In the setting of retinopathy, there have been few large-scale lifestyle/dietary interventions focused on patients with established retinopathy. Lutein, found in dark leafy vegetables and egg yolk, has been felt to be helpful in diabetes retinopathy and other diseases of the retina, such as age-related macular degeneration, due to its anti-inflammatory and antioxidant function.[162] Similarly, vitamins including B-complex, vitamin C, vitamin D, folate, and N-acetyl cysteine can help protect the retina by improving blood vessel elasticity, improving neuron function, and improving vision.[163] The PREDIMED study, one of the largest prospective studies assessing the benefit of a Mediterranean diet in patients with T2D, found that a Mediterranean diet supplemented with EVOO reduced the incidence of diabetes retinopathy, but did not include those with pre-existing retinopathy.[164]

32.6 CONCLUSION

Diabetes mellitus is a growing worldwide problem with significant morbidity and mortality that not only affects individual patients living with the disease but also places a significant burden on healthcare systems. While there are many medical therapies that can be used to improve management of diabetes and reduce the risk of its complications, as with many chronic diseases, safe and effective prevention strategies remain of critical importance throughout the various stages of DBCD.[5] Lifestyle interventions, such as

TABLE 32.3
Summary of Management Strategies for DBCD

DBCD Stage	Pathophysiological Target	Strategy
1	Insulin resistance	Diet—increased fiber, increased MUFA and PUFA Exercise—aerobic and resistance training Sleep hygiene Smoking cessation
2	Prediabetes	Intensive lifestyle modification Weight loss Behavioral counseling and support Sleep apnea-treatment
3	T2D	Diet—Mediterranean and low carbohydrate Weight loss Exercise-aerobic and resistance training Behavioral counseling and support
4	T2D with complications	Diet—Mediterranean Behavioral counseling and support Supplements and nutraceuticals

T2D—Type 2 diabetes.

improvements in nutrition, physical activity, and sleep, are of key importance in the mitigation of DBCD progression (Table 32.3). Currently, most research regarding the role of lifestyle interventions in T2D prevention when applied to the DBCD model pertains to stages 1 (insulin resistance) and 2 (prediabetes). There are promising data that specific dietary patterns such as the Mediterranean diet and low-carb diets can improve measures of glycemic control in patients with T2DM or reduce cardiovascular events. There is limited research on the role of lifestyle interventions for management of T2DM complications, as more research focuses on the role of various pharmaceutical interventions for T2D management. Overall, it is clear that lifestyle interventions play an important role in management throughout the DBCD paradigm, though this is a growing area of research, and further studies are needed to better quantify the magnitude of impact these interventions provide in preventive medicine.

DISCLOSURES

JM received honoraria from Abbott Nutrition and serves on advisory boards for Aveta.Life, L-Nutra, and Twin Health.

33 Implementation: Lifestyle Medicine Tactics to Optimize Dysglycemia Care

Ramfis Nieto-Martínez, MD, MSc, Diana De Oliveira-Gomes, MD, and Jeffrey I. Mechanick, MD

KEY POINTS

- DBCD is a care model centered on early and sustainable preventive actions to retard or even eliminate dysglycemia progression and consequences, mitigating disease burden, cost, and related suffering.
- Tactics implemented to reduce DBCD burden should be patient-centered and consider ethnocultural factors, SDOH, and biopsychosocial factors, with the additional requirement of being sustainable over time.
- Lifestyle interventions to reduce DBCD burden have been widely investigated, showing improvement of care. The use of a multidisciplinary approach, specialized institutions for lifestyle interventions, and wearable technologies have been shown to improve T2D prevention and care.
- Lifestyle interventions can be done at community or national levels, targeting hundreds of thousands of individuals at risk.

ABBREVIATIONS

- A1C—Hemoglobin A1c

- SDOH—Social determinants of health
- T2D—Type 2 diabetes
- tCMBCD—Transcultural cardiometabolic-based chronic disease model
- tDNA—Transcultural Diabetes Nutrition Algorithm

33.1 WHY ARE LIFESTYLE MEDICINE TACTICS NECESSARY TO MANAGE DYSGLYCEMIA?

There are several key mechanistic metabolic drivers for cardiovascular disease (CVD) that constitute cardiometabolic risk: abnormal adiposity, dysglycemia, hypertension, dyslipidemia, and other residual risks (inflammation, thrombosis, etc.). Unfortunately, the prevalence of overweight/obesity and type 2 diabetes (T2D) has increased in the Americas from 1980 to 2014.[1] Since 1990, the number of disability-adjusted life years (DALYs) for diabetes increased by 1.68% per year in the United States, reaching 4.01% of total DALYs in 2019.[2] In addition, T2D is associated with increased severity of coronavirus disease 2019 (COVID-19)[3] and is a component of COVID-related cardiometabolic syndrome.[4]

"Dysglycemia" is a term that encompasses the progressive impairment of glucose regulation, spanning from early insulin resistance, to beta-cell dysfunction with mild hyperglycemia (prediabetes), to more severe hyperglycemia (T2D), to macro- and microvascular complications. This disease progression model has been termed "dysglycemia based chronic disease" (DBCD) and is intended to simplify the biological continuum of this cardiometabolic driver into a comprehensible and actionable format for preventive interventions.[5] Many patients with DBCD harbor other cardiometabolic risk factors, so management must be comprehensive in nature and not just glycemia centric. Moreover, at the earliest pathogenic step, DBCD arises from a complex interaction of biological and social determinants, or primary drivers, consisting of genetic, environmental, and behavioral factors.[6]

Lifestyle medicine is the non-pharmacological and non-procedural management of chronic disease.[7] It is estimated that more than 80% of chronic conditions could be avoided by the implementation of lifestyle recommendations.[8] Type 2 diabetes is intimately associated with lifestyles and specifically, food behaviors, with abnormal adiposity and dietary risks as the two most important risk factors.[9] Lifestyle impacts not only the development of cardiometabolic risk factors but also their prognoses.[8,10] For example, in a systematic review including 128 studies, behavior-based interventions with or without weight loss, medications were more effective at reducing excess weight

DOI: 10.1201/9781003227793-38

and the risk of developing T2D than control conditions, and besides, weight-loss medications were associated with higher rates of harm.[11]

The weight of evidence and body of knowledge that guide lifestyle strategies to prevent DBCD development and progression are considerable. However, ideas and intent, workflows and business plans cannot directly heal. This requires action—actualization of plans. Strategy refers to long-term deliverables and what needs to happen. Tactics refer to shorter-term actions and how they are implemented. The difficulties in translating knowledge to action are referred to as practice gaps. There is an urgent need to close practice gaps in lifestyle medicine, especially in the management of DBCD. Specifically, this requires the implementation of concrete, easily understood tactical steps that focus on lifestyle modifications, including healthy nutrition, physical activity, stress management, behavior modification, sleep hygiene, and tobacco/alcohol cessation, adapted to various social determinants of health, ethnocultural factors, patient-centered approaches, and economic barriers to confer a reasonable degree of sustainability.[12] In this chapter, a set of distinct tactics are presented.

33.2 TACTIC 1: TO CONSTRUCT NEW DYSGLYCEMIA CHRONIC DISEASE MODELS

Lifestyle medicine recommendations need to be formulated and interpreted in a chronic care model that is comprehensive, robust, and predictive of relevant events. Current models of cardiometabolic risk that are body mass index (BMI) centric,[13] gluco-centric,[6,14] or metabolic syndrome (MetS) centric[15,16] have demonstrated pitfalls when applied to complex, real-world clinical scenarios (e.g., obesity paradoxes,[17] CVD mortality with tight glycemic control,[18,19] and unclear pragmatic use of a static cluster of MetS traits.[16]

The cardiometabolic-based chronic disease (CMBCD) model was designed to address these pitfalls and also optimize early and sustainable cardiometabolic preventive care that mitigates CVD risk, primarily focusing on structured lifestyle changes.[20,21] The tCMBCD comprises three dimensions: stages, drivers, and social determinants of health (SDOH). In the first dimension, the four stages are mapped to specific prevention modalities: stage 1 (Risk ↦ Primordial prevention of risk development and progression), stage 2 (Predisease ↦ Primary prevention of disease), stage 3 (Disease ↦ Secondary prevention of complications), and stage 4 (Complications ↦ Tertiary prevention of suffering and mortality); each stage is also subject to quaternary prevention (the avoidance of overmedicalization and unethical behavior).[6,21,22] In the second dimension, individual metabolic drivers are considered as progressing and interacting along these four stages. These metabolic drivers are regarded as adiposity-based chronic disease (ABCD), dysglycemia-based chronic disease (DBCD), hypertension-based chronic disease (HBCD), and lipid-based chronic disease (LBCD), with residual factors recognized in the overall CMBCD model. In the third dimension, each stage × driver cell is populated with SDOH that confer precision to preventive actions. When cardiometabolic risk is interpreted in terms of transcultural factors, as part of SDOH, the result is a transcultural CMBCD model (tCMBCD).[6, 22] The tCMBCD components are being validated in populations of diverse cultures and ethnicities in the United States, Iran, Brazil, and Romania; ABCD and DBCD validations and specific transcultural adaptations in Czech Republic; and ABCD validations in Venezuela.[23–26]

The DBCD model is understood in the context of the larger tCMBCD model and constitutes a new way to approach diabetes prevention and management. This model focused on the pathophysiology, natural history, and clinical impact of dysglycemia, and was originally designed to address pragmatic questions of whether insulin resistance and prediabetes should be treated.[20] The DBCD model answers this question by exposing these early stages as opportunities for preventive care, primarily with lifestyle medicine. Further studies have characterized DBCD in more complex ways: for example, by depicting prediabetes progressing directly to T2D or leapfrogging to vascular complications, or even regressing to normoglycemia; or interacting with abnormal adiposity, hypertension, and dyslipidemia at the level of inflammation. Similarly to the CMBCD template, DBCD stages map to specific preventive care modalities (Figure 33.1). In stage 1, "Risk," the insulin resistance state with normoglycemic levels but also increased risk for macrovascular complications, maps to primordial preventive strategies (i.e., community/school education) and also primary/secondary prevention strategies in the setting of accelerated atherosclerosis.[27] In stage 2, "Prediabetes," mild hyperglycemia, which increases the risk for microvascular complications (around 10% of subjects with prediabetes already present hyperglycemia-related complications,[28] and about 70% progress to T2D during their life),[27] maps to primary preventive strategies (i.e., those modeled by the National Diabetes Prevention Program are recommended).[29,30] In stage 3, T2D, in which sustained hyperglycemia severely increases the development of complications, maps to secondary preventive strategies (i.e., modeled by the Look AHEAD Program) that should be applied to prevent the progression to complications.[31] In stage 4, Complications, where microvascular and/or macrovascular events are present, tertiary preventive care with greater participation of pharmacotherapy is available to improve quality of life, decrease suffering, and avoid future events and mortality.

33.3 TACTIC 2: TO CREATE LIFESTYLE MEDICINE CENTERS AND CLINICAL SERVICE LINES FOR DYSGLYCEMIA

Guideline-directed, evidence-based lifestyle medicine recommendations are best implemented when the

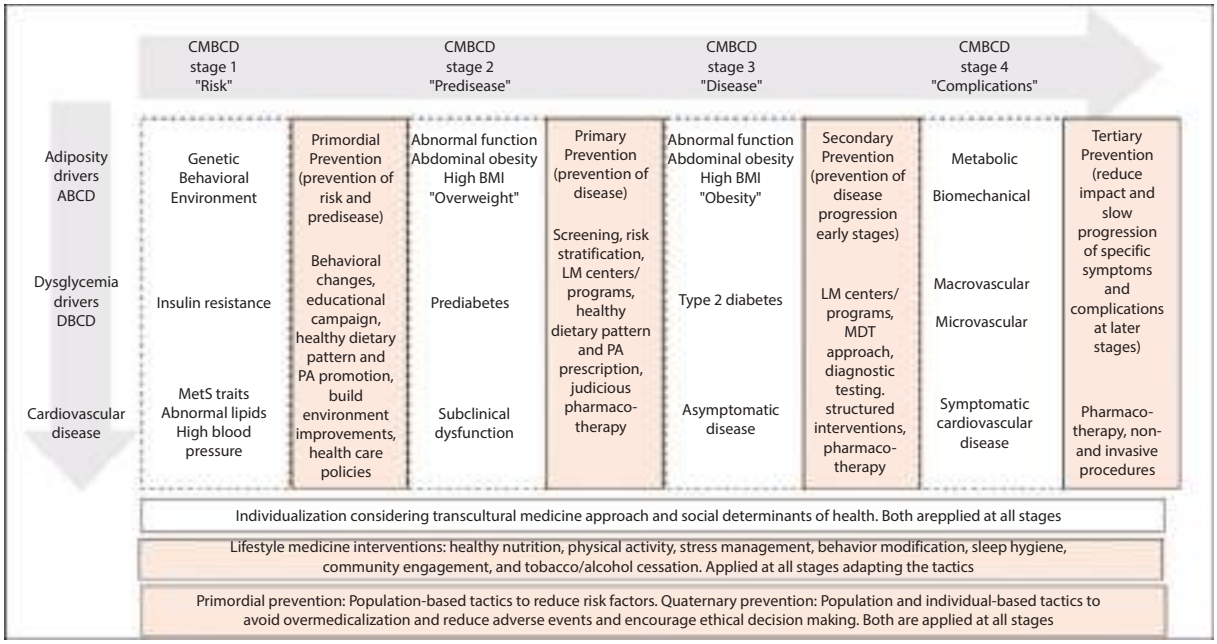

FIGURE 33.1 The transcultural cardiometabolic-based chronic disease model and prevention strategies. (Adapted from Mechanick, J.I., et al., ***Journal of the American College of Cardiology***, 75(5), 525–38, 2020)

infrastructure for service delivery is optimized, such as in Lifestyle Medicine Centers (LMC) and Lifestyle Medicine Clinical Service Lines (LMCSL).[32] A diligent literature search (MEDLINE database) was conducted to detect transcultural LMC/LMSLs that implement successful and evidence-based lifestyle medicine protocols addressing diabetes prevention and management in the United States, with results published in peer-reviewed journals in English up to July 2021. In addition, diabetes centers reported in Google Maps with the terms "diabetes," "lifestyle," AND "center" were reviewed and vetted in terms of peer-reviewed journal publications; these references were then reviewed with respect to evidence-based lifestyle medicine interventions or protocols for the prevention and treatment of diabetes. Results in the form of specific LMC/LMCSLs were curated according to different operational and performance aspects. Of the 3,172 results in MEDLINE and 56 centers located in the United States via Google Maps, 3 reports published as book chapters describing components of the implementation were found[33–35] (other centers were added as informative examples) (Table 33.1).

All of the LMC/LMCSLs included interventions to treat T2D that involved healthy eating and physical activity. Other lifestyle medicine services, such as sleep hygiene, stress reduction, behavioral science, tobacco cessation, alcohol moderation, and community engagement, were provided by more specialized centers. The staff of most institutions included endocrinologists, diabetes educators, and nurse practitioners, although other centers employed different medical specialists (i.e., cardiologists), exercise physiologists, nutritionists, dietitians, health coaches, and social workers. Aspects related to the transculturalization of care were reported by a few centers. For instance, Lifedoc Health[36] routinely considered cultural competency during the screening and intervention processes for Latino/Hispanic and African American populations; roughly 90% of their staff were bilingual and provided patients with nutrition meal plans and food exchange lists specific to culture and country; the Marie-Josée and Henry R. Kravis Center for Clinical Cardiovascular Health[33] included transculturalization of care as a lecture topic of their medical education program for healthcare professionals (HCPs) and staff; the Joslin Diabetes Center[37] offers two multicultural clinics, a Latino Clinic and an Asian American Clinic; and the Northwestern Medicine Center[38] offers educational materials in Spanish. Many of the centers offer more than one program that adapts to the needs of the patients and focuses on specific goals, including the utilization of telemedicine strategies and the focus on diabetes education. Research activities are also an important part of some of these centers, especially the university-affiliated institutions. Participation in clinical trials is widely reported by the biggest centers that conduct several research activities, such as the Joslin Diabetes Center,[37] Northwest Medicine Center,[38] Mayo Clinic,[39] Diabetes Center at Tufts Medical Center,[40] Boston Medical Center,[41] and LifeDoc Health.[36]

33.4 TACTIC 3: TO TRANSLATE DYSGLYCEMIA EVIDENCE INTO WHITE PAPERS IN PROFESSIONAL MEDICAL SOCIETIES

Lifestyle medicine is explicitly included in many, but not all, clinical practice guidelines (CPG) developed by scientific societies and health institutions worldwide promoting a multidisciplinary/comprehensive approach to DBCD

TABLE 33.1
Lifestyle Recommendations in Clinical Practice Guidelines

CPG (Region–Country)	AACE/ACE (United States)[42,43]	ADA (United States)[44]	ESC/EASD (Europe)[45]	Diabetes Canada Clinical Practice Guidelines Expert Committee (Canada)[46]	IDF (World)[47,48]	ACC/AHA[105]
Prevention or delay of T2D	Patients with prediabetes should modify their lifestyle by having a reduced-calorie healthy meal plan, physical activity, and behavioral interventions.	Patients with prediabetes should have intensive lifestyle behavior change to achieve 7% loss of initial body weight and increase moderate-intensity physical activity to at least 150 min/week.	Lifestyle intervention is recommended to delay or prevent the progression of pre-DM states, such as IGT to T2D.	In individuals with prediabetes, a structured program of healthy behavioral interventions is recommended that includes moderate weight loss and regular physical activity.	Lifestyle modification with physical activity and/or healthy diet can delay or prevent the onset of T2D.	Patients with prediabetes should lose 5% to 10% of initial weight with intensive lifestyle interventions. This is recommended in adults with obesity to reduce caloric intake by ≥500 kcal/day from baseline, limiting women to 1,200 to 1,500 kcal/day and men to 1,500 to 1,800 kcal/day.
MNT	Individualized MNT by a trained nutritionist in all patients with diabetes/prediabetes. Patients with overweight should restrict their caloric intake with the initial goal of reducing body weight by at least 5% to 10%.	MNT should be used to promote and support healthful eating patterns, address individual nutrition needs, maintain the pleasure of eating, and provide practical tools.	Nutrient distribution should be based on an individualized assessment of current eating patterns, preferences, and metabolic goals. Among people at high CV risk (49% had diabetes), a Mediterranean diet supplemented with olive oil or nuts is recommended. There is no ideal percentage of calories from carbohydrate, protein, and fat for people with diabetes.	Patients should receive nutrition counseling by a registered dietitian. Nutrition education may be delivered in either a small group or a one-on one setting. The macronutrient distribution as a percentage of total energy can range from 45% to 60% carbohydrate, 15% to 20% protein, and 20% to 35% fat.	Multidisciplinary, patient-centered, and well-coordinated approaches.	A plant-based and Mediterranean diet is recommended, along with increased fruit, nut, vegetable, legume, and lean vegetable or animal protein (preferably fish) intake.
DSME	People with DM should receive DSME at the time of DM diagnosis and subsequently as appropriate. This includes MNT, physical activity, avoidance of tobacco products, and adequate sleep.	All people with diabetes should participate in DSME and receive support needed to facilitate the knowledge, decision making, and skill mastery necessary for diabetes self-care.	Group-based structured education programs are recommended in patients with diabetes, to improve knowledge, glycemic control, disease management, and patient empowerment.	DSME that incorporates cognitive-behavioral educational interventions, such as problem solving, goal setting, self-monitoring of health parameters, dietary modifications, and physical activity, should be implemented for all able individuals with diabetes.	Provide ongoing self-management support, taking account of culture, ethnicity, psychosocial, and disability issues.	N/R

(*Continued*)

TABLE 33.1 (CONTINUED)
Lifestyle Recommendations in Clinical Practice Guidelines

CPG (Region–Country)	AACE/ACE (United States)[42,43]	ADA (United States)[44]	ESC/EASD (Europe)[45]	Diabetes Canada Clinical Practice Guidelines Expert Committee (Canada)[46]	IDF (World)[47,48]	ACC/AHA[105]
Physical activity	At least ≥150 minutes per week of moderate-intensity activity, such as brisk walking (e.g., 15- to 20-minute miles) and strength training.	Children with diabetes or prediabetes should perform at least 60 min of physical activity/day. Adults with diabetes should perform at least 150 min/week of moderate-intensity aerobic physical activity, as well as reduce sedentary time.	Moderate-to-vigorous physical activity, combination of aerobic and resistance exercise, for ≥150 min/week is recommended.	150 minutes of moderate- to vigorous-intensity aerobic exercise each week, spread over at least 3 days of the week, with no more than 2 consecutive days without exercise, to improve glycemic control. Interval training, resistance exercise at least twice a week, should also be practiced.	At least between 3 and five days a week, for a minimum of 30–45 minutes/day.	At least 150 minutes per week of moderate-intensity aerobic physical activity or 75 minutes per week of vigorous-intensity aerobic physical activity (or an equivalent combination of moderate and vigorous activity).
Psychosocial Assessment and Care	Behavioral support from family and friends. Obesity and diabetes are associated with high rates of anxiety and depression, psychosocial interventions should be performed routinely.	A collaborative patient-centered approach is recommended with the goal of optimizing health outcomes and health-related quality of life. Psychological screening and follow up assessment for symptoms of diabetes distress, depression, anxiety, and cognitive capacities should be performed. Older adults (>65 years) must be considered for evaluation of cognitive impairment and depression.		Motivational interventions, coping skills, self-efficacy enhancement, stress management, and family interventions are all helpful. An expert in mental health and/or psychosocial issues should provide intervention when required.	Teams can include community health workers and peer supporters trained to meet the physical and psychosocial needs of the person with diabetes.	Environmental and psychosocial factors, including depression, stress, self-efficacy, and social support, should be evaluated to improve achievement of glycemic control and adherence to treatment.

