some programs have a strong integrative health focus, and others emphasize subspecialties such as nurse coaching.[37–39] Program fees vary widely from approximately $3,000 for a private sector training program to over $50,000 for the cost of a master's degree.

Currently, those from both non-clinical and licensed clinical backgrounds are eligible to become NBC-HWC. Future studies on the impact of a coach's background and training on the effectiveness of coaching may lead to further refinement of standards for the education of health and wellness coaches.

29.3 HEALTH AND WELLNESS COACHING—BEST PRACTICES IN CLINICAL AREAS OF INNOVATION

29.3.1 Health and Wellness Coaching in the Healthcare Setting

While HWC began most often as an adjunct service, often separated from the primary care team, a newer role for HWC is its integration into the healthcare delivery system, with settings including: worksite wellness centers, recreation facilities, employee health programs, community centers, and educational environments, and it is being offered for special populations like the homeless and other underserved populations.[40–46] This relatively new integration into the healthcare delivery system increases the potential for innovative HWC to become an impactful systemic change agent for health promotion and well-being optimization.

It has been well demonstrated that physician counseling for health behaviors can help patients implement positive lifestyle changes.[47] Therefore, one potential strategy to enhance HWC's impact is to integrate HWC into a patient's routine medical care. For example, in one study, nearly 1,000 patients (average body mass index [BMI] 34.5) were referred to a telephonic health coaching program by their healthcare provider for assistance with weight management. The participants receiving HWC demonstrated a 1-unit reduction in their BMI over 12 months, compared with the approximately 19,000 control patients who remained weight stable.[48] Studies have documented benefits of wellness coaching for self-care behaviors among primary care patients with prediabetes and for increasing physical activity level and improving dietary habits in breast cancer survivors.[49,50] Similarly, a recent randomized, controlled trial of patients in Air Force primary care evaluated the impact

of coaching for those with elevated risk for heart disease and/or diabetes. They found that those who received health coaching were 3.6 times more likely to exercise at recommended levels by the end of coaching, and this effect was sustained 6 months after the conclusion of the coaching.[51] Finally, Mayo Clinic researchers recently found that an eight-week health coaching home-based rehabilitation program for patients with chronic obstructive pulmonary disease (COPD) improved the patients' self-management abilities.[52]

Another setting for HWC is within a worksite wellness center. It has been well documented that stress, prevalent in the workplace, is associated with negative health behaviors and increased presence of health conditions in employees.[41] A survey of 676 healthcare employees found that the relationship between a high stress level and negative health behaviors remained consistent over five years.[52] Participation in a 12-week HWC program improved the quality of life, reduced the perceived stress level, was associated with weight loss, and improved the health behaviors of healthcare employees.[41,53]

The systematic transformation to a Whole Health approach to care by the Veteran's administration is a radical action by the largest healthcare system in the United States, and has HWC as a critical component of this new initiative.[54] A mixed-method pilot study of HWC for veterans in this new model found significant improvements in mental health, stress, and perceived health competence.[55] Growing evidence supports that having a HWC as a member of the healthcare team or wellness team can enhance behavioral and health outcomes.

29.3.2 Visit Structures and Delivery Methods

The optimal choice of structure and method for a HWC visit varies. In terms of the content of HWC interventions, MI and goal setting appear to be consistent components of the HWC interventions.[56] Contextually, in Wolever et al.'s (2013) systematic review of health coaching literature, it was noted that:

> 78% of articles indicated that the coaching occurs in the context of a consistent, ongoing relationship with a human coach who is trained in specific behavior change, communication, and motivational skills.[30]

The needs for direct connection and safe relationship both appear to be requisite for HWC, as it is defined here; therefore, synchronous, voice-to-voice connection (either in person or virtually) with a consistent provider appears optimal for effective coaching. While asynchronous interventions with healthcare providers are utilized in other areas, these have been predominantly for the purposes of education, not coaching.[57] New virtual interventions (sometimes mistakenly called coaching) are continually being explored, but their impacts on lasting behavior change are not well established at this time.[58] While single sessions with any particular health and wellness coach may have some benefit, such an intervention has been minimally examined.[59] Industry and academia continue to rapidly create novel digital interventions and refer to them as "coaching" whether or not they involve human interactions and/or evidence-based coaching methodology.

As noted, synchronous health coaching sessions can be offered in person (most studied), telephonically, or online (least studied). The format, length, frequency, and method of delivery vary widely.[60] The number, frequency, and length of HWC sessions, and the duration of engagement, are not standardized for practice or research. The typical coaching "dose" was explored in the Wolever et al. review (2013), although published studies at the time did not typically report length of session (75%), number of sessions (52%), and duration of a series of sessions (64%).[30] Where data did exist, the average duration of a coaching session was 36 minutes (ranging from 5 minutes to 2.5 hours); the average number of sessions was 10.1 (median of 6 sessions with a range of 1–90 sessions); and the average contact hours reported were 6.2 hours (median of 3 hours, with a range of 15 minutes to 135 hours). Similarly, HWC program duration for clients was quite varied. For example, 23% of the interventions were 5 weeks to 3 months; 25% were 3.5 to 6 months; and 22% were 10 to 12.5 months. More recent dosing based on HWC literature recommends initial programming of 12 sessions for a duration of 40 minutes over a period of 7–8 months.[61] Clearly, more needs to be learned about what format of delivery, length, number of sessions, and time frames of session are most effective for which outcomes in which patients.

One approach to help guide decision-making about the method of delivery for HWC is to examine the participants' own perspectives on their experience. Clark and colleagues conducted a qualitative study aimed at understanding the perspectives of employees who had completed a three-month wellness coaching program.[62] Twenty-seven worksite participants reported appreciating the personal connection with their wellness coach, and being surprised by the impact of the professional relationship they developed with their coach. They rated humor, non-judgmental communications, and evocation as being positive aspects of wellness coaching. While enjoying collaborative decision-making, they found being accountable to their wellness coach motivating. The participants felt more confident in their abilities, were able to reprioritize their wellness goals, and had a broader definition of wellness.

Similar findings were noted in a qualitative study of adult coaching participants who sought integrative HWC to address a chronic health condition. Taken together, participants described their coaching experience as "engagement in transformative change."[63] Participants also noted that mindfulness enhanced "the coaching relationship as well as promoted their engagement, competence, and autonomy in self-determined goal attainment." Participants defined their

lived experiences with integrative HWC as "whole-person engagement" in "a journey … to address a health concern and surprisingly discovered a 'new me.'"

Group coaching has been used successfully in business and leadership for some time, while individual coaching has historically been more common in HWC.[64,65] Nonetheless, group HWC is rapidly expanding, since it increases access and decreases costs.[66] Its effectiveness, however, still needs to be empirically demonstrated. In 2020, a task force initiated through the NBHWC identified core group health coaching competencies, which were validated through a national survey in 2021. Competency and training recommendations from that work will be published soon (Wolever et al. pending) and also made available through the www.NBHWC.org website.

29.3.3 Employment of Health and Wellness Coaches

In the corporate wellness sector, employers typically pay for coaching as part of a broader offering of health services, intending to control rising healthcare costs as well as improve productivity and presenteeism. Many vendors offer HWC by phone or videoconferencing at low or no cost to individual employees.[67] Health and wellness coaches who offer private practice services are predominantly working fee-for-service, and often also offer other services such as yoga, mindfulness training, energy work, personal training, cooking/nutritional instruction, and therapy (from licensed mental health providers) (Figure 29.2).

For the last several years, NBHWC has been advocating for reimbursement of coaching services within U.S. healthcare. In 2019, the U.S. Department of Veterans Affairs (VA) and NBHWC successfully applied for the creation of Current Procedural Terminology (CPT) tracking codes (Category III) for health and well-being coaching services.[68] CPT codes provide doctors and healthcare professionals with a uniform language for coding medical services and procedures to streamline reporting and increase accuracy and efficiency. NBHWC also completed a legal review supporting the use of Medicare CPT codes by HWC, including annual wellness visits, obesity counseling, chronic care management, and remote physiological monitoring services.[69] In April 2021, a taxonomy code was approved for HWC, allowing HWC to become credentialed providers with public and private payers.[70] Reimbursement of the NBC-HWC's is not mandatory with Category III CPT coaching codes, or with other existing reimbursement codes that relate to prevention, wellness, and engagement in healthy lifestyles. However, efforts to evolve these to Category I CPT codes are actively underway, and U.S. healthcare organizations are beginning to use the coaching and other CPT codes with variable reimbursement. NBHWC has documented over a million visits between 2015 and 2020 with these codes. HWC is solidly on the path to becoming an everyday healthcare intervention.

29.4 EVALUATION AND RESEARCH IN HEALTH AND WELLNESS COACHING

29.4.1 Current Evidence Base

Research from Europe, Australia, and the United States has converged to clearly demonstrate that HWC is an

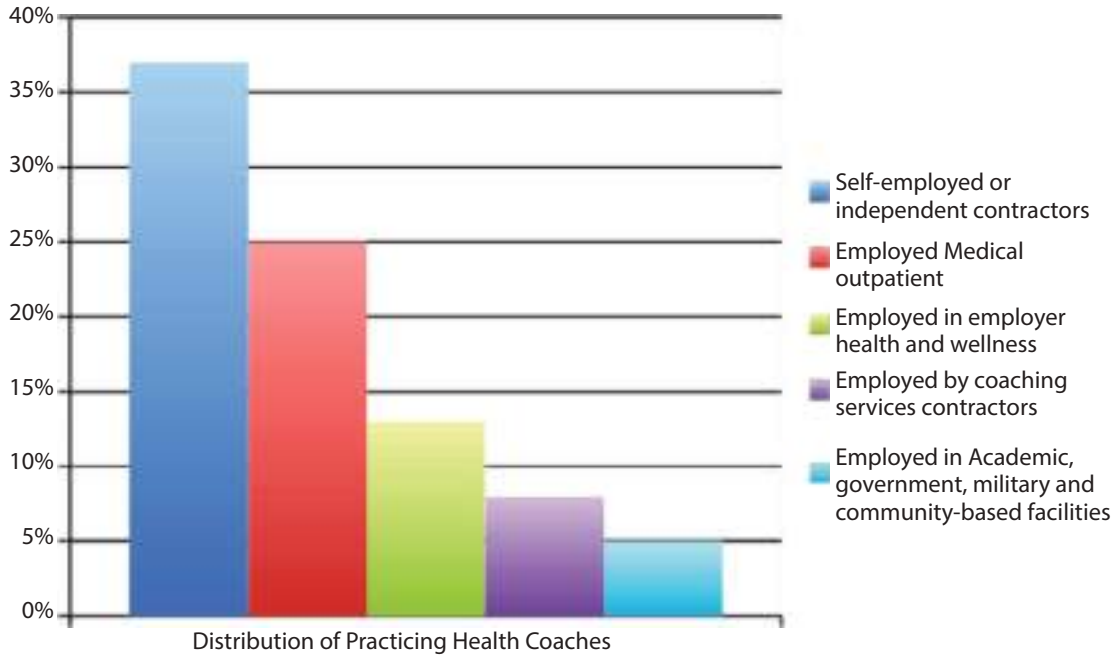

FIGURE 29.2 2014 survey of practicing health and wellness coaches.

effective approach for many health behaviors that can lead to positive outcomes for many health conditions. The first review of the HWC literature was published in 2003 in Australia.[71] Since that time, over a dozen reviews of the HWC literature have been published worldwide.[30,56,60,72–77] The HWC literature as a whole is quite consistent in demonstrating improvements in patient self-efficacy, psychological measures, and quality of life. In addition, systematic reviews and meta-analyses show change in both self-management behaviors and relevant physiological indicators; for example, type 2 diabetes and cardiovascular risk.[78,79] There continue to be equivocal findings, however, when inclusion rules are loosely defined (i.e., any study described as "health coaching" without attention to the actual methods employed). For example, recent meta-analytic studies for overweight or obesity showed HWC to produce negligible findings, but the report has these methodological problems.[43,80]

To manage this major issue, the HWC literature has been organized into a compendium using the only empirically established definition of HWC.[30,56,76] As of 2019, the literature evaluating better-defined HWC includes 231 data-based and peer-reviewed studies, with 108 being randomized designs; 58 studies address obesity and 44 address diabetes.[76] More than 50 of these investigate HWC's effects on well-being and risk reduction (employee wellness, hypertension, cholesterol). Ten studies address cancer-related challenges, while other conditions (e.g., fibromyalgia, multiple sclerosis) are addressed to a lesser extent.

Of the compendium studies examining obesity, more than 80% reported improvements in BMI or body weight after HWC. This is a robust success rate for weight loss studies reporting outcomes between six months and two years. Of the compendium studies examining diabetes, more than 80% reported improvements in A1C (a measure of long-term blood glucose control and the primary outcome for most diabetes studies). A variety of other important variables, such as diabetic self-care, body weight, and medication adherence, also improved in many of these HWC studies.

Almost 90% of the compendium studies examining wellness reported improvement in a key behavioral variable (e.g., exercise or nutritional behaviors), and many studies showed improvement in important biometric outcomes (e.g., blood pressure, cholesterol, body weight, anxiety).

In the area of cancer, about 67% of compendium studies show favorable outcomes in a population where positive outcomes are difficult to achieve. These outcomes are often psychological (e.g., stress, anxiety) but also behavioral (e.g., exercise habits). HWC can improve quality of life for cancer patients and survivors with regular access to a coach.

HWC has also been used to successfully treat aspects of other debilitating conditions, such as MS, fibromyalgia, COPD, and renal disease. While much of the research on these conditions is preliminary, it is promising.

29.5 HEALTH AND WELLNESS COACHING—PRACTICAL NUTS AND BOLTS

29.5.1 Coaches Need Coaching

It is widely accepted across all domains of professional coaching—including executive or leadership, life, and health and wellness coaching—that competent coaches regularly employ their own coaches to support their personal and professional growth. It is also similarly valuable for other healthcare providers to receive HWC for their personal health and well-being so that they "walk the wellness walk" and are better able to refer patients to coaches and support patient engagement in HWC. Walking the coaching walk enables coaches to engage in a similar process as their clients and more fully engage in lifelong learning and growth.

During professional training and education programs, health and wellness coaches are typically working with fellow students or professional coaches on their own well-being goals. In fact, emerging evidence suggests that the HWC training process itself may be seminal to improving or even optimizing the health and well-being of the trainee.[81] As an example, in the University of Minnesota's graduate programs in Integrative Health and Well-Being Coaching, all students receive three hours a semester of HWC provided by an outside professional coach who is not otherwise involved in their education (www.csh.umn.edu/education/master-arts-degree-integrative-health-and-well-being-coaching).

29.5.2 Referral to Health and Wellness Coaches

HWC calls clients to develop new health behaviors, a new positive lifestyle, or even, and sometimes most importantly, to transform underlying cognitive and belief structures. Hence, the U.S. national standards include the competency of assisting clients in assessing whether they are ready to effectively engage in a HWC program, developing and sustaining new healthy habits of mind and body. While physician referrals are rarely required for HWC, and since validated instruments to assess suitability for coaching don't yet exist, healthcare providers are best positioned to recognize patients best suited to the HWC process. The absolute best way for any healthcare provider to understand and refer to HWC is to receive HWC themselves, even if they do only an isolated session.

29.5.3 Hiring Health and Wellness Coaches

To date, there is no research that compares the effectiveness of HWC based upon coaches' educational and/or

professional backgrounds. Hence, common sense principles and evaluation of an individual's demonstrated skills are critical in employing health and wellness coaches. Ideally, a health and wellness coach has completed a reputable accredited professional program that provides skills training and integrated application of coaching-related theories, and that requires demonstration of adequate coaching skills. The health and wellness coach should demonstrate knowledge of HWC competencies, excellent communication skills, curiosity, compassion, and empathy; and should model their own commitment to optimizing their personal health and well-being. Hiring of NBC-HWCs is strongly recommended.

Healthcare organizations recruiting health and wellness coaches often look for a combination of a credible coaching credential with other health credentials. Nurses are often desired, as they bring considerable clinical and patient management experience and understanding of healthcare system issues, including scopes of practice and Health Insurance Portability and Accountability Act (HIPAA). This is true of physician assistants, nurse practitioners, and physicians as well, although more costly. Some may seek health and wellness coaches who are also dietitians or exercise physiologists, who can contribute healthy lifestyle expertise under reimbursement protocols. Health and wellness coaches with formal mental health licensure may perform dual roles—delivering therapy services as well as coaching, provided they clearly articulate which role they are using with a client.

29.5.4 Assimilation of Health and Wellness Coaches

A challenge for health and wellness coaches in many organizations is that the culture and leadership practices in a particular setting may not align with key coaching principles—such as fostering autonomy, intrinsic motivation, compassion, mindfulness, strengths, self-awareness, and an open, creative, and collaborative change process. Consequently, health and wellness coaches may feel isolated and unsupported by their teams and leaders. Ideally, health and wellness coaches have supervisors who have a deep understanding of coaching and teams that are well informed on the nature of HWC. Fortunately, there is an emerging interest in developing coaching cultures within organizations such that all leaders and team members learn basic coaching and communication skills. This will enhance the acceptance and support of professional coaches and their effectiveness in their roles.

29.5.5 Protecting Client/Patient Privacy

A successful HWC engagement depends upon trust (i.e., the health and wellness coach is benevolent, authentic, honest, and competent), privacy, and confidentiality. It is important for health and wellness coaches to follow established practices to protect the privacy and confidentiality of client/patient information, including following HIPAA requirements for technology security and sharing of patient/client information with other providers. It's vital that clients are informed of practices that protect their privacy and require their permission for sharing of personal information.

29.6 HEALTH COACHING IN THE FUTURE OF HEALTHCARE—A VISION OF HOPE

An existing body of outcome studies suggests that the key levers for achieving healthy change include *the therapeutic alliance*, *the client's active participation*, *the client's perception of the issues*, *the client's guided generation of the solution*, *and the client's use of resources.* HWC, as defined by the NBHWC, embodies these aspects of a supportive and creative relationship to elicit positive lifestyle change. The health and wellness coach is effective in supporting the competence of the patient by eliciting intrinsic motivation based on the personal values and strengths of the individual and by inviting active participation and empowerment through specific communication techniques.[82] The client's perceptions of the issue and generation of the solution are explored in the context of the client's values. An emphasis on strengths and continued learning allows the health and wellness coach to support the clients' own vision of their best selves. Borrowing from positive psychology and other strength-based approaches, the health and wellness coach also trains clients both to recognize how they are continuing to learn and to see the impact of their own positive behavior in bringing about their vision.[82, 83] This process applies key lessons from health psychology on the importance of tracking behaviors.[84] Effective self-management interventions that are central to care of chronic disease are then provided using particular education techniques that align with how adults best learn.[85–90] Finally, the health and wellness coach plays a key role in helping the client to develop support networks and resources that access the client's community and healthcare system.

It is time for us to call in a new vision of health and healthcare in America. Health coaching can play a pivotal role in the creation of this new narrative. Innovative models that partner education for self-efficacy with health and wellness coaching, like the PACT program for chronic pain, leverage our healthcare dollars and improve outcomes. Health and wellness coaches can provide critical skills to our evolving interprofessional healthcare teams that place the client, or patient, at the center of their own care.[91] As noted previously, the VA healthcare system has been implementing early initiatives along this line, bringing in a holistic philosophy of care, empowering the patient in their own

care, and actively employing coaching techniques with patients.[92,93]

This new narrative will very much emerge from the dreams, the pioneering initiatives, and the intentions we generate today. In systems theory, the most unstable systems are those most able to be suddenly and powerfully changed. Transformation arises through chaos, which is an accurate descriptor of our current system of medical care in the United States. HWC has the potential, right now, to change our stories of health and well-being, individually and as a system. HWC can be a transformative agent, helping to create a system of care—nationally, if not globally—that empowers individuals in their efforts not just to survive or recover from disease, but to create and sustain holistic health and optimal well-being.

CLINICAL APPLICATIONS

Consider connecting patients to individual or group HWC, especially in the following situations. A patient:

- Receives a new diagnosis of any illness for which lifestyle behaviors contribute significantly, either to the cause or to the course of that illness. This could include anything from cardiac disease and diabetes to cancer.
- Is living with a chronic disease and would functionally do better if able to make improvements in habits around eating, exercise, sleep, stress management, medication utilization, relationships, or perspectives on their challenges.
- Wants to improve their overall health and well-being, and decrease risks for future disease or disabilities. They are asking for help in making real change.

Lifestyle Medicine Approaches to Dysglycemia

Taylor & Francis
Taylor & Francis Group
http://taylorandfrancis.com

30 Overview: Dysglycemia-Based Chronic Disease—Exposing Lifestyle Medicine Targets

Michael A. Via, MD and Jeffrey I. Mechanick, MD

KEY POINTS

1. Disease manifestations of insulin resistance are highly prevalent in modern populations.
2. A classification system for dysglycemia-based chronic disease includes disease progression and severity, and allows the clinician to appropriately gauge risk to make recommendations.
3. Lifestyle recommendations are central to the treatment plan at all stages, and should include optimizing nutrition, physical activity, sleep hygiene, and behavior.