CV: cardiovascular, DM: diabetes mellitus, DSME: diabetes self-management education, IGT: impaired glucose tolerance, MNT: medical nutrition therapy, T2D: type 2 diabetes, N/R: not reported.

care. The various approaches to lifestyle medicine in dysglycemia care by CPG development teams of the American Association of Clinical Endocrinologists (AACE) and American College of Endocrinology (ACE),[42,43] the American Diabetes Association (ADA),[44] the European Society of Cardiology (ESC) and the European Association for the Study of Diabetes (EASD),[45] Diabetes Canada Clinical Practice Guidelines Expert Committee,[46] and International Diabetes Federation[47,48] are compared (Table 33.2).

In 2020, a consensus statement published by the AACE/ACE[42] on the comprehensive T2D management algorithm, emphasized the importance of lifestyle optimization and loss of excess weight in patients with ABCD and DBCD. This is reflected by the top hierarchical ranking of lifestyle prescriptions that include reduced-calorie healthy meal plans, physical activity, and behavioral interventions.[42] Of note, most CPGs on dysglycemia recommend lifestyle modifications (focused on weight loss) starting with the prediabetes (DBCD stage 2) to delay the progression to T2D and complications, with the bulk of the document devoted to diabetes (DBCD stage 3 and other types of diabetes). Most CPGs encourage individualized medical nutrition therapy (MNT) and multidisciplinary team approaches, physical activity, recognition and interventions directed to behavioral and psychological factors, and the prevention and management of complications (DBCD stage 4), such as CVD, nephropathy, retinopathy, and neuropathy.

The American College of Lifestyle Medicine (ACLM)[49] and the Institute of Lifestyle Medicine were created in 2004 and 2007, respectively, to promote medical education, lifestyle training programs, public advocacy, and the formation of Lifestyle Medicine Centers to protocolize evidence-based lifestyle interventions in research and clinical settings. In 2015, the Lifestyle Medicine Global Alliance (LMGA)[50] started as an initiative of the ACLM to increase the communication among lifestyle medicine professional organizations in the world, representing different regions (Africa, Asia, Australasia, Europe, Latin America, and South Pacific) and countries (Albania, Brazil, Canada, China, India, Iran, Israel, Italy, Japan, Korea, Lithuania, Philippines, Poland, Portugal, Romania, the United Kingdom, and the United States).[51]

33.5 TACTIC 4: TO CULTURALLY ADAPT WHITE PAPERS FOR PRECISION DYSGLYCEMIA CARE

Beyond scientific meetings and continuing medical education, it is recommended that professional medical societies, institutions, and other organizations deepen their contribution to dysglycemia care by advancing the transcultural adaptations of lifestyle medicine recommendations for DBCD in their specific countries. In the United States between 2017 and 2020, diabetes prevalence rates varied according to ethnicity (non-Hispanic white [13.6%], Hispanic [15.5%], non-Hispanic Asian [16.7%], and non-Hispanic African American [17.4%]),[52] which can be explained in part by biological, environmental, and cultural factors. The high level of diversity in the U.S. population compromises the precision of T2D care, necessitating the use of transcultural medicine in the routine patient–provider encounter.[53,54].

Each DBCD stage is patient-centered and considers ethnocultural factors (e.g., language, beliefs, values, food security, food preferences, eating patterns and culinary practices, religion, health policies, politics, environmental exposures, alcohol and tobacco use, physical activity, behaviors, specific anthropometric and laboratory cutoffs), SDOH (e.g., socio-economic status, education, social and community context, structural racism and discrimination, housing instability, education, occupation, healthcare access, health literacy, health inequities, local healthcare practices, neighborhood, socio-economic environment, and the built environment), and biopsychosocial factors (anxiety/depression, stressful situations, allostatic load), which in aggregate modify the DBCD phenotype and response to lifestyle, pharmacological, and procedural interventions. This again argues for a formal, protocolized transcultural approach.

"Transcultural" is a term applied to gaining knowledge about how diseases are expressed and managed in different cultures, and how evidence-based clinical recommendations are adapted from a source to a target population by experts from both sources to achieve better outcomes.[5,54,55] Broadly speaking, the comprehensive transculturalization process comprises the following sequential actions: (a) capturing and curating pragmatic, relevant evidence–based recommendations from source CPG and culturally adapting to a specific target population, (b) creating derivative cutoffs and screening tools, (c) packaging recommendations and tools into easily messaged evidence-based lifestyle interventions, and (d) building Lifestyle Medicine Centers/Service Lines/Programs in source and target populations for successful implementation of these interventions. This process results in a set of individualized evidence-based recommendations for each patient (Figure 33.2).

Once material is selected for transculturalization, the required actions and resources must be identified and organized. This process involves the use of available evidence, taxonomies, and frameworks that would allow the translation of theory into practice under different settings (clinical, organizational, public health, or policy contexts).[5] Various taxonomies have been developed to adapt and replicate health interventions in a systematic way. For implementation, Proctor et al.[56] proposed a model of outcomes that involve eight different elements: acceptability, adoption, appropriateness, feasibility, fidelity, implementation cost, penetration, and sustainability, which help to specify processes and measures for success on multiple levels. After an intervention is implemented, it is necessary to evaluate the effectiveness of the strategy. The Reach, Effectiveness,

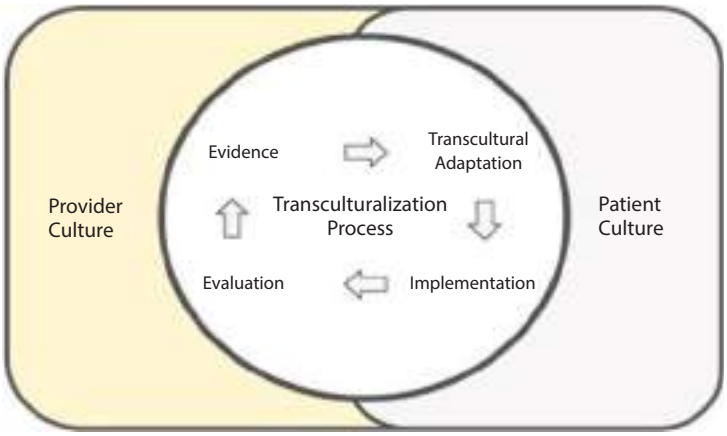

FIGURE 33.2 Transculturalization process closes the gap between the provider and patient cultures.[151]

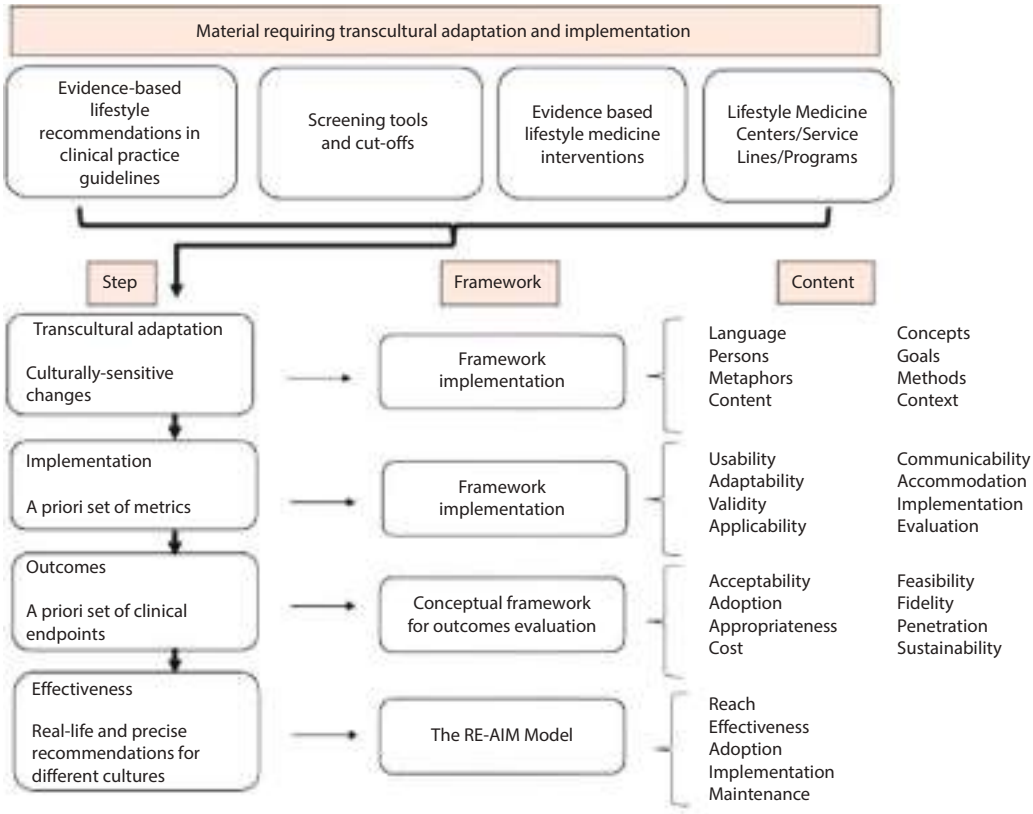

FIGURE 33.3 Stepwise approach and frameworks for transcultural adaptation and implementation of lifestyle recommendations. Ecological validity model,[67] implementation framework,[152] conceptual framework for outcomes,[82,152] and the Reach, Effectiveness, Adoption, Implementation, and Maintenance (RE-AIM) framework. [153] (Adapted from Nieto-Martínez, R., et al., ***Endocrinology and Metabolism Clinics of North America***, 45(4), 967–1009, 2016.)

Adoption, Implementation, and Maintenance (RE-AIM) framework allows the reporting of key issues related to the implementation and external validity of health interventions.[57] The final goal of implementation is to improve patient- and population-based clinical outcomes. Challenges in the implementation process occur at individual and organizational levels (e.g., patient education, health policies) and include practical issues (e.g., cost and acceptability). A previously proposed algorithm[5] is updated in Figure 33.3.

In 2010, an international core committee of diabetes specialists and endocrinologists developed an evidence-based algorithmic template of diabetes care—the transcultural Diabetes Nutrition Algorithm (tDNA).[58] The tDNA was developed to culturally adapt the recommendations from the AACE/ACE/ADA diabetes CPGs with a focus on MNT for different settings on a global scale. This strategy provided HCPs with a validated portable tool, in electronic or printed format, that was culturally adapted and

inclusive of the best scientific evidence available in each country or region. Specifically, the tDNA was adapted to seven countries/regions (South-East Asia, Asian-India, Malaysia, Canada, Venezuela, Mexico, and Brazil)[59–65] and validated in Malaysia.[66] The steps in the tDNA transcultural adaptation process include: (a) identification of the target population, (b) identification of the clinical question, (c) identification of the appropriate source evidence base, (d) identification of experts in the source and target populations to adapt the evidence using validated frameworks (e.g., the Ecological Validity Model,[67] and (e) synthesis of the transcultural recommendations and algorithm.[68]

33.5.1 Transcultural Component 1: Lifestyle Medicine in Clinical Practice Guidelines

Transcultural factors in CPG adaptations for diabetes prevention and management[5] and HCP–patient encounters should recognize and address cultural barriers to implementing lifestyle strategies.[12] Lifestyle recommendations suggested by professional medical societies are typically implemented under different socio-economics, political settings, and cultures. The validation of CPG in many international-target settings would result in an improvement in adherence and outcomes in dysglycemia care. Every region has barriers that could preclude the implementation of certain lifestyle medicine tactics developed and recommended under ideal conditions. For example, the implementation of the DPP in other settings has shown lower effectiveness than in the original U.S. DPP trial.[5] Common barriers found in the implementation of guideline recommendations include fragmentation of the healthcare system, the need to adapt to chronic disease management, and education. These barriers can be addressed through the comprehensive transculturalization process.

One example of a transcultural adaptation of lifestyle recommendations in CPGs on dysglycemia was the initiative developed by the Brazil Society of Diabetes, which adapted American and European diabetes guidelines based on the resources and therapies available through Brazil's public health system, called the Sistema Único de Saúde.[69] Another transcultural consideration effort is represented by the Native Diabetes Wellness Program (NDWP), fostered by the Division of Diabetes Translation of the Centers for Disease Control and Prevention (CDC), which, using shared messages and other tactics, supports sustainable ecological approaches and health practices to promote traditional foods, physical activity, and social support in American Indian / Alaska Native populations.[70]

33.5.2 Transcultural Component 2: Adapting Screening Tools, Cutoffs, and Interventions

The validation of risk scores in different settings is an important step in the process of screening and implementation of prevention programs. Some screening tools are widely used across the globe despite being developed for certain populations. One of the most popular screening tools to detect T2D risk is the Finland Diabetes Risk Score (FINDRISC), which has been externally validated in many countries (e.g., the United States,[71] Venezuela,[72] Colombia,[73] Peru,[74] Uruguay[75]). Another example of culturally adapted diagnostic tools is abdominal cutoffs to detect aggregation of cardiometabolic risk factors,[28,56] as well as BMI cutoffs for identifying excess adiposity and cardiovascular risk.[76–78] The determination of ≥94 cm in men and ≥90 cm in women as cutoff points to identify people with abdominal obesity, after comparing measurements of visceral adipose tissue obtained by computerized axial tomography with abdominal circumference in participants from five Latin American countries, is another transcultural approach experience.[79] The modification of the Mediterranean pyramid using local foods and culinary techniques proposed in the Venezuelan tDNA version is also an example of transcultural adaptation.[77] New data from lifestyle clinical trials and practical experiences would allow the use of more specific interventions for each population,[55,80,81] but it is important to highlight that every adaptation should be followed by validation studies of implementability, endpoints, and effectiveness.[5,82]

33.5.3 Transcultural Component 3: Routine Use in Lifestyle Medicine Centers

Implementation strategies are used to translate evidence-based recommendations into actions within the framework of an *a priori* healthcare model (e.g., DBCD). This translation incorporates physical components, human resources, policies, and protocols that constitute a LMC/LMCSL. In a LMC/LMCSL, the implementation of new interventions should be appropriate for the target settings and population. Ideally, all DBCD interventions should be culturally sensitive, involving exercise plans and diabetes-specific nutrition.[58] More importantly, in a transculturalized LMC/LMCSL, it is necessary to adapt the nutritional strategies and physical exercise plans to the specific population (e.g., delivering menus involving foods from different countries and exercise plans adapted to preferences, customs, and routines). In a patient-centered care model, transculturation plays an even greater role; this is why the implementation and validation of ethno-culturally adapted interventions is becoming more important[54] (Table 33.2).

Diabetes oriented LMC/LMCSL guide prevention, screening, diagnosis, and treatment strategies. The services should reflect the cultural diversity of the targeted population, as well as the characteristics of the area of influence (e.g., migrating population, availability of resources, physical spaces, among others), avoiding health disparities. The main human diversity challenges facing a LMC/LMCSL are summarized in the following.[12]

(a) *Cultural competence of the staff*
- Familiarization with the target community and the appropriate evidence-based culturally adapted materials needed
- Awareness of SDOH and cultural differences
- Development of communication skills that enhance interaction with patients (e.g., motivational interviewing) by showing cultural respect and a safe environment (e.g., bilingual staff and printed/web-based materials)

(b) *Infrastructure and services*
- Separation of spaces by gender in Arab cultures
- Avoiding religious symbolisms

(c) *Information and software resources*
- Medical history to include SDOH
- Written tools (questionnaires, screening tools, scores) adapted by language with cultural customization
- Use of specific cutoff points in anthropometric and laboratory assessments by age, gender, and ethnicity (see example in Table 33.3)

(d) *Administrative and organizational elements*
- Universal healthcare and different payment models
- Decreasing inequities in access to lifestyle medicine care[83]

33.6 TACTIC 5: TO BUILD MULTIDISCIPLINARY TEAMS FOR DYSGLYCEMIA CARE

Multidisciplinary care is associated with improved outcome in dysglycemia care and involves the participation of two or more HCPs (e.g., nurses, doctors, nutritionists, dietitians, and exercise physiologists) working together with the same patient. A meta-analysis of 16 clinical trials in 2007–2017, performed in Asia, Australia, Europe, and the United States, comparing the outcomes in patients with uncontrolled T2D undergoing MDT care (with more than two different HCPs) versus usual care (provided solely by physicians), reported that the patients in the MDT group had a higher reduction of hemoglobin A1c (A1C) (median difference = −0.55%, 95% confidence interval [CI] = −0.65% to −0.45%, $p < 0.001$) and systolic blood pressure (median difference = −4.89 mmHg, 95% CI = −6.64 to −3.13 mmHg, $p < 0.001$).[84] Moreover, MDT costs and utilization were similar in the MDT group compared with usual care,[84] possibly due to redistribution of ancillary tasks (e.g., monitoring, counseling, assessing, and optimizing medications of patients), which could help to reduce patient load for physicians.[84]

A review assessing patients' and HCPs' perceptions toward MDT care in T2D found that synergistic teamwork was more efficient and expeditious.[85] Furthermore, HCPs reported that trust in the other team members was essential

to provide better care.[85] Other challenges for MDT include improving communication and addressing differences in opinion among team members. Patients expressed more satisfaction and reduced waiting times with the MDT approach, leading to improved relationships and better use of other healthcare services, such as dietitians and podiatrists.[85].

A one-year retrospective review in 2018 of 598 adults (African American 59%, Hispanic 35%, and Caucasian 6%) with a mean age of 43.8 years ± 14.0 who attended in Lifedoc Health—a multidisciplinary center for CMBCD—was performed.[83] Patients who were activated for change, with ≥ one cardiometabolic risk factor (overweight/obesity, prediabetes/diabetes, or hypertension), and treated under a MDT protocol were compared with patients who qualified for MDT but instead were treated solely by a PCP.[83] After one year of intervention, patients treated by the MDT had a greater reduction (β, 95% CI) in weight (−4.29 kg, −7.62, −0.97), BMI (−1.43 kg/m^2, −2.68, −0.18), systolic blood pressure (−2.18 mmHg, −4.09, −0.26), and diastolic blood pressure (−1.97 mmHg, −3.34, −0.60).[83] They also had 77% higher odds of reducing their initial weight by ≥5%, 83% higher odds of reducing their body mass index by ≥1 point, and 59% higher odds of reducing their diastolic blood pressure by ≥2 mmHg.[83] The number of encounters was an important factor in mediating these positive results; among those engaged with the MDT, 30.9% of their visits were for lifestyle intervention.[83]

A meta-analysis showed that T2D care provided by a MDT consisting of at least a registered nurse, registered dietician, and physician (primary care and/or specialist) (model 1), or a MDT consisting of a pharmacist and primary care physician (model 2), produced a clinically significant reduction in A1C compared with usual care (−1.00%, 95% CI −1.27, −0.73 for model 1 and −1.05%, 95% CI −1.57, −0.52 for model 2).[86] Moreover, model 2 showed a significant decrease in systolic blood pressure (−7.13 mmHg, 95% CI −11.78, −2.48).[86] In both models, the outcomes were similar independently of the setting of healthcare delivery (primary care vs. hospital outpatient clinic vs. community clinic).[86]

Reported strategies to improve HCP practices in low- and middle-income countries include the use of job aids as well as information and communication technology, the combination of training with other strategies, such as supervision or group problem solving, and financial incentives for HCPs.[87] Although those strategies alone seem to have a low to moderate effect, the combination of training with group discussions seem to have better outcomes.[87] Additionally, some studies have shown that this effect is more significant when they are combined with community support.[87]

33.7 TACTIC 6: TO ENGAGE COMMUNITY RESOURCES IN DYSGLYCEMIA CARE

Some studies have reported that the most effective educational strategies to prevent diabetes were implemented at the community level, especially when they were permanent or maintained for long periods of time.[88] This highlights the relevance of sustainability. An example of community interventions at a national level is Project IMPACT, a diabetes self-management program conducted by the American Pharmacists Association (APhA) Foundation to help patients with T2D and limited access to healthcare.[89] This project involved the participation of different HCPs in 25 communities across the United States. Some of the tactics used by Project IMPACT involved determining the patient's individualized needs by identifying knowledge deficits (low health literacy).[89] Some of the strategies included one-on-one patient visits, motivational interviewing, point-of-care testing to gain an understanding of the patient's health condition, creating a personalized plan of care, and teaching patients about insulin injection techniques and the importance of medication adherence. Patients receiving care from the MDT had a reduction of 1.2% in A1C and a decrease in other cardiovascular risk factors, such as systolic and diastolic blood pressure (8.3 mmHg and 3.5 mmHg, respectively), and low-density lipoprotein (16.6 mg/dL).[89]

A Canadian study analyzing the association between built and natural environment features (walkability and park availability) and physical activity, obesity, and diabetes prevalence found that walkable neighborhoods were associated with lower rates of diabetes (highest vs. lowest quintile odds ratio [OR] = 0.62, 95% CI: 0.45, 0.85, and OR = 0.63, 95% CI: 0.47, 0.84, respectively).[90] The results of this study support the need to increase walkable and green areas and highlights how environmental factors impact the prevalence of diabetes.[90]

In another review, community health worker (CHW) interventions for the prevention and management of chronic diseases, including patient education, referral of high-risk individuals to physicians, and provision of social support through home visits, were associated with positive outcomes for patients with diabetes in seven of ten studies included.[91] Some of these improvements were increased knowledge of T2D symptoms and prevention measures, medication adherence, and improved outcomes (e.g., fasting blood sugar, A1C, and BMI).[91] Tactics based on CHWs in preventing and treating T2D are best understood when considering the gaps in healthcare delivery. In low-resource settings with fragmented healthcare systems, CHWs can identify individuals at high risk of diabetes through non-laboratory screening tools or point-of-care capillary glucose tests, and then facilitate diabetes self-management.[91] The evidence on the combination of responsibilities, training of CHWs, and length of intervention varies significantly, but such programs have improved treatment adherence.[91] Also, CHWs can help patients to understand integrative medicine in pluralistic health environments and navigate the health system due to CHWs' intimate knowledge of the local culture and health practices.[91] Nevertheless, CHW interventions need to be transculturalized to a population's genetic, social, racial, and environmental factors to optimize effectiveness.[92]

33.8 TACTIC 7: TO PROMOTE SCALABLE PUBLIC POLICIES ON DYSGLYCEMIA RISK REDUCTION

Public policies to decrease cardiovascular risk factors have been successfully implemented in many parts of the world. An example of a national initiative to decrease the burden of T2D in the United States is the National Diabetes Prevention Program (NDPP), an evidence-based lifestyle intervention applied to prevent diabetes in hundreds of thousands of individuals at risk.[29] This program was implemented under the leadership of the CDC, based on the result of the Diabetes Prevention Program (DPP), a 27-center clinical trial that demonstrated a 58% reduction in the incidence of T2D over three years and a sustainable benefit in decreasing cardiovascular risk factors and the incidence of metabolic syndrome.[29] Over one year, the NDPP promoted weight loss using different strategies, including in-person or virtual modalities.[29] Similar strategies have been implemented in China, Finland, India, and Venezuela.[93,94]

Other examples of policy strategies to improve population health include changing the quality of the food supply (e.g., secure healthier foods in educational institutions),[95] improving transportation systems,[96] and developing awareness campaigns by public health agencies (e.g., Do I Have Prediabetes Campaign, Your Health with Joan Lunden).[69] Media campaigns, including televisions and radio broadcasts (e.g., Five Steps for Your Health),[69] are a common approach to significantly promote healthy behaviors.

It is important to increase the awareness and diagnosis of T2D and prediabetes. More than 80 million Americans are estimated to have prediabetes.[29] Increasing awareness of prediabetes has been shown to promote behavioral changes to decrease the risk of progression to T2D.[29]

Some strategies that can increase patients' and HCPs' assessment of T2D include the expansion of point-of-care devices for diabetes screening in dental offices, pharmacies, and community-based settings, and encouraging diabetes risk assessment practices among HCPs with tools such as the ADA Diabetes Risk Test and the CDC Prediabetes Test.[97] It is also important to encourage NCPs to assess associated conditions in patients with diabetes.[98] An example of this is the VIDA Project, an 18-month intervention that provided structured diabetes education, training in foot care, and an in-service for HCPs on diabetes management.[69]

33.9 TACTIC 8: TO LEVERAGE TECHNOLOGY FOR DYSGLYCEMIA MANAGEMENT

The impact of technology in healthcare systems and patient care is growing every day. The U.S. Food and Drug Administration defines mobile health as the use of mobile and wireless devices to improve health delivery and outcomes, potentially reaching thousands of people. Many strategies have been developed allowing patients to access easy-to-use technologies. The use of technology in treating chronic conditions that require lifelong control, such as diabetes, can be an important step to improve outcomes. A meta-analysis studying the results of 6 interventions and 1,001 patients determined that wearable device-based interventions for 12 months or less could result in better glycemic control in patients with T2D than the usual care.[99] Clinical trials have demonstrated a significant decrease in levels of A1C in patients benefitting from mobile health interventions. Although wearable activity trackers are effective to improve the levels of physical activity in patients with cardiometabolic conditions,[100] when these strategies are combined with other approaches, such as in-person HCP consultations, the improvement in physical activity rates has been higher.[101]

Recently, several companies are offering what are called connected diabetes care products. These are digital diabetes management systems that involve the use of smartphones and other devices with connectivity, in conjunction with remote coaching with continuous support. Such strategies are currently growing and can improve healthcare delivery care in underserved areas, where empowering the patients on their own care could significantly impact how diabetes is managed. Nevertheless, more evidence of the effectiveness of these tools is needed.[102,103] The efficacy of mobile phone apps for lifestyle modification in diabetes management comparing five types of interventions—web-based, mobile phone applications (apps), a digital versatile disc (DVD), virtual reality, or telehealth—showed a significant reduction in the mean A1C level in patients with T2D.[104] The study analyzed subgroups for the short-term (3–6 months) and long term (9–12 months), finding the overall effect on A1C significant ($p < 0.01$) in both subgroups.[104] The effect remained statistically significant ($p < 0.01$) after adjusting for publication bias.[104]

33.10 CONCLUSION

DBCD, a representation of different stages of chronic disease resulting from dysglycemia, is a pathophysiologically based care model with an actionable approach, centered on early and sustainable prevention tactics that mitigate disease burden, cost, and related suffering (Table 33.4). T2D (DBCD stage 3) is a significant cause of morbidity and mortality worldwide; therefore, there is an urgent need to create comprehensive care models and tactics that incorporate preventive actions to retard or even eliminate DBCD progression and consequences. Those tactics should consider ethnocultural factors, SDOH, and biopsychosocial factors, with the additional requirement of being sustainable over time. Lifestyle interventions are explicitly included in T2D CPGs, and some tactics can be implemented in specialized institutions (e.g., LMC/LMCSL) with a MDT approach, which has shown a significant benefit compared with usual care. Moreover, other tactics can be implemented at a community or national level, such as the DPP, a preventive care program focusing on diabetes and applied to hundreds of thousands of individuals at risk. Finally, wearable technologies have been shown to improve T2D care, presenting now as a promising strategy to promote lifestyle interventions.

TABLE 33.4
Clinical Applications

Case: African American female evaluated in a Lifestyle Medicine Center for T2D and Cardiovascular Risk Management.

Scope: This is an example that includes new cardiometabolic models, multidisciplinary teams, and transcultural approaches for screening, diagnosis, and implementation of lifestyle interventions implemented in a Lifestyle Medicine Program.

Patient presentation

A 65-year-old African American woman with obesity, hypertension, and T2D is referred to a Lifestyle Medicine Center to improve her diabetes control and reduce her cardiovascular disease risks. Since her husband passed away two years ago, she lives alone, has developed major depression, and has increased tobacco consumption significantly. Her only daughter lives in New York. She has multimorbid chronic disease, defined as the presence of two or more chronic conditions.[130]

Evidence-based theory

Evaluation and transcultural approach

CDC reports show that African American (AA) women have the highest rates of obesity and T2D compared with other race groups in the United States.[131,132] In a cross-sectional study of 4,856,326 participants, it was shown that AA adults have higher prevalence of diabetes, hypertension, and physical inactivity than Caucasian adults, and that these disparities have consistently trended upward among the AA population.[133] Additionally, AAs may have higher levels of A1C than non-Hispanic whites, but with similar fasting and post–glucose load glucose levels.[44] Due to the disproportionate burden of diabetes in these populations, it is necessary to develop and implement greater strategies that allow better disease management. An increased adherence to lifestyle interventions and medication can be achieved in African Americans with T2D by implementation of culturally targeted self-management programs in the community.[54]

Transcultural factors with social determinants must be incorporated into the evaluation of this patient and should be part of the Lifestyle Medicine Center protocol. The availability of proper information and culturally specific anthropometric and laboratory cutoffs led to higher diagnostic accuracy for risk factors and chronic diseases amenable to lifestyle medicine interventions. A critical part of the transcultural approach for different ethnicities is the formal assessment of SDOH.[54] SDOH can be captured through the Protocol for Responding to and Assessing Patient's Assets, Risk, and Experiences (PRAPARE) tool,[134] referring them to community-based resources, and ultimately, closing the loop to confirm whether the patients' needs were met.

Lifestyle and behavioral questionnaires should be applied in this patient. Mild cognitive impairment was evaluated with the Montreal Cognitive Assessment, which has demonstrated its cross-cultural applicability.[135] The Geriatric Depression Scale has been widely used in ethno-culturally diverse elderly medical patient populations (i.e., Asians, AAs, Mexican Americans) and has demonstrated good internal consistency and stability over a 15-month interval in AAs.[136] The Mini Nutritional Assessment (MNA) has also demonstrated reliability in defining the nutritional state of elderly patients[137] and has been validated in different cultures.[138–140]

Clinical practice applications

The patient was received by a diligent, compassionate, and culturally competent staff with knowledge, attitudes, and skills, and the patient perceived respect from all the personnel. The CMBCD protocol included individualized case finding and risk stratification with a detailed history focusing on modifiable cardiovascular risk factors, anthropometric assessment (e.g., weight, height, waist circumference, and % body fat using bioimpedance), physical examination, and biochemical evaluation using validated markers (e.g., A1C, C-reactive protein, and lipids).

Questionnaires were created and presented to the patient in the reception area prior to each encounter to capture this information. This patient did not complete high school. Although her house has the benefit of all necessary utilities (water, electricity, gas, etc.), housing instability (e.g., difficulty with rent or mortgage payments, overcrowding, moving frequently, and/or staying with relatives) was detected, and her daughter is planning to relocate her to a nursing home facility. Food insecurity, defined as either a limited or uncertain availability of nutritionally adequate and innocuous foods or the incapacity to acquire them by socially acceptable means,[141] in the last year was also reported. Annual income categorized her into low income/poverty status. She maintains her medical insurance but has stopped taking some of her medications because of the lack of transportation to pick them up.

Several additional specific lifestyle and behavioral questionnaires were applied in this patient. Cognition was intact by Montreal Cognitive Assessment,[135] Geriatric Depression Scale (short version 15 items) was consistent with severe depression,[136] Sleep quality score[142] reported bad sleep quality (8 points), and Sleep apnea screening (No SAS score) was negative to detect.[143] Multiple factors for malnutrition were detected: poor dentition, depression, living alone, functional status, multiple chronic diseases, and food insecurity.

(*Continued*)

TABLE 33.4 (CONTINUED)
Clinical Applications

Physical examination and laboratory

Vitamin D insufficiency is established from the point at which serum intact parathyroid hormone levels significantly rise.[144] The 25-hydroxyvitamin D threshold for insufficiency is approximately 20 ng/mL for AAs versus approximately 30 ng/mL in Caucasians.[145] Thus, in this patient, a level of 25-hydroxyvitamin D of 26 ng/mL is considered normal. If the specific eGFR cutoff point for AAs had not been considered, the patient would have been categorized with chronic kidney disease 3b with possible unnecessary therapeutic interventions. Compared with Caucasians, AA females have 13.8% lower FEV1 and 14.4% lower FVC.[146] Therefore, the use of specific ethno-culturally adjusted predictive data is recommended for routine encounters and interpretation of a host of metrics in a lifestyle medicine center.

Physical examination showed high values of BMI (31.2 kg/m^2) and body fat (37%). Fasting blood glucose was 147 mg/dl, and A1C was 7.8%, evidencing suboptimal control of diabetes. The patient reported incomplete adherence to her prescribed medication (metformin 1,000 mg and sitagliptin 50 mg combined twice daily). Chest auscultation detected expiratory wheeze, and she uses accessory muscles when short of breath. Oral exam reveals tooth loss and periodontal disease. There is no peripheral edema.

Other significant laboratory results include Hgb 9.6 g/L (low); LDL cholesterol 147 mg/dL (goal <70 mg/dL); creatinine 1.28 mg/dL (high); estimated glomerular filtration rate 50 mL/min/1.73 m^2 (chronic kidney disease 3A for African Americans);[147] and 25-hydroxyvitamin D 26 ng/mL (low for Caucasian population, but normal for African Americans). Spirometry reported a forced expiratory volume 1st second (FEV1) of 1.04 L (37% of predictive value for African Americans), forced vital capacity (FVC) of 2.03 L (61% of predictive value for African Americans), and FEV1/FVC of 51% (low; normal >80%) with both obstructive and restrictive findings. Chronic conditions diagnosed during the evaluation included chronic obstructive pulmonary disease (COPD), anemia, chronic kidney disease stage 3A due to hypertension, depression, and tobacco use disorder. Based on muscular strength and muscle mass, a sarcopenia diagnosis was also established.

Discussion and interventions

Interventions for all aspects of the lifestyle medicine evaluation must be considered.

Evidence-based physical activity prescription should be provided.

A physical rehabilitation protocol to stop and overcome sarcopenia and frailty was designed with supervised resistance training, which is demonstrated to improve muscle strength and physical performance.[148] Recommendations for older patients are available.[149] The tDNA[77] includes physical activity recommendations to start at low intensity for this patient: aerobic (slow walking, stationary cycling) for a minimum of 10 minutes to increase the pulse rate less than 40% of the maximum heart rate. The progressive resistance training program should initially involve at least three large muscle groups (e.g., quadriceps, biceps, and triceps) with two sets of ten repetitions per muscle group, performed on three nonconsecutive days per week. Flexibility and balance exercises include stretching to the point of tightness and holding the position for a few seconds on all days that aerobic or muscle-strengthening activity is performed. Balance training exercise should occur two to three times per week. The lack of transportation and living alone are barriers to physical rehabilitation, so an outpatient physiotherapist is an alternative while the patient gains autonomy in their daily tasks. Patient's preferences should always be considered. Motivations (e.g., perceived health benefits, social support, and enjoyment) and barriers (e.g., time, physical limitations, peer pressure and family responsibilities, and weather and poor neighborhood conditions) to physical activity have been identified in older African American women.[150] Dancing in groups and other modalities such as as tai-chi or yoga were preferred choices and are easy to customize based on African American cultural preferences.[150] In these patients, chair-based exercises can be an option.

MNT prescription should be provided.

Medical nutritional therapy is an important component of lifestyle medicine. This patient's preference is African American cuisine, including barbecued meats, sweet cornbread, fried chicken, and desserts. Sides include black-eyed peas, candied yams, macaroni and cheese, and stewed greens. Thus, a nutritional recommendation was made based on detailed conversations between the patient and the nutritionist. An individualized healthy eating plan was fashioned considering physiologic changes (poor dentition and less sense of taste), customs, and preferences. Cultural attitudes toward dietary supplements should be explored prior to their prescription. Parenthetically, diabetes-specific formulas should be used in cases of DBCD.

Recommendation for other lifestyle medicine components should be provided.

Screening of sleep quality prompt to sleep hygiene recommendations and sleep apnea detected. Sleep hygiene recommendations are routinely provided and should include at least seven hours of sleep. The management of depression and smoking cessation was also addressed.

Conclusion and reflection

This is an example of how complex it is to manage a patient with multimorbid chronic disease, In this patient, tertiary prevention measures should be implemented to avoid the appearance and impact of the complications associated with DBCD, although the ideal would be to have intervened beforehand to avoid these complications; now, the burden for the patient and the health system is much greater. Is it possible to cover all the details in a routine medical visit? Is it feasible for the provider to know, or have the information available, about the clinical practice guidelines and their respective transcultural adaptations to make diagnostic and treatment decisions with greater precision?

AA: African American, CMBCD: cardiometabolic-based chronic disease, CDC: Centers for Disease Control and Prevention, DBCD: dysglycemia-based chronic disease, AC1: glycated hemoglobin, MNT: medical nutrition therapy, SDOH: social determinants of health, tDNA: Transcultural Diabetes Nutrition Algorithm, T2D: type 2 diabetes.

34 Adiposity-Based Chronic Disease

Michael A. Via, MD and Jeffrey I. Mechanick, MD

KEY POINTS

- Adipose tissue plays an important role in the regulation and implementation of energy homeostasis.
- Dysfunction of adipose tissue and accumulation as visceral and intracellular lipid storage is associated with insulin resistance syndromes, especially type 2 diabetes and sequelae such as cardiometabolic disease.
- Use of the term "obesity" fails to identify some patients with dysfunctional adipose tissue and may overestimate risk for adverse outcomes in other patients.
- Categorization of patients based on accumulation and dysfunction of adipose tissue adds value for identification and clinical attention.
- The nature of adiposity-based chronic disease identifies an at-risk population that stands to benefit from a lifestyle intervention.