30.1 INTRODUCTION

Glucose is the main currency for human energy homeostasis. Dysregulation of glucose metabolism, or dysglycemia, encompasses pathophysiological events that yield chronic non-communicable diseases. The extremely high prevalence of dysglycemia gives rise to high economic cost, reduced life expectancy, and through multiple potential complications, reduced quality of life.[1] Many diseases, such as type 2 diabetes (T2D) or polycystic ovary syndrome (PCOS), result from dysglycemia. Collectively, when specific mechanistic drivers produce a specific pathophysiological state and clinical phenotype that persist for more than three months, a "driver-based chronic disease" ensues. In the case of dysglycemia as the driver, this state is dysglycemia-based chronic disease (DBCD), which is pragmatically modeled according to four distinct, sequential stages in the natural history. The impetus for developing this model was criticism that diagnoses of insulin resistance syndrome or prediabetes were not cost-effective (in the context of providing pharmacological intervention, such as metformin); the response to this was to consider these states not in isolation but rather, in the context of a natural progression of dysglycemic states amenable to early prevention of vascular complications.[1] The major advantage of this new construct is that early and sustainable prevention targets are codified. In other words, the targets are clearer, easy to identify, and actionable through specific prevention modalities to reduce morbidity and mortality attributable to dysglycemia.

30.2 DEFINITION AND CLINICAL MANIFESTATIONS

The pathophysiology of insulin resistance and downstream effects that upset pancreatic β-cell function create a dysglycemic state.[1] Early signs of DBCD include abnormal adiposity (e.g., elevated body mass index [BMI], waist circumference [WC], ectopic fat, and measurable adipokine changes), insulin resistance (e.g., euglycemia, hyperinsulinemia, and abnormal homeostatic model assessment [HOMA]), and eventually with a β-cell defect, mild hyperglycemia (prediabetes; e.g., impaired fasting glucose and/or glucose tolerance).[2] Moreover, patients who develop hypertriglyceridemia, reduced high-density lipoprotein (HDL) cholesterol, and/or hypertension meet one of several published criteria for the metabolic syndrome (MetS).[3–5] In contrast to the static cluster of pathological states comprising MetS, configuring other driver-based chronic diseases (adiposity-based [ABCD], hypertension-based [HBCD], and lipid-based [LBCD] chronic disease) into a comprehensive cardiometabolic-based chronic disease (CMBCD) represents a dynamic model also amenable to early/sustainable preventive care.[6,7] Further progression of insulin resistance and β-cell defects leads to T2D. Other conditions directly associated with insulin resistance include PCOS, gestational diabetes mellitus (GDM), obstructive sleep apnea (OSA), and hepatosteatosis. Additionally, patients with insulin resistance are at increased risk for cardiovascular disease (CVD) and cancer, the top two causes of mortality worldwide.[8,9] These clinical manifestations of DBCD can greatly impact the lives of patients with disease-specific effects, disease state interactions, and increased mortality.

Another common feature among dysglycemic states is scientific controversy over the definition of disease. For example, there are six validated definitions of MetS[9] and three definitions of PCOS.[10] In fact, the definition of prediabetes can vary by published study and clinical practice.[1] In general, prediabetes is present when serum levels of glucose are elevated while the patient is fasting, postprandial, or after oral glucose challenge, but not high enough to be classified as T2D. Many authors divide prediabetes into two categories: impaired glucose tolerance and impaired fasting glucose, based on glucose tolerance testing and fasting

DOI: 10.1201/9781003227793-35

glucose levels, respectively. Additionally, hemoglobin A1c (A1C) levels above normal (≥5.7%) but below 6.5% may be considered as prediabetes. Using this definition based on A1C, patients diagnosed with prediabetes demonstrate an approximate 70–74% lifetime risk for the development of frank T2D.[11] Additionally, a 10–30% increased risk of CVD is reported in patients with prediabetes,[12] and the risk for many common types of cancer is 30–50% higher than in the general population.[9] While it should be noted that the variance of definitions of prediabetes can affect the observed risk levels, these risks remain elevated regardless of the specific definition of prediabetes.[12] The association of CVD with prediabetes changes the context of prediabetes from just a predisease state defined by diabetes risk to a specific cardiometabolic risk descriptor. For instance, there is an average 20% increased risk for cardiovascular events in patients with prediabetes than in those without prediabetes.[13] In a cohort study of almost 7000 patients, the risk for development of heart failure over five years was 7.8% among those with prediabetes (and 12% for patients with T2D), compared with only 0.78% for patients with euglycemia.[14] Published trials demonstrate beneficial effects of lifestyle and weight loss strategies to mitigate the cardiovascular risk increase in this prediabetes population, further supporting the role of the DBCD framework for early preventive measures.[15]

More important than dividing patients into the binary "haves" and "have-nots" with respect to T2D risk for complications, the continuum of risk represented in the DBCD framework should guide an appropriate clinical response, viewed as an intervention to prevent disease progression. Successful examples of this practice are incorporated into current guidelines for hyperlipidemia and hypertension management.[16] Hepatosteatosis and OSA are also graded in a similar fashion by disease severity.[17,18] The high risk for CMBCD among patients with DBCD necessitates intervention, mainly through identification and implementation of opportune healthy lifestyle practices, with guideline-directed pharmacological and procedural interventions as indicated. Accordingly, a four-stage system based on the natural history has been proposed for DBCD classification to enhance precision, clarity, target exposure, and successful outcomes with preventive care (Figure 30.1).[1]

Stage 1 is risk (conferred by primary drivers of genetics, environment, and behavior), stage 2 is predisease (or prediabetes), stage 3 is disease (or T2D), and stage 4 is complications. It should be made very clear that DBCD is not a competing term with T2D. Rather, T2D is interpreted as stage 3 DBCD and part of a spectrum that mandates preventive care. Similarly, prediabetes is interpreted as stage 2 DBCD and likewise, mandates prevention of this pathophysiological state at high risk for not only T2D but CVD as

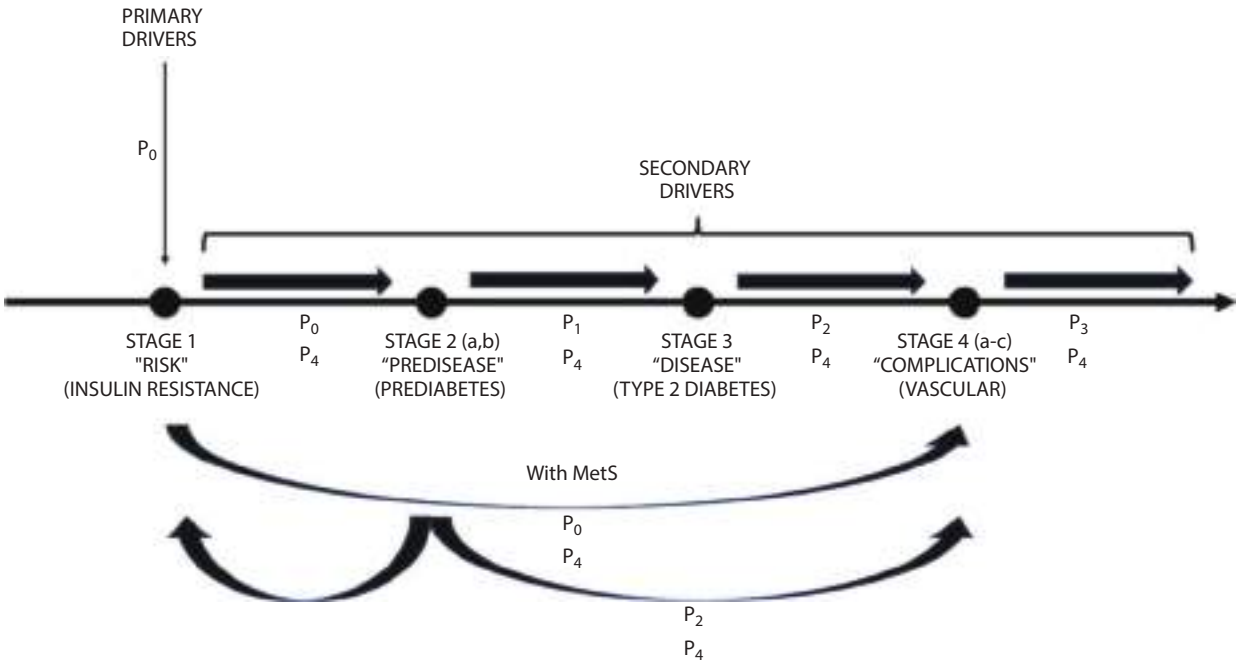

FIGURE 30.1 The dysglycemia-based chronic disease model. In this four-stage model, primary drivers are genetic, epigenetic, environmental, and behavioral factors, and secondary drivers are abnormal adiposity, systemic inflammation, disrupted control of energy homeostasis, vascular endothelium, cardiomyocyte pathophysiology, and pancreatic islet cell function. DBCD stage 2 prediabetes is subclassified into 2a (lower A1C) and 2b (higher A1C), and DBCD stage 4 complications are subclassified into 4a (mild), 4b (moderate), and 4c (severe). DBCD stage 1 (insulin resistance) can leapfrog to CVD in the setting of MetS (with/without prediabetes or T2D). DBCD stage 2 (prediabetes) can regress to normoglycemia, remain as prediabetes, directly/stepwise progress to T2D, or leapfrog to vascular complications (especially CVD) without developing T2D. Prevention modalities ($P_{0–4}$) are mapped to DBCD stages, drivers, and pathophysiological targets, and then modified based on SDOH and other ethno-cultural factors, to facilitate early intervention. (Adapted from Mechanick, J.I., et al., ***Endocr. Pract***., 24(11), 995–1011, 2018).

well.[13,19] Each of the DBCD stages is managed with a specific form of prevention (Table 30.1), modified by individualized social determinants of health (SDOH) (Table 30.2).

Several comments deserve special mention at this point to add clarity to the DBCD model. First, this model principally applies to T2D and not type 1 diabetes or other types of diabetes (gestational, atypical, mitochondrial, pancreatogenous, etc.), though the progression of DBCD from stage 3 to stage 4 is relevant to all diabetes types. Second, the implementation of lifestyle medicine at all DBCD stages potentially reduces the need for pharmacological and procedural interventions, accentuating the need for quaternary prevention (the avoidance of overmedicalization). Third, there are overlapping uses of prevention modalities for any given DBCD stage (e.g., even though primary prevention is most important for stage 2 prediabetes, primordial and quaternary prevention should also be applied, secondary prevention is needed if there is already some CVD even without T2D, and tertiary prevention is needed for comorbidities and other diseases, if they exist). Fourth and last, all recommendations are subjected to modification based on ethno-cultural and other individual factors. Hence, the DBCD model is fluid and complex, requiring further study and validation. Nevertheless, there is sufficient DBCD structure now to demonstrate the critical role of lifestyle medicine in the management of patients with dysglycemia.

30.3 STAGE 1: INSULIN RESISTANCE

Stage 1 DBCD is classified as "risk" or insulin resistance and is managed with primordial prevention. Patients with insulin resistance demonstrate normal glucose levels but elevations in serum insulin. Oftentimes, patients in this "risk" stage are overlooked, as a normal glucose is falsely

TABLE 30.1
Types of Prevention

Type	Scale	Description	Stage of DBCD
Primordial	Population	Prevention of risk	**1**
Primary	Individual	Prevention of disease	**2**
Secondary	Individual	Prevention of complications	2,3
Tertiary	Individual	Prevention of suffering/mortality	**4**
Quaternary	Population Individual	Prevention of overmedicalization	1–4

Primary and secondary prevention are both applied to prediabetes, since stage 2 DBCD can either sequentially progress to stage 3 DBCD (T2D) or leapfrog to stage 4 (complications); stage 2 DBCD can also revert to stage 1 DBCD with euglycemia with implementation of primary prevention. Quaternary prevention is ethically sound practice of medicine and exemplified through the routine use of properly implemented structured lifestyle medicine at all stages of DBCD to reduce the need for more risky/costly pharmacotherapy/procedures.

TABLE 30.2
Social Determinants of Health

Determinant	Description
Childhood Development	Allostatic stress and abnormal adiposity
Crime	Allostatic stress and decreased perceived safety
Culture	Nonphysical human factors that aggregate in a specific population/ethnicity
Discrimination/Oppression	Structural conflict
Disparities in Access to Quality Healthcare	Correlates with ethno-cultural and socio-economic factors
Education	Correlates with health literacy and access to care
Employment	Correlates with socio-economic factors
Food Insecurity	Leads to unhealthy dietary patterns
Housing/Amenities	Structural deterioration
Income/Poverty	Correlates with access to care
Religion/Spirituality (R/S)	In certain cultures, decreased R/S is associated with increased chronic disease risk
Work Conditions	Unhealthy lifestyle in many workplaces

Social determinants of health are non-biological drivers of chronic disease phenotypes that require prompt detection and remediation at both population and individual scales.

reassuring, and routine measurements of serum insulin and glucose tolerance testing are impractical. Moreover, insulin resistance is so highly prevalent now. with unhealthy lifestyles and abnormal adiposity,[20,21] that it may be reasonable to approach every patient with a case-finding strategy as though there is already some degree of insulin resistance present. Early lifestyle interventions may yield the most effective and sustainable results, notwithstanding infrastructural and socio-economic challenges with implementation (e.g., affordability, lack of reimbursement, inadequate training, too few lifestyle medicine centers, etc.). The presence of risk factors for insulin resistance, including a family history of T2D, *in utero* exposure to GDM, a personal history of GDM, PCOS, weight gain with abnormal adiposity, or hypertension should strengthen the need for a lifestyle intervention.[1] Many patients with insulin resistance also meet criteria for MetS and increased CVD risk,[5] which can aid in the recognition of insulin resistance without measurement of insulin levels.

The high prevalence of insulin resistance represents opportunities for public health measures. Policies targeting modifiable primary drivers of DBCD (behavior and some environmental factors; genetics are not modifiable) have been implemented with varying degrees of success.[22] Examples include taxes on sugar-containing beverages; construction of bicycle lanes, hiking trails, and other outdoor spaces that encourage physical activity; posted nutritional contents of menu items in restaurants and proper nutritional labeling on foods; and general informational campaigns to educate the public on healthy lifestyle choices.[1] Clearly, more work is needed on a societal level as part of primordial prevention in a diabetogenic environment, particularly for young children and women of reproductive age. For individual patients, healthy lifestyle choices at this stage can mitigate risk at stage 1 DBCD and by inference, all subsequent stages of DBCD. In the future, stage 1 DBCD may be more easily detected not only with commercially validated, accessible, and affordable biochemical testing but with molecular profiling as well (e.g., genomics, epigenomics, transcriptomics, and metabolomics).

30.4 STAGE 2: PREDIABETES

Stage 2 DBCD is classified as "predisease" or prediabetes and is managed with primary (to prevent progression to DBCD stage 3—T2D) and secondary (to prevent progression of early/asymptomatic CVD in CMBCD stage 3 to later/symptomatic CVD in CMBCD stage 4, even without T2D) prevention. Presently, there is no standard definition of prediabetes. However, the demonstrable increase in glycemia as well as the increase in cardiometabolic and cancer risks supports recognition and preventive interventions at this stage.[1,15] Besides the risk of regression of prediabetes to normoglycemia, there is a high risk for advancement of prediabetes to T2D as well as to microvascular, atherosclerotic, and heart failure complications, constituting a basis for structured lifestyle modification.[1,13,19]

Prediabetes may be subdivided into DBCD stage 2a: lower risk—fasting glucose of 110 mg/dL or lower, or A1c of 6.0% or lower; and DBCD stage 2b: higher risk—fasting glucose above 110 mg/dL, or A1c higher than 6.0%.[23] In the future, there may be additional diagnostic criteria for prediabetes based on continuous glucose monitoring data, especially regarding postprandial excursions and glycemic variability.[24] In addition, many of the current diagnostic criteria may need adjustment for different ethno-cultural populations based on biological determinants and SDOH, similar to that seen for BMI and WC for abnormal adiposity.[25] Primary and secondary prevention tactics consist of intensive lifestyle change and when needed, pharmacotherapy, especially for stage 2b.[1] Patients who demonstrate higher levels of insulin resistance markers are at increased risk for progression to DBCD stages 3 and 4.[26]

30.5 STAGE 3: TYPE 2 DIABETES

Stage 3 DBCD is classified as "disease" or T2D and is managed with secondary prevention. Frank T2D is diagnosed by fasting plasma glucose of 126 mg/dL or higher, two non-fasting "casual" glucose levels of 200 mg/dL or higher (not in a stressed state), or A1C of 6.5% or higher. Similarly to stage 2, the diagnostic criteria for T2D may be refined with continuous glucose monitoring data and various biological determinants and SDOH that vary with different ethno-cultural populations.[25,27] This stage represents a threshold for higher cardiometabolic risk than stage 2 DBCD and justifies pharmacological therapy in many patients or bariatric/metabolic surgery in highly selected patients. However, an intensive lifestyle intervention should be applied in all patients with T2D; this has been shown to reduce multiple risks, including cardiovascular and microvascular outcomes, and has the potential to greatly modify the trajectory of this chronic condition, including obviating the need for pharmacotherapy or procedures.[28] There are several definitions (validated and unvalidated) authored by different professional medical societies on diabetes reversal, remission, and even cure, many of which have been studied in the context of lifestyle medicine interventions. These include partial remission (A1C 5.7% to 6.4%) and complete remission (A1C <5.7%) applicable at least three months after cessation of glucose-lowering medications.[29,30]

30.6 STAGE 4: TYPE 2 DIABETES WITH VASCULAR COMPLICATIONS

Stage 4 DBCD is classified as "complications" (typically, macrovascular from insulin resistance and microvascular from hyperglycemia) and is managed with tertiary prevention. Complications arise in patients with advanced T2D not only from the many mechanisms of metabolic disruption but also from the length of time these derangements were at play causing tissue damage.[31] Severe microvascular disease (e.g., nephropathy, neuropathy, and retinopathy) and

macrovascular (e.g., atherosclerosis of coronary, carotid/cerebral, and peripheral arteries, as well as aorta and other large vessels) disease represent two of the most significant complications of DBCD and the defining feature of stage 4 DBCD. Patients with atherosclerotic CVD can develop heart failure (along with cardiac microvascular disease), myocardial infarction, and dysrhythmias (with/without stroke). Cerebrovascular disease can lead to stroke and/or cognitive dysfunction.[31] Peripheral vascular disease may manifest as ischemic ulcers or amputations. Interestingly, diabetes may have a protective role in patients with aortic aneurysm, possibly through increased vascular stiffness generated by enhanced protein glycation in patients with diabetes, which may prevent aneurysm formation.[32] Patients with advanced renal disease may require hemodialysis, which further disrupts metabolic efficiency. Chronic kidney disease, especially with microalbuminuria, can be a risk itself for CVD.[33] The development of peripheral and autonomic neuropathy in patients with T2D is also associated with increased cardiovascular risk.[34] The wide range in type and severity of complications in stage 4 DBCD supports subclassifications into stage 4a DBCD—mild; 4b DBCD—moderate; and 4c DBCD—severe disease, with specific interventional implications.[1]

While medical and possibly surgical treatments are required for nearly all types and severities of complications in stage 4 DBCD, lifestyle intervention must still be applied to mitigate various pathogenic mechanisms and improve quality of life metrics.[1,35] The management strategy in patients with stage 4 DBCD is centered on psychosocial, behavioral, and economic targets to prevent clinical suffering, further progression of complications, and mortality. The clinician–patient relationship should be driven by patient-directed goals of care with an emphasis on minimizing iatrogenic adverse effects of therapies.[1]

30.7 PREVALENCE

Dysglycemia-based chronic disease is highly prevalent in current populations, both in the United States and worldwide. Prevalence rates of each stage and associated conditions are given in Table 30.3. In cross-sectional studies, nearly 75% of the U.S. population demonstrate the presence of insulin resistance (stage 1 DBCD), and over 10% have T2D (stage 3 DBCD).[36,37] With such staggering numbers, the need for widespread lifestyle modification becomes resolutely clear.

30.8 PATHOPHYSIOLOGY

The molecular mechanisms of DBCD are grounded in genetic, epigenetic, environmental, and behavioral factors that constitute primary drivers. The multigene hypothesis suggests that patients with genetic predisposition faced with modern environmental conditions are at high risk. However, genome-wide studies demonstrate that just about 2–3% of the heritability for DBCD may be explained by genes.[38] The vast majority of DBCD risk is carried by environmental factors that alter molecular, cellular, tissue, and organ levels of function, as well as altering lifestyle behaviors.[39–41] Once primary drivers instigate DBCD stage 1, further stage progression is impelled by secondary drivers:

TABLE 30.3
Prevalence by Stage of DBCD and Associated Conditions

	Prevalence	
	U.S.	Worldwide
DBCD Stage 1: Insulin Resistance	74.5%	50–60%
DBCD Stage 2: Prediabetes	28–35%	30–45%
DBCD Stage 3: Type 2 Diabetes	10.5%	7.2%
DBCD Stage 4: Type 2 Diabetes with Complications	6.0%	1–2%
The Metabolic Syndrome (National Cholesterol Education Program criteria)	35.0%	20–40%
Obesity	42.4%	10.9%
Hypertension	45.4%	17.1%
Hepatosteatosis	24.1%	24.5%
Obstructive Sleep Apnea—Moderate to Severe (men)	25.0%	4.0%
Obstructive Sleep Apnea—Moderate to Severe (women)	9.0%	2.0%

abnormal adiposity and insulin resistance, systemic inflammation, disrupted control of energy homeostasis, vascular endothelium, cardiomyocyte pathophysiology, and pancreatic islet cell function. With the exception of genetics (non-modifiable), it is these rudimentary pathophysiological events that map to specific lifestyle medicine actions and specific prevention modalities.