34.1 INTRODUCTION

The physiological role of intracellular fat deposition in the regulation of energy metabolism allows the classification of adiposity-based chronic disease (ABCD) as a distinct entity and diagnostic term, with opportunities for research, clinical applications, and intensive lifestyle interventions.[1] Fat deposition occurs in eutopic adipose tissue (adipocytes) with various body distributions, as well as in ectopic sites (non-adipocytes, such as myocytes and hepatocytes).[2] Depending on the deposition location, distribution, and function, intracellular fat directly and indirectly participates in energy metabolism through intermediary metabolism and hormone receptor signal transduction, producing states of inflammation, insulin resistance, abnormal food-seeking behavior, and organ dysfunction.[3] Some specific examples include impaired cardiomyocyte contractility and hepatocyte inflammation associated with intracellular ectopic lipid deposits. For the purpose of clarity and communication, the term "adiposity" refers to all sites of intracellular fat deposition, constituting a full range of healthy to unhealthy pathophysiological mechanisms. The term ABCD refers to the chronic disease state causally associated with abnormalities of adiposity (Table 34.1). This is distinguished from the term "obesity," which is currently and strictly defined as having a body mass index (BMI) greater than a defined cutoff (e.g., 30 kg/m^2 or greater for Caucasians), and is the most common descriptor used in clinical studies of patients with abnormal adiposity. The clinical diagnosis of ABCD may be supported by anthropometrics (e.g., BMI and waist circumference), body composition technologies (e.g., bioelectrical impedance and dual X-ray absorptiometry), and other imaging studies (e.g., ultrasonography, computerized tomography, magnetic resonance, and positron emission tomography),[4] as well as serum markers of adipose function, including adipokines, triglycerides, and inflammation (Table 34.2).[5,6]

Unfortunately, multiple and conflicting health messaging about the definition and the causes of obesity, best lifestyle practices, and unproven therapies only aggravates confusion within the scientific literature,[7,8] lay press,[9] and popular culture.[10,11] Abnormal adiposity poses significant and irrefutable health risks, but sustainable lifestyle interventions, though logically sound and evidence-based, are very difficult to implement. This incongruence commonly leads to therapeutic nihilism and clinical inertia on the part of both healthcare professionals (HCPs) and patients. To some degree, this follows from the widely held belief that obesity is a personal choice rather than a *bona fide* chronic disease state with hallmark biological and behavioral components.

Despite the classification of obesity as a disease a decade ago, negative personal and societal connotations remain associated with the word "obesity."[1,7,8] Moreover, limitations in the use of BMI to predict adverse risk, especially among Asian populations,[12] as well as acceptance of changing societal norms may cast doubt on the urgency and severity of risk among patients with obesity.[13] To address these concerns, the concept of ABCD emphasizes the unhealthy nature of adiposity extending well beyond simple BMI or body weight, which includes abnormal body fat distribution, anthropometrics, and adipocyte secretome patterns. Changes in production of adipokines, such as leptin, resistin, and adiponectin, as well as activation of systemic inflammatory pathways within adipose tissue are among the most notable alterations of adipocyte function.[6,14] This greater detail allows more precise therapeutic interventions, particularly structured lifestyle interventions, but also requires a more robust diagnostic coding system for reimbursement and economic incentive for ABCD tactics.[15]

On this basis, the condition of ABCD may be described in a staging system that conveys severity of risk and likelihood of progression to subsequent stages.[1] ABCD stage 1 is defined as "risk" for abnormal adiposity (amount, distribution, and/or function) and is based on primary drivers (genetics, environment, and behavior that in aggregate contribute to a person's lifestyle). ABCD stage 2 is defined

DOI: 10.1201/9781003227793-39

TABLE 34.1
Defining Characteristics of ABCD

Adiposity Variable	Metric
Increased mass	Anthropometrics (e.g., weight and BMI)
	Body composition imaging (e.g., DXA)
Abnormal distribution	Anthropometrics (e.g., WC and WHR)
	Body composition imaging (e.g., DXA)
	Organ imaging (e.g., cardiac CT/MR, echocardiogram, FibroScan, and liver/kidney/pancreas ultrasound)
Abnormal function	Adipokine/cytokine levels (e.g., adiponectin and leptin)

ABCD is differentiated from "obesity" by abnormal distribution and function, as well as considering all four ABCD stages instead of just stages 3 and 4.
ABCD: adiposity-based chronic disease; BMI: body mass index; DXA: dual energy X-ray absorption; WC: waist circumference; WHR: waist-to-hip ratio; CT: computed tomography; MR: magnetic resonance.
See Lu et al.,[4] Kouli et al.,[5] and Vallance et al.[129]

TABLE 34.2
Selected Energy and Inflammation Signal Networks Affected in ABCD

Adipokines	Change in ABCD
Adiponectin	Reduced
Leptin	Elevated
Resistin	Elevated
Visfatin	Elevated
Cytokines	
Interleukin-1	Elevated
Interleukin-6	Elevated
Tumor Necrosis Factor-α	Elevated
Other Signal Molecules	
Fibroblast Growth Factor-21	Elevated
Glucagon-Like Peptide 1	Reduced
Ghrelin	Elevated
Plasminogen Activator Inhibitor-1	Elevated
Mechanistic Target of Rapamycin	Reduced

ABCD: adiposity-based chronic disease. See Kouli et al.[5]

as "predisease" and includes not only overweight (which is defined exclusively in terms of BMI) but also disease-level abnormalities in adiposity distribution and function (not yet defined). ABCD stage 3 is defined as "disease" and includes not only obesity (which is defined exclusively in terms of BMI) but also disease-level abnormalities in adiposity distribution and function (not yet defined). The condition of prediabetes, though considered as predisease, may be included within stage 3 ABCD as a measure of advanced dysmetabolic state.[1] Interestingly, as happenstance would have it, a pure BMI-based overweight (e.g., 25 kg/m^2 or greater for Caucasians) state could be considered as "overweight-based chronic disease," or "OBCD" ("obesity"—"O"—"B"—"C"—"D"). ABCD stage 4 is defined as "complications" and includes metabolic and non-metabolic (including biomechanical) adiposity-based conditions that have adverse effects on quality-adjusted life years (QALYs). This framework highlights the preventive care paradigm, wherein early detection of abnormal adiposity factors and sustainable action can mitigate or even abrogate pathophysiological progression, leading to improved individual and population health.

Several important points need to be emphasized here. First, there are distinct advantages of the ABCD framework over the conventional "obesity" framework: more accurate pathophysiology, easier recognition of antecedent preventive care intervention opportunities, and use of more precise and less stigmatizing numerical (cf. semantic) classifiers. Second, the ABCD framework is not a metabolic model of obesity, since non-metabolic drivers and complications are included (social determinants of health [SDOH], stigma and mental health, other organ system dysfunction [e.g., gastrointestinal/microbiome, neurocognitive, orthopedic/arthropathic, and cardiopulmonary], and patient-centered care). In fact, two sound and well-validated complication scoring tools—the Edmonton Obesity Staging System[16] and the Cardiometabolic Disease Staging System[17]—may be used to subclassify adiposity-related complications in ABCD stage 4.

Interventions for ABCD should be viewed as preventive (decreased risk and predisease for patients in stage 1; decreased disease and complications for patients in stage 2; decreased complications for patients in stage 3; and decreased suffering and mortality for patients in stage 4). In addition, these preventive interventions should be performed in the context of improving "health" and not just an ABCD metric or descriptor.

Until routine and validated assessments of abnormal adiposity distribution and function are available, individual clinical priorities should be based on the percentage of weight loss needed (according to evidence relating complication improvement with amounts of weight loss).[7] Intervention modalities (lifestyle, medications, and procedures) should then be identified, which are associated with the amount of weight loss needed. The first actual interventional step in ABCD management is a laser-focused behavioral intervention to activate patients for change; this intensive lifestyle intervention approach must be continued even as pharmaceutical and procedural interventions are considered and potentially delivered. Given the high prevalence rate of obesity in modern populations, which has reached 42% in the United States and 9% worldwide in 2018,[18] as well as the limited access to other therapeutic options,[19] an intensive lifestyle modification may be the only available option for the majority of patients with ABCD worldwide. Fortunately, in many people, the effective implementation of structured lifestyle change for patients with ABCD promises to decrease the need for more costly medical and surgical interventions (quaternary prevention).

34.2 CONSEQUENCES OF ABCD

The health consequences of ABCD are far-reaching and include metabolic and non-metabolic conditions (Table 34.3). Prediction of specific ABCD sequelae can be difficult. Not all patients with ABCD develop each of the associated complications. Additionally, the degree of adipose tissue accumulation may not correlate with the severity or the incidence of ABCD-associated complications, especially in conditions characterized by abnormalities in the distribution and function of adipose tissue. Some authors propose the existence of a subset of patients with "metabolically healthy" obesity (MHO), who are not at increased risk for cardiovascular disease (CVD) or type 2 diabetes (T2D) despite the presence of a BMI above 30 kg/m^2 (highlighting the problem of defining obesity by a simple arithmetical formula).[20,21] Depending on definition, this may account for 7–20% of patients with obesity in cross-sectional studies.[22] However, this phenomenon may be transient.[20] Over time, patients with MHO demonstrate conversion with increased rates of T2D, insulin resistance, and CVD.[20,23,24] These patients with MHO are also at risk for other ABCD-associated complications (Table 34.3),[25] consistently with a more complex networking model that demonstrates multiple affected pathways and emergent properties.[6]

More significantly, many ABCD-associated complications instigate adverse lifestyle choices associated with vicious cycles involving abnormal adiposity, stigma and weight bias, and unhealthy behaviors. For example, orthopedic injuries, cardiovascular atherosclerotic disease, or depression can prevent regular exercise and favor individual preference for sedentary activity.[26–28] Obstructive sleep apnea (OSA), with a prevalence observed between 35% and 96% in patients with obesity, disrupts healthy sleep hygiene.[29–31] Dysglycemia syndromes, such as T2D, polycystic ovary syndrome (PCOS), and the metabolic syndrome, affect hormonal control of energy homeostasis, which may render attempts at weight loss through lifestyle intervention more difficult.[32] In several studies, patients with T2D achieved approximately 50% of the weight loss that was sustained by patients without T2D following identical dietary and exercise protocols.[33,34] Similarly, women with PCOS demonstrate less weight loss than obesity-matched women without PCOS,[35] and high rates of relapse are noted among patients with PCOS who have initial success with weight loss.[36]

[a]Relative risk in stage 3 or 4 ABCD in comparison to patients without obesity.

34.3 INTENSIVE LIFESTYLE INTERVENTION

All patients with ABCD should strive for a healthy lifestyle, avoiding or minimizing modern conveniences and living practices that are detrimental to metabolic health. It may be difficult to define specific populations at risk for ABCD, though the vast differences in modern lifestyles and built environments compared with those of prior generations and even distant ancestors are suggestive that the current population would benefit from healthy lifestyle interventions.

Among the most obvious aspects is the choice of a dietary pattern. Any demonstrably healthy dietary pattern is recommended, provided a durable effect can be realized.[37] Enhanced adherence and sustainability will require motivational interviewing and behavioral assessments of food preferences, daily activities and logistics, cultural mores, tastes, religion-based rules, and other idiosyncrasies.[38,39] HCPs should exercise flexibility and poise to offer up quick alternatives for a successful trajectory when clinical progress has stalled.[40,41] A dietary pattern that is high in fruits, vegetables, nuts, and complex carbohydrates, with controlled amounts of meats and fish, and negligible amounts of processed foods and sugar-containing beverages provides the greatest benefit to patients with ABCD.[7,42] Some of the most widely studied dietary patterns with these attributes include Mediterranean diets, the New Nordic Diet, the Ornish Diet, and the Dietary Approaches to Stop Hypertension (DASH) diet, among others.[43–46] In the largest published randomized trial, patients assigned to a Mediterranean diet group had the greatest amount of weight loss, as well as reduction in T2D, reduction in cardiovascular events, and reduction in mortality, compared with those assigned to low-fat or low-carbohydrate diet groups.[43] The New Nordic Diet, the Ornish Diet, and the DASH diet, which overlap substantially with Mediterranean Diets in categorized food content, may have similar benefits. A very useful tactic to enhance adherence is to have website addresses, electronic and printed materials, and other information modalities for these dietary patterns at the ready for every patient.[40] Various wearable technologies that synchronize with smartphones and access cloud-based software can be trialed and optimized for individual patients.[47]

In addition to total body adipose content, the localized distribution and function of adipose tissue can be improved by the adoption of healthy dietary patterns. In one randomized trial, subjects assigned to a Mediterranean diet demonstrated improvement in insulin resistance by 37%, reduced inflammation by 37%, and increased adiponectin by 43% after one year, suggesting improved adipose function.[48] A population study of 5,079 individuals demonstrated reduced visceral, cardiac, and hepatic but no change in subcutaneous adipose tissue among those who followed dietary patterns that closely resembled the Mediterranean diet.[49]

Increased physical activity and exercise should also be incorporated into daily routines. Although the amount and type of exercise have not been fully settled, regular participation in physical activity is important. Many studies and organizations suggest that at least 150 minutes of physical activity divided over 5–7 days per week constitutes a reasonable minimum.[7] Although this level of physical activity may yield only modest (0–3 kg) weight loss, it generates significant improvement in metabolic health and insulin resistance, reduced risk of T2D incidence (30–60%), and improvement in hypertension cardiometabolic risk.[50] Continued regular physical activity is also associated with greater success in the maintenance of weight loss, with the greatest efficacy among patients who combined physical activity with dietary and other lifestyle changes.[50] Strength training provides the benefit of increased muscle mass, reducing myocyte adipose content, while cardiovascular exercise promotes reduction of visceral adipose accumulation.[51] Both of these endpoints are desirable in ABCD. Adipose function, assessed by adipokine production and inflammation, is also greatly enhanced through regular physical activity and exercise.[52] In addition to optimizing the choice of dietary pattern and amount of physical activity, many other individual lifestyle factors can impact the risk of ABCD (Table 34.4).[1]

TABLE 34.4
Effects of Lifestyle Intervention on Components of ABCD

Intervention (reference)	Abnormal Adipose Amount	Abnormal Adipose Distribution	Abnormal Adipose Function
Dietary Pattern[43]	Moderate	Moderate	Moderate
Physical Activity[7]	Negligible	Moderate	Moderate
Sleep Hygiene[66,67]	Strong	Moderate	Moderate
Stress Reduction[78,79,86]	Mild	Moderate	Strong
Antibiotic Use[101]	Mild	–	–

Mood[124,126]	Moderate	NA	Strong
Community Engagement[144]	Moderate	NA	Strong

Dashes indicate that sufficient data are not available.

34.4 SLEEP HYGIENE

Sleep affects metabolic regulation. As a defining feature of circadian rhythm, the amount, quality, and timing of sleep cycles affect hypothalamic function, cortisol release, thyroid function, hepatic glucose production, brown fat activation, and insulin resistance.[53] Additionally, pancreatic β-cell function is impaired in states of sleep deprivation.[54] This may reflect the responsiveness that β-cells demonstrate to melatonin secretion, which is itself diminished in disrupted circadian rhythms.[55]

In the modern era, average sleep duration has been declining. Time spent sleeping by adults has decreased from an average of 9 hours per night to 7 hours per night over the past 40 years.[56] In children, sleep time has reduced by an average of 0.75 min/night/year for the past century.[57] These trends continue to spread worldwide.[56,57] In addition to reduced sleep time, the presence of insomnia, defined as waking in the middle of the night at least three times weekly, is reported among 25–35% of adults.[58]

In children, no upper limit of healthy sleep has been identified, and a longer duration of sleep is associated with reduced amounts of adiposity, improved quality of life, and improved academic success.[59] In a meta-analysis of longitudinal trials in children, longer sleep duration was associated with reduced adiposity by an odds ratio of 1.89.[59] For every one hour of sleep duration, the annual rate of BMI increase was reduced by 0.05 kg/m^2.

In adults, between seven and nine hours of sleep is recommended nightly, and eight to ten hours of sleep is recommended in adolescents.[60,61] As with studies in children, adults exhibit increased adiposity, especially visceral adiposity, in association with shorter sleep duration.[62] In one observational trial, an increase in sleep time from less than six hours to seven or eight hours resulted in a reduction of visceral fat gain over six years of follow-up.[63]

Several randomized trials demonstrate that even short-term sleep restriction for five days causes weight gain in adults. This is attributed to increased calorie consumption (by 130%) in the sleep-deprived group compared with the control group.[64,65] In a crossover study, a 52% increase in consumption of sweets and desserts was observed during times of sleep deprivation.[66] These results may be explained by elevation in circulating ghrelin levels and reduction in leptin levels, which are observed in periods of sleep restriction.[67] Both of these hormonal markers of adipose dysfunction within ABCD would be expected to increase appetite and exacerbate insulin resistance.[54,67]

The importance of adequate sleep combined with other lifestyle interventions has also been demonstrated in a series of cross-sectional trials.[62] One observational study demonstrated an association of decreased sleep time and increased calorie consumption among obese women compared with normal-weight controls.[68] In another study, an inverse linear relationship between self-reported sleep duration and BMI was observed.[69] Data from the National Health and Nutrition Examination Survey also demonstrate a strong association between reduced sleep time and adiposity.[70] Additionally, patients with obesity demonstrate increased sleep latency and reduced percentage of time in rapid eye movement (REM) sleep.[56] A concerted effort to attain sufficient time for sleep is an important part of a healthy lifestyle, especially in the prevention and treatment of ABCD.[53,56]

Disordered sleep is disruptive to circadian rhythms and associated with weight gain.[56] OSA is highly prevalent in adults with obesity and disruptive to healthy sleep. In one longitudinal study, a 10% increase in body weight was associated with a sixfold increased risk of OSA.[71] The use of devices that provide continuous positive airway pressure (CPAP) can reduce the cardiovascular impact of OSA and improve symptoms of daytime drowsiness. Additionally, randomized trials demonstrate that the use of CPAP devices among patients with OSA improved insulin resistance by an average of 0.39 units in the homeostasis model, mainly through reduction in fasting insulin levels.[72] It remains unclear how this intervention may specifically affect adipose distribution and function in ABCD.[73] On the other hand, weight loss through intensive lifestyle modification can improve measures of OSA, simultaneously improving overall sleep hygiene synergistically with CPAP use.[74,75]

34.5 STRESS REDUCTION

The human response to chronic stress is associated with ABCD and involves hypothalamic dysfunction, increased consumption of palatable and calorie-dense foods, and reduced physical activity.[76,77] The hormonal profile in chronic stress includes elevations of cortisol, catecholamines, and insulin as part of an insulin resistant state.[77] In one cross-sectional study, chronic stress was associated with increased food cravings despite increased leptin levels, suggesting the presence of leptin resistance and adipose dysfunction in response to stress, as well as diminished adiponectin release.[78] Another study demonstrated that elevated cortisol and increased visceral fat accumulation are associated with increased stress.[79] Moreover, elevated cortisol induces visceral adipose release of inflammatory factors, including tumor necrosis factor α, interleukin(IL)-1, IL-6, and reactive oxygen species, through greater production and reduced glutathione antioxidant activity.[80]

Interventions to reduce stress are central to any healthy lifestyle. However, given the multiple stressors that are regularly present in everyday life, simple avoidance of stressful situations is often not possible. Modalities to address stress and activities to lessen pathophysiologic effects of stress may be beneficial in ABCD.[1] A lifestyle intervention of healthy dietary choices and physical activity >150 min/week itself can reduce stress and symptoms of depression.[81] Incorporation of a Mediterranean diet demonstrates a 41% reduction in the incidence of depression, a marker of reduced psychological stress.[82]

Direct techniques for stress reduction include mindfulness, cognitive-behavioral therapies (CBTs), and psychodynamic

techniques, which may be beneficial, though results are not always consistent.[83] In studies of mindfulness based stress reduction, markers of inflammation and adipokine levels in patients with obesity are observed.[84, 85] In one randomized controlled trial, women with obesity or overweight were assigned to either a mindfulness group that met once weekly to discuss stress reduction techniques and given recommendations for daily home sessions for 30–45 minutes each, or a control group that met weekly with a dietitian to review nutritional recommendations.[86] By eight weeks, depression and anxiety declined in the mindfulness group, and quality of life improved. These effects persisted at 16 weeks after the end of intervention. Additionally, fasting insulin and systolic blood pressure improved in the mindfulness group compared with controls both at the end of the trial and 16 weeks after its conclusion. Mindfulness techniques of stress reduction are promising lifestyle interventions in ABCD. This approach has also been shown to reduce binge-eating episodes in at-risk patients.[87]

Another method for stress reduction is through regular participation in low-impact exercises such as yoga. In a randomized trial of women with overweight or obesity, those assigned to the treatment group sustained a 2.4-kg weight loss and a 3.8-cm decrease in waist circumference after 12 weeks of twice-weekly 90-minute yoga classes.[88] Additionally, self-assessment measures of stress declined, while measures of quality of life and of self-esteem improved with yoga treatment. A second published randomized trial in men with overweight or obesity demonstrates reduction in weight by 2.2 kg and reduction in perceived stress score.[89] These results are similar to earlier observational studies indicating that the practice of yoga can improve stress and adipose tissue accumulation over the short term.[90]

As a lifestyle intervention, behavior therapy incorporates interventional methods to adjust a person's maladaptive behavior practices. This is particularly helpful in the approach to a patient with ABCD. Behavior modification intervention should include measures for stimulus control, use of rewards, which may be verbal, setting achievable goals and discouraging unrealistic goals, relapse prevention, and patient-driven self-correction for problems that may arise. A meta-analysis of seven trials demonstrates a significant improvement in sustainable weight loss (8.5 kg vs. 0.4 kg) when regular behavior sessions are incorporated in a comprehensive lifestyle intervention.[91]

34.6 ANTIBIOTIC USE AND THE MICROBIOME

34.6.1 Antibiotic Use by Humans

Since their discovery, antibiotics have been critical for the treatment of infectious disease of bacterial or fungal origin. Clear success has led to widespread use and overuse of antibiotics, including dubious medical practices that employ antibiotic use for conditions that may not be bacterial in origin. A 2019 survey of U.S. Medicare beneficiaries found that there were 454 prescriptions for antibiotics filled for every 1,000 patients.[92] This figure leads to concerns regarding the development of antibiotic resistance and pathological metabolic effects.

Antibiotic use can affect microflora residing within the gastrointestinal (GI) tract, serving as an exemplar of how other lifestyle changes that affect gut microbiota can indirectly lead to ABCD. Hundreds of species of bacteria and fungi are present within the colon of each individual and take part in a complex relationship between the host and other species of microflora.[93] These microbes directly affect host energy homeostasis through metabolism of sugars and fiber present in the intestinal chyme to produce short chain fatty acids that are available for utilization by the host. Approximately 5–10% of the total daily calorie consumption is obtained in this fashion.[94] Additionally, through multiple routes of signaling with the host, the GI microflora can influence the degree of insulin resistance, systemic inflammation, and metabolic rate, and may affect other health aspects of the host such as mood and cardiovascular function.[93,95,96]

Fermentation of undigestible dietary starches and fiber leads to production by the GI microflora of short chain fatty acids (SCFA), which can act as signal molecules. Through activation of the free fatty acid receptor 2 and 3 located on neuroendocrine cells of the GI tract, pancreatic β-cells, macrophages, and adipocytes, SCFA potentially affect several pathways in metabolic regulation.[97,98] Reduced SCFA activity diminishes leptin production and may contribute to ABCD, as well as to insulin resistance, through reductions in release of glucagon-like peptides 1 and 2.[99] However, it is presently unclear if SCFA levels are affected by antibiotic therapies.[98]

Still, a number of population studies have been published that associate the use of antibiotics with weight gain and obesity. This is especially evident among infants and children treated with antibiotics. In a study of children born to normal-weight mothers within the Danish National Birth Cohort, the use of any class of antibiotics in early life was associated with an increased risk of overweight by age 7 (odds ratio of 1.54).[100] A large international study demonstrates increased BMI at ages 5–8 among boys who were treated with antibiotics within the first year of life.[101] In another international cohort involving 8 medical centers located in low-resource settings, 1,954 infants followed until age 2 demonstrated significant weight gain without change in body length among those treated with one or more courses of various classes of antibiotics.[102] In this trial, penicillins, cephalosporins, macrolides, and metronidazole had the largest effects on weight gain. A recent analysis of the Irish National Longitudinal Study of Children that included longitudinal follow-up to age 5 demonstrated that four or more treatment courses with antibiotics were associated with obesity by age 5 (odds ratio 1.6; 1.1–2.3).[103] A meta-analysis of 15 trials corroborates this association of childhood antibiotic use and increased risk of obesity.[104]

Few studies have been conducted regarding the metabolic effect of antibiotics in adults. In one seven-day study, oral vancomycin significantly altered the species composition of GI microflora of subjects with obesity but did not demonstrate metabolic changes either during this trial or afterward.[105] Amoxicillin also had no discernable effect on metabolism. In another trial, 11 patients with obesity, insulin resistance, and detectable methane on breath testing were treated with neomycin and rifaximin until methane could no longer be detected, which took an average of ten days of treatment.[106] The bacterium *Methanobrevibacter smithii* is presumed responsible for methane production, and stool levels of *M. smithii* were eradicated in 8 of 11 subjects after the treatment course. In all subjects, low-density lipoprotein levels declined and insulin sensitivity by oral glucose tolerance testing improved after treatment. This trial suggests a potential cardiometabolic risk benefit from GI microflora manipulation.

Though other confounding factors within many of these reported studies may influence the results, the prudent and minimal use of antibiotics in medical practice may help prevent weight gain and influence other aspects of ABCD, especially among infants and children. Certain classes of antibiotics, such as sulfonamides, appear to have neutral effects on weight and may be preferred in appropriate clinical settings. Protocols for the active manipulation of GI microflora to generate beneficial metabolic effects require more study before firm recommendations can be made.

34.6.2 Antibiotic Use in Farming

The use of antibiotics outside the medical field may also play an indirect role in the development of ABCD and lead to sound conjecture about optimal food sourcing as part of healthy lifestyles. Widespread use of antibiotics by livestock farmers yields animals that gain weight faster and require less feed.[107] Nutrient changes within food products due to this practice have not been formally evaluated. However, changes within the livestock microbiome have been reported.[108] These observations of accelerated growth and altered microbiome are suggestive that the nutrient makeup of meat derived from antibiotic treated livestock may be altered, though further study is warranted in this field.

34.7 ENDOCRINE DISRUPTORS

Multiple classes of industrially produced chemical compounds demonstrate biological properties that affect hormone signaling. A subset of these endocrine disrupting compounds (EDC) has been shown to affect adipose tissue accumulation, distribution, and function.[109,110] In several studies, childhood exposure to bisphenol A, among the more well-studied EDC, is associated with weight gain and obesity.[111] Exposure to bisphenol A is also associated with reduced adiponectin and increased resistin gene expression,[112] as is exposure to octylphenol, another EDC.[113] Exposure to tetrabromobisphenol A, a flame retardant, reduces melancortin-4 receptor expression in the arcuate nucleus of the hypothalamus that regulates metabolism, leading to increased calorie consumption and weight gain.[114] Another exposure risk occurs as patients with ABCD successfully lose weight; lipid soluble EDC may be released into the circulation, especially from visceral adipose depots that may concentrate toxins.[115] Many other EDC can affect energy metabolism and mechanisms leading to ABCD, requiring ongoing clinical study.

34.8 ALCOHOL MODERATION

High alcohol intake is associated with adverse health outcomes, including death. In contrast, moderate alcohol consumption, especially consumption of wine, has been demonstrated to improve markers of insulin resistance, cholesterol levels, and systemic inflammation, suggesting improvement in adipose function.[116] Recently published trials continue to support the findings that moderate alcohol intake, defined as 14 drinks per week for men and 9 drinks per week for women, is associated with a lower incidence of T2D compared with non-drinkers and compared with heavy alcohol consumption in a "J-shaped" association.[117,118] In a study of 224 subjects with T2D who were assigned to receive 150 mL of either red wine, white wine, or water daily, both of the groups given wine showed reduced insulin resistance measured by fasting insulin levels, with increases in high-density lipoprotein levels in the red wine group.[119] Adipose tissue distribution is not affected by moderate alcohol intake.[120] Additionally, a recent analysis of global disease burden for non-communicable disease suggests that any level of alcohol consumption may convey cardiometabolic risk.[121]

General drawbacks of alcohol consumption include the risk of dependence and the potential for cognitive impairment, especially while operating motor vehicles or simply walking along a busy street. Another concern is the theoretical risk of accelerated hepatosteatosis when patients at high risk for non-alcoholic fatty liver disease consume alcohol regularly.[122] The DIONYSOS study appeared to support this claim; however, in this trial, an increase in steatosis was observed only in subjects with obesity who consumed more than 60 g alcohol, or four standard drinks, daily.[123] Within the trial, this group was known as the "heavy drinkers." Moderate alcohol consumption was not associated with increased hepatosteatosis in patients with obesity.

34.9 MOOD

Disorders of mood, such as depression and anxiety, have a complex relationship with weight gain and risk of ABCD. Obesity and depression often occur together in the same patient, in part due to common molecular mechanisms, including altered hypothalamic-pituitary-adrenal axis signaling, increased oxidative stress, and increased systemic inflammation.[124] In a published cohort, an increased

prevalence of depression is associated with increased leptin levels, suggesting that adipose function is affected in patients with depression.[125] The presence of depression is also associated with increased risk for the development of obesity later in life.[126–129] In the Whitehall II study, patients with increased levels of psychological stress over a ten-year period had BMI increased by 0.6 kg/m^2 and demonstrated a greater central distribution of adiposity.[130]

Patients with obesity demonstrate a poorer response to antidepressant therapy.[131–133] Additionally, many antidepressant medications induce weight gain and adiposity, including tricyclic antidepressants, selective serotonin reuptake inhibitors, and monoamine oxidase inhibitors.[134] Atypical antipsychotics, which may be applied in major depressive disorder, induce intense weight gain, insulin resistance, increased circulating leptin, and reduced adiponectin.[135] Still, the successful treatment of depression is often accompanied by significant weight loss and improvement in ABCD.[136] Moreover, weight loss in patients with ABCD has been shown to reduce depressive symptoms and improve quality of life.[137]

Aside from pharmacologic therapies, CBT can improve mood disorders and weight loss efforts. In one trial, patients with depression and obesity randomized to receive modified CBT that included aspects of healthy living had more sustainable weight loss and improved mood compared with standard CBT practices over 48 weeks of observation.[138] In another trial, CBT was associated with weight loss among adolescents with obesity and depression.[139] Multiple studies in adult patients with obesity and depression demonstrate the effectiveness of CBT in addressing both conditions.[91]

Other forms of behavior modification, including control of stimulus exposure, empowerment for self-correction of problems that arise, modification of unrealistic goals, systems for use of rewards, and relapse prevention, can be beneficial.[41] When combined with regular behavioral sessions, these strategies demonstrate an average 8.4-kg weight loss over two years.[91] Improvements in adipose function and distribution would be expected in association with weight loss; however, these effects of CBT have not been assessed.[91,139] Practically speaking, with proper training, HCPs outside the specialty of psychiatry can successfully implement CBT in the management of ABCD.[140]

34.10 COMMUNITY ENGAGEMENT

Close personal contacts and community involvement exhibit considerable influence on individual behavior patterns and on patterns of weight gain.[141] Moreover, efforts within communities to emphasize healthy lifestyle choices can reduce the impact of ABCD. Community programs that engage whole families in healthy dietary patterns, physical activity, and well-being have been shown to diminish childhood obesity.[142] These programs regularly meet as a group, create and nurture self-encouragement behaviors, and result in better health.[143] Improvements in quality of life and reductions in adiposity have been observed with these type of interventions.[143] In one randomized trial, a community-based intervention induced weight loss of 7.8%, adiponectin increases by 27%, and leptin decreases by 22% after one year, suggesting improvement in adipose function and overall decreased ABCD-related risks.[144]

Several barriers to program efficacy have been observed, including the main driver of program avoidance: parental concerns of psychosocial well-being, with little regard for other long-term sequelae of ABCD.[143] Denial or lack of recognition by parents also presents a significant barrier to program initiation. With any lifestyle intervention, care should be taken to avoid incurring body dissatisfaction, reduced self-esteem, or other effects detrimental to mental health in the target audience.[145] Programs that frame their central message as promotion of a healthy lifestyle are more successful than programs that specifically target weight loss.[146] To repeat, "health" is the preferred therapeutic target in ABCD care.

The direct involvement of families may be fundamental to this process; implementation of a five-year health and well-being intervention program through elementary schools with minimal parental involvement had no effect on adiposity.[147] In contrast, faith-based programs may represent important modes of community outreach for ABCD prevention.[148] In one randomized study involving congregations of 20 churches, a therapeutic intervention consisting of hourly weekly meetings emphasizing dietary patterns and physical activity achieved in the Diabetes Prevention Project (DPP) was compared with a control intervention that just involved general information.[149] The DPP arm showed a 2.4-kg weight loss after six months compared with a 0.4-kg weight gain by the control group. Several other observational trials of faith-based community intervention programs also show promise of improved weight reduction.[150,151]

The recognition of community engagement as a means to drive healthy behaviors has prompted the development of online virtual communities with the goal of improved health.[152] Though these have received much fanfare, results are inconsistent and depend on perceived emotional support (though levels of support can vary greatly).[152] In contract, in-person, family-oriented community engagement is a successful approach to adopting a healthy lifestyle.[150–152]

34.11 TRANSCULTURALIZATION

The cultural background of each individual has significant impact on lifestyle choices and response to medical advice. Any lifestyle directive, such as a suggested dietary pattern, should be congruent with a patient's cultural tradition to be sustainable.[153] This approach garners community support and promotes durable and successful healthy lifestyle changes. In contrast, recommended dietary patterns at odds with a patient's own culture will often incur transgressions if they are not adequately addressed.[154] In

some cases, advising a reversion to tradition may be beneficial. For example, persons of Asian descent who return to a traditional Asian diet that is rich in fruits and vegetables, green tea, beans, nuts, and spices, and is low in red meat, demonstrate improvement in insulin resistance and ABCD, and cardiovascular outcome reduction.[153,155] Patients with other backgrounds may be responsive to traditional lifestyles.

Some cultures traditionally place value on weight gain as a marker of wealth, high social standing, and overall well-being. However, the worldwide increased prevalence of adiposity has triggered responses by governments, cultural leaders, international charitable organizations, the World Health Organization, and the United Nations to address non-communicable chronic diseases, including ABCD.[156–158] Recommendations to address ABCD among various nations include the identification and education of physicians and cultural leaders within different regions who would serve as agents of change.[154] A respectful understanding of local culture can allow adaptation of lifestyle interventions to curtail ABCD and associated complications, with the potential for broad impact when implemented globally.

In addition to cultural adaptations for lifestyle medicine approaches, ethnic variation can lead to a range of ABCD phenotypes. Traditional measures of obesity, such as waist-to-hip ratio or BMI, do not capture the full risk conferred by adiposity in Eastern Asian and Indian populations.[12] As a model of cardiometabolic risk, the distribution, function, and amount of adiposity among these populations are more predictive than BMI alone.[159,160] As an example, when matched for age and BMI, Asian patients demonstrate higher circulating leptin and lower adiponectin, emphasizing the importance of adipose function rather than BMI.[161]

34.12 CONCLUSION

The growing worldwide epidemic of obesity is among the highest intervention priorities in healthcare. A number of important lifestyle factors have been identified in addition to the individualization of dietary patterns and physical activity. Unfortunately, a slow rate of success coupled with therapeutic inertia on local and national scales requires new ways to regard the problem. Moreover, a clinically meaningful lifestyle approach requires resources and dedicated clinical attention as well as disease delineation.[15]

ABCD is a new diagnostic term that incorporates not only body weight and BMI, which is all that current obesity definitions and interventions rely on, but also healthy and unhealthy distributions and secretory functions of body fat. This broader conceptualization of this metabolic problem permits a better understanding of pathophysiology, analysis of current evidence, and formulation of effective interventions. Future directions should focus on validation studies involving biological data on drivers and complications; statistical associations related to stage progression; causal relationships (linear and non-linear) among drivers (biological and social determinants of health) and complications; and interventional studies that prevent stage development and/or progression. Potential clinical applications of these studies would be the routine incorporation of not only anthropometrics but also body scanning for adipose distribution assessment and broad molecular testing to identify multiple adipokine abnormalities in order to improve health in patients with ABCD.[1]

Healthy lifestyle interventions to mitigate ABCD include individualization and adoption of healthy dietary patterns and physical activity programs. Improvements in sleep hygiene, reduction in stress, and treatment of both clinical and subclinical disorders of mood can also impact weight gain, improve adipose tissue function and distribution, and improve overall well-being among patients with ABCD. Judicious and minimal use of antibiotics, especially among infants and children, can also mitigate weight gain and possibly prevent the development of ABCD. Avoidance of EDC wherever possible, population-based improvements in food sourcing, and moderation of alcohol intake among adults may also have a role. Beyond the individual, the involvement of community and culturally–sensitive medical practices can help to redirect normative trends in clinical practice. When optimized, these important lifestyle factors can significantly reduce ABCD and its associated detrimental effects.

CLINICAL APPLICATIONS

- Identification of patients with ABCD may include waist circumference measurement, presence of conditions associated with insulin resistance, signs of insulin resistance (e.g., acanthosis nigricans, skin tags), and abnormal lipid profiles, among other measures to be determined within this relatively new classification system.
- Selection of a demonstrably healthy dietary pattern should be congruent with a patient's preferences and sustainable over the long term.
- Physical activity of at least 150 minutes per week divided over 5–7 days is recommended to mitigate the health consequences of ABCD.
- For adults, between seven and nine hours of sleep per night can reduce insulin resistance and is associated with reduced adipose accumulation.
- A comprehensive approach to lifestyle medicine for ABCD should also include methods for stress reduction, avoidance of endocrine disrupting compounds, recognition and treatment of mood disorders, and participation in active community engagement.

35 Exercise Oncology: The Role of Exercise across the Cancer Control Continuum

Maxime Caru, PhD and Kathryn H. Schmitz, MPH, PhD, FACSM, FTOS, FNAK

KEY POINTS

- Research continues to affirm physical activity's role in primary, secondary, and tertiary cancer prevention.
- Multiple guidelines have been released urging clinicians to prescribe physical activity to patients according to their cancer status.
- Multiple barriers often stand between patients and their ability or desire to engage in physical activity; clinicians have a duty to help and support their patients.
- There are multiple models of exercise oncology practice in common use in the United States.

35.1 GLOBAL CANCER BURDEN

35.1.1 Adults and Older Adults

There were 19.3 million new diagnoses of cancer and approximately 10 million deaths from cancer in 2020.[1] This is expected to rise to an estimated 28.4 million diagnoses per year by 2040. The most common diagnoses were female breast, followed by lung, colorectum, prostate, stomach, and liver cancers. Figure 35.1 presents the distribution of diagnoses and causes of cancer death in 2020. Cancer is presently the second leading cause of death worldwide, with expectations that it will be the leading cause of death by 2060.[2] Lung, colorectum, and liver are the most common causes of cancer death.

The variability in incidence of cancer globally largely arises from environmental and behavioral exposures rather than biology. The incidence of cancers is lower in lower income countries, but once diagnosed, mortality is higher in lower income countries.

Cancer is a disease of aging. The incidence of cancer increases with age (Figure 35.2), with estimates of 25 cases per 100,000 among people under age 20, 350 per 100,000 people among those aged 45–49, and more than 1,000 per 100,000 among those aged 60 years or more.

Further, the majority of cancer survivors are older adults as well. In 2016, it was estimated that 62% of cancer survivors were 65 or older. By 2040, it is estimated that 73% of cancer survivors will be 65 or older. When we outline the physical activity needs of those who have been diagnosed with cancer, this age distribution must be kept in mind.

35.1.2 Children, Adolescents and Young Adults

Although it could be expected that children are less likely to have chronic diseases, the fact remains that cancer is a common disease and is a leading cause of death for children, adolescents, and young adults. Children (ages 0 to 14 years) and adolescent and young adult patients (ages of 15 to 39 years) with cancer make up a unique population in oncology. Each year, almost 10,500 children receive a diagnosis of cancer, and approximately 77,000 adolescent and young adult patients are newly diagnosed each year in the United States.[3] In the last two decades, the survival rates have significantly improved, and almost 85% of children, adolescents, and young adults are living at least five years post diagnosis. A recent report from the National Cancer Institute informed that there are at least 483,000 childhood cancer survivors in the United States as of 2019.[4] As a result of their survival, cancer survivors face chronic health problems related to their cancer treatments that can be moderated with physical activity.[5,6]

35.2 PHYSICAL ACTIVITY AND CANCER PREVENTION

35.2.1 Overview

In recent years, clinicians and researchers have been working together to strengthen evidence-based medicine on the benefits of adopting a healthy lifestyle for patients living with and beyond cancer. Physical activity plays a key role in the development and regulation of multiple body systems and begins from an early age with the movement of the body in space. There are age-specific physical activity guidelines for healthy people to help prevent and manage chronic diseases, in addition to providing a myriad of other physical and mental health benefits.[7]

DOI: 10.1201/9781003227793-41

Reproduced by permission of John Wiley and Sons.)