30.8.1 Primary Drivers

30.8.1.1 Genetics

Genome-wide association studies (GWAS) have identified over 400 genes that confer risk for insulin resistance, obesity, and T2D.[42] Several large GWAS studies have evaluated approximately 27 million gene variants to yield these findings.[41,43] The genes identified influence processes that affect fasting glucose, insulin activity, and hemoglobin glycosylation, among other metabolic pathways. However, risk modeling using genetic scores based on GWAS data is rather disappointing. Gene-based models are less predictive for the development of T2D than simple anthropomorphic measures, such as BMI.[42] Presently, the utility of genetics in DBCD risk mapping is unclear, though there may be value in identifying targets for personalized medicine.[42] While genetic predisposition contributes to the development of DBCD, the rapid rise in prevalence of all stages of DBCD suggests that other factors hold greater influence.[42]

30.8.1.2 Epigenetics

Epigenetic processes include heritable, non-translational modification of genes and gene expression that are influenced by environmental conditions. Some examples include DNA modification by methylation, acetylation, or phosphorylation; or histone modification by acetylation or ubiquitination.[44] These processes influence gene expression over generations. A landmark study demonstrates that specific DNA methylation sites, as well as an overall increase in DNA methylation variance, are present among patients with obesity, suggesting the importance of epigenetic mechanisms in DBCD development.[45] Genome-wide methylation studies demonstrate that approximately 18% of the individual variance in BMI of an individual patient can be explained by DNA methylation.[46] Other epigenetic processes, such as histone acetylation affecting pancreatic β-cell function, are being identified as risks for DBCD and cardiometabolic disease.[44] Lifestyle interventions, such as increased physical activity and dietary pattern, can beneficially affect DNA methylation.[44] It is also likely that lifestyle interventions can affect other epigenetic mechanisms that underlie DBCD.[44]

30.8.1.3 Environment, Behavior, and Lifestyles

The concept of environmental factors encompasses all influences on physiology outside those conferred by genetics. This primary driver represents the lion's share of risk for DBCD.[1,47] Behavioral factors result from the interplay between genetics and environment. In turn, modern lifestyles result from the aggregated effects of the three primary drivers: genetics, environment, and behavior. Lifestyles have evolved through industrialization and information age technologies and form the final common pathway to DBCD stage 1.[1,48] Sedentary behavior, food choice and availability, reduced sleep duration, stress, and alcohol consumption are among the most influential lifestyle choices and behaviors conferring cardiometabolic risk.[47] Various SDOH, including food and housing security, daily work schedules and conditions, culture, and crime, among others, also influence risk in vulnerable populations (Table 30.2).[49]

30.8.2 Secondary Drivers

30.8.2.1 Abnormal Adiposity and Insulin Resistance

Insulin resistance, the central concept driving DBCD, encompasses systemic metabolic dysfunction that affects a wide range of biochemical and hormonal regulatory pathways within metabolically active tissues. Increased adiposity, in both volume and distribution (abdominal, especially visceral adipose tissue), drives systemic inflammation and leads to changes in levels of circulating adipokines, such as leptin, omentin, resistin, visfatin, and adiponectin. Network analyses of adipokines and associated proteins are highly suggestive of dysfunctional adipose signaling in the development and progression of DBCD.[50,51]

In additional to signaling, visceral adipose tissue processes energy pathways inefficiently, leading to reduced uptake and increased circulation of free fatty acids (FFA).[6] The resultant excess FFA in circulation may be ectopically taken up by tissues that do not ordinarily store so much fat, such as skeletal muscle, cardiac muscle and surrounding tissue (epi- and pericardium), liver, kidney, bone marrow, vasculature, and pancreas, contributing to further insulin resistance.[6] Abdominal obesity, assessed by WC, correlates more closely with insulin resistance and with cardiovascular risk than BMI.[1] Epicardial adipose tissue is associated with atherosclerosis, vascular inflammation, and arterial stiffness. Together, these specific mechanisms induced by dysfunctional and excessive adipose tissue are described as adiposity-based chronic disease (ABCD),[52] which serves as a key metabolic driver of DBCD.

30.8.2.2 Systemic Inflammation

Systemic inflammation is another hallmark feature of DBCD and is associated with abnormal adiposity. Immune cells, including macrophages, T cells, and neutrophils, are recruited to adipose depots and are highly active, as demonstrated by increased expression of cytokine/chemokine receptors, as well as CDC11c and β2 integrin, in macrophages.[53] Additionally, direct cell–cell contact among TH1 cells and adipocytes contributes to immune activation and reduces the generation of brown adipose tissue.[53] Tumor necrosis factor-α, interleukin (IL)-1β, IL-6, and IL-10 levels are increased.[53] Systemic inflammation is also driven

by generalized endoplasmic reticulum stress, leading to protein misfolding,[54] and by reduced clearance of advanced glycated end-products.[55] The various aspects of systemic inflammation, including cytokines, chemokines, plasminogen activator inhibitor-1, sialic acid, and fibrinogen, affect insulin production, pancreatic β-cell function, and target tissue insulin sensitivity, all contributing to DBCD.[56]

30.8.2.3 Disrupted Control of Energy Homeostasis

Another aspect of DBCD is central metabolic dysregulation. Many regulatory pathways are affected in DBCD. Among these, resistance to leptin, a hormone released by adipocytes that promotes satiety and influences hypothalamic metabolic regulation and insulin resistance, is common.[57] Leptin resistance results in elevated leptin levels, which confer a three- to fourfold increase in risk of cardiovascular events[58] as well as an approximately 30% increased risk in mortality among patients with known atherosclerotic disease.[59]

Adiponectin is the most abundant adipokine hormone produced by adipocytes, and its activity contributes to cardiometabolic risk.[60] GWAS have identified polymorphisms of the adiponectin gene as risks for T2D.[61] In patients with abdominal obesity, reduced circulating adiponectin levels are associated with insulin resistance through diminished adiponectin receptor activation in skeletal muscle and hepatocytes.[62] An animal model study of adiponectin infusion demonstrates reduced hepatic gluconeogenesis, suggesting that low levels of adiponectin promote hepatic glucose synthesis.[63] Diminished adiponectin activity also impairs insulin release by pancreatic β-cells and is associated with β-cell apoptosis.[64] Within adipocytes themselves, reduced adiponectin activity leads to reduced peroxisome proliferator-activated receptor-α activity, which promotes glucose and fatty acid uptake.[60] These effects of reduced adiponectin serve to drive DBCD progression.

Other disruptions in energy metabolism include improper hepatic glucose release during meals, which is partly due to a reduction in the levels and activity of incretin hormones, such as glucagon-like peptide 1 (GLP1) and 2 (GLP2).[6] The diminished satiety regulation that is consequent to low GLP1 and GLP2, as well as reduced leptin activity and changes in many other adipokine signals, leads to greater caloric intake.[6]

The gastrointestinal (GI) microflora speciation and activity are also affected by insulin resistance and obesity within the host.[65] An increased ratio of Bacteroidetes to Firmicute bacteria and a reduced GI bacterial diversity, which are observed among patients following Western dietary patterns, are associated with insulin resistance and cardiometabolic risk.[60] These changes drive DBCD through microflora–host signaling, disruption of circadian cycles, and excessive appetite stimulation through ghrelin release.[65] In some studies, altered microflora are associated with dietary preferences for diminished fruit and vegetable intake, choices detrimental to DBCD and cardiometabolic risk.[66]

30.8.2.4 Vascular Endothelium

Within the vascular endothelium, insulin resistance directly leads to reduced lipoprotein lipase and endothelial nitric oxide (NO) synthase activities, as well as increased endothelin-1 secretion, giving rise to increased oxidative free radical species production.[67] Vascular lipoprotein lipase activity is mediated by insulin and diminished in states of insulin resistance.[68] This results in hypertriglyceridemia (a component of MetS), which is independently associated with cardiometabolic risk.[68] Also, NO synthase is influenced by insulin activity. In states of insulin resistance, reduced NO production leads to vasoconstriction and is associated with hypertension, another driver of cardiometabolic risk.[69] Activity of the renin angiotensin pathway is also increased in insulin resistance, raising the risk of hypertension even further.[70] Other activities of the vascular endothelium affected by insulin resistance include increased expression of E-selectin and vascular cell adhesion molecule-1, which leads to macrophage recruitment and increased activation of inflammatory pathways.[71]

30.8.2.5 Cardiomyocyte Pathophysiology

Impaired energy metabolism and contractility of cardiomyocytes and reduced capillary recruitment within skeletal muscle are observed in DBCD. Cardiomyocyte metabolism shifts from balanced utilization of both fatty acids and glucose as energy substrate to a reliance on fatty acid oxidation.[72] This leads to increased reactive oxygen species and is associated with increased intracellular lipid storage within cardiomyocytes, resulting in myocardial lipotoxicity (impaired function associated with accumulation of lipid).[72] Animal models of insulin resistance demonstrate reduced cardiac contractility with this change in substrate utilization that is demonstrated prior to the development of hyperglycemia.[72] Left ventricular hypertrophy and cardiac fibrosis result from cardiac insulin resistance, hyperlipidemia, systemic inflammation, increased activity of the renin angiotensin pathway, cardiac microvascular disease, and reduced NO synthesis.[73] These effects contribute to diastolic dysfunction, which is commonly observed in T2D. Voltage gated ion channel activity within cardiomyocytes is also diminished, which may be associated with the observed increased cardiac arrhythmia risk, reduced electrocardiogram activity, and increased rate of T-wave inversions seen in patients with T2D.[74]

30.8.2.6 Pancreatic Islet Function

In the setting of insulin resistance, pancreatic β-cells produce increased amounts of insulin to meet demand; however, dysfunction develops in the timing and amount of insulin produced.[75] Lipotoxicity to β-cells, which results from excess circulating FFA in DBCD, is suggested by pre-clinical models as a potential mechanism for dysfunction.[76] Glucotoxicity, which occurs during hyperglycemia as patients progress to stage 2/3 DBCD, reduces the expression of genes needed to maintain β-cell differentiation and function.[77] Amyloid deposition within pancreatic islets,

replacing functional β-cells, is also observed as DBCD progresses and likely contributes to diminished β-cell activity.[78] Another mechanism seen in animal models of T2D involves macrophage infiltration within pancreatic islets, which may also reduce β-cell activity.[79]

These factors and possibly others contribute to pancreatic β-cell apoptosis and quiescence to nonfunctional cells within the pancreatic islets in response to systemic insulin resistance. The continued loss of β-cell activity drives the progression of stage 1 to stage 2/3 DBCD when hyperglycemia develops/worsens.[75] Pancreatic α-cells are also affected in the evolution of DBCD, possibly through diminished GLP1 and GLP2 activity, leading to untimely glucagon secretion that stimulates inappropriate hepatic glucose release.

30.9 LIFESTYLE TARGETS

A healthy lifestyle is paramount at all stages of DBCD. Modern living affords many instances and conveniences that threaten metabolic health. Recognition and implementation of healthy lifestyle choices should be considered among all patients with DBCD, who represent a large portion of current populations. Change is often difficult to implement, but making sustained steps in definable aspects of lifestyle can optimize clinical outcomes.[1] The DBCD model serves as a tool to clearly expose specific lifestyle targets at specific timepoints in the natural history of dysglycemia. The strategy is to intervene as early as possible, with an implementation tactic that is sustainable over the lifespan, to achieve significant clinical benefits.

30.9.1 Dietary Choice

Dietary patterns represent perhaps the most obvious lifestyle aspect worth addressing. In general, a healthy dietary pattern is recommended, with an emphasis on sustainability.[80] This will require clinical agility in assessments of food preferences, barriers to change, logistics of daily activities, as well as cultural and other personal considerations.[81] Both dietary content as well as timing of food consumption should be reviewed. In general, dietary patterns with a high content of fruits, vegetables, legumes, and nuts provide high amounts of fiber, are low in sodium, impart a beneficial influence on GI microflora, reduce systemic inflammation, and can reduce the risk of DBCD stage progression as well as promote regression to improved states of glucose metabolism.[1] Avoidance of detrimental dietary components such as simple sugars, *trans*-fats, and calorie-dense foods is also beneficial in DBCD.[2]

30.9.2 Physical Activity

Another common target is physical activity and exercise, which should be incorporated into daily routines. However, the amount and type of exercise remain controversial, with the sustainability of regular physical activity among the most important considerations. Direct incorporation, such as modifying a regular commute, or dedicating a specific time for exercise represent achievable targets for lifestyle intervention in most patients. On the basis of many clinical studies and published guidelines, at least 150 minutes of physical activity divided over 5–7 days per week is a reasonable suggested minimum.[1,6,52] Both cardiovascular exercise, which promotes reduction of visceral adipose accumulation and reduced insulin resistance, and strength training, which provides the benefit of increased muscle mass and reduced myocyte adipose content, should be considered.[82] Exercise also improves glucose metabolism through non-insulin-induced glucose utilization, improving hyperglycemia and potentially reducing glucotoxicity.[83]

30.9.3 Sleep Hygiene

Sleep is a defining feature of circadian rhythmicity and affects the metabolic function of the hypothalamus, liver, pancreas, adipose tissue, and skeletal muscle, among other tissues. Disrupted sleep promotes insulin resistance and impairs pancreatic β-cell function.[84,85] As a lifestyle choice, the amount and quality of sleep has been declining. In 1960, adults spent an average of nine hours sleeping per night compared with seven hours currently.[86] In children, the average sleep time has reduced by one hour per night over this same interval.[87] The quality of sleep has also deteriorated: insomnia, defined as waking at night at least three times per week, is reported among 25–35% of adults.[88]

Cross-sectional studies demonstrate a close association between reduced sleep time and weight gain.[89] In a randomized trial, adults who sustained sleep restriction for only five days demonstrated increased calorie consumption and weight gain.[90,91] Food preferences are also affected by sleep.[92] A 52% increase in consumption of sweets and desserts was reported in one crossover trial of sleep deprivation.[92] An elevation in ghrelin levels and a reduction in leptin levels are observed in people who are sleep deprived, which may affect dietary choice and consumption.[93] Both the quality and the amount of sleep are important potential targets for the prevention and treatment of DBCD.[84,86] Conversely, improvements in dietary patterns and increased physical activity can increase the total time and quality of sleep.[94]

Disordered sleep is associated with weight gain and worsened insulin resistance through disruption of circadian rhythmicity.[86] Among the most common sleep disorders, OSA is highly prevalent in adults with DBCD, especially in men (Table 30.3), and among patients with more advanced stages of DBCD. For example, a 60% prevalence of OSA is reported in patients with MetS.[95,96] In patients with T2D and obesity, 75% to 85% demonstrate OSA to any degree, and 50–55% have moderate to severe OSA.[97] OSA represents a common risk in DBCD that is often overlooked and underdiagnosed.[95]

Interventional treatment of OSA includes continuous positive airway pressure (CPAP) devices, which reduce

the cardiovascular risk and improve symptoms of headache and daytime drowsiness. In patients with moderate to severe OSA, cardiometabolic improvements, mainly in blood pressure and lipid profile, are also noted with CPAP use. In one series, 13% of patients with OSA and MetS no longer met criteria for MetS after three months of CPAP therapy.[96] Additionally, an intensive lifestyle modification that promotes weight loss can also improve the severity of OSA and confer improvement in sleep hygiene.[98]

30.9.4 Environmental Lighting

The mammalian circadian clock is generated by a pacemaker in the suprachiasmatic nucleus (SCN) of the hypothalamus with involvement of specific genes and a molecular mechanism that has been elucidated over the past few decades.[99] In humans, the endogenous circadian rhythm is longer than 24 hours and must be entrained daily by environmental cues, mainly light.[99] Other organ systems have separate clocks. These include the gastrointestinal tract clock set by food intake, the musculoskeletal clock set by food intake and physical activity, the adipose clock synchronized to the SCN clock and modified by food intake, and the pancreatic clock, which is influenced by light/dark cycles through SCN signaling.[100] The basic circadian clock function is generated by expression of positive arm genes (CLOCK, PAS2, BMAL1), which induces subsequent expression of negative arm genes (PER1, PER2, PER3, CRY1, CRY2).[101] In turn, the negative arm genes inhibit the transcription of positive arm genes, generating a negative feedback loop that cycles daily.[101]

Under the influence and synchronization of several clocks located in different organs and tissues, glucose tolerance varies by time of day. For instance, glucose tolerance is approximately 15–20% higher in the morning than in the evening.[102] Pancreatic β-cell activity also demonstrates a diurnal pattern, demonstrated by glucose clamping studies.[100] This pattern is disrupted by circadian misalignment protocol studies after mixed meal testing in patients without diabetes, in which light and dark cycles are inverted over one week, with a consequent 27% reduction of first phase insulin secretion, a 14% increase in late phase insulin secretion, and a 1.6% increase in glucose levels.[102]

By entraining the SCN clock, light exposure emerges as one of the many modifiable primary environmental factors that contribute to ABCD and DBCD risk. Observational studies of light exposure during the night reveal a 1.89 odds ratio (OR) for obesity that increases by light exposure level.[100] A randomized trial of healthy subjects demonstrates increased postprandial insulin and glucose levels with exposure to bright light at night.[103] The quality of light also affects insulin resistance. Randomized trials of blue light, which mimics the light produced by screen devices (e.g., smartphones, tablets, and computers), demonstrate increased association with insulin resistance among healthy individuals.[100] In sum, the timing and quality of light exposure as part of a modern lifestyle, as well as timing of other factors that influence circadian rhythm, such as food intake and physical activity, are potential targets in the prevention of development and progression of DBCD.

30.9.5 Stress Reduction

Chronic stress impacts multiple systemic functions. In the case of DBCD, states of chronic stress activate the hypothalamic-pituitary-adrenal axis and sympathetic nervous system, leading to increased cortisol and catecholamine levels, and consequent worsened insulin resistance.[104] Glucagon levels are also elevated, and leptin resistance is observed, which may drive intake of calorie-dense food.[105] Additionally, consumption of palatable calorie-dense food may trigger endogenous opioid release, stimulating reward pathways and reinforcing poor food choice in response to chronic stress.[105] Stress, which may be psychological or non-psychological (such as systemic inflammation) in nature, is associated with increased cardiometabolic risk.[106] The INTERHEART study showed an OR of 1.55 (1.4–1.6 95% confidence interval [CI]) for cardiovascular events with high chronic stress, as well as significant ($p < 0.01$) OR for presence of T2D (2.6 in men, 4.2 in women), abdominal obesity (2.2 in both sexes), and reduced physical activity (0.48 in both sexes).[106] Sleep is also commonly disrupted by stress.[106] Methods for stress reduction can help to reverse these trends and should be included among lifestyle interventions for DBCD.[107,108]

30.9.6 Alcohol Intake

Alcohol intake is always a controversial topic, especially in the context of healthy lifestyle. Abstinence of alcohol is commonly promoted for health, including cardiometabolic health.[109] A meta-analysis of global health data suggests that any alcohol consumption is associated with increased risk.[110] However, other studies may suggest that moderate alcohol consumption may also promote favorable cardiometabolic risk.[111] Analysis of moderate alcohol consumption, especially when in the form of wine, demonstrates improvement in insulin resistance, as well as reduction in cholesterol levels and reduction in systemic inflammation.[112] At excessive levels, alcohol intake is associated with increased cardiometabolic risk, including higher rates of MetS, hypertension, and abdominal adiposity, as well as other general risks.[111,113] Another concern with alcohol consumption in patients with DBCD is the theoretical risk of accelerated hepatosteatosis.[114] It is currently unclear whether moderate alcohol consumption exacerbates this condition. In one small study, moderate alcohol consumption was not associated with increased hepatosteatosis among patients with obesity,[115] but more study is needed.

30.9.7 Endocrine Disruptors

Many chemicals with various industrial uses demonstrate biological properties that affect hormone signaling.

Common products that contain currently known endocrine disrupting compounds (EDCs) include plastic containers, toys, cosmetics, perfumes, paints, flame retardants, packaging material, insecticides, and fungicides, among many other sources. Most commonly, these EDCs affect reproductive and metabolic pathways.[116] A large number of EDCs have been associated with the development of DBCD. Among the most studied is bisphenol A, which is associated with weight gain and obesity as well as affecting adipokine signaling, which contributes to insulin resistance.[117,118] Additionally, bisphenol A blocks calcium and potassium channels of pancreatic β-cells, decreasing insulin release.[116] Similarly, the persistent organic pollutant tetrachloro-dibenzo-dioxin diminishes glucose entry into β-cells, also blunting insulin release.[116] Exposure to polychlorinated biphenyl compounds or organochlorine pesticide mixtures leads to reduced insulin activity in skeletal muscle and adipose tissue.[116]

Central control of metabolism within the hypothalamus may also be affected by EDCs. The flame retardant tetrabromobisphenol A reduces melanocortin-4 receptor activity within the arcuate nucleus, which leads to reduced thermogenesis and increased calorie consumption.[119] Many other EDCs can affect regulation of energy metabolism, leading to DBCD. As novel industrial chemicals are regularly introduced, continual study is needed. Implementation of methods to reduce EDC exposure to humans represents a form of primordial prevention and another underutilized lifestyle intervention in patients with DBCD.

30.10 CONCLUSIONS AND CONSIDERATIONS

DBCD spans the non-communicable conditions of insulin resistance, prediabetes, T2D, and vascular consequences, as well as the associated conditions of PCOS, OSA, GDM, hepatosteatosis, and hypertension, and presents a great societal disease burden. The extraordinarily high prevalence of DBCD stages 1 and 2, with potential for progression and complications, makes these early conditions prime targets for lifestyle medicine. Lifestyle interventions in the later DBCD stages 3 and 4 also yield significant benefits in complication rates and quality of life. Approaches should address multiple aspects of lifestyle, such as dietary pattern, exercise and physical activity, sleep hygiene and circadian rhythms, stress reduction, alcohol moderation or abstinence, and minimizing exposure to EDCs. Modern culture often promotes unhealthy choices in each of these areas, and this trend is progressing, leading to even more pressure for new paradigms of care for chronic metabolic diseases, such as the DBCD model. A successful program in lifestyle medicine should implement healthful choices and objectives for each stage of DBCD to maximally impact metabolic health of individuals and society as a whole.

SUMMARY OF CLINICAL APPLICATIONS AND TARGETS IN DBCD[1,7,52,86,99,107,109]

Dietary Pattern	High content of fruits, vegetables, legumes, nuts, providing high amounts of fiber and low in sodium
Physical Activity	At least 150 minutes over 5–7 days per week
Sleep Duration	At least seven hours nightly
Sleep Quality	Screen for disorders of sleep, especially OSA
Environmental Lighting	Bright lighting in the mornings and dim lighting in the evenings
Stress Reduction	Methods to reduce and minimize stressors
Alcohol Consumption	Abstinence or minimal intake
Endocrine Disruptors	Avoidance and minimization of exposure, where possible

31 Context: Impact of Dysglycemia and Lifestyle Medicine on Cardiometabolic-Based Chronic Disease

Waqas A. Malick, MD and Jeffrey I. Mechanick, MD

KEY POINTS

- Patients with dysglycemia are at high risk for cardiovascular disease.
- The cardiometabolic-based chronic disease model exposes opportunities for early and sustainable prevention of cardiovascular disease in patients with dysglycemia.
- Genetics, environment, and behavior are primary drivers, and dysglycemia is an important secondary/metabolic driver of cardiometabolic-based chronic disease.
- Cardiometabolic disease endpoints include coronary heart disease, heart failure, and atrial fibrillation.

31.1 INTRODUCTION

Dysglycemia-based chronic disease (DBCD) exerts a large impact on cardiometabolic-based chronic disease (CMBCD) development and progression in terms of measurable cardiovascular disease (CVD) endpoints. Importantly, DBCD is largely driven by abnormal adiposity, inflammation, and subsequent insulin resistance. In this chapter, the context of dysglycemia is emphasized, namely, the prevention of CVD. Specifically, the impact of lifestyle on abnormal adiposity and the impact of dysglycemia, as well as other metabolic factors, on CVD using the CMBCD model will be discussed.

CVD includes a wide spectrum of disorders affecting the heart and blood vessels, clustered into atherosclerosis and coronary heart disease (CHD; coronary artery disease [CAD] plus cardiac microvascular disease), heart failure (HF), and atrial fibrillation (AF). CVD is the leading cause of death in the world, and despite overall decreases in mortality rates, total CVD-related deaths appear to be increasing again due to population growth, aging, obesity, and type 2 diabetes (T2D) prevalence trajectories.[1–3] Additionally, increased CVD mortality trends are noted in the low- and middle-income socioeconomic and educational strata, as well as certain ethnocultural populations with unhealthy lifestyles, due to less access to effective preventive strategies.[4,5] Notwithstanding these population disparities, it is imperative that healthcare systems effectively promote lifestyle and risk factor modifications to prevent CVD for all people.

CVD is often first recognized when patients present with significant symptoms such as angina, acute coronary syndrome (ACS), stroke, HF, and claudication (as a manifestation of peripheral arterial disease [PAD]). These conditions often manifest after prolonged exposure to modifiable CVD risk factors, including dyslipidemia, T2D, smoking, hypertension, and obesity (conventionally defined as a body mass index [BMI] ≥30 kg/m^2 [≥25 kg/m^2 for Asians]).[6,7] The advent of statins as a low-density lipoprotein cholesterol (LDL-C) lowering therapy led to significant CVD risk reduction on a population level,[8] and high potency statins have been shown to lower CVD risk by 44%.[9] However, despite reduction in LDL-C, residual CVD risk remains, largely due to other unaddressed metabolic factors such as insulin resistance.[10] Given the burden of CVD borne by populations and individual patients, more effective prevention strategies are needed. Therefore, it is important to recognize CVD as a chronic disease process with opportunities for primordial, primary, secondary, and tertiary prevention that can lead to mitigation of end-stage CVD events, particularly advanced CHD and advanced HF requiring advanced therapies or transplantation.

31.2 WHAT IS CARDIOMETABOLIC-BASED CHRONIC DISEASE?

Cardiometabolic-based chronic disease describes a model for the identification and optimization of early risk factors for CHD, HF, and AF for delivery of sustainable preventive care.[11] The postulated architecture of this model begins with primary drivers (genetics, environment, and behavior) that establish a particular lifestyle and an array of secondary or metabolic drivers (abnormal adiposity, dysglycemia, hypertension, dyslipidemia, and residual risk factors, all associated with the metabolic syndrome [MetS]). The central abnormality in CMBCD is insulin resistance, occupying a locus where abnormal adiposity (adiposity-based chronic disease [ABCD]) and dysglycemia (DBCD) intersect. Even though any of the metabolic

DOI: 10.1201/9781003227793-36

drivers can individually lead to CVD, a common scenario is the aggregate effect of these metabolic drivers, in varying levels of contribution and timing on the development and progression of CVD.

CMBCD can be divided into four stages: stage 1, risk; stage 2, predisease; stage 3, disease; and stage 4, complications. Stage 1 describes how primary and secondary drivers confer CVD risk. Stage 2 describes how the risk factors result in the predisease phenotype, such as the development of subclinical atherosclerosis. Stage 3 describes the presence of CMBCD as an early disease without symptoms: for example, diastolic dysfunction and signs of HF but without significant symptoms. Stage 4 describes symptomatic manifestations such as macrovascular CVD events (anginal coronary disease and myocardial infarction [MI] potentially requiring intervention). For clarity, several conventional terms can be interpreted within terms of the ABCD/DBCD/CMBCD models: "overweight" is ABCD stage 2; "obesity" is ABCD stage 3; "insulin resistance" is DBCD stage 1; "prediabetes" is DBCD stage 2; and "T2D" is DBCD stage 3. Also, the ABCD, DBCD, and CMBCD models all fall within a larger paradigm of "driver-based chronic disease," principally based on the causal relationships of key mechanistic drivers with chronic disease.[11]

31.3 PRIMARY DRIVERS OF CMBCD RISK

31.3.1 Genetics

The risk of developing CMBCD is driven by a complex interplay among genetics, environment, and behavior. Although it is known that family history plays a significant role in the development of CMBCD and CVD events, it has been difficult to pinpoint monogenic etiologies. Rather, CVD is inherited through a complex polygenic pattern resulting in variable phenotypic expression.[12] Although monogenic variants can still result in high-risk phenotypic conditions such as familial hypercholesterolemia, CAD is driven largely by single-nucleotide polymorphisms. Consequently, polygenic risk scores have been developed for CAD prediction, but most of these risk scores are suited to research and not routine clinical practice.[13] Furthermore, there is variability in the polygenic risk score based on ethnicity, limiting a generalized approach. For instance, certain polygenic risk scores have been developed and validated in European Caucasian populations and therefore may underestimate the risk in populations descended from African, South Asian, and Hispanic ancestries.[14–16]

In addition to genetic variants, gene regulatory networks play a significant role in the phenotypic expression of these variants and explaining the heritability of CAD.[17] Epigenetic regulation provides a logical explanation for how environment interacts with genes to create a specific phenotype. For example, epigenetic modifications arising *in utero* with maternal gestational diabetes may confer an insulin resistance phenotype in the offspring, which persists into adulthood, potentially leading to T2D, obesity, and CVD.[18,19] Additionally, newborns born to women with obesity tend to have thicker interventricular septa and reduced cardiac function as measured by global strain, strain rate, and tissue Doppler velocities compared with newborns born to women of normal weight.[20] As advances in genomics research continue to occur, it is expected that validated polygenic risk scores will be available for clinical application in CMBCD risk.

31.3.2 Environment, Behavior, and Lifestyles

Environment, which includes both the nonphysical (e.g., cultural) and the physical (e.g., built or human-made) environment, can significantly influence the risk of developing CMBCD and its progression. Particularly, socioeconomic strata, decreased access to quality healthcare, low education and literacy levels, air and noise pollution, and poor quality of drinking water are all associated with increased risk of CVD.[21] Exposure to persistent air pollution, particularly in urban environments, has been shown to be associated with increased CVD risk.[22,23] Increased exposure to fine particulate matter has also been shown to be associated with T2D. In a longitudinal cohort study of 1,729,108 participants, Bowe et al. found that increased exposure to fine particulate matter was associated with increased incident cases of and mortality from. Additionally, the burden of T2D was skewed more heavily toward low-income and lower-to-middle-income countries.[24]

A low socioeconomic stratum, particularly the lowest quartile, confers significant risk for the development of CMBCD. In a longitudinal cross-sectional analysis of CVD mortality trends from 1980 to 2014, lower literacy levels, poverty rates, and violent crime rates accounted for 60% of the variance in the CV mortality trajectory among 3,133 U.S. counties.[25] Additionally, individuals from these backgrounds have lower access to and utilization of preventive resources. These individuals are less likely to receive counseling, have annual checkups, participate in exercise, and receive smoking cessation counseling compared with high-income adults.[26] Additionally, low socioeconomic status is significantly associated with the incidence of T2D.[27] These factors combine to impel significant progression of CMBCD from stage 1 to eventually, stage 4.

Once genetics and environment have initialized physiological events leading to abnormal adiposity, insulin resistance, and CMBCD, individual behaviors can modulate this progression and expose opportunities for intervention. As an example, in at-risk patients with unhealthy dietary patterns, instituting healthy eating patterns can lower BMI, waist-to-height ratio, and waist circumference, resulting in lower CMBCD risk.[28] Lifestyle interventions in children, particularly through effective nutrition counseling and messaging, can potentially lead to increased knowledge and health literacy that can be sustained in the future.[29]. However, similar interventions in adults from low socioeconomic status were not found to be as sustainable, suggesting

that primordial prevention through promotion of healthy lifestyle habits needs to begin at an earlier age.[30]

Together, genetics, environment, and behavior play a significant role in classifying individuals as being in stage 1 of CMBCD, namely, exhibiting a lifestyle that is at risk for abnormal adiposity, insulin resistance, and downstream consequences of insulin resistance, including CVD. Although genomics continues to be an area of fascination for prediction of risk, this branch of study provides little utility for intervention. On the other hand, environmental stressors and behavioral factors continue to confer risk in people, especially those from low socioeconomic strata with poor health literacy. Policies geared toward intervening and supporting the lifestyles of these populations by addressing unhealthy aspects of the built environment and behavior may decrease the risk associated with the development and progression of CMBCD.

31.4 SECONDARY/METABOLIC DRIVERS OF CMBCD RISK

31.4.1 Adiposity-Based Chronic Disease

Once primary drivers and a resultant unhealthy lifestyle orchestrate physiological events that induce abnormal adiposity, insulin resistance ensues. In this fashion, ABCD is an early and critical secondary and metabolic driver of CMBCD. In addition, ABCD is a more scientifically accurate, actionable, and less stigmatized diagnostic term than obesity (which is more narrowly defined as ABCD stage 3), and was developed by the American Association of Clinical Endocrinologists (AACE) to describe the complex progressive disease that develops from abnormalities not only in the (increased) amount of adiposity, but also in the distribution and function of adiposity.[31]

Adipose tissue is made up of adipocytes, fibroblasts, vascular cells, lymphocytes, and macrophages. Excess caloric intake promotes recruitment of adipocyte precursors and resultant adipocyte hyperplasia. However, the hyperplastic response becomes impaired with aging, insulin resistance, and other disease states as well as with chronic overeating. This results in adipocyte hypertrophy and adipose tissue dysfunction.[32]

Abnormal adiposity has historically been viewed as excessive weight gain with abnormally increased BMI. However, the use of just weight gain and abnormally increased BMI to describe pathological adiposity has led to confusion, paradoxes, and therapeutic failures, since not all patients with obesity are insulin resistant, and individuals without obesity may still harbor an insulin resistant state despite not being obese. In fact, only about 11% of the individual variability in insulin sensitivity can be explained by differences in BMI.[33] Additionally, if weight gain occurs on an insulin resistant background, then asymmetric adipose tissue accumulation is favored, particularly in the intra-abdominal area. Furthermore, this adipose tissue can induce inflammation with influx of macrophages and abnormalities in circulating adipokines. Further weight gain can worsen insulin resistance and intensify inflammation, oxidative stress, and glucose intolerance.[33]

Abnormal distribution of adiposity is now understood as an intermediary step between excess calorie consumption (unhealthy lifestyle from primary drivers) and inflammation, leading to insulin resistance and CVD. Increased gluteofemoral subcutaneous adipose tissue is associated with entrapment of free fatty acids, which decreases ectopic free fatty acid uptake and therefore, exerts significant cardioprotective effects.[34,35] Conversely, increased adipose tissue accumulation in the intra-abdominal area is associated with increases in free fatty acid uptake in ectopic areas (liver, skeletal muscle, pericardium, epicardium, intestines, kidney, and pancreas) and therefore contributes to increased CVD risk.[33] Additionally, the presence of dysfunctional adipose tissue reflects inadequate accommodation of free fatty acids as fuel storage and therefore, more free fatty acids available to adversely affect the vasculature.[36]

Adipocytes release adipokines, which are regulatory peptides that produce a state of interconnectedness among the immune, endocrine-metabolic, and CV systems through autocrine/paracrine effects in adipose tissue and endocrine effects among multiple remote organs.[37] Within this network, the two most studied are adiponectin and leptin. Leptin acts in the hypothalamus to suppress appetite and food intake, increase energy expenditure, and regulate body weight.[38] Simply put, elevated levels of leptin signal satiety, whereas decreased levels signal hunger.

Abnormal adiposity also produces changes in adipokine signatures and consequent interactions with satiety centers in the hypothalamus, affecting eating behaviors. These changes promote increased caloric intake and therefore, maintenance of excess adipose tissue mass. In one study of 50 overweight/obese patients, despite persistent caloric restriction induced weight loss at one year, leptin levels remained decreased, as well as other maladaptive responses in satiety hormones, providing an explanation for the difficulty in maintaining weight loss with dietary changes.[39]

Additionally, ABCD can lead to hyperglycemia in the setting of insulin resistance by compromising the compensatory insulin secretion rate. In a murine model, obesity leads to increased macrophages in the pancreas, resulting in β-cell dysfunction and hyperglycemia. However, evidence of direct signaling from adipose tissue to β-cells is lacking. Other potential mechanisms linking abnormal adiposity with β-cell dysfunction include abnormal autophagy, apoptosis via IL-1β-FasL pathways, lipotoxicity, and others.[11] Adiposity is directly associated with inflammation; patients with ABCD stage 3 preferentially accumulate fat in the intra-abdominal compartment containing increased macrophages, which produce tumor necrosis factor (TNF)-α, IL-6, and MCP-1. In multiple studies of obese mice, white adipose tissue has been found to upregulate the transcription of inflammatory and macrophage-related genes.[40,41] Furthermore, this upregulation was found to precede a

dramatic increase in circulating insulin level, indicative of developing insulin resistance.[40]

In short, ABCD is a significant metabolic driver of inflammation, insulin resistance, hyperglycemia, and CMBCD, as once accumulation of dysfunctional adipose tissue occurs, there are multiple biological mechanisms in place to further ectopic fat distribution (Figure 31.1).

31.4.2 Dysglycemia-Based Chronic Disease

Dysglycemia refers to abnormal glucose physiology and comprises insulin resistance, prediabetes, and T2D. Similarly to CMBCD, DBCD refers to a framework with implications for intervention to prevent the progression from insulin resistance to β-cell defects causing hyperglycemia (mild/early = prediabetes; more severe/late = T2D) and vascular complications (macrovascular from insulin resistance; microvascular from hyperglycemia).[42] More specifically, insulin resistance leads to CVD, specifically CHD and HF, through direct effects on glucose homeostasis, alterations in lipids and lipoproteins, inflammation, vascular endothelium, and cardiac metabolism (Figure 31.2).

31.5 PATHOPHYSIOLOGY OF DBCD IN THE PROGRESSION OF CMBCD

Glucose homeostasis occurs as insulin is secreted by the pancreatic β-cells via glucose sensing and metabolism-–secretion coupling, and then insulin promotes glucose uptake in skeletal muscle, hepatocytes, and other tissues to maintain a euglycemic state. However, once insulin resistance occurs as a result of abnormal adiposity, inflammation, and/or genetic predispositions, pancreatic β-cells have to compensate and increase insulin secretion. Over time, as insulin resistance progresses, insulin secretion becomes insufficient, and hyperglycemia (fasting and/or postprandial, depending on primary and secondary drivers) ensues.[42] Hyperglycemia leads to the formation of advanced glycation end-products (AGE), which can generate reactive oxygen species, thereby increasing oxidative stress on the artery wall. Additionally, hyperglycemia enhances monocyte adhesion to endothelial cells by activation of nuclear factor kappa beta (NF-κβ).[43]

Insulin plays a role in the regulation of lipid metabolism; it promotes storage of triglycerides and inhibits lipolysis in adipose tissue.[43] Insulin also reduces hepatic very low-density lipoprotein (VLDL) production due to its effect on reducing the availability of free fatty acids.[43] Furthermore, insulin also reduces apolipoprotein B production and is a potent activator of lipoprotein lipase, promoting the catabolism of triglyceride-rich lipoproteins. Insulin also increases low-density lipoprotein (LDL) receptor expression on the surface of hepatocytes, increasing LDL clearance from the plasma.[44]

Given insulin's significant role in lipid metabolism, insulin resistance leads to increased plasma triglycerides, reduced high-density lipoprotein (HDL) cholesterol, increased hepatic VLDL production, and increased LDL particle concentration without necessarily a change in LDL-C levels.[43] The high levels of VLDL are due to increased hepatic production coupled with reduced lipoprotein lipase activity and catabolism of VLDL.[43] The high levels of VLDL combined with the actions of cholesteryl ester transfer protein (CETP) and hepatic lipase lead to increases in small dense LDL particle generation. This is because CETP works to transfer triglycerides to HDL and LDL in exchange for cholesterol esters to VLDL and chylomicrons. The triglyceride-rich LDL is a substrate for hepatic lipase, which works to generate small dense LDL particles,[45] which are known to be proatherogenic and associated with increased risk of atherosclerotic CVD.[46]

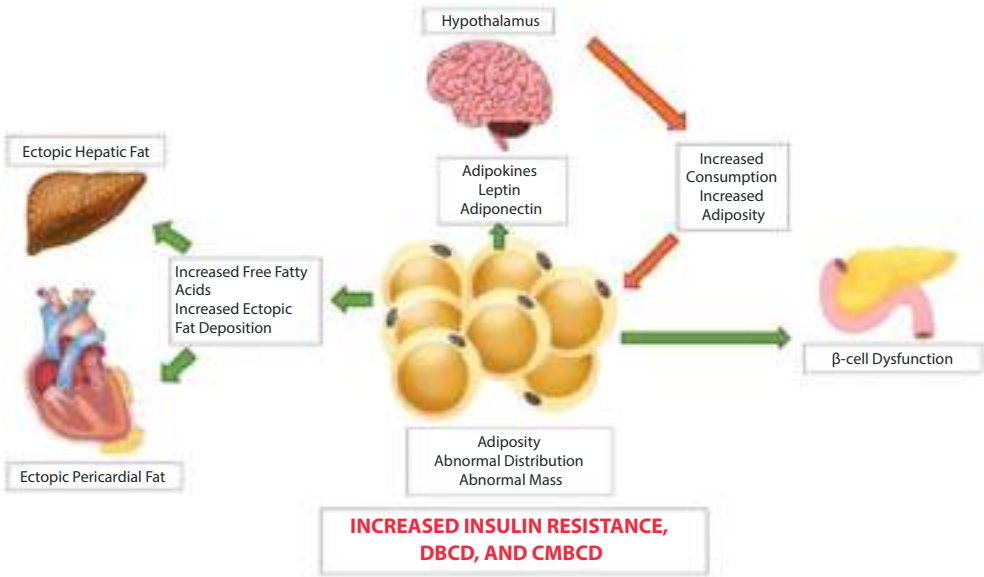

FIGURE 31.1 Mechanistic drivers of insulin resistance due to abnormal adiposity. CMBCD = cardiometabolic-based chronic disease; DBCD = dysglycemia-based chronic disease.