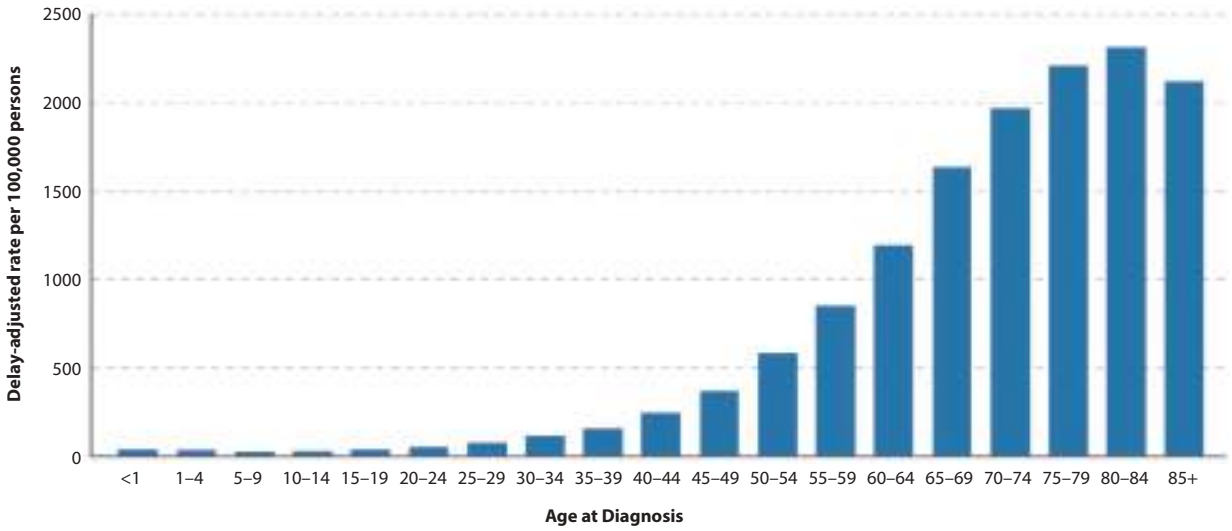

FIGURE 35.2 Incidence rates by age at diagnosis, all cancer types. (From National Cancer Institute 2021. ***Age and Cancer Risk***. Reproduced by permission of NCI.)

Physical activity must be differentiated from the term "exercise," which refers to "a type of physical activity that involves planned, structured, and repetitive bodily movement to maintain or improve one or more components of physical fitness."[8] Physical activity, however, is defined as "any bodily movement produced by contracting skeletal muscles, with a concomitant increase in energy expenditure."[8] The U.S. Physical Activity Guidelines recommend that healthy children and adolescents engage in at least 60 minutes of enjoyable moderate-to-vigorous intensity physical activity every day.[7] Adults should engage in at least 150 minutes a week of moderate intensity physical activity, with at least 2 days a week of muscle-strengthening activities, whereas older adults (>65 years old) should also

add activities that improve their balance.[7] According to the American College of Sports Medicine (ACSM), moderate intensity is performed at a level that allows an evident increase in a person's heart rate and breathing, while still being able to hold a conversation that could not be maintained at vigorous intensity.[9] Physical inactivity is a major public health problem and should be avoided at all costs.

Patients with cancer who are not engaging in regular physical activity expose themselves to a higher risk of chronic diseases or premature death, justifying the need for specific guidelines in exercise and oncology. The American Cancer Society (ACS) issued guidelines for nutrition and physical activity for cancer prevention,[10] while the ACSM recently endorsed the updated consensus statement and guidelines on exercise for adult patients with cancer and survivors.[11] In pediatric oncology, the first guidelines on exercise were published in 2021,[12] which testifies not only to the emergent nature of the research field but also to the willingness to include exercise in the continuum of health and disease prevention. Clinicians and researchers support physical activity as an integral strategy across the cancer prevention continuum. It is important, however, to understand the key role of physical activity at different levels of prevention, regardless of the age of the patients.

35.2.2 Role of Physical Activity in Primary Prevention

Primary prevention is defined as preventing a cancer before it occurs, through measures such as healthy lifestyle behavior to reduce behavioral risk factors associated with the disease. The World Health Organization states that between 30% and 50% of cancers can be prevented by avoiding risk factors and that cancer risk can be reduced by engaging in regular physical activity.[13] Studies have reported that modifiable and preventable lifestyle-related behaviors (e.g., tobacco use, poor diet, physical inactivity, alcohol consumption) are the underlying cause of half of all deaths in the United States.[14,15] Several other studies have also shown that physical inactivity and unhealthy behaviors are associated with higher mortality rates,[16] while physical activity is associated with lower mortality rates.[17,18]

Back in 1985, the pioneering work of Dr. Rose E. Frisch found that women who engaged in athletic training had a lower risk of breast cancer and cancer of the reproductive organs, such as cancers of the uterus, ovaries, cervix and vagina, compared with their non-athletic counterparts.[19] Since then, several studies and meta-analyses have been published showing that physical activity is associated with a lower risk of many cancer types. A systematic review and meta-analysis highlighted that running was associated with a reduction of 23% in cancer mortality.[20] Researchers at the American Cancer Society and the National Cancer Institute pooled data from 12 prospective U.S. and European cohort studies for a total of 1.44 million adults and showed that leisure-time physical activity was associated with a lower risk of developing 13 cancers: esophageal adenocarcinoma, liver, lung, kidney, gastric cardia, endometrial, myeloid leukemia, myeloma, colon, head and neck, rectal, bladder, and breast.[21]

Emerging data have suggested that physical activity enhances patients' inflammatory and immune function.[22] In fact, there are several biological mechanisms that can explain how physical activity has an effect on cancer risk and prevention. For example, physical activity has the potential of reducing the amount of adipose tissue and the production of sex hormones, insulin, leptin, and inflammatory markers, which has the effect of reducing exposure to carcinogenic hormones and peptides, reducing the risk of cancer.[23] Physical activity–mediated reduction of biologically available sex hormones has been described as playing a significant role in decreasing the risk of developing cancer in different sites, such as breast, prostate, endometrium, ovary, and testis.[24]

The effects of physical activity have been described as multifactorial, and patients' age, gender, and body composition should also be taken into consideration when clinicians and researchers want to understand the underlying mechanisms of physical activity. Regarding this aspect, there is a very large field of research focusing on the effects of physical activity on immune function.[25] It is important for the audience to note that the scientific evidence in this regard is mainly derived from animal studies or studies in adults with cancer. Thus, many mechanisms remain to be explored, and some mechanisms are still in the hypothesis stage in adults. Some of the biological mechanisms have been, however, described by Zhu and collaborators (Figure 35.3).[26] Unfortunately, our knowledge of the mechanisms by which physical activity reduces the risk of cancer in children, adolescents, and young adults is still limited.

35.2.3 Role of Physical Activity in Secondary Prevention

Secondary prevention is defined as reducing the impact of a cancer that has already occurred through interventions such as physical activity to reduce the impact of cancer on patients' health, psychosocial, and physical function. Cancer affects patients in many areas of their lives, both personally and professionally. In comparison with the general population (without cancer), patients with cancer may experience anxiety, pain, depressive symptoms, fatigue, physical function impairment, and low health-related quality of life.[27,28] Symptom burden is even more severe in patients with advanced cancer.[28] In children with cancer, both physical and mental health are affected during cancer. It has been reported that at least 70% of them will experience at least two distressing symptoms during their treatment.[29] Adolescents and young adults are more likely to have a lower or impaired health-related quality of life compared with their healthy counterparts.[30] This is a symptom that lasts several years after the end of treatment.

Strong evidence is in favor of regular physical activity in patients with cancer to improve patient-reported

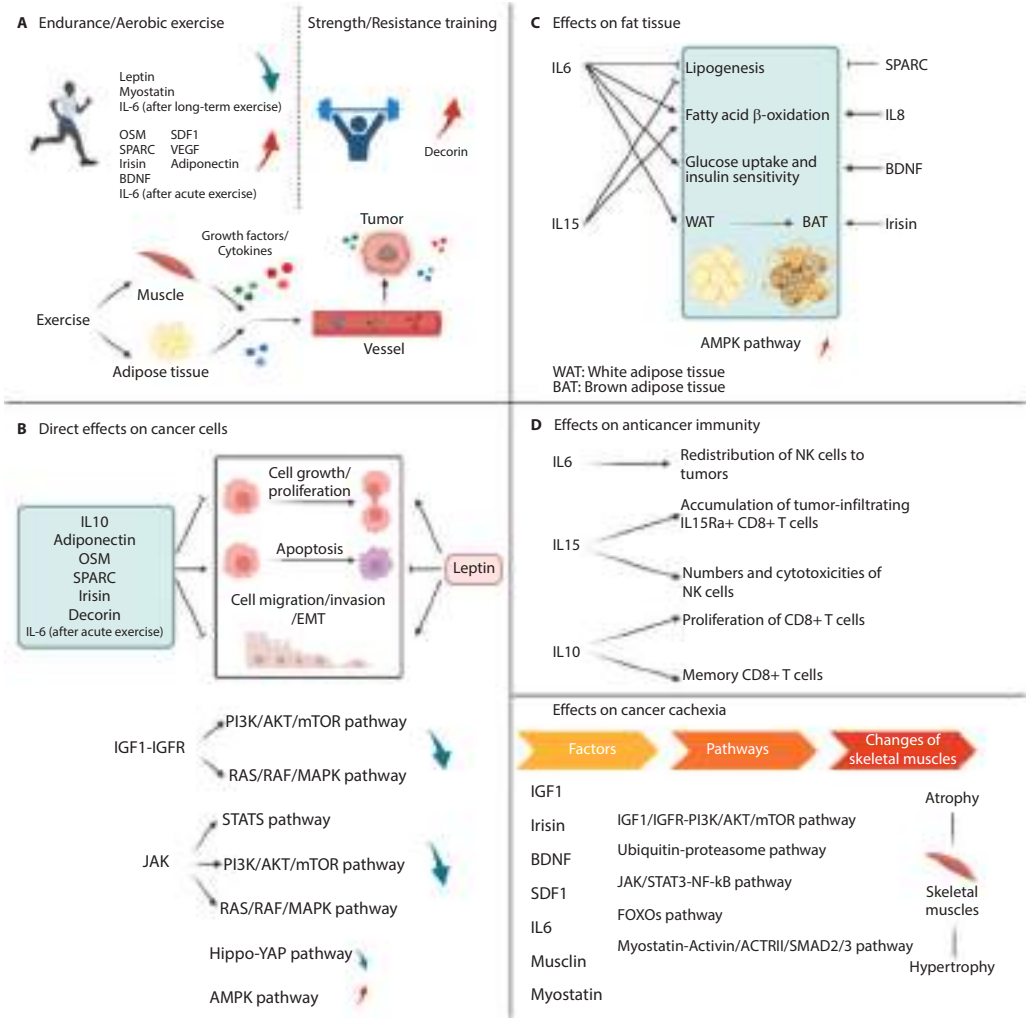

FIGURE 35.3 Biological mechanisms involved in the association between physical activity and cancer. (From Zhu, C., Ma, H., He, A., Li, Y., He, C., & Xia, Y. (2022). Exercise in cancer prevention and anticancer therapy: Efficacy, molecular mechanisms and clinical information. ***Cancer Letters***, 215814. Reproduced by permission of Elsevier.)

outcomes, including fatigue, anxiety, depressive symptoms, health-related quality of life, and physical function.[11] A recent study showed that treatment-related symptoms (e.g., fatigue) vary daily in patients with cancer and that physical activity should be adapted accordingly.[31] Cancer-related fatigue affects almost every adult patient with cancer,[32] a rate similar to the one observed in pediatric oncology.[33] A meta-analysis showed that physical activity is significantly more effective to reduce cancer-related fatigue than the available pharmaceutical options.[34] Physical activity can also improve patients' health status and long-term outcomes. A longitudinal study of 4,643 women diagnosed with invasive breast cancer showed that women engaging in regular physical activity before their diagnosis had lower breast cancer mortality and lower all-cause mortality.[35] Even if they were inactive before their cancer diagnosis, women who increased or maintained physical activity had lower all-cause mortality.[35] These findings strengthen the impact of physical activity on cancer.

To better understand its impact, mechanisms by which physical activity would influence cancer (incidence and symptoms) have been and continue to be explored. Before the 1990s, the role of physical activity had been studied in elderly women, showing its influence on natural killer cell tumor cytotoxicity.[36] This study generated many hypotheses, of which one of the best known involves the role of physical activity in increasing the number or improving the function of natural killer cells that play a role in tumor suppression.[37] Further, physical activity may increase the antioxidant capacity of the cells, reduce oxidative stress, improve DNA repair, and reduce cell proliferation, as well as improve apoptosis to block the initiation of cancer cells and fight their replication in the human body.[38,39] In animal models, it has been shown that physical activity inhibits tumor initiation and tumor multiplicity in addition to changing the tumor microenvironment.[38] Studies have suggested that engaging in regular physical activity improves immune function and the body's overall cancer control, regardless of the patient's age.[37,40,41]

35.2.4 Role of Physical Activity in Tertiary Prevention

Tertiary prevention is defined as managing the long-term impact and complex health problems related to a cancer that has already occurred through interventions such as physical activity to prevent long-term problems and cancer recurrence. Physical activity plays an important role in oncology (adults and pediatrics) to help patients with cancer recover their autonomy by improving their physical function. Patients who engage in regular physical activity give themselves a chance to increase their longevity as well as their physical and mental health. Pooled data from the National Cancer Institute Cohort Consortium in 6 prospective cohort studies for a total of 654,827 adults showed that leisure-time physical activity was associated with a longer life expectancy (up to 4.5 years).[42]

Throughout 26 studies of patients with breast, colorectal, and prostate cancers, it has been observed that those who are physically active reduce their risk of cancer-specific mortality by 37% compared with patients who are not active.[43] In adult survivors of childhood cancer, increased physical activity over eight years is associated with a 40% reduction in all-cause mortality.[44] Findings from the Childhood Cancer Survivor Study (CCSS) cohort have shown that a decreased risk for all-cause mortality is associated with being physically active more than three days per week, with a lower risk of death among females.[45] In colorectal cancer, patients engaging in regular physical activity, in addition to avoiding risk factors (tobacco use, alcohol consumption, overweight/obesity) and modifying their eating habits, have the potential to reduce cancer-specific and overall mortality by up to 40%.[46] They are also more likely to significantly increase their health-related quality of life compared with those who do not engage in regular physical activity.[46] Similar observations are reported in breast cancer survivors, since physical activity has been associated with better health-related quality of life, better reported symptoms (e.g., fatigue, pain, sexual function), and better survival.[47–49] Physical activity seems to be powerful enough to decrease patients' likelihood of dying.

A systematic review and meta-analysis reported that physical activity in cancer survivors was significantly associated with a reduction in the risk of recurrence by over 50%.[50] Patients with breast, colorectal, and prostate cancers engaging in regular physical activity decreased their risks of recurrence and recurrence/cancer-specific death.[43] Mechanistically, physical activity may boost the immune system of patients with cancer, as observed in patients with breast or colon cancers.[51, 52] Moreover, physical activity has been associated with reduced insulin secretion, insulin-like growth factor-1 (IGF-1) production, and insulin resistance, which can lead to enhanced normal cell division and inhibit cell death in patients with cancer.[52,53] Regulation of IGF-1 concentrations and signaling, natural killer cell function, and inflammation have been identified as key cancer biomarkers positively affected by physical activity. Other mechanisms related to physical activity also have to be taken into consideration, such as gene suppression and oxidative stress reduction, which play an important role in gastric and colorectal cancers, respectively.[54]

Furthermore, it seems crystal clear that physical activity should be promoted and implemented in oncology, and clinicians must understand and be educated on current guidelines surrounding physical activity practice after a cancer diagnosis.

35.3 PHYSICAL ACTIVITY GUIDELINES AND PRACTICE BEFORE AND AFTER A DIAGNOSIS OF CANCER

The focus of physical activity intervention shifts across the cancer control continuum. Courneya and Friedenreich have developed the Physical Activity and Cancer Control Framework (Figure 35.4), which clarifies the categories

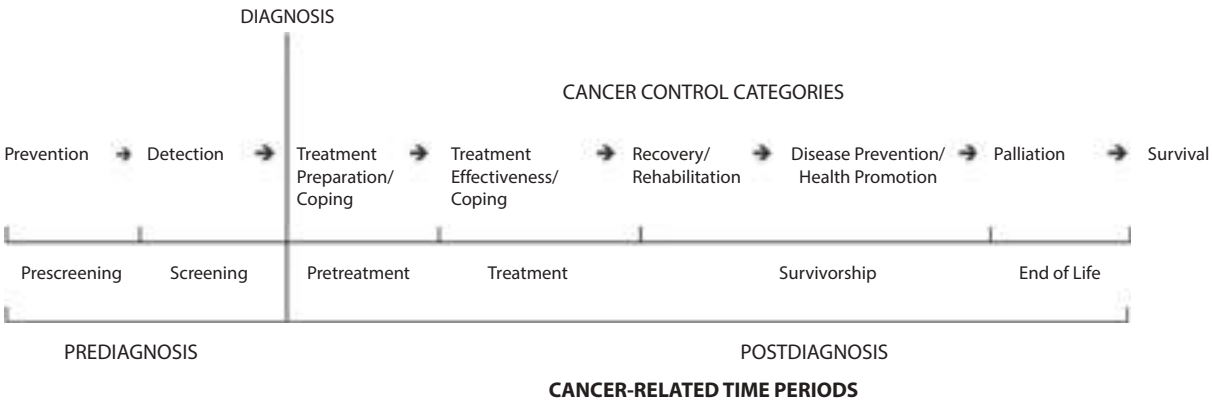

FIGURE 35.4 Physical activity and cancer control framework. (From Courneya, K. S., & Friedenreich, C. M. (2007, November). Physical activity and cancer control. In ***Seminars in Oncology Nursing*** (Vol. 23, No. 4, pp. 242–252). WB Saunders. Reproduced by permission of Elsevier.)

of outcomes that might be the focus of physical activity interventions from the point of primary prevention, immediately after diagnosis, throughout treatment and recovery, and through the end of life.[55]. Given this framework, it follows that physical activity guidance is distinct for patients from diagnosis to the end of treatment versus post treatment through the end of life. For example, the outcomes of greatest interest during the pretreatment time frame might be addressing anxiety and increasing muscle mass and physical function. By contrast, outcomes of greatest interest during active treatment would be coping with symptoms and improving treatment tolerance. In turn, during the recovery time frame, there would be a return to focus on body composition and physical function.