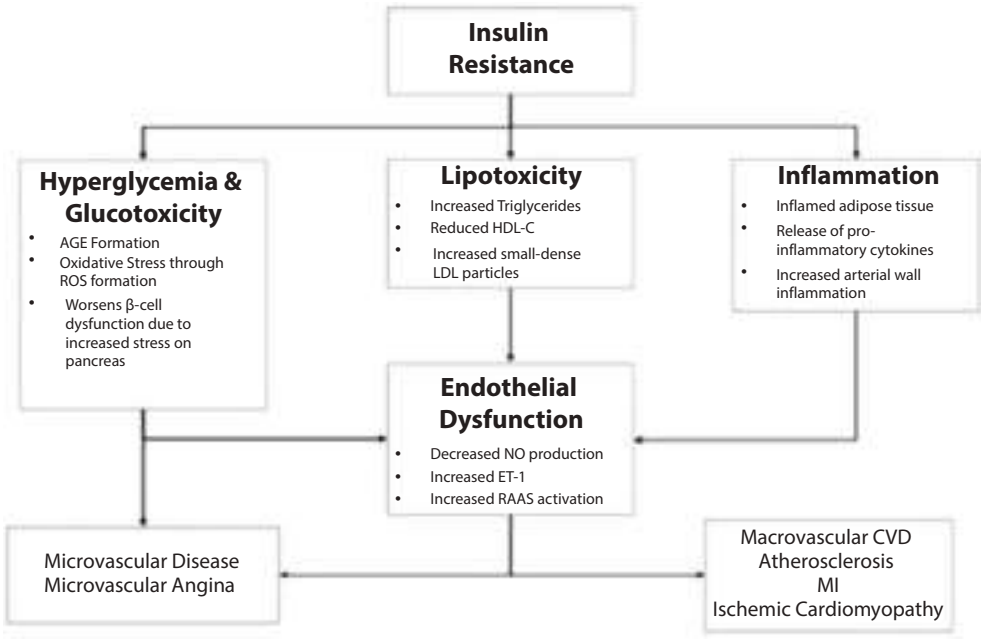

FIGURE 31.2 Mechanistic drivers of microvascular and macrovascular disease due to insulin resistance. AGE = advanced glycation end-products; CVD = cardiovascular disease; ET-1 = endothelin-1; HDL-C = high-density lipoprotein cholesterol; LDL-C = low-density lipoprotein cholesterol; MI = myocardial infarction; NO = nitric oxide; RAAS = renin-angiotensin-aldosterone system; ROS = reactive oxygen species.

Insulin resistance also leads to inflammation, which compounds the effects of dyslipidemia and hyperglycemia, specifically, inflammation of adipose tissue. This leads to the release of proinflammatory cytokines and subsequent oxidation of triglyceride-rich lipoproteins. Also, the hyperglycemic state promotes glycation of small dense LDL. These lipoprotein particles are rendered proinflammatory and induce an immune response causing macrophage activation and vascular wall inflammation, resulting in coronary plaque genesis and progression.[47,48]

Insulin resistance also has direct effects on the vascular endothelium, leading to vascular smooth muscle progression and coronary artery stenoses. Insulin signaling regulates endothelial nitric oxide synthase activity and production of the vasodilator nitric oxide. With the development of insulin resistance, the ability to produce nitric oxide is inhibited, causing increased vasoconstriction. Additionally, hyperinsulinemia in the insulin resistant state leads to increased endothelin-1 production via the mitogen-activated protein kinase (MAPK) signaling pathway, yielding further vasoconstriction and promotion of vascular smooth muscle cell proliferation.[49] Additionally, insulin resistance has been linked to increased signaling in the renin-angiotensin-aldosterone system (RAAS), leading to impaired vascular relaxation and increased production of reactive oxygen species.[50] Furthermore, this contributes to increased incidence of hypertension and progression of CMBCD in patients with insulin resistance.

Insulin resistance also affects the myocardium. With enhanced lipolysis and increased availability of free fatty acids, there is increased ectopic lipid accumulation, resulting in myocardial lipotoxicity. Intracellular inflammatory factors, mitochondrial dysfunction, and oxidative stress impair insulin signaling and lead to activation of NF-κβ-mediated pathways that enhance myocyte inflammation.[51] The myocardium preferentially relies on free fatty acids for fuel. With ischemia, the heart switches to glucose for fuel. However, in the insulin resistant state, the ability to utilize glucose as a substrate for fuel for the myocyte is impaired, and when combined with endothelial dysfunction, increased activation of the RAAS, and increased inflammation and oxidative stress, structural dysfunction can result, typically ischemic cardiomyopathy with a reduced ejection fraction.

Alternatively, HF can manifest with preserved ejection fraction. Repeated cellular injury and abnormalities in contractile proteins in the setting of diabetes and insulin resistance can lead to cardiac tissue interstitial fibrosis and therefore, cardiac stiffness. Cardiac stiffness impairs the myocardial relaxation during diastole. The result is HF with preserved ejection fraction (HFpEF) accompanied by left atrial dilation and increased left ventricular (LV) mass. Left atrial dilation often leads to AF and therefore, worsens HFpEF.[52] Table 31.1 summarizes the pathophysiological effects of adiposity and dysglycemia on CVD.

31.6 THE PROGRESSION FROM INSULIN RESISTANCE TO CVD

Insulin resistance is a consequence of abnormal adiposity, particularly ABCD stage 2 (overweight) and stage 3 (obesity). Insulin resistance also represents the DBCD

TABLE 31.1
Key Effects of Adiposity and Dysglycemia on CVD

Effect	Coronary Heart Disease	Heart Failure	Atrial Fibrillation
ABCD	↑ Prevalence↑ CAC progression	↑ HFpEF	↑ Prevalence↑ Peri/epicardial adipose tissue
DBCD	↑ Platelet reactivity↑ Risk of MI↓ Myocardial perfusion	↑ ECV↑ HFpEF↑ Microvascular disease↑ Diastolic dysfunction↑ Cardiac lipotoxicity↓ Myocardial performance	↑ Prevalence
MetS	↑ Prevalence↑ Coronary plaques↓ Prognosis after first ACS	↑ Prevalence	↑ Prevalence

ABCD = adiposity-based chronic disease; ACS = acute coronary syndrome; CAC = coronary artery calcium; DBCD = dysglycemia-based chronic disease; ECV = extracellular volume; HFpEF = heart failure with preserved ejection fraction; MetS = metabolic syndrome; MI = myocardial infarction.

stage 1 and can impel progression to DBCD stage 2 (prediabetes), stage 3 (T2D), and stage 4 (vascular complications) through various pathophysiological pathways. Furthermore, each stage of ABCD and DBCD can lead to progression of CMBCD alone or in combination with other metabolic drivers (i.e., the interactive array of MetS traits). As CMBCD progresses, asymptomatic phenotypes deteriorate into symptomatic phenotypes, which then often require urgent intervention. Figure 31.3 displays the imputation of the ABCD and DBCD models into CMBCD risk and progression.

The intent of building and implementing these driver-based chronic disease models in the cardiometabolic space is to identify early targets for prevention of severe DBCD, CVD complications, and events. Early targets are preferred over later targets when possible. Early targets include unhealthy lifestyles, abnormal adiposity, and insulin resistance, and are primarily managed with intensive lifestyle change. Later targets are addressed with coronary revascularization for CAD via coronary artery bypass grafting (CABG) or percutaneous coronary intervention (PCI), advanced therapies such as left ventricular assist devices or transplantation for advanced ischemic cardiomyopathy leading to ventricular arrhythmias, and pharmacotherapy/electrophysiological ablations for AF. Compared with lifestyle interventions to address early targets, addressing these

later events is riskier and more costly. It is important to note that there is an evidence-based role for the addition of judicious pharmacotherapy with lifestyle change when addressing early targets, such as insulin resistance. The most recent iteration of the American College of Cardiology/American Heart Association (ACC/AHA) guidelines for primary prevention recommends the initiation of anti-glycemic therapies once the hemoglobin A1c (A1C) is greater than 6.5%.[53] However, it is well known that insulin resistance begins at A1C levels below 6.5%, and the lifetime risk of insulin resistance progressing to T2D is 70–74%.[54,55] Furthermore, insulin resistance and prediabetes are independently associated with increased risk of atherosclerotic CVD and increased CVD morbidity and mortality despite the lack of progression to T2D.[56,57]

31.7 PROGRESSION FROM HYPERGLYCEMIA TO CMBCD

In DBCD stages 3 and 4, hyperglycemia with a backdrop of insulin resistance is highly impactful on the prevalence of CHD. Through direct effects of hyperglycemia and hyperinsulinemia, the coronary vasculature has progressive plaque development that leads to atherosclerotic CVD. Progressive plaque development leads to the CMBCD stage, and particularly CHD. Patients with advanced T2D present with stable angina and are at increased risk for MI. Stable angina is a result of progressive vascular smooth muscle proliferation, leading to fibrous plaque formation, and eventually, the stenoses progress to cause symptoms of exertional angina. The increased risk for MI is due to significant atherosclerotic plaque burden, and plaque confers risk for ACS due to rupture. Additionally, patients with diabetes tend to have more aggressive atherosclerosis, more diffuse coronary lesions, smaller coronary vessels, and more extensive disease. For this reason, T2D is associated with a two- to four-fold increased mortality from heart disease.[58]

Additionally, the presence of T2D significantly affects revascularization strategies for patients with CHD, and this should be considered an additional impetus to prevent the progression of insulin resistance to T2D. Due to the increased risk of repeat revascularization, patients with T2D tend to experience a higher mortality rate.[59] Multiple clinical trials have led to the conclusion that patients with T2D and multivessel disease, defined as the presence of obstructive CAD in at least two vessels, should undergo revascularization with CABG to improve mortality.[60,61] Additionally, patients with T2D requiring revascularization often present with ischemic cardiomyopathy, as the insulin resistant state drives lipotoxicity, inflammation, and fibrosis in the myocardium. Revascularization of ischemic cardiomyopathy has shown mortality benefits over the long term, but in the short term, there is significant upfront risk of morbidity and mortality.[62] Overall, the impact of DBCD stages 3 and 4 on CVD is well defined and is significantly linked to cardiovascular morbidity and mortality.

31.8 DIFFERENTIATING THE RELATIONSHIPS BETWEEN TYPE 1 AND TYPE 2 DIABETES AND CMBCD

The focus of the DBCD model is on the prevention of progression of insulin resistance to T2D. However, type 1 diabetes mellitus (T1D) has a significant impact on CMBCD, albeit different from that of T2D. The central pathophysiological abnormality causing hyperglycemia in T1D is the absence of insulin production, typically due to autoimmune destruction of β-cells, whereas in T2D, it is insulin resistance and a subsequent β-cell defect. Since the insulin deficiency and resultant hyperglycemia are generally earlier in patients with T1D compared with T2D, it is not surprising that these patients with T1D have an almost threefold higher mortality than the general population, driven mainly by premature atherosclerotic disease.[63,64]

Hyperglycemia due to T1D results in significant downstream effects from an early age. Increased glucose in the bloodstream results in protein glycation, and early-stage protein glycation products undergo complex reactions, such as oxidation, dehydration, and condensation to form AGEs. These AGEs are not easily metabolized and tend to accumulate more in those with a history of inadequate glucose control. Additionally, these AGEs accelerate the progression of vascular disorders.[65] In one study of 105 Japanese patients with T1D, there was increased presence of skin AGEs in patients with T1D compared with healthy control patients, indicative of early presence of AGEs in skin vasculature.[66] Given the predilection of AGEs for the microvasculature, patients with T1D tend to present with microvascular dysfunction in various arterial beds, particularly diabetic nephropathy, which can further contribute to CMBCD and CVD risk.[63] The findings of the Diabetes Control and Complications Trial (DCCT) and Epidemiology of Diabetes Interventions and Complications (EDIC) Study revealed that intensive treatment to achieve strict glucose control versus conventional therapy resulted in significant benefits regarding CVD risk.[67,68]

Due to the presence of hyperglycemia, patients with T1D are more likely to present with atherosclerotic microvascular complications, including chronic kidney disease (CKD), PAD, and microvascular dysfunction in the heart. These microvascular complications result in angina that is not treatable by epicardial coronary interventions. Additionally, the microvascular angiopathy can lead to diastolic dysfunction and HFpEF, and when coupled with CKD, these patients often have chronic chest discomfort and shortness of breath.

The cardiovascular manifestations of T1D are different from those of T2D due to their varying pathophysiological mechanisms. Because T2D is due to insulin resistance, hyperglycemia and its consequences may take years to manifest, as the pancreas is initially capable of secreting more insulin to overcome the resistance. Therefore, as

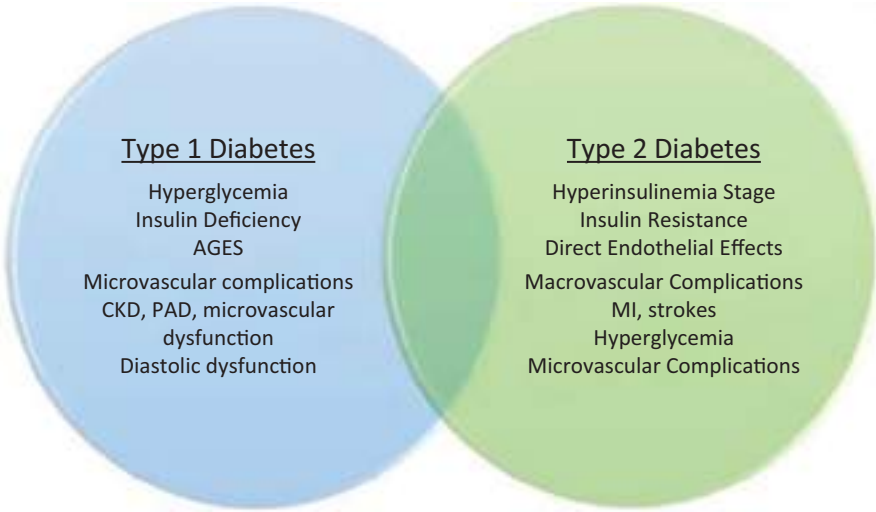

FIGURE 31.4 Type 1 versus Type 2 diabetes with regard to cardiovascular manifestations. AGEs.= advanced glycation end-products; CKD = chronic kidney disease; MI = myocardial infarction; PAD = peripheral artery disease.

TABLE 31.2
Cardiometabolic-Based Chronic Disease Prevention Types, Targets, and Features

Primordial	Primary	Secondary	Tertiary	Quaternary
Targets: • Environment • Behavior • CMBCD Stage 1	Targets: • Insulin resistance • Subclinical atherosclerosis • CMBCD Stage 2	Targets: • T2D • Coronary artery disease • CMBCD Stage 3	Targets: • Ischemic CHD • HFpEF • CMBCD Stage 4	Ethical behavior: • Avoid over-medicalization • Avoid action if in doubt • Judicious use of pharmacotherapy
Interventions: • Screening • Lifestyle education • Behavioral programs • Nutrition education • Aerobic physical activity • Progressive resistance training	Interventions (Primordial prevention plus): • Body imaging • Weight-loss medications • Metformin • Statins	Interventions (Primary prevention plus): • Diagnostic testing • Risk stratification • SGLT2i/GLP1ra • Other pharmacology	Interventions (Secondary prevention plus): • Cardiac catheterization/PCI • Surgical procedures • ↑ Cost • ↑ Iatrogenesis	

CHD = coronary heart disease; CMBCD = cardiometabolic-based chronic disease; GLP1ra = glucagon-like peptide 1 receptor agonist; HFpEF = heart failure with preserved ejection fraction; PCI = percutaneous coronary intervention; SGLT2i = sodium-glucose cotransporter-2 inhibitors; T2D = type 2 diabetes.

it takes time for the hyperglycemia to develop, the CVD manifestations in patients with T2D are more due to the direct effects of increased insulin resistance on the endothelium, including increased inflammation, oxidative stress, and vasoconstriction, which if left uncontrolled, can lead to macrovascular complications in the epicardial vessels. However, as DBCD progresses in the patient with T2D toward significant hyperglycemia, microvascular complications result as they do in patients with T1D. Figure 31.4 delineates the differences in the cardiovascular manifestations between patients with T1D and T2D.

31.9 CMBCD IDENTIFICATION OF DYSGLYCEMIA TARGETS FOR LIFESTYLE INTERVENTION

The CMBCD model is designed to identify targets for intervention prior to the onset of significant CVD, and even before significant T2D and insulin resistance. The specific prevention modality that can be implemented depends on the particular DBCD/CMBCD stage-dependent target. Prevention modalities are primordial, primary, secondary, tertiary, and quaternary (Table 31.2).

31.10 PRIMORDIAL PREVENTION OF DYSGLYCEMIA RISK AND PREDIABETES IN CMBCD STAGE 1 USING LIFESTYLE MEDICINE

Primordial prevention targets stage 1 of driver-based chronic disease models. The targets are primary drivers that modify behavior and environment to prevent the development of MetS traits. In ABCD, the goal is to prevent the accumulation of dysfunctional adipose tissue. In DBCD, the goal is to prevent insulin resistance. In CMBCD, the goal is to prevent MetS traits or the initiation of any secondary/metabolic driver of CVD. Primordial prevention is therefore implemented using lifestyle medicine interventions, e.g., adopting a healthy lifestyle, preventing abnormal weight gain, promoting healthy dietary habits, and encouraging regular aerobic exercise.[69] Additionally, government policies at the local and national levels are typically needed to promote healthy lifestyles, especially for underserved populations.

31.11 PRIMARY PREVENTION OF T2D IN CMBCD STAGE 2 USING LIFESTYLE MEDICINE

Primary prevention targets stage 2 of driver-based chronic disease models. For ABCD, the target is to focus on detection and reduction of abnormal adipose tissue through exercise and resistance training. For DBCD, the focus is prediabetes and preventing the progression to T2D. In ABCD stage 2, control of adiposity with weight loss and healthy lifestyles will help prevent DBCD stages 2 and 3. Both ABCD and DBCD stage 2 contribute to the definition of CMBCD stage 2, which is defined as subclinical atherosclerotic disease, HF, or electrical disease, typically detected with specialized cardiac testing. Interventions for both ABCD and DBCD stage 2 involve lifestyle interventions but can also include guideline-directed pharmacology; metformin is historically the favored agent for primary prevention of T2D.[31,42] However, one may consider other medications that are associated with weight loss and glycemic control, as well as cardio- and renal protection (e.g., sodium-glucose cotransport-2 inhibitors or glucagon-like peptide-1 receptor agonists), in ABCD/DBCD stage 2.[69]

31.12 SECONDARY PREVENTION OF T2D COMPLICATIONS IN CMBCD STAGE 3 USING LIFESTYLE MEDICINE

Secondary prevention targets stage 3 of driver-based chronic disease models. ABCD stage 3 refers to obesity, which is strictly defined by BMI only; DBCD stage 3 refers to T2D, which is strictly defined by glucose or A1C levels only; and CMBCD stage 3 refers to atherosclerotic CAD/CHD (and other atherosclerosis of other arterial beds) without symptoms, cardiac dysfunction without symptoms, specifically diastolic dysfunction, and AF without symptoms. At this stage, the goal is to modify the cardiovascular risk factors and prevent CVD events, such as worsening HF or ischemic CHD requiring revascularization, and prevent strokes and myocardial infarctions. Treatment of stage 3 ABCD/DBCD stage 3 includes lifestyle change, but for stage 3 DBCD, pharmacology is usually required. Metformin is historically first-line therapy for T2D treatment. However, glucagon-like peptide-1 receptor agonists have shown significant benefit in cardiovascular outcomes, have been particularly effective in helping with weight loss, and should be considered at this stage. given the ability to prevent progression of both ABCD and DBCD.[70,71] Sodium-glucose cotransport-2 inhibitors have also shown significant benefit in patients with CVD[72,73] and are increasingly utilized in cardiovascular clinical practice to treat patients with CHD and HF.[74] At CMBCD stage 3, cardiovascular testing may be requested to assess atherosclerotic burden with coronary computed tomography imaging. One can also consider nuclear perfusion imaging testing to assess for obstructive CAD. Of note, bariatric surgery may be considered in higher risk ABCD stage 3, as multiple studies have demonstrated that bariatric surgery not only reduces excess weight long term but also leads to reduction in T2D, HTN, and dyslipidemia.[75,76]

31.13 TERTIARY PREVENTION OF COMPLICATIONS, MORBIDITY, AND MORTALITY IN CMBCD STAGE 4 USING LIFESTYLE MEDICINE

Tertiary prevention targets stage 4 of driver-based chronic disease. At this stage, complications of adiposity and dysglycemia have occurred, including both microvascular and macrovascular complications. The patient may have developed clinical CAD, presents with symptoms of exertional angina, and requires revascularization. Alternatively, the patient has progressed from diastolic dysfunction to HF with preserved, mid-range, or reduced ejection fraction and may be hospitalized for decompensated heart failure. Or, the patient with AF develops incapacitating symptoms and is at high risk for stroke. At this stage, the goal is to manage the disease burden and symptoms and prevent recurrence of events, such as need for revascularization procedures, MI/stroke, heart failure hospitalizations, and/or electrophysiological studies, ablations, and other procedures. Preventive interventions at this stage can be costly, and future efforts should focus on reducing these costs of healthcare and the overall economic burden to the healthcare system. At this stage of CMBCD, there is also increased risk of mortality from the disease or the procedure.

31.14 QUATERNARY PREVENTION OF OVER-MEDICALIZATION IN DYSGLYCEMIA CARE IN ALL STAGES OF CMBCD

Quaternary prevention is a relatively new concept to identify patients who are at risk for over-medicalization and

to therefore prevent unnecessary testing and potentially harmful interventions. Quaternary prevention is represented by ethical behavior by the healthcare professional and is applied at all stages of ABCD, DBCD, and CMBCD. Lifestyle interventions must be prioritized at all stages of CMBCD, and when necessary, pharmacotherapy and procedures should be utilized judiciously.[77]

CLINICAL APPLICATIONS

The ABCD, DBCD, and CMBCD models have significant clinical applications, which are summarized here. Early recognition of risk factors for the development of adiposity and discussion of lifestyle interventions with patients at the initial visit are important. Additionally, these clinical visits require assessing the presence of stage 1 and stage 2 of these driver-based chronic disease models by checking height, weight, BMI, waist to hip ratio, blood pressure, A1C, and a lipid panel. An early assessment of these sometimes overlooked factors can allow prompt classification into one of the stages of the models. facilitating a lifestyle medicine care plan. In short, it is recommended that these classification systems be utilized to promote earlier identification of risk factors to prevent progression to more significant disease.

31.16 CONCLUSIONS

In the CMBCD model, the main drivers of progression of CMBCD are adiposity and dysglycemia, modeled as ABCD and DBCD, respectively. The nascence of CMBCD stage 1 begins with abnormal adiposity, defined as abnormal amount, distribution, and function of adipose tissue. ABCD drives insulin resistance and progression of hyperglycemia, leading to significant effects on the macro- and microvasculature and the structural function of the heart. The CMBCD model provides a practical guide for early intervention and prevention of progression of CMBCD to stages 3 and 4.

32 Management: Lifestyle Medicine Approaches to Insulin Resistance, Prediabetes, Type 2 Diabetes, and Diabetes Complications

Reshmi Srinath, MD, Tracey Rosa, MD, Leena Shah, MD, and Jeffrey I. Mechanick, MD

KEY POINTS

- Given the growing prevalence of type 2 diabetes, awareness of insulin resistant and prediabetes states, and the need for early and sustainable preventive care, the dysglycemia-based chronic disease (DBCD) model was developed with a focus on reducing cardiometabolic risk and cardiovascular event rates.
- Lifestyle interventions focused on healthy dietary patterns, such as Mediterranean diets, regular physical activity, stress reduction, and sleep hygiene, and behavioral interventions utilizing mobile technology have a role in preventing the progression of type 2 diabetes.
- Large-scale lifestyle interventions, such as the Diabetes Prevention Program (DPP), which randomized subjects with impaired fasting glucose or impaired glucose tolerance to a curriculum focused on diet, physical activity, and weight loss, have shown significant benefit in reduced progression toward type 2 diabetes.
- The Look AHEAD study is the largest study assessing the benefit of an intensive lifestyle intervention in patients with type 2 diabetes and obesity; however, the intervention was not associated with a reduction in cardiovascular outcomes.
- While management of patients with uncontrolled type 2 diabetes with severe complications tends to be focused on pharmacological therapy and surgery, healthy dietary patterns, such as Mediterranean diets, and daily physical activity, in combination with the use of dietary supplements and nutraceuticals, may reduce disease progression.

32.1 INTRODUCTION

More than 34 million Americans (about 1 in 10) have diabetes, according to the National Diabetes Statistics Report for 2020 by the Centers for Disease Control and Prevention.[1] Patients with type 2 diabetes (T2D) are affected by microvascular and macrovascular (including cardiovascular [e.g., coronary heart disease, peripheral vascular disease, and cerebrovascular disease]) complications.[2] Moreover, diabetes and its complications are extremely costly, both resulting in loss in quality of life and incurring greater than $300 billion annually in healthcare expenditures, including costs of anti-hyperglycemic medications, diagnostic and therapeutic procedures, hospitalizations, and other aspects of chronic care.[1,3,4] While glycemic control and prevention of diabetes complications are crucial, there is significant value in focusing on interventions that are known to specifically delay the onset, slow the progression, and/or prevent diabetes and consequent complications altogether.

Dysglycemia is defined as any abnormality in glycemic status that is associated with disease or the potential for disease. The dysglycemia-based chronic disease (DBCD) model was created by the American Association of Clinical Endocrinology (AACE) and characterizes four distinct stages (risk, predisease, disease, and complications) that are actionable to reduce the potential impact of T2D, cardiometabolic risk, and cardiovascular events.[5] The DBCD care model prompts early intervention, emphasizes structured lifestyle change, and focuses on mitigation of progression from one stage to a subsequent worse stage, thereby lowering risk, morbidity, suffering, costs, and mortality.[6] From a pragmatic standpoint and to clarify nomenclature, prediabetes is DBCD stage 2, and T2D is DBCD stage 3.

A healthy lifestyle has been shown to reduce mortality, and numerous evidence-based, clinical practice guidelines support lifestyle medicine as an effective approach in the prevention, treatment, and reversal of chronic diseases, such as cardiovascular disease (CVD), diabetes, obesity, and cancer.[7–9] In the United States and other countries, lifestyle interventions have been shown to be extremely effective for T2D prevention in terms of cost, number of diabetes cases prevented, and quality-adjusted life years (QALYs).[10–12] For example, a clinical trial by Herman et al.[13] showed

DOI: 10.1201/9781003227793-37

that lifestyle intervention was not only cost-effective in all age groups, but effectively delayed the development of T2D by approximately 11 years, compared with metformin, which delayed the development of T2D by only 3 years. Given the chronic nature of diabetes and the increased costs associated with its progression, lifestyle medicine is especially important in delaying diabetes onset. This chapter highlights various DBCD stage–specific lifestyle interventions (including dietary patterns, physical activity, stress management, sleep hygiene, behavioral changes, glucose monitoring technologies, and legislation) with a spotlight on mitigating disease progression.

32.2 DBCD STAGE 1: INSULIN RESISTANCE

32.2.1 General Concepts

Insulin resistance is the earliest stage (stage 1) of DBCD and starts at birth, involving various factors, such as molecular risk for islet-cell dysfunction and genomic/epigenomic risk.[5] The prevalence of insulin resistance ranges from 15.5% to 46.5% among adults worldwide, and approximately 40% of American adults aged 18–44 years without diabetes have insulin resistance.[14–16]

In the insulin resistant state, there is reduced biological effect for any given concentration of insulin, and this can occur physiologically or pathologically.[17] There are no commercially available molecular screening tests to detect the molecular risk for islet-cell dysfunction.[5] However, there are some quantitative estimates of insulin resistance, two of which are the euglycemic clamp test and the homeostasis assessment model for insulin resistance (HOMA-IR), which correlate well ($p < 0.0001$).[18] The "gold-standard" test is the euglycemic clamp, which is useful for smaller studies and measures stimulated insulin resistance.[17] HOMA-IR estimates basal (compared with stimulated) insulin resistance, is more appropriate for large epidemiological studies, and is a mathematical model obtained when fasting plasma glucose and fasting insulin/c-peptide concentrations are available.[17]

32.2.2 Drivers

32.2.2.1 Family History of T2D

Family history (FHx) of T2D is associated with increased risk for insulin resistance in various populations of different ages and ethnicities.[19–22] In a cross-sectional analysis by Anderwald et al.[19] (N = 1,048 healthy European adults), a positive FHx of T2D is associated with insulin resistance using the hyperinsulinemic clamp test. Specifically, the M-value was lower in those patients with a FHx of T2D (indicating a greater degree of insulin resistance) when compared with patients without a FHx of T2D or patients with a FHx of CVD alone ($p < 0.02$).[19] Another study by Zhu et al.[20] found that Chinese patients with a positive FHx of diabetes benefit more from lifestyle interventions than those without a positive FHx, irrespective of age, baseline body mass index (BMI), waist circumference, sex, and weight change.

32.2.2.2 Abnormal Adiposity

Abnormal adiposity results from the net effect of primary drivers (genetics, environment, and behavior), which determine one's lifestyle, healthy or unhealthy.[23] Adiposity-based chronic disease (ABCD) also consists of four stages (risk, predisease, disease, and complications) but incorporates abnormal distribution and function of fat in addition to abnormally high amounts.[23] ABCD, along with DBCD and hypertension- and dyslipidemia-based chronic disease, is a secondary, or metabolic, driver of cardiometabolic-based chronic disease (CMBCD). In these frameworks, overweight is ABCD stage 2, and obesity is ABCD stage 3 (Figure 32.1).[23]

ABCD in general, and obesity in particular, leads to insulin resistance and hyperinsulinemia through impaired insulin signaling, but inversely, insulin resistance can lead to obesity through various mechanisms studied in both rodents and humans.[24] These relationships between obesity and insulin resistance are seen across all ethno-cultural populations and across a full range of body weights.[24] The risk for T2D and insulin resistance rises as body fat content increases.[24] Moreover, central/visceral (intra-abdominal) fat depots are more strongly linked to insulin resistance than peripheral fat depots.[25] In a cross-sectional study in Lebanon of 286 subjects (134 males, mean age 43.7 years), a higher proportion of men with obesity were insulin resistant (42.9%) compared with not insulin resistant (18.3%, $p > 0.001$) and had higher body fat, waist circumference, and glucose and insulin levels.[16]

32.2.2.3 Stress

Chronic stress has been recognized as an independent risk factor for insulin resistance, especially given the effects of increased cortisol levels on blood glucose levels and fat accumulation.[26] Recent studies have also looked at the role of acute stress in insulin resistance: Li et al.[27] conducted glucose/insulin tolerance tests in mice exposed to an acute psychological stressor (foot shock and behavioral escape test). Mice exposed to the foot shocks had abnormal glycemic responses when compared with normal mice, implicating a hepatic mechanism.[27] Yan et al.[26] measured the degree of insulin resistance by HOMA-IR and job-related psychosocial stress (via the Copenhagen Psychosocial Questionnaire) in 766 Chinese workers. There was a significant association with insulin resistance with respect to specific scales on the questionnaire, and cortisol was positively correlated with HOMA-IR and found to be an independent positive predictor for HOMA-IR ($p < 0.05$).[26]

32.2.2.4 Sleep Hygiene

The quality and quantity of sleep affect insulin resistance and therefore, both T2D and obesity. To start, obstructive sleep apnea (OSA) is found in 71% of people with diabetes and characterized by intermittent hypoxia and sleep

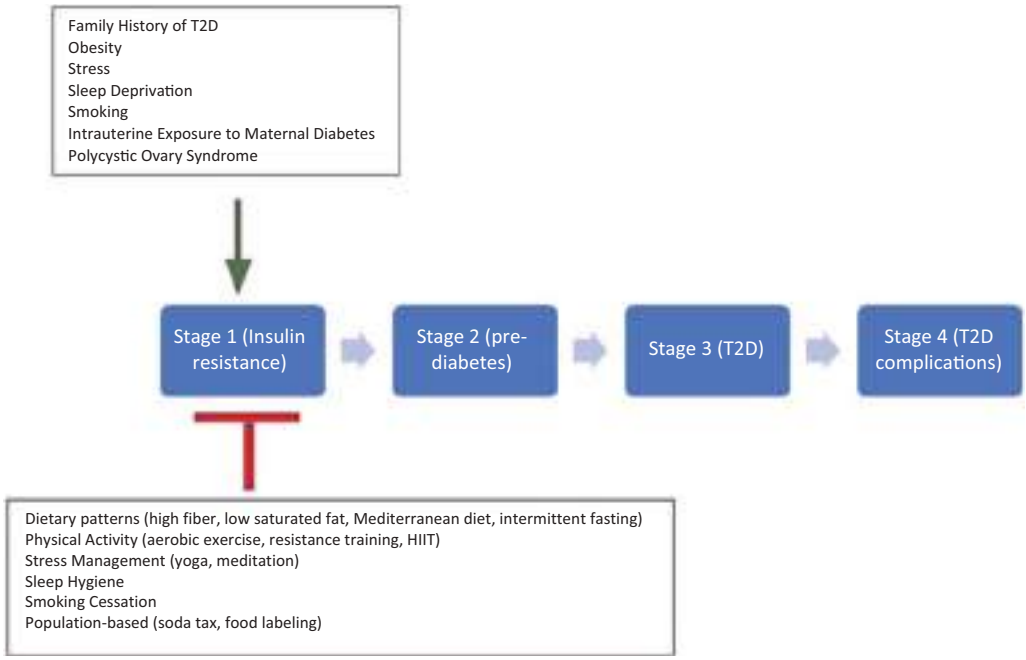

FIGURE 32.1 Factors contributing to insulin resistance and lifestyle interventions proposed to delay progression. Green arrow represents mechanistic drivers; red bar represents mitigation by lifestyle interventions. T2D = type 2 diabetes.

fragmentation, both of which have been shown to be associated with glucose intolerance.[28] Intermittent hypoxia has been studied in murine models of OSA and shown to lead to glucose intolerance and impaired insulin secretion.[29] In humans, intermittent hypoxia in healthy volunteers decreased insulin sensitivity.[30] Also, sleep fragmentation in healthy volunteers who were frequently awakened from sleep showed decreased morning insulin sensitivity and increased morning cortisol levels, with the degree of disruption of sleep correlating with the degree of blunting of insulin sensitivity.[31,32] There are also several cross-sectional studies showing a strong association between OSA and insulin resistance.[28] For example, a study by McArdle et al.[33] of 21 men with OSA, matched with 21 men without OSA, showed that insulin resistance (measured by HOMA) was higher in those with OSA ($p = 0.02$).

Interestingly, there are a number of studies that look at sleep deprivation over time and its effects on insulin resistance in healthy adults. A study by Donga et al.[34] looked at partial sleep deprivation during only a single night in nine healthy subjects and showed that there was increased insulin resistance (assessed via hyperinsulinemic euglycemic clamp) and endogenous glucose production when individuals had four hours of sleep compared with when individuals had about eight hours of sleep ($p = 0.017$). Subsequently, Buxton et al.[35] looked at sleep restriction for one week in 20 healthy mean with five hours of sleep for seven nights (normally, subjects slept for around ten hours). This study showed that insulin sensitivity was reduced on average by 20% after sleep restriction for one week ($p = 0.001$) when assessed by the intravenous glucose tolerance test and by 11% when assessed by the clamp method.[35] Lastly, chronic sleep loss affects diabetes and obesity risk.[36] Loss of sleep affects appetite, in part, by causing decreased levels of leptin and increased levels of ghrelin.[36] Together, these changes resulting from sleep deprivation correlate with increased hunger and appetite and lead to overeating and weight gain.[36]

32.2.2.5 Smoking

Tobacco smoking is associated with insulin resistance. There is a dose-dependent relationship between the quantity of cigarettes smoked per day and the degree of insulin resistance observed.[37] Smoking directly increases risk for insulin resistance via hormone activation as well as indirectly via effects that increase abdominal adiposity.[38]

32.2.2.6 Intrauterine Exposure to Maternal Diabetes

Another important risk factor and genetic component of insulin resistance is intrauterine exposure to maternal diabetes (type 1, type 2, or gestational [GDM]). Pregnancy is an insulin resistant state, and insulin resistance increases as pregnancy advances to ensure adequate carbohydrate supply for the fetus.[39] A number of factors, including maternal hormones (e.g., estrogen, progesterone, and human placental lactogen), increases in cortisol, and changes in other cytokines mediate the decline in insulin sensitivity during pregnancy.[39,40] Factors such as genetics and epigenetics, obesity, unhealthy dietary patterns, and physical inactivity can increase insulin resistance in pregnancy and have implications for both the mother and the offspring, in the short term and the long term.[41,42] For example, up to 30% of women of reproductive age are obese, and the prevalence of women starting pregnancy with a BMI of 30 kg/m^2 or greater has

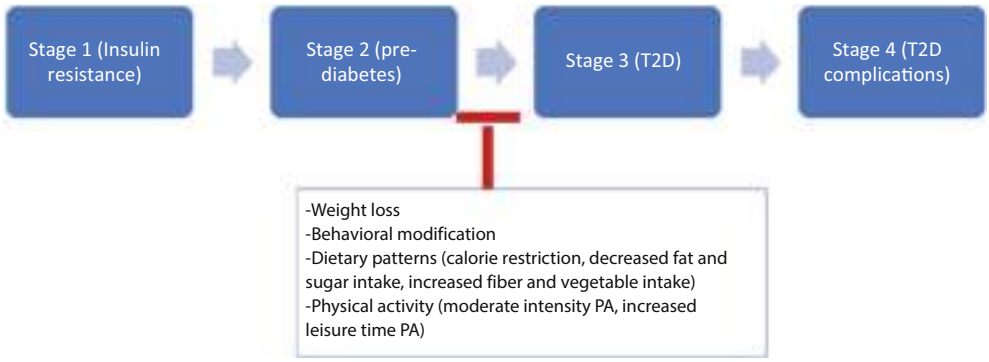

FIGURE 32.2 Diabetes-based chronic disease stages and lifestyle interventions proposed to delay progression. Red bar represents mitigation by lifestyle interventions. T2D = Type 2 diabetes, PA = physical activity.

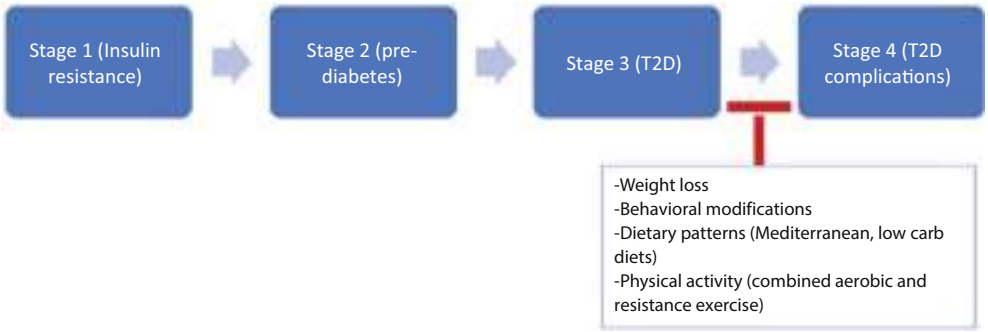

FIGURE 32.3 Diabetes-based chronic disease stages and lifestyle interventions proposed to delay progression. Red bar represents mitigation by lifestyle interventions. T2D = Type 2 diabetes.

steadily increased.[42,43] Maternal overweight and obesity are associated with a higher risk of GDM.[43] Moreover, *in utero* exposure to higher levels of glucose, such as in the offspring of mothers with GDM, was associated with impaired glucose intolerance (10.6% of children affected compared with 5% of children of mothers who did not have GDM) and increased adiposity at 10–14 years of age.[42]

32.2.2.7 Polycystic Ovary Syndrome

Polycystic ovary syndrome (PCOS) affects as many as 6–12% of women of reproductive age in the United States; women with PCOS are often insulin resistant and therefore, at higher risk to develop prediabetes and T2D.[44] According to the Centers for Disease Control (CDC), more than half of women with PCOS develop T2D by the age of 40 years.[44] PCOS is familial, and women with a FHx of PCOS or T2D are more likely to develop PCOS.[44] Bacha et al.[45] studied the ontogeny of PCOS and insulin resistance *in utero* and early childhood and found that hyperinsulinemic traits can be detectable as early as two months of age in daughters of PCOS women. Specifically, intrauterine testosterone excess and gestational hyperglycemia may contribute to early differentiation of PCOS, but fetal testosterone exposure needs to be clarified.[45] Focusing on early childhood markers for hyperinsulinemia and adiposity, along with ovarian and adrenal endocrine abnormalities, even before the diagnosis of PCOS may be beneficial, as it would allow lifestyle intervention during childhood and adolescence, and possibly prevent familial genetic predisposition to PCOS from manifesting as a phenotype in adulthood. This, in turn, would decrease both insulin resistance and the incidence of T2D.