35.3.1 Physical Activity Guidelines and Practice During and After Cancer Treatment

Multiple organizations have reviewed the scientific evidence and drawn the conclusion that exercise should be recommended during cancer treatment, including the National Comprehensive Cancer Network, American Cancer Society, Exercise Sport Science Australia, Clinical Oncology Society of Australia, American College of Sports Medicine, and the American Society of Clinical Oncology.[11,56–60] In particular, the ACSM reviewed 16 cancer health-related outcomes to discern whether there was randomized controlled trial evidence that exercise would benefit these outcomes during and after cancer treatment.[11] The reviewed outcomes included anxiety, depression, fatigue, health-related quality of life, breast cancer–related lymphedema, physical function, bone health, sleep, cardiotoxicity, chemotherapy-induced peripheral neuropathy, cognitive function, falls, nausea, pain, sexual function, and treatment tolerance. Systematic reviews of randomized controlled trials or individual randomized controlled trials were reviewed. If at least 5 trials with at least 150 participants showed an effect that was statistically significant, heterogeneity of effects was reviewed. With no heterogeneity, or heterogeneity with more promising results from recent trials, the expert panel chose to make a FITT prescription (Frequency, Intensity, Time, and Type) for the cancer health-related outcome. The eight outcomes for which there was sufficient evidence included anxiety, depression, fatigue, health-related quality of life, breast cancer–related lymphedema, physical function, bone health, and sleep. For these cancer health-related outcomes, the exercise prescription for patients during cancer treatment can be summarized as three times weekly moderate intensity aerobic exercise of 30 minutes in duration and two times weekly progressive resistance training. More specifics are provided in Figure 35.5. The ACSM guidelines are unique in that they provide greater specificity for the exercise prescription during treatment, which can be helpful when translating these recommendations into clinical practice.

35.3.2 Physical Activity Guidelines for Primary and Secondary Prevention of Cancer

The U.S. Department of Health and Human Services Physical Activity Guidelines Advisory Committee (PAGAC) and the ACSM both reviewed the observational epidemiologic evidence regarding the relationship between physical activity and primary or secondary prevention of several common types of cancer.[61,62] Both reviews concluded that there is strong evidence of a reduction of incidence of seven common types of cancer for those who are more physically active, including colon, breast, kidney, endometrium, bladder, stomach, and esophageal adenocarcinoma. There is also moderate evidence of an inverse association between physical activity and incident lung cancer. The magnitude of the preventive effect generally ranges from 10% to 20%.

The U.S. PAGAC and ACSM Roundtable also reviewed the epidemiologic evidence regarding the role of physical activity and cancer-specific and all-cause mortality.[61,62] The review included many cancer sites (breast, colorectal, prostate, endometrium, ovarian, kidney, lung, melanoma, non-Hodgkin lymphoma, childhood cancers, esophageal, gastric, and malignant glioma). Review of meta-analyses and pooled analyses suggests that post-diagnosis physical activity is associated with a substantive prevention of cancer-specific mortality and all-cause mortality for breast, colorectal, and prostate cancers. The magnitude of these secondary prevention effects ranged from 30% to 45%, a notably larger effect than observed for primary prevention. The lack of effects for other examined cancers is thought to be largely due to lack of studies examining post-diagnosis physical activity and survival outcomes in those cancer sites.

35.3.3 Models of Exercise Oncology Practice during and after Treatment

Given the proliferation of clinical guidelines stating that exercise should be prescribed to those who have had a cancer diagnosis, both during and after treatment, it becomes important to describe how such programming would be delivered in cancer treatment settings. In the United States, qualified exercise oncology professionals are not yet covered by third party payers. This influences how exercise oncology is practiced in the United States. There are other countries in which qualified exercise oncology professionals are paid through a national insurance scheme, including the United Kingdom and Australia. In those countries, the challenges to practice center around triage, referral, and recommendations (issues addressed in the next section of this chapter). Herein, we describe how exercise oncology is typically practiced in the United States. There are three common models: group fitness, exercise consultation, and formal exercise programming. Each is described in the following. Notably, all three can be offered through telehealth. Referral into these programs includes self-referral and referrals from clinicians.

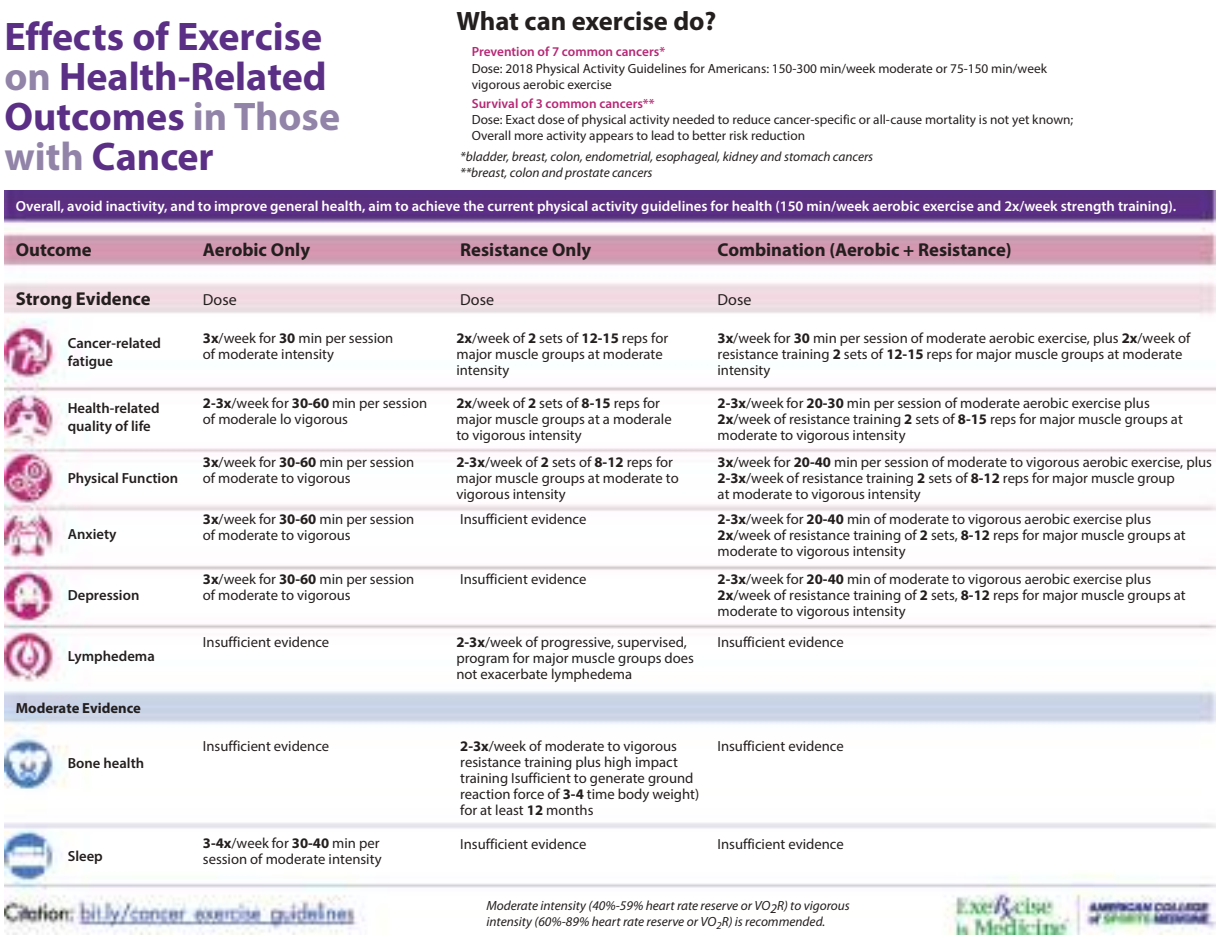

FIGURE 35.5 American College of Sports Medicine guidelines for specific cancer health-related outcomes. (From Campbell, K. L., Winters-Stone, K., Wiskemann, J., May, A. M., Schwartz, A. L., Courneya, K. S., ... & Schmitz, K. H. (2019). Exercise guidelines for cancer survivors: consensus statement from international multidisciplinary roundtable. ***Medicine and Science in Sports and Exercise***, 51(11), 2375. Reproduced by permission of Wolters Kluwer Health, Inc.)

Group Fitness. The examples of this approach include LiveStrong at the YMCA and Fitsteps for Life in Texas. These programs are generally supported by charity fundraisers and offered to patients and survivors at no cost. The programs generally include two in-person (or virtual synchronous) exercise sessions per week, led by a staff person with special training to provide exercise training to cancer patients and survivors. At present, the LiveStrong at the YMCA program is the largest in the United States, having served over 68,000 patients and survivors.[63] The program is carried out in groups, runs for 12 weeks, twice weekly, and is generally offered two to four times per year by YMCAs. There is documented efficacy of the LiveStrong program to improve physiologic and psychosocial outcomes.[64]

Exercise Consultation. An example of this approach is the Cancer Wellness for Life program in Kansas (www.cancerwellnessforlife.com). The program is paid for by the health system through a contract to the exercise oncology professionals and is offered to patients free of charge. The exercise oncology professionals contact referred patients to discuss goals and plans, to carry out a baseline triage to discern the need for outpatient rehabilitation, and to perform a baseline assessment prior to developing a personalized exercise plan. There are multiple community settings in which the patient can carry out the exercise plan (including their home). The exercise oncology team can check in with patients periodically to update the exercise plan as needed.

Formal Exercise Programming. An example of this approach is Maple Tree Cancer Alliance, which has over 55 locations across the United States (www.mapletreecanceralliance.org). The program is paid for either by charity fundraising or by health system investment and is offered to patients free of charge. An initial consultation/evaluation discerns whether outpatient rehabilitation is needed for specific impairments. The baseline evaluation is used to develop a personalized exercise plan. Patients come to the centers where this program is offered once weekly to perform the exercise program under the supervision of a qualified exercise oncology professional, and they are given exercise homework to do in between the sessions. The program is available for prehabilitation (pre treatment), during treatment (12 weeks), immediately post treatment

(12 weeks), and longer post treatment (12 weeks). All sessions are one on one with a qualified exercise oncology professional.

35.3.4 The Role of the Clinician in Triage, Referral, and Recommendations

One of the most challenging issues in making exercise standard of care, as has been suggested by multiple expert panels from multiple organizations, is getting clinicians to make referrals into exercise programming during and after cancer treatment. There are multiple reasons for this: 1) lack of education of oncology clinical staff regarding the effectiveness of exercise for multiple clinical outcomes during and after cancer treatment; 2) lack of time to talk to patients about exercise during busy oncology clinical encounters; 3) lack of clarity regarding who should be referred to outpatient rehabilitation versus exercise programming. Recently published evidence underscores that most oncologists agree they should be talking to their patients about exercise,[65] but that only 14.7% of patients are getting referrals to exercise from their oncology care team.[66] The challenge of lack of time and lack of clarity regarding trial to outpatient rehabilitation versus exercise could be solved by inserting an exercise oncology staff member to talk about exercise and carry out the triage process, as is the case with the consultation model and formal exercise program approaches described earlier.

There is a newly validated triage tool that could be included in this process and that would ease this challenge, called "EXCEEDS-S"[67] (Figure 35.6). The tool is patient facing but could be completed in the presence of an exercise oncology professional so that appropriate referrals could then be made. There is also a new directory of exercise oncology and rehabilitation programs developed by the ACSM to which patients can be referred upon completion of the EXCEEDS-S triage tool. The directory will only show patients programs that would be appropriate for them, based on answers to the EXCEEDS-S tool (www.exerciseismedicine.org/eim-in-action/moving-through-cancer/exercise-program-registry).

35.3.5 Cost and Healthcare Outcomes

The rising cost of cancer care is a primary focus for patients, payers, and providers. Over the past 40 years, the mean monthly cost of cancer drugs has risen from less than $100 in 1965–1969 to more than $10,000.[68] Finding innovative ways to reduce this cost burden is of value from the patient, payer, and societal perspective. Given that many competing cancer treatment modalities exist, it is essential to ensure that scarce healthcare resources are allocated in the most effective way to benefit cancer patients by considering the cost-effectiveness, sustainability, and economic aspects. Cost-effectiveness analysis (CEA) is a widely used analytical tool to choose between two alternative treatments by comparing the cost relative to the effectiveness.[69,70] CEA is increasingly being considered in developing cancer treatment guidelines.[71,72]

A search in PubMed using keywords "cost effectiveness cancer exercise" yielded 250+ hits (we also tried other keyword combinations to increase our search results). For the hundreds of hits, we reviewed all the titles/abstracts (and full contents when needed) to identify truly relevant studies. Only a few of the identified studies conducted genuine cost-effectiveness analyses (others just merely mentioned the concept that exercise might be cost-effective without actually conducting a CEA). Among the small number of existing CEA studies, almost all are conducted in other countries, including the United Kingdom, the Netherlands, Australia, etc.[73–79] Results consistently favor exercise programming, with a trend toward more formal and supervised programs being most cost-effective, perhaps because they garner the greatest physiologic benefit. Unfortunately, these results may or may not be applicable to the U.S. healthcare environment, given large differences in organization of care and payment structure. We found only one study that is based on U.S. patient-level data, with a focus on lung cancer survivors, that documented organizational-level cost-effectiveness of a lifestyle intervention that included exercise.[80]

It seems that despite international guidelines promoting the implementation of exercise in cancer treatment,[11,81] little is known about its cost-effectiveness. Understanding cost-effectiveness would facilitate incorporating exercise as a standard (and furthermore, reimbursable) form of treatment. It is unquestionably important to study the efficacy of exercise among cancer patients, given the high prevalence of cancer and far-reaching benefits of exercise. Nevertheless, to ensure the feasibility and economic sustainability of the exercise intervention, formal CEA is essential. Recent data from an uncontrolled pragmatic exercise oncology trial supports further economic evaluation of exercise oncology programming. The intervention cost approximately $191/patient, and the authors observe cost savings of $3,513 when comparing emergency department and hospitalization costs for patients who receive a consultative intervention (described earlier) as compared with matched comparison patients.[82]

35.4 PHYSICAL ACTIVITY BEHAVIOR CHANGE

35.4.1 Epidemiology of Physical Activity

The fight against cancer is a long-term public health issue in which physical activity plays an important part. The prevalence of physical inactivity among cancer-free American adults has reached 25% in the last few years.[83] The U.S. Department of Health and Human Services has identified, however, that approximately 80% of men and women are insufficiently active in the general population.[84] There is an equally frightening observation in children and adolescents.[85,86] Low levels of physical activity have been associated with chronic diseases, such as cardiovascular diseases

The Exercise in Cancer Evaluation and Decision Support - Survivor (EXCEEDS-S) Tool

Directions: Answer "yes" or "no" to the questions below. When you answer "yes", review the corresponding recommendation. Use the ACSM Exercise is Medicine, Moving Through Cancer registry[2] to locate a program near you.

Note: Always discuss with your doctor before starting a new exercise program.

Question	Answer	Recommendation
1. Do any of the following limit your ability to complete daily activities including work, hobbies, home care, socializing, and caring for yourself or loved ones? ☐ Difficulty with any of the following activities: • getting in or out of a vehicle, or using public transportation • walking one block without using a mobility aid like a cane or a walker • moving or reaching with your arms ☐ Difficulty being without a caregiver or another person who can assist you with activities ☐ New or worsening of any of the following conditions: • muscle weaknesses or coordination • difficulty with eating or drinking • difficulty with memory, multitasking, or thinking • numbness or loss of sensation in feet or hands • dizziness or blurred vision, or feeling lightheaded or disoriented ☐ Moderate to high pain that you rate as 7 out of 10 (0 = no pain, 10 = highest pain) ☐ Moderate to high fatigue that you rate as 7 out of 10 (0 = no fatigue, 10 = highest fatigue)	**Yes** **No**	**Outpatient cancer rehabilitation**
Continue to the next section if you answered "no" above or if there are no recommended programs in your area		
2. Have you fallen in the past 6 months?	**Yes** **No**	**Clinically supervised exercise program**
3. In the past 3 months, have you had any of the following cancer treatments? ☐ Surgery ☐ Stem cell transplant ☐ Chemotherapy ☐ Targeted therapy or immunotherapy ☐ Radiation therapy or brachytherapy	**Yes** **No**	
4. In the past week, have you experienced any of the following conditions? ☐ Mild daily fatigue that you rate as 3 to 6 out of 10 (0 = no fatigue, 10 = highest fatigue) ☐ Tingling sensation or loss of feeling in your feet or hands ☐ Difficulty with memory, multitasking, or thinking ☐ Dizziness after you stand up from either sitting in a chair or from lying down ☐ Nausea or frequent vomiting/diarrhea that interferes with daily activities ☐ Frequent feelings of dehydration ☐ Loss or gain of more than 5% body weight ☐ Lack of voluntary control over urination or defecation (incontinence) ☐ Persistent heaviness or swelling in your arm(s), leg(s), or trunk (lymphedema) ☐ Immunosuppression due to anemia, neutropenia, or thrombocytopenia	**Yes** **No**	
Continue to the next section if you answered "no" above or if there are no recommended programs in your area		
5. Do you currently have or are you planning to receive a catheter? *Including but not limited to: peripherally Inserted Central Cather (PICC), port, intraperitoneal catheter, or ostomy*	**Yes** **No**	**Cancer-specific community-based exercise program**
6. Confidence for independent exercise *Would you describe yourself as "highly confident" that you will exercise at moderate or vigorous intensity for 30 minutes, at least 3 times a week, for the next 12 weeks without receiving support from an exercise professional?*	**Yes** **No**	
Continue to the next section if you answered "no" above or if there are no recommended programs in your area		
Independent exercise *Try to do at least 150 minutes of moderate-intensity physical activity every week* *Examples: brisk walk, water aerobics, casual biking, doubles tennis*

FIGURE 35.6 Validated triage tool "The Exercise in Cancer Evaluation and Decision Support - Survivor (EXCEEDS-S) Tool." (From Covington, K. R., Marshall, T., Campbell, G., Williams, G. R., Fu, J. B., Kendig, T. D., ... & Pergolotti, M. (2021). Development of the exercise in cancer evaluation and decision support (EXCEEDS) algorithm. ***Supportive Care in Cancer***, 29(11), 6469–6480. Reproduced by permission of Springer Nature.)

and cancer.[87] According to the World Health Organization, sedentary behavior is the fourth leading risk factor for death worldwide and is responsible for almost a quarter of cancers.[88] A cohort study in 334,161 European men and women showed that physical inactivity was a larger contributor to all-cause mortality than obesity (considered to be one of the most important risk factors for cancer).[89] The authors also suggested that "efforts to encourage even small increases in activity in inactive individuals may be beneficial to public health,"[89] reinforcing the benefits of exercise for the general population.

From our youngest age, physical activity should be part of our good habits. Children need more daily physical activity than adults to ensure optimal development. It is during childhood that the chronic adaptations associated with training are intended to be more effective and beneficial in the long term (i.e., adulthood).[90] Physical activity during childhood and adulthood has been described as a key health behavior to prevent chronic diseases.[91] While it was historically recommended to avoid physical activity when diagnosed with an illness, the safety of exercise for those with chronic conditions, including cancer, has been established, and the following message is now highly endorsed by the Centers for Disease Control and Prevention: "Some activity is better than none."[92]

In oncology, physical activity programs are designed to support patients by enhancing their health behavior in order to replace their unhealthy lifestyle habits or risky health behaviors. One of the challenges is to design a program that will favor patients' adherence to physical activity, whether during or after cancer treatments. Several factors can predict physical activity adherence, such as baseline physical fitness, pretreatment fatigue level, treatment-related mood disturbance, and marital status.[93] Nevertheless, self-efficacy, or patients' belief that they can change their behavior, is a key concept in motivating the patient to maintain their behavior.[94] It has been shown that individuals who have control over their behavior are more likely to engage in physical activity than those who do not have control.[95,96] This aspect is reinforced in pediatric patients, especially in adolescents, who want to have control of their lives and indirectly, of their behavior. To help their patients, researchers and clinicians have started implementing lifestyle interventions. These types of interventions provide information to patients regarding physical activity–related benefits, goal-setting, self-monitoring, and how to increase physical activity.[97]

Patients' knowledge about the benefits of physical activity is also an important key factor in their adherence to this health behavior. Patient education starts by explaining why physical activity is important and how it can be done and adapted to patients' health status. For some patients, physical activity is construed as engaging in a sport or competition instead of being performed for one's health. For example, walking is associated with a reduction of 11% in all-cause mortality, 20% in cardiovascular mortality, and 9% in cancer mortality.[20,98] The U.S. Department of Health and Human Services made a call to action in 2015, focusing on walking to help Americans increase their moderate-to-vigorous physical activity, and prevent and reduce their risk of chronic diseases and premature death.[99]

Therefore, clinicians should encourage their patients to engage in regular physical activity, in addition to enable patients' self-efficacy and enjoyment.[100] Developing fun, safe, appropriate, and personalized physical activity programs is not just for children. Doing so is important for everyone to increase adoption of and adherence to better long-term health behaviors. To reach this goal, a key factor is working with patients, and for them to be actors in their changes and in overcoming the barriers they face.