32.2.3 Lifestyle Interventions to Mitigate Progression of Insulin Resistance to Later DBCD Stages

32.2.3.1 Dietary Patterns

Dietary interventions focus on reducing body weight and abnormal adiposity (while sparing muscle tissue), as well as nurturing a healthy metabolism.[46] Diets high in certain types of fiber promote improved post-prandial glucose and insulin responses, with oat fiber and guar gum being the most beneficial types of dietary fiber for insulin resistance.[46] A double-blind placebo-controlled trial by Landin et al.[47] tested the effectiveness of guar gum on insulin sensitivity in 25 healthy, non-obese men. The study involved 10 grams of guar gum or placebo three times daily for six weeks, and this intervention was effective in decreasing fasting blood glucose ($p < 0.001$) and improving insulin sensitivity ($p < 0.01$, via the euglycemic clamp technique; Figures 32.2 and 32.3).[47]

The type of fat consumed is also important. Patients at higher risk of diabetes should specifically focus on a diet lower in saturated fats and higher in monounsaturated fats

(MUFAs) and polyunsaturated fats (PUFAs).[48–50] A meta-analysis by Imamura et al.[48] concluded that the most favorable effects on glycemic status and insulin resistance were seen when carbohydrates, saturated fats, and even MUFAs were replaced with PUFAs. In particular, the study concluded that each 5% energy of increased MUFAs or PUFAs improved hemoglobin A1c (A1C) by approximately 0.1%, which in turn predicts a potential reduction in the incidence of T2D by as much as 22%.[48]

Jurado-Ruiz et al.[51] found that high-fat EVOO diets significantly improved insulin sensitivity and glucose tolerance in mice with diet induced diabetes. Similar results were also seen in MUFA-rich diets in humans, where ingestion of a virgin olive oil–based breakfast improved HOMA-IR, postprandial glucose, and insulin concentrations when compared with a carbohydrate rich diet.[49] On the other hand, there is no consensus on the ideal carbohydrate content for diets in the prevention of insulin resistance. While a diet low in carbohydrates improves fasting blood sugars and facilitates weight loss (adipose tissue and lean body mass), loss of muscle tissue is not ideal for improving insulin resistance.[46]

The ATTICA study in Greece involved 1,485 participants without diabetes at baseline and determined the incidence of diabetes over ten years. In participants who were non-adherent to a Mediterranean diet (measured by Trichopoulou's Mediterranean diet score), the incidence of diabetes was 21%, compared with an 8% incidence in those with intermediate adherence and a 5% incidence in those with high adherence to the diet ($p < 0.001$).[52] Mediterranean diets refer to several dietary patterns observed in multiple regions on the Mediterranean Sea. These dietary patterns involve higher plant protein and lower animal protein consumption when compared with Western diets, and this difference is worth noting because of the different amino acid content. For example, branched-chain amino acids, such as leucine, isoleucine, and valine, are 20–40% lower in Mediterranean diets when compared with Western diets, and these branched-chain amino acids have been found to modulate insulin sensitivity.[53,54] Reducing dietary intake of branched-chain amino acids can improve glucose tolerance and body composition.[55]

Liang et al.[56] studied insulin resistant rats and compared treatment with intermittent fasting (every other day) to treatment with metformin (and no intermittent fasting) or no intervention at all (all insulin resistant rats were fed a high fat diet). HOMA-IR induced by a high fat diet was found to be significantly decreased by intermittent fasting therapy in mice when compared with the control group ($p < 0.05$), and these results were comparable to those of the metformin group, showing that intermittent fasting significantly improves insulin sensitivity.[56] Furthermore, time-restricted eating (TRE), which is a form of the intermittent fasting dietary pattern that restricts eating to a period of four to ten hours a day, has shown improvement in glycemic control in animal and human studies. Specifically, Chung et al.[57] studied TRE in obese mice that had access to a high fat diet for only eight hours compared with obese mice that were fed a high fat diet *ad libitum* and found that HOMA-IR was significantly reduced in the TRE mice.[57] Moreover, in a recent review by Cienfuegos et al.[58] on TRE in humans, fasting insulin was reduced with improvement in insulin sensitivity in subjects with prediabetes and obesity. Subsequent randomized controlled clinical trials (RCTs) of TRE in patients with T2D and obesity have shown improvement in blood glucose and insulin sensitivity.[59,60]

32.2.3.2 Physical Activity

A review on exercise training and insulin resistance by Keshel et al.[61] concluded that significant improvements in insulin sensitivity are seen with weight reduction, but exercise-induced weight loss allows more sustained improvements in weight and glucose metabolism. This is largely because dietary weight loss may lower fat tissue but will not influence muscle metabolism as exercise training will do.

Studies have suggested that both aerobic exercise and resistance training are important in weight loss and in the prevention of insulin resistance.[61] A meta-analysis by Jelleyman et al.[62] saw that study participants with or at risk for T2D had greater reductions in fasting glucose ($p < 0.001$) with high-intensity interval training (HIIT) when compared with controls (i.e., without other interventions, such as diet restriction or resistance training). Another study by Hwang et al.[63] compared HIIT with moderate-intensity continuous training in healthy older adults (mean age 65 years) and observed that insulin resistance (via HOMA-IR) decreased in HIIT by 26% ($p = 0.016$) but not with moderate-intensity continuous training.

A study by McAuley et al.[64] looked at 79 men and women with insulin resistance (determined by the euglycemic insulin clamp) and randomized them to either a control lifestyle intervention, a modest lifestyle intervention (based on current diet and lifestyle recommendations, <11% saturated fat, 50% carbohydrates, and 30 min activity/5 days a week) and a more intensive lifestyle intervention (lower fat and higher fiber, <6% from saturated fat, 55% carbohydrates with >35 grams fiber/day, and at least 20 minutes daily reaching 80–90% of age-predicted maximum heart rate). This study showed a significant improvement in insulin sensitivity (23% increase, $p = 0.006$) in the intensive group when compared with the modest group (9% increase but not statistically significant), suggesting the need for more intensive interventions, which include more fiber and higher-intensity training.[64]

Lifestyle interventions can also help prevent early insulin resistance, such as that seen in adolescents and children. In the PANIC study, Lakka et al.[65] showed that a two-year dietary and physical activity intervention over six time points in 504 normal weight children (ages six to nine years) attenuated the increase in insulin resistance when compared with a control group.[65] After these interventions, HOMA-IR increased by 0.18 units less over a span of two years in the intervention group when compared with the

control group (p = 0.023).[65] The findings support that prevention of insulin resistance, and T2D by extension, should begin in childhood in the general pediatric population. This is a powerful example of primordial prevention—a population-based intervention design to decrease risk (e.g., DBCD stage 1) of chronic disease.

32.2.3.3 Mobile Technology

In the modern world, many technologies have taken advantage of the smartphone platform for mobile health, specifically for weight loss and diabetes prevention. A pilot study by Michaelides et al.[66] concentrated on the effectiveness of Noom™, which delivers structured curricula with human coaches, in 54 patients with prediabetes, ages 18–75 years, with A1C values ranging from 5.7% to 6.4%. Weight loss and BMI were significant at 16 and 24 weeks ($p < 0.001$). However, this study did not measure A1C levels or other markers for insulin resistance as main endpoints.

32.2.3.4 Stress Management

Meditation and yoga assist with stress management and the prevention of insulin resistance. A RCT by Paul-Labrador et al.[67] looked at the efficacy of transcendental meditation (TM) compared with health education in 84 subjects with coronary heart disease (only ~15–20% of these patients had a previous diagnosis of diabetes). The study found the TM group to have beneficial changes in insulin resistance (p = 0.01) compared with the health education group.[67] A second, more recent study by Sinha et al.[68] looked at the effect of meditation on blood glucose, A1C, and insulin levels in patients with coronary artery disease. After six months of meditation (in person twice a week and also at home for a minimum of five times a week), fasting blood glucose, postprandial blood glucose, and A1C levels all significantly improved in the meditation group when compared with the control group.[68] These results show that meditation and yoga can improve insulin resistance in patients with and without diabetes.

32.2.3.5 Sleep Hygiene

In patients with habitual sleep restriction, studies suggest that sleep extension may have a beneficial impact on insulin sensitivity. Leproult et al.[69] studied glucose metabolism in 16 adults (healthy and not obese) with chronic sleep restriction during a six-week period. Subjects were instructed to increase sleep by just one hour per day, which successfully improved fasting insulin sensitivity (p = 0.002).[69] Another recent study by So-ngern et al.[70] investigated the potential benefits of a two-week sleep extension on glucose metabolism with a crossover study involving 21 participants. All subjects reported sleeping 6 hours or less nightly (average of 318.7 minutes), and after a 2-week period of sleep extension, there was improved glucose metabolism (measured by HOMA-IR) in the eight subjects who were able to sleep more than 6 hours a night (average of 396 minutes).[70] It has been recently suggested in some studies that longer sleep duration in children is associated with lower levels of insulin resistance (by HOMA-IR), though properly conducted studies are lacking.[71]

32.2.3.6 Smoking Cessation

Several studies have shown the beneficial effects of smoking intervention on improving insulin sensitivity. One such study of 40 male, non-obese smokers used the euglycemic hyperinsulinemic clamp technique to show that in spite of a modest increase in body weight in 17 subjects who successfully quit smoking over eight weeks, the degree of insulin sensitivity increased significantly (by an average of 11%) following smoking cessation, while it remained completely unchanged in the control group of 23 patients (p = 0.0095).[72] Another study by Kim et al.[73] analyzed the correlation between length of time since smoking cessation and markers of insulin resistance (HOMA-IR) in 164 former Korean male smokers and compared them with 104 never smokers. There was a statistically significant negative correlation with the length of time since smoking cessation (p = 0.009); that is, the length of time was an independent predictor of HOMA-IR (p = 0.039).[73] Clearly, smoking reduction or cessation is an important intervention for those at risk for insulin resistance or already identified as insulin resistant.

32.2.3.7 Maternal Health

A recent study by Most et al.[74] suggests that women with obesity should not consume additional energy in pregnancy; rather, fetal development can be supported by maternal fat mass, commensurate with a daily calorie deficit of about 100 kcal. Moreover, recent studies all suggest that weight targets should be individualized based on pre-pregnancy BMI in women with obesity, and both dietary and physical activity interventions for weight loss in the preconception period can reduce the risk of excessive weight gain in pregnancy.[42]

The low glycemic index diet (LGID), where at least 50% of daily calories consists of high fiber carbohydrate, was shown to be most effective in improving insulin sensitivity in women with GDM. The effectiveness of the LGID was demonstrated in several studies, including a RCT by Hernandez et al.[75] where 12 pregnant women with overweight or obesity and GDM at 31 weeks were assigned to a LGID (high fiber) versus a low-carbohydrate/high-fat diet. The results showed that with the LGID, fasting glucose levels improved significantly (p = 0.03), along with insulin resistance (p = 0.005), with less need for insulin therapy.[75]

Clinical studies have overwhelmingly concluded that diet and exercise interventions should start preconception, as limited success has been seen when these lifestyle interventions are implemented late, when mothers are already overweight or have GDM.[76] Moreover, due to poor adherence to some strategies, such as targeting 150 minutes/week of moderate-intensity exercise during pregnancy, which is too time consuming, there have been some more practical diet–exercise strategies, such as TRE (a daily eating window of ten hours or less) and high-intensity intermittent exercise (HIT) two or three times weekly (a more time

efficient intervention). Initial studies suggest that supervised HIT in the first trimester of pregnancy reduces the incidence of GDM twofold among women who are overweight or obese.[77]

Lastly, few studies exist regarding the benefits of wearable technology, such as continuous glucose monitoring (CGM) devices, during pregnancy in preventing insulin resistance. In patients with type 1 diabetes on insulin pumps during pregnancy, CGMs are accurate and affordable, suggesting that such technology might be useful in the future for detecting and managing early DBCD stages.[78]

32.2.3.8 Population-Based Interventions

Several lifestyle-based diabetes prevention programs have shown that incorporating education and community-based peer support (in addition to diet and exercise) is both successful and cost-effective in individuals who are at high risk for developing diabetes.[10,11,65] In looking at population-based interventions, a systematic review by Zhou et al.[10] showed that implementing a population-wide tax on sugar-sweetened beverages is an important and cost-saving population-based policy approach to prevent T2D globally. With respect to a soda tax, Maa[79] found that consuming one sugar-sweetened beverage (SSB) a day can increase the risk of developing T2D by 26%. A cross-sectional study by Lana et al.[80] conducted in 7,842 individuals in Spain looked at the relationship of habitual SSBs to insulin resistance and found that an increase of one serving of SSB per day resulted in higher concentrations of insulin, leptin, and HOMA-IR (1.9%, $p = 0.04$) in women with normal weight and in men (HOMA-IR > 3%, $p = 0.021$). Moreover, a longitudinal analysis of the effects of a tax on SSBs implemented in Mexico shows that three years after implementation, there was a 4.7 percentage point increase in the probability of being non-consumers of soft drinks, and the probability of being a medium or high level consumer of soft drinks decreased by 6.8 and 6.1 percentage points, respectively.[81] Taken together, these studies affirm that a SSB tax is cost-effective and can decrease the risk of insulin resistance.

The U.S. Food and Drug Administration under the Obama Administration in 2016 advocated for an "added sugar" label to allow consumers to make more informed choices about healthy eating, but unfortunately, the implementation of this label was placed on hold by the Trump Administration in 2017. Nevertheless, there is research regarding food labeling and effects on insulin resistance from other countries. A study by Han et al. [82] studied the relationship between food labeling and HOMA-IR in adults without diabetes in South Korea after nutrition labeling became mandatory in 1995. Of the 2,931 participants surveyed, 24.8% indicated that they checked nutrition labeling and actively used the labels. Moreover, checking nutrition labels was inversely associated with HOMA-IR scores ($p = 0.0164$), with the association being more significant in people with obesity or in those who paid attention to their health.[82]

A meta-analysis by Afshin et al.[83] attempted to look at the prospective impact of food pricing on dietary consumption and concluded that the use of subsidies (i.e., a 10% decrease in the price of healthy foods) increased the consumption of fruits and vegetables by 14%. Additionally, changes in the price of fruits and vegetables reduced BMI by -0.04 kg/m^2 per 10% price decrease.[83] However, despite the positive effects of individual policies and behavioral economics on BMI and dysglycemia, the failure of current legislative actions to effect pervasive and durable change is likely due to the lack of a true cultural transformation to healthy living.[84] This will likely require a large number of legislative acts and a critical mass effect where populations find increased value in being healthy.[84]

32.3 DBCD STAGE 2: PREDIABETES

32.3.1 General Concepts

Prediabetes is considered a "predisease" state that results from insulin resistance (normoglycemia) and an consequent early β-cell defect with eventual mild hyperglycemia, and leads to DBCD progression with worsening hyperglycemia (T2D), diabetes complications (especially CVD), and in some, even regression to normoglycemia.[5] According to the American Diabetes Association (ADA), prediabetes can be defined by any one of the following: impaired fasting glucose (100–125 mg/dL), impaired glucose tolerance (plasma glucose of 140–199 mg/dL two hours after 75 g oral glucose load), or A1C of 5.7 to 6.4%.[85] The World Health Organization defines prediabetes as either impaired fasting glucose (110–125 mg/dL) or impaired glucose tolerance (plasma glucose of 140–200 mg/dL two hours after 75 g oral glucose load) but does not consider A1C in its diagnostic criteria.[86] From 2013 to 2016, the CDC estimated that 34.5% of all U.S. adults over the age of 18 had prediabetes.[87] Given the variability in definitions for prediabetes and variability across populations, it is difficult to estimate how many patients who meet criteria for prediabetes will develop T2D during their lifetimes, though according to the ADA, this is estimated at 70%.[88]

32.3.2 Lifestyle Interventions to Mitigate Progression of Prediabetes to Later DBCD Stages

32.3.2.1 Dietary Patterns and Physical Activity

In the United States, one of the largest RCTs looking at the effect of lifestyle interventions on the progression to T2D in at-risk individuals was conducted in the late 1990s and early 2000s by the Diabetes Prevention Program Research Group (DPPRG).[89] In this study, 3,234 people without T2D but with elevated fasting blood glucose levels or elevated blood glucose after a two-hour oral glucose tolerance test were randomized into one of three trial arms: 1) standard lifestyle recommendations plus 850 mg metformin twice

per day, 2) standard lifestyle recommendations plus placebo pill twice per day, or 3) intensive lifestyle recommendations with a 16-lesson curriculum that encouraged weight loss and moderate-intensity physical activity. After a follow-up period of about three years, the cumulative incidence of T2D was 28.9% in the standard lifestyle recommendations plus placebo group, 21.7% in the standard lifestyle recommendations plus metformin group, and 14.4% in the intensive lifestyle recommendations group. After the initial three-year follow-up period, the DPPRG continued to follow this original cohort of patients over ten years and noted that the incidence of T2DM was decreased by 18% and 34% in the original metformin and intensive lifestyle therapy groups, respectively, when compared with placebo.[90] Further studies looking at the independent effect of physical activity on diabetes prevention in this cohort have shown that over a 12-year follow-up, there was a 6% decrease in T2DM incidence for every six metabolic equivalents of task (METs) per week for all treatment groups combined.[91]

Other studies have investigated the effect of lifestyle interventions on the progression of prediabetes to T2D in non-U.S. populations. One such study conducted in Da Qing, China randomized 577 participants with impaired glucose tolerance and a mean BMI 25.7 kg/m^2 to one of four groups: dietary interventions, physical activity interventions, diet plus physical activity interventions, and control, which were then combined after the initial six year intervention period.[92] At the end of their 30-year follow-up period, they found that the median delay in onset of T2DM was 3.96 years for the intervention group, and the number needed to treat (NNT) with lifestyle interventions to prevent one case of T2DM over 30 years was 10 (95% confident interval [CI] 7 to 23). In a follow-up trial by Gong et al.,[93] the original Da Qing Diabetes Prevention Outcomes study participants were followed for an additional 20-year period after the initial 6-year intervention and monitored for the development of microvascular complications of T2D. In this study, the incidence of severe retinopathy was 47% lower in the original intervention group, but when adjusted for the delay in onset of T2D in the intervention group, the incidence of severe retinopathy between the two groups was similar, suggesting that the delayed onset of T2D is what led to this decrease in retinopathy incidence.[93] Unfortunately, there were no differences in incidence of severe nephropathy or neuropathy during this follow-up period, a finding which the authors felt may have been explained by overall low rates and relatively short duration of T2D in both groups.[93]

A similar large RCT was conducted in Finland, in which 522 middle aged individuals with overweight and impaired glucose tolerance were randomized to either a control group (received annual information on general diet and exercise) or an intervention group where they were encouraged to lose 5% body weight, engage in physical activity, and reduce fat intake.[94] After initial mean follow-up of 3.2 years, it was found that the risk of progression to T2D was reduced by 58% in the intervention group, and after 6 years, the absolute risk reduction was 15% for the intervention group.[95]

A 2006 study in India randomized 531 patients with impaired glucose tolerance to one of four intervention arms: control, lifestyle interventions, twice-daily metformin, and lifestyle measures plus twice-daily metformin.[96] After a median follow-up period of 30 months, the researchers found that compared with controls, there was a relative risk reduction in progression to T2D of 28.5% in the lifestyle intervention group, 26.4% in the metformin group, and 28.2% in the lifestyle plus metformin group.[96] The results of the U.S., Da Qing, Finnish, and Indian trials are summarized in Table 32.1.

32.3.2.2 Mobile Technology

A 2013 trial in India addressed whether SMS-text messaging encouraging lifestyle change could be effective in preventing the onset of T2D in 537 men aged 35–55 years with impaired glucose tolerance.[97] After a mean follow-up of 20.2 months, the researchers found that the absolute risk reduction for development of T2D as measured by oral glucose tolerance test was 9% in the intervention group, and the NNT to prevent 1 case of T2D was 11.

A similar, larger study was conducted in both India and the United Kingdom, including men and women and the use of A1C determinations.[98] However, after a mean two-year follow-up period, there were no significant differences in the incidence of T2D between the intervention and control groups (22.7% and 21% control and intervention, respectively; hazard ratio [HR] 0.89, 95% CI 0.74–1.07, p = 0.22).

32.3.2.3 Sleep Hygiene

Disordered sleep, specifically OSA, has been suggested as an independent risk factor for insulin resistance.[99,100] A RCT showed that treatment of OSA with continuous positive airway pressure (CPAP) for eight hours nightly for two weeks could improve insulin sensitivity in individuals with prediabetes.[101] Additionally, sleep apnea has been shown in observational trials to be associated with an increased risk of development of clinical T2D; this risk is attenuated by consistent use of CPAP.[102]

32.4 DBCD STAGE 3: TYPE 2 DIABETES

32.4.1 General Concepts

In 2019, it was estimated that there are 37.3 million people in the United States living with diabetes, amounting to 11.3% of the total population, and 14.7% of adults over the age of 18 and 29.2% of adults over the age of 65 have diabetes.[87] Worldwide, 2019 estimates show that 493 million people are living with diabetes, and that number is projected to reach 700 million by 2045.[103] Independently of other risk factors, diabetes incurs a twofold increased risk of CVD.[104] Given the widespread prevalence of T2D and its associated morbidity, improved management of this condition is of great clinical and research concern. Though pharmacologic treatments are part of the mainstay of treatment for T2D, lifestyle therapies and treatments remain

TABLE 32.1
Summary of Diabetes Prevention Trials

Trial	Lifestyle intervention	Follow-up period	Results
United States Diabetes Prevention Program[90]	• Individual and group educational sessions • Low-calorie, low-fat diet • Moderate PA for 150 min/week • Goal weight loss of 7%	10 years	34% lower incidence of T2D in lifestyle intervention group compared with control, median delay in onset of T2D of 4 years
Da Qing Diabetes Prevention Outcomes Study[92]	• Dietary changes (increased vegetable intake, decreased sugar and alcohol intake) • PA (increased leisure-time PA) • Only recommended decreased caloric intake to overweight and obese participants	30 years	Median delay in onset of T2D of 3.96 years in intervention group, NNT = 10
Finnish Diabetes Prevention Study[95]	• Individual and group sessions • Dietary recommendations to: reduce total fat to <30% and saturated fats to <10% of total caloric intake, increase fiber intake • PA of at least 30 min moderate intensity per day • Goal weight loss 5% or greater	6 years	Absolute risk reduction in T2D of 15% in intervention group
Indian Diabetes Prevention Programme[96]	• Monthly phone calls and biannual personal sessions • Dietary advice focused on: reduction in intake of total calories, refined carbohydrates, fats, and sugars, and increased intake of fiber	30 months	Relative risk reduction in T2D incidence of 28.5% in lifestyle intervention compared with control, NNT over 30 months = 6.4

NNT = number needed to treat; PA = physical activity; T2D = type 2 diabetes.

critical for successful outcomes. AACE recommends lifestyle therapies as standard of care for management of T2D and prevention of its associated adverse outcomes.[105] The ADA considers lifestyle medicine to be part of standard of care to improve glycemic control and clinical outcomes in patients with diabetes.[106]

32.4.2 Lifestyle Interventions to Mitigate Progression of T2D to Diabetes Complications

32.4.2.1 Dietary Patterns

One of the most important aspects of lifestyle intervention for the management of T2D is weight loss through dietary changes and increased physical activity—the focus of the Look AHEAD trial (Table 32.2).[107]

In this large multicenter trial, 5,145 people with overweight or obesity between the ages of 45 and 75 years old with a diagnosis of T2D were randomized to either an intensive lifestyle program aimed at promoting weight loss of 7% or more through decreased caloric intake and increased physical activity, or a control group that received diabetes support and education. This study's intervention period was terminated early due to futility after a median follow-up period of 9.6 years. While there was significantly greater weight loss in the intervention group compared with the control group at the study's end (6.0% loss from baseline vs. 3.5%), there was no significant difference in primary outcome: death from cardiovascular causes, nonfatal myocardial infarction, nonfatal stroke, and hospitalization for angina (1.83 and 1.92 events per 100 person years). Notably, at the end of the follow-up period, the HgbA1c in the intervention group was significantly (0.22%) lower than in the control group. However, low-density lipoprotein cholesterol (LDL-C) levels were 1.6 mg/dL lower in the control group, and the use of statins was higher in the control group, as was the use of antihypertensive medications and insulin. The authors concluded that the lack of difference in outcome rates may have been explained by the increased use of statins in the control group, or that the degree of weight loss in the intervention group may not have been large enough. To address the latter, a *post-hoc* analysis [108] found that participants in the intensive lifestyle group who lost at least 10% of their bodyweight had a 20% lower risk of the primary outcome compared with the control group. Even though this trial showed no difference in cardiovascular outcomes between intensive lifestyle interventions and control, the fact that there was an improvement in HgbA1c in the intervention group suggests that it would be worthwhile for future research to revisit this question, especially given that the differing rates of statin use may have affected results. Additionally, *post-hoc* analyses of renal outcomes of the Look AHEAD trial found that the incidence of very-high-risk chronic kidney disease (CKD) was 31% lower in the intensive lifestyle intervention group.[109]

Mediterranean diets are associated with lower A1C levels in T2D.[110] A large meta-analysis in 2015, including nine randomized controlled trials on Mediterranean style diets (N = 1,178 participants), found improvements in measures

TABLE 32.2
Summary of the Look AHEAD Trial

Population	Intervention	Control	Outcomes
5,145 individuals with overweight or obesity between ages 45 and 75 with a diagnosis of T2D	Aimed to promote weight loss of 7% or more through dietary plan with individual caloric goals and 30% total calories from fat and 15% from protein, plus 175 min/week of moderate-intensity PA, plus individual counseling and coaching	Three group sessions per year covering topics related to nutrition, exercise, and living with diabetes	• Significantly greater weight loss in intervention group (6.0% loss from baseline vs. 3.5%) • A1C 0.22% lower in intervention group • LDL-C 1.6 mg/dL lower in control group • Higher use of statins and antihypertensive meds in control • No differences in cardiovascular outcomes (composite of death from CVD, nonfatal MI, nonfatal stroke, hospitalization for angina) with 1.83 and 1.92 events per 100 person years in intervention and control, respectively

A1C = hemoglobin A1c; CVD = cardiovascular disease; LDL-C = low-density lipoprotein cholesterol; MI = myocardial infarction; PA = physical activity; T2D = type 2 diabetes.
See Wing et al. [107]

of glycemic control and CVD risk in T2D.[111] Huo et al.[111] found that Mediterranean style diets were associated with a 0.30% mean greater decrease in A1C, a 0.29 kg/m^2 greater reduction in BMI, and a 0.14 mmol/L greater decrease in total cholesterol compared with controls. There is also evidence from the PREDIMED trial that a Mediterranean diet is associated with reduced incidence of myocardial infarction, stroke, or death from cardiovascular causes.[112] In this study, 7,447 middle aged men and women from Spain with high cardiovascular risk (but no history of known CVD) were randomized to one of three diets: Mediterranean with EVOO, Mediterranean with nuts, or control diet with advice to reduce dietary fat intake.[112] Subgroup analysis showed that in participants with T2D at baseline, there was a 29% decreased risk of major cardiovascular event in the combined Mediterranean diet groups compared with controls (HR 0.71, 95% CI 0.51–0.98).

In a randomized controlled trial comparing isocaloric low-carbohydrate, high–unsaturated fat diets (14% carbohydrate, 28% protein, 58% fat, of which <10% was saturated fats) versus high-carbohydrate, low-fat diets (53% carbohydrate, 17% protein, 30% fat, of which <10% was saturated fats) over a two year period in adults with T2D, both groups achieved equivalent mean weight losses of 6.6 to 6.8 kg and reductions in A1C of 0.6% and 0.9%, respectively.[113] However, the low-carbohydrate group achieved a statistically greater reduction in diabetes medication use.[113]

In another large meta-analysis, the effects of a low-carbohydrate (less than 26% of total calories from carbohydrate) and very low-carbohydrate (less than 10% of total calories from carbohydrates, enough to induce ketosis) diet on various outcomes in patients with T2D were examined.[114] This study found that low-carb and very low-carb diets were associated with a mean 0.23% greater reduction in A1C at one year compared with controls.[114]

32.4.2.2 Physical Activity

Aerobic and resistance training exercise reduce A1C levels, as supported by a study of 250 previously sedentary individuals 39–70 years of age with A1C levels of 6.6% to 9.9% at baseline, randomized to aerobic training, resistance training, combined exercise training, or control. [115] After six months, there was a decrease in A1C levels in all three exercise groups. This study demonstrates that both aerobic and resistance training exercise can improve glycemic control in T2D and that combined exercise programs are even more beneficial. Subsequent *post-hoc* analysis showed a dose-dependent response with every 20% increase in adherence to the three assigned sessions per week, though this was only significant in the aerobic and combined exercise groups.[116] Additionally, an Italian study found that a 12-month combined aerobic and resistance exercise program with supervised sessions of 150 min/week plus exercise counseling was associated with a 0.30% greater decrease in A1C compared with exercise counseling alone in adults who were previously sedentary, overweight or obese, with T2DM and metabolic syndrome (MetS).[117]

In a randomized study by Balducci et al.,[118] participants with T2D received exercise counseling or 150 min/week of supervised aerobic and resistance training, the intensity of which was adjusted throughout the study to meet 55–70% of VO_{2max} and 60–80% of maximum resistance repetition maximums.[118] At the end of the 12-month intervention, improvements in cardiopulmonary fitness as measured by VO_{2max} and strength were associated with improvements in A1C, high-density lipoprotein cholesterol (HDL-C), and high sensitivity C reactive protein (hs-CRP), independently of weight loss, suggesting a reduction in overall CVD risk.[118] Though these results are promising, the highly regulated design of the exercise intervention and the impracticality of quantifying measures of physical fitness in the clinical

setting limit the generalizability of these results to a real-world patient setting.

32.4.2.3 Mobile Technology

The first of the mobile apps to be approved by the Food and Drug Administration (FDA), BlueStar, was designed to improve self-monitoring of blood glucose, encourage lifestyle modification, and assist with medication titration.[119] A randomized controlled trial of the app versus standard of care to improve A1C in 223 individuals with poorly controlled T2D (A1C ≥8.0%) took place in Canada and found that after three months, there was no statistically significant difference in A1C.[120] However, there was low overall usage of the app in this trial, and there may not have been a long enough follow-up period to produce reductions in A1C levels.[120]

An additional study in Germany randomized 2,441 individuals with T2D to either standard of care or a telemedicine-based lifestyle management program, though ultimately, only 115 individuals whom baseline and three-month follow-up data was available were included in the analysis.[121] There was a statistically significant reduction in A1C in the intervention group (7.05% to 6.58%, $p < 0.05$) but not in the control group (6.89% to 6.95%, $p = 0.465$).[121] In another study conducted in New Zealand, the effects of a nine-month text message–based intervention on A1C reductions in poorly controlled type 1 and type 2 diabetes were examined. There was a 4.23 mmol/mol greater decrease in A1C in the intervention compared with control groups at the end of nine months.[122]

32.5 DBCD STAGE 4: COMPLICATIONS

32.5.1 General Concepts

Stage 4 of the DBCD model is represented by those with diabetes who have progressed to having vascular complications and therefore, are at greatest risk for morbidity and mortality.[5] It is felt that dysglycemia and insulin resistance can contribute to the formation of reactive oxygen species (ROS), which in combination with oxidative stress, inflammation, mitochondrial dysfunction, formation of advanced glycated end-products (AGE), and neurohumoral mechanisms, lead to dysfunction of the endothelium and atherothrombosis.[123,124] Other components of MetS, including dyslipidemia, hypertension, and obesity, as well as age, sex, duration of diabetes, and genetic factors, contribute to the development of microvascular complications.[125]

It is well known that CVD is the leading cause of morbidity and mortality in those with diabetes, who have two to five times greater risk of heart disease.[126] The CDC reports that in 2018, approximately 1.87 million hospital admissions were attributable to heart disease in the setting of diabetes, with a smaller proportion attributed to amputation and other diabetes complications.[127] In terms of microvascular disease, between 2009 and 2014, the estimated prevalence of diabetic kidney disease was 26.2%,[128] and data from 1980 to 2008 estimate that 34.6% of individuals worldwide with diabetes had some form of diabetic retinopathy.[129] Estimates of diabetic neuropathy prevalence are more difficult to ascertain, given variability in the definition across studies, but diabetes has been estimated to be the cause of distal polyneuropathies in up to 50% of cases.[130,131]

Intensive glucose control emphasizing pharmacotherapy and/or surgical intervention is the standard of care to help patients with complications from uncontrolled T2D.[132] While lifestyle interventions may not play a central role in the management of severe complications, changes in lifestyle may help improve cardiometabolic risk factors and morbidity.

32.5.2 Lifestyle Interventions to Mitigate Development of Further Morbidity and Prevent Mortality from Diabetes Complications

32.5.2.1 Macrovascular Disease: Dietary Patterns and Physical Activity

Most clinical research looking at dietary patterns in diabetes populations has focused on Mediterranean diets, which are rich in alpha-linolenic acid, a plant based omega 3 PUFA found in many seeds and oils, and suggested to be cardioprotective.[133] The Mediterranean dietary pattern has been shown to reduce the risk of T2D, reduce metabolic markers, and lower cardiovascular events and mortality.[134] However there have only been a few studies involving subjects with established coronary heart disease (CHD) and specifically focused on subjects with T2D. The Lyon Heart Study examined whether a Mediterranean diet could reduce the risk of recurrent myocardial infarction and included a subset of patients with T2D.[133] Between 1988 and 1992, 605 participants from France were recruited and randomized to a Mediterranean diet or a more prudent Western diet with appropriate counseling. After a mean of 27 months, the group randomized to the Mediterranean diet had significantly fewer events, with the primary endpoint being death from cardiovascular causes or nonfatal myocardial infarction.[133] In another smaller study, 101 participants with established heart disease were assigned to an education program for one year or written advice only on the Mediterranean diet. After one year, there was no significant improvement in inflammatory markers or fasting insulin.[135] Both of these studies included a small proportion (<10%) of subjects with T2D.

Other diets, including the low-carbohydrate diet, have also been shown to improve glucose homeostasis, reduce diabetes risk, and improve weight loss, but have not been fully tested for secondary prevention of heart disease in diabetes populations.[136] The DASH (Dietary Approaches to Stop Hypertension) eating pattern focuses on low-fat foods, whole grains, and a variety of fruits, vegetables, and nuts, with limited sweets, and has been shown to be helpful in controlling hypertension and reducing insulin resistance,

hyperlipidemia, and obesity.[137] While suggestive of benefit in populations with diabetes and heart disease, there is some concern about the recommended carbohydrate intake in the DASH diet being excessive, so more studies are needed.

Dietary supplements and nutraceuticals with proven benefit > risk play a growing role for patients wanting to reduce cardiometabolic risk factors[138]. Vitamins C, D, and E have been tested in animal models and show some benefit in terms of assisting with cardiac vascular remodeling.[139] Preclinical data with carnitine, which plays a role in fatty acid transfer within mitochondria, amino acids, ribose, and flavonoids may also assist in ischemia-reperfusion injury.[139] Supplementation with coenzyme Q10, essential for cellular energy production, in combination with selenium was given over four years to 443 elderly patients in Sweden, of whom 21% had T2D and a similar percentage had heart disease. The treatment group with T2D was noted to have significantly reduced cardiovascular mortality (HR: 0.51; 95%CI 0.36–0.74; p = 0.0003) over ten years compared with placebo, and there was a trend toward reduced cardiovascular mortality in those with ischemic heart disease (p = 0.071).[140] Supplementation with omega 3 PUFAs has also been promising, given preclinical data suggesting benefit in ischemia-reperfusion and clinical studies indicating a role in cardiac prevention.[139] In a randomized placebo-controlled double-blinded study of 90 subjects with both T2D and heart disease, supplementation was provided with 1,000 mg fish oil or 1,000 mg flax-seed oil or placebo for 12 weeks. Those treated with fish oil or flax-seed oil had significant reductions in serum insulin levels, total nitrate, and total antioxidant capacity; this suggested that flax-seed oil can be a vegetarian/vegan alternative to fish oil to provide metabolic benefits.[141]

It is well known that regular physical activity is crucial and recommended in the setting of CHD prevention and treatment. While underutilized, cardiac rehabilitation programs can help patients with recovery, assist with weight loss, provide psychological benefit, and reduce cardiometabolic risk factors.[142] By meeting the guidelines of 150–300 minutes per week of moderate activity or 75–150 minutes of vigorous physical activity, cardiovascular morbidity and mortality is reduced independently of diabetes status.[143] Duration, intensity, and specifics of aerobic and resistance training should be personalized to the patient, with further research needed in this high-risk population.[142]

In the Look AHEAD study, there were changes in cardiorespiratory fitness as measured by a graded exercise test, independently associated with improvements in glucose, A1C, HDL-C, and triglycerides, in those randomized to the intensive lifestyle intervention compared with the diabetes support/education arm.[144] Of concern, in 14% of the total subjects with a CVD history, there was a non-significant increase in primary outcome of myocardial infarction, stroke, hospitalized angina or mortality, with a HR for ILI versus DSE of 1.13 (95% CI 0.90–1.41).[145] In further exploratory analysis, those with established heart disease were more often white, male, and older, with greater use of statins, anti-hypertensives, and insulin, but the treatment response heterogeneity could not be explained by changes in fitness, hypoglycemia rates, or differences in weight loss. *Post-hoc* analysis demonstrated that this effect was found to be secondary to increased rates of nonfatal myocardial infarction, which could have been driven by the physical activity component of the lifestyle intervention.[145] These results further reinforce the idea that studies looking at cardiovascular outcomes must take into account heterogeneity in treatment response based on CVD history.

32.5.2.2 Mobile Technology

Mobile technology poses an attractive approach to help patients with CHD in terms of monitoring symptoms, medication adherence, and encouraging healthy lifestyle behaviors. The CHAT-DM study randomized 502 subjects in China with T2D and heart disease to either text messaging with educational information (six per week) for six months or usual care[146]. Researchers noted a significant reduction in A1C over six months, and a reduction in fasting glucose in the intervention group, but no other differences in BMI, LDL-C, systolic blood pressure, or physical activity.[146] In the Australian Tobacco, Exercise and Diet Messages (TEXT ME) trial, 710 subjects with established heart disease, of whom 32% had T2D, were randomized to frequent lifestyle-based text messaging versus usual care for six months.[147] Those receiving the text message messages found them useful and were noted to have a significant reduction in LDL-C, systolic blood pressure, and BMI, and increase in physical activity, compared with the control group at the end of six months.[147]

32.5.3 Microvascular: Dietary Patterns and Physical Activity

There is growing interest in the role of dietary patterns, dietary supplements and nutraceuticals, and behavioral interventions in the management of diabetic microvascular disease. Traditionally, dietary management of nephropathy has emphasized restriction of protein and moderation of electrolytes and minerals, including sodium, potassium, magnesium, and phosphorus.[148] To further investigate the potential benefit of DASH or Mediterranean style dietary patterns in end stage renal disease, more than 9,000 subjects in a multinational cohort, of whom 32% had diabetes and nephropathy, were followed for almost three years for cardiovascular or all-cause mortality. Diet scores were derived from a food frequency questionnaire provided to subjects. There was no association between following a DASH or Mediterranean eating pattern and cardiovascular mortality or all-cause mortality.[149]

In a six-month behavioral intervention study, 121 patients with uncontrolled T2D and nephropathy and 49 healthy volunteers were randomized to an intensive lifestyle intervention of twice weekly phone calls for six months versus twice weekly phone calls for the first three months followed by

monthly phone calls for the second three months combined with caloric restriction and at least 300 minutes per week of moderate-intensity activity.[150] After six months, there was significant reduction in BMI and A1C in the intensive lifestyle intervention group compared with the control group, and reductions in interleukin-6 and tumor necrosis factor-α, but no change in renal function.[150] In sum, these results indicate that close supervision and frequent encouragement of lifestyle changes can reduce the progression of diabetes nephropathy.

In the setting of neuropathy, dietary interventions have focused on dietary supplements and nutraceuticals with antioxidant properties. Alpha-lipoic acid (ALA) has been tested both orally and intravenously, with short-term studies indicating benefit in reducing total symptom score and deficits.[151] In a longer randomized, double-blind, parallel-group trial, ALA was given orally over four years to 460 patients with symmetric distal diabetic polyneuropathy.[152] While there was no significant difference in the primary outcome, a composite of Neuropathy Impairment Score (NIS), neurophysiologic testing, and other markers indicated improvement in symptoms and reduction in deficits with ALA.[152] Nicotinamide riboside has also been postulated to help improve symptoms of neuropathy by directly enhancing energy metabolism in neuronal mitochondria.[153] In patients with neuropathy and vascular disease who have progressed to developing foot ulcers, zinc, vitamin D, vitamin E, and probiotics have been investigated. In a small study of 57 patients with grade 3 diabetic foot ulcers, supplementation with 250 mg daily magnesium and 400 IU vitamin E over 12 weeks helped reduce ulcer size and also reduced fasting glucose, A1C, and lipid levels.[154] In another 12-week study, 200 mg of coenzyme Q10 was provided daily to 70 patients with diabetic neuropathy, with no difference in symptoms of neuropathy, but the inflammatory marker hs-CRP was reduced in the intervention group.[155] In another RCT of 60 patients from Iran with grade 3 diabetic foot ulcers, patients received either a probiotic containing *Lactobacillus acidophilus*, *Lactobacillus casei*, *Lactobacillus fermentum*, and *Bifidobacterium bifidum* (2×10^9 CFU/g each) or placebo.[156] Over 12 weeks, probiotic administration significantly lowered ulcer length and depth and was associated with lower fasting glucose, A1C, and inflammatory markers without adverse effects.[156] In a parallel study in 60 subjects with grade 3 diabetic foot ulcer, administration of zinc sulfate supplements containing 50 mg elemental zinc was associated with reduction in ulcer length and width, significant lowering of fasting glucose and A1C, and reduction in hs-CRP and markers of antioxidants over 12 weeks.[157] In another study, the combination of B12, acetyl-L carnitine, ALA, and superoxide dismutase was compared with placebo over 12 months in a group of 85 patients with diabetic neuropathy.[158] Significant differences were noted in the Michigan Neuropathy Screening Instrument Questionnaire and Examination (MNSIQ and MNSIE), measurement of the vibration perception threshold (BIO), Cardiovascular Autonomic Reflex Tests (CART), measurement of nerve function, and pain (PS) and quality of life (QL) questionnaires.[158]

In the setting of neuropathy, exercise must be closely monitored due to the risk of developing foot ulcers with weight bearing exercise, and to assess for treatment induced neuropathy, which can occur acutely after the onset of glucose control in those with previously poorly controlled diabetes. In a 10-week study involving an exercise intervention with both aerobic and strengthening exercise based on the American College of Sports Medicine guidelines, 17 patients with established diabetic neuropathy and an average duration of diabetes of 12.4 years were followed. After the ten-week intervention, there was significant improvement in pain, using a visual analog scale as well as reduction in neuropathy symptoms based on the Michigan Neuropathy Screening instrument, and increase in intraepidermal nerve fiber density measured by proximal skin biopsy.[159] While short in duration and limited by the "very poor" exercise capacity measured by VO_{2max} at baseline, the results suggest the importance of both aerobic and strengthening exercises in neuropathy.[159] In a pilot study assessing the benefits of Tai chi, 20 subjects with diabetic neuropathy were given a 1-hour lesson twice weekly for 12 weeks, with noted improved balance, reduction in total symptom score, and reduced fasting glucose.[160] Overall, exercise interventions > four weeks focused on mobility, balance, proprioception, and resistance training have shown mixed benefits in patients with neuropathy, with varied outcome measures and duration making it hard to determine efficacy.[161]