35.4.2 Barriers to Physical Activity

Barriers to physical activity must be understood and recognized to better understand and support patients with cancer and survivors. As also observed in the general population, many patients, regardless of their age, are sometimes unable to maintain regular daily physical activity, affecting their quality of life and wellbeing. In adult cancer survivors, the most common barriers are difficulty getting motivated, lack of self-discipline, health issues, and adverse effects from treatment, such as fatigue and pain.[101,102] Similar observations are reported in childhood cancer survivors. Almost 50% report that they are "simply too tired" to be active, while nearly 22% report that "pain prevents them from being active."[103]

Cancer-related fatigue is a common and multifactorial symptom, and above all, the most debilitating side effect during and after treatment. All cancer survivors (children, adolescents, and adults) will experience this symptom at least once in their life. The National Comprehensive Cancer Network defines cancer-related fatigue as "a distressing, persistent, subjective sense of physical, emotional, and/or cognitive tiredness or exhaustion related to cancer or cancer treatment that is not proportional to recent activity and interferes with usual functioning."[104] This symptom cannot be resolved by sleep and is a major barrier to maintaining regular physical activity in patients with cancer and survivors. In 646 cancer survivors, cancer-related fatigue was significantly associated with depressive symptoms, anxiety, sleep difficulties, adjustment to the illness, pain, dyspnea, age, and lack of social support.[105] Regular physical activity has been shown to have benefits for cancer-related fatigue.[34]

Cancer-related pain is also a barrier to adherence to regular physical activity. The International Association for the Study of Pain defines pain as "an unpleasant sensory and emotional experience associated with, or resembling that associated with, actual or potential tissue damage."[106] Pain in oncology is a complex phenomenon, and the perception of pain varies from one patient to another. Its evolution and the effectiveness of treatments to address patients' pain depend on many biological, psychological,

and social factors.[107] It is reported that all cancer patients will, at some point in their lives, have a painful experience. A report from the St. Jude Lifetime Cohort Study observed that almost one in two adult survivors of childhood cancer still experience pain.[108] Physical activity, in addition to pain medication, has strong potential to reduce patients' pain.[109]

Thus, various obstacles and barriers can prevent the practice and maintenance of a physically active lifestyle. In order to enhance patients' health and physical activity, these barriers have to be recognized, especially since a lot can happen in the life of a patient living with and beyond cancer. Time restrictions due to medical examinations and school commitments can also prevent regular physical activity, as observed in children and adolescents diagnosed with cancer.[110]

35.4.3 Health Equity and Physical Activity

Physical activity has not always been available to everyone, and while one might think it is now accessible to everyone, it still is not. The Centers for Disease Control and Prevention published the U.S. physical inactivity prevalence maps by race and ethnicity and showed that non-Hispanic Asian adults had the lowest prevalence of physical inactivity (~20%), followed by non-Hispanic Whites (23%), non-Hispanic American Indians/Alaska Natives (~29%), non-Hispanic Blacks (30%), and Hispanic adults (~32%).[111] It has also been reported that non-Hispanic Blacks, Hispanics and other non-White adults, people with lower levels of education, and unemployed individuals have lower levels of leisure-time physical activity.[112] Thus, enhancing physical activity participation requires a comprehensive effort, and personal beliefs and awareness are vital to consider when physical activity programs are designed in oncology settings. The Centers for Disease Control and Prevention also highlight that the place of residence plays an important role in increasing the prevalence of physical inactivity.[111] The lack of safe space, time, and social support has also been pointed out by their recent report.[111]

The distinction between sex and gender should also be considered when establishing a physical activity program in oncology. In childhood cancer survivors, it has been observed that female survivors have a lower cardiorespiratory fitness level than male survivors, and that this difference increases with childhood cancer survivors' age.[113] Cardiorespiratory fitness is an important parameter in exercise physiology and an excellent predictor of cardiac health in patients with cancer. Efforts must be pursued to make physical activity equally accessible to all genders.[114] To support our point, a systematic review shows gaps in the understanding of cancer among LGBTI adolescents and young adults. This review discusses in particular the unique disparities in access to healthcare in this population.[115] Clinicians and researchers have the opportunity to avoid making this mistake in exercise and oncology settings.

35.5 Opportunities in Physical Activity and Cancer Research

In the last two decades, evidence on the benefits of physical activity on health has caught the attention of the general population. The 2018 U.S. physical activity guidelines for Americans document where the U.S. government stands on physical activity, sedentary behavior, and health.[7] Nevertheless, the implementation of physical activity in standard patient care in oncology is still in its early stages. Important work remains to be done in the field of implementation and health services research to make physical activity available as a standard of care in patients with cancer and survivors. To reach this goal, clinicians, public policy, and researchers must work together for the benefit of all.

The exercise oncology field is well recognized as a multidisciplinary field where collaborations between researchers and clinicians are needed.[116] It is also a field that could benefit from more multi-site projects to extend the scope of research findings. A question that the scientific community regularly asks is related to the significance of results and their generalizability to other populations. In many cases, samples are too small to answer this question positively, and significance and generalizability could depend on the research focus. In adolescent and young adult patients with cancer, the literature points out the heterogeneity of samples and the small sample sizes. Multi-site projects could help recruit more participants. They could also help to have more exercise oncology clinical trials that are representative of the ethnicity, race, sex, and geographical location of patients diagnosed with cancer.

Implementing multi-site multidisciplinary projects could be a great way to address gaps in knowledge and also for collaborations between different research fields. For example, chemotherapy-related cardiotoxicity is well documented in childhood cancer survivors,[117] and the fields of exercise and cardio-oncology, mainly in childhood cancer survivors, would benefit from working together. Indeed, subclinical cardiac dysfunction has been reported only a few years after the end of cancer treatments,[118] and it could be prevented by engaging in regular physical activity.[119,120] Unfortunately, this seems to be just the tip of the iceberg, and Figure 35.7 emphasizes the need for the fields of exercise and cardio-oncology to work together; physical activity having shown promising benefits on chemotherapy-related cardiomyopathy both during and after treatments.[121–123] This is only one example of the need for multidisciplinarity to make forward progress in the field of exercise oncology.

To address these complex challenges between fields, transdisciplinary research is required, along with more efficacy research to better understand biological mechanisms in human subjects.[26] And, it is time to translate animal research to exercise oncology clinical trials. The ACSM Roundtable has nicely highlighted that there is insufficient evidence in human subjects regarding the benefits of exercise and cardiotoxicity, chemotherapy-induced peripheral

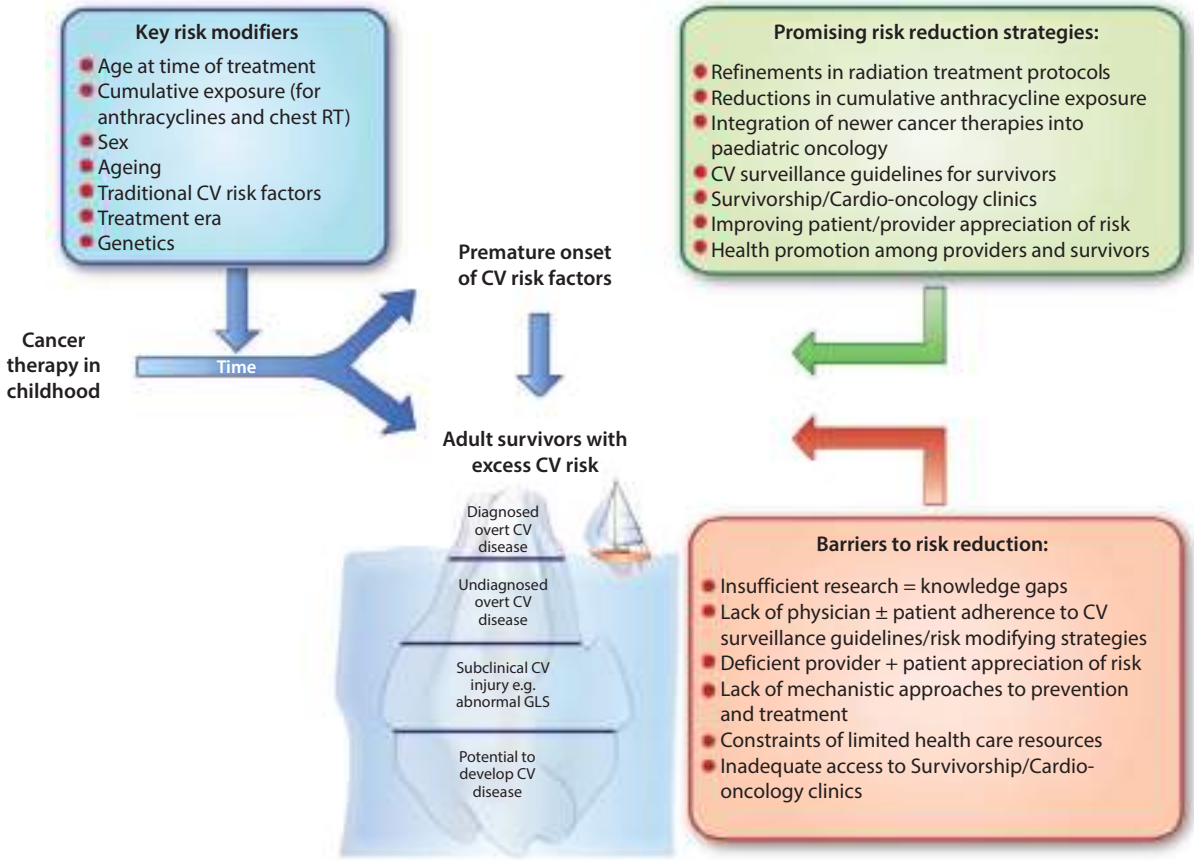

FIGURE 35.7 Association between cancer treatments and excessive cardiovascular disease risk. (From Groarke, J. D. (2018). Cardiovascular vulnerability of childhood cancer survivors: time to progress from risk observation to risk modification. ***European Heart Journal***. Reproduced by permission of Oxford University Press.)

neuropathy, cognitive function, falls, nausea, pain, sexual function, and treatment tolerance, despite animal studies that have presented promising results.[11] The complexity of what needs to happen next is an excellent opportunity for clinicians and researchers to work together in order to generate more research questions and answers in the field of exercise oncology.

35.6 CONCLUSION

Physical activity prevents and manages chronic diseases, in addition to providing a myriad of other physical and mental health benefits. Clinicians and researchers have been working together to demonstrate that engaging in regular physical activity and adopting a healthy lifestyle has benefits for patients living with and beyond cancer. In the last decades, multiple systematic reviews of randomized controlled trials or individual randomized controlled trials have been published and reviewed to prompt strong international exercise guidelines in exercise, as presented by the ACSM. Nevertheless, while the field of exercise and oncology in adults continues to progress and nears the discovery of biological mechanisms in exercise and cancer, the field of exercise and pediatric oncology is still in its early stages, and promising findings have been reported. This chapter has presented the state of evidence-based medicine in exercise, in addition to suggesting great opportunities for future research in exercise oncology. Important challenges remain for clinicians, including the key role that they can play in making exercise the standard of care.

CLINICAL APPLICATIONS

- Although significant progress has been made in understanding biological mechanisms, more research is needed to understand these mechanisms in exercise and cancer, in particular in human subjects.
- Triage referral and recommendations in exercise oncology remain a challenging issue in making exercise the standard of care.
- Clinicians and researchers have the opportunity to work together to reduce disparities in access to exercise in the healthcare setting.
- Emerging evidence suggests that exercise in oncology might be cost-effective; however, more research is required.

36 The Health Consequences of Tobacco Use and Addiction: Assessment and Treatment

Jonathan Foulds, MAppSci, PhD

KEY POINTS

- Tobacco smoking is addictive and harmful to every organ in the body, and continued smoking causes the loss of an average of ten years of life.
- Clinical practice guidelines recommend implementation of the "5 As" with every smoker.
- The "5 As" are Ask, Advise, Assess, Assist, and Arrange (a follow-up).
- Meta-analyses have demonstrated the efficacy and safety of numerous pharmacotherapies and different types of behavioral support or counseling.
- Because tobacco smoking is so harmful, even brief interventions with smokers remain among the most cost-effective healthcare interventions (top equal with childhood immunization).

36.1 CIGARETTE SMOKING AND HEALTH

At the time of the landmark 1964 U.S. Surgeon General's report on tobacco and health, over 50% of men and 30% of women were cigarette smokers.[1] Substantial public health efforts over decades (including educating the public about the health effects, increases in cigarette taxes, smoke-free air legislation, age-of-sale laws, etc.) have succeeded in consistently reducing the prevalence of cigarette smoking, such that by 2020, 14% of men and 11% of women in the United States smoke cigarettes "every day or some days." In addition, 3.7% used electronic cigarettes, 3.5% smoked cigars, and 2.3% used smokeless tobacco products.[2]

While the prevalence of cigarette smoking has been declining in most high-income countries over recent decades, it remains a major cause of premature death and disease. It has been estimated that tobacco smoking causes over 400,000 premature deaths per year in the United States,[3,4], and over 6 million premature deaths per year worldwide.[5,6] In addition, for every case of premature death caused by tobacco smoking each year in the United States, there are approximately 20 cases of non-fatal serious smoking-caused illness in someone who does not die in that year.[7] The vast majority of these illnesses (59%) are chronic respiratory diseases such as chronic obstructive pulmonary disease (COPD).

The net effect of these smoking-caused diseases is that the continuing smoker is likely to die an average of ten years earlier than a never-smoker.[8] The approximate doubling of mortality risks for smokers is evident at age 50 (6% of smokers have already died, versus 3% of never-smokers) and continues past age 70 (by which time 42% of smokers have died, versus 19% of never-smokers).

While over 90% of smokers are aware that smoking cigarettes causes lung cancer (with a 20-fold excess risk), there is less awareness that smoking increases cancer risks at 9 other sites (mouth, esophagus, stomach, pancreas, larynx, cervix, bladder, kidney, and acute myeloid leukemia). The age-adjusted risk of death from COPD is tenfold higher for smokers than for never-smokers. This effect is relatively easy for smokers to understand, but there is less awareness that smokers have approximately threefold the risks of death from ischemic heart disease, stroke, and atherosclerosis at ages 35–64.[4]

36.2 HEALTH BENEFITS OF SMOKING CESSATION

The 1990 U.S. Surgeon General's report reviewed the health benefits of ceasing tobacco use and concluded that smoking cessation has major health benefits for men and women of all ages. For example, smokers who quit smoking by age 50 have one-half the risk of dying in the next 15 years, compared with continuing smokers.[9] The timescale for reduction in risks of disease after smoking cessation varies with each disease and even with the stage of the disease. Thus, the excess risk of death from coronary heart disease will be cut in half within a year of stopping smoking, but the same level of risk reduction may take 10–15 years for lung cancer.[9]

Lung function declines with age after reaching adulthood in non-smokers, but it declines at a significantly faster rate for smokers. However, when a smoker stops smoking, the rate of decline of lung function normalizes to a rate similar to that for never-smokers. Figure 36.1 is based on data from various epidemiological studies[10–14] but is primarily designed to help clinicians educate people who smoke about the potential benefits for lung function from

DOI: 10.1201/9781003227793-42

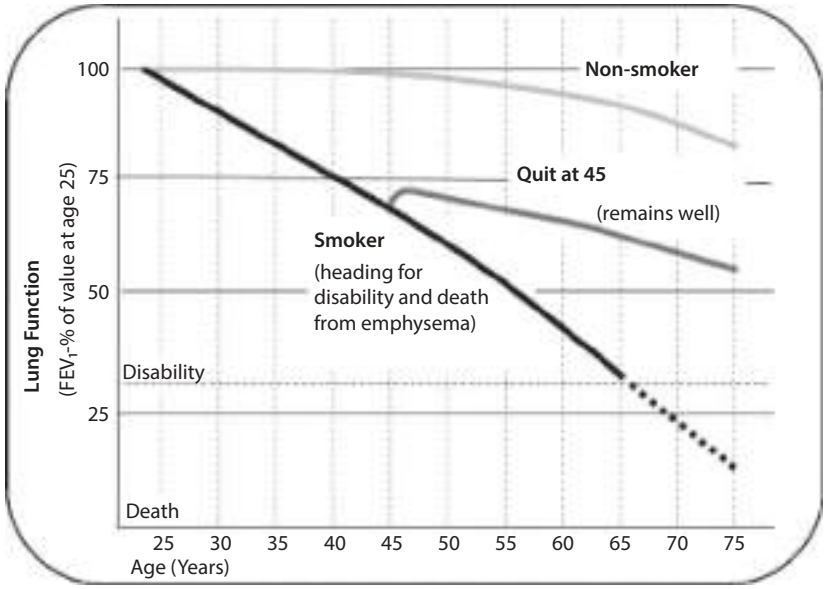

FIGURE 36.1 Schematic diagram illustrating effects of smoking cessation on lung function.

successfully quitting smoking and the likelihood of a small improvement in lung function followed by a significantly slower age-related decline.[14]

Overall, for most people who smoke cigarettes, the single best thing they could do to improve their health is to quit smoking completely. In the United States, the tobacco treatment strategy often referred to as "the 5 As" has been recommended in treatment guidelines since 2008.[15] The five steps proposed by this mnemonic are summarized here:

1. ASK about tobacco use.
2. ADVISE about the importance of quitting.
3. ASSESS motivation to change and dependence.
4. ASSIST to quit by providing treatment.
5. ARRANGE a follow-up.

The rest of this chapter will provide suggestions of practical evidence-based methods for implementing the 5 As.

36.3 "ASK": SCREENING FOR USE OF TOBACCO OR NICOTINE PRODUCTS

Screening: While cigarettes remain the nicotine products most commonly used by adults, other products and dual product use have become very common among young people over recent decades. In 2020, 17.3% of current tobacco users reported using two or more products.[2] For this reason when screening for current tobacco use, it is important to ask about all nicotine product use, using questions like the following:

(a) Have you used a nicotine or tobacco product some days or every day in the past 30 days? Yes No
(b) Which of the following products have you used some days or everyday in the past 30 days?
(a) *Cigarettes (manufactured or "roll-your-own" cigarettes)*
(b) *Cigars (e.g., large cigar or little cigar/cigarillo)*
(c) *Smokeless tobacco (e.g., snuff, chew, or snus)*
(d) *Electronic cigarette (e.g., Juul, NJOY, nicotine vape, mod device, etc.)*
(e) *Hookah or waterpipe*
(f) *Pipe*
(g) *Heat-not-burn cigarettes (e.g., electronic product that heats tobacco without burning it, e.g., IQOS)*
(h) *Nicotine pouches (oral nicotine pouch product not containing tobacco, e.g., Zyn, On!, etc.)*
(i) *Nicotine replacement therapy products (e.g., nicotine patch, gum, lozenge, inhaler, spray)*
(j) *Traditional tobacco product (e.g., gutka or paan from southeast Asia, or Iqmik from Alaska)*
(k) *Other nicotine products (please list type of products you have used not mentioned above).*

36.4 "ADVISE": BRIEF MOTIVATIONAL INTERVENTIONS AND ADVICE

It may seem more sensible to conduct a more detailed assessment prior to giving smoking cessation advice. This also relates to the fact that some aspects of assessment may also contain a motivational component. For example, the measurement of exhaled carbon monoxide (eCO) is often used as an assessment of recent smoke intake, but it can also be considered as one of many potential interventions designed to enhance motivation to take steps toward quitting smoking. Motivational Interviewing (MI) is a directive patient-centered style of counseling, designed to help people to explore and resolve ambivalence about behavior change. For some patients, assessment of their eCO, dependence, motivations, barriers, etc. can provide information that can be discussed in a way that may help increase their motivation to quit. However, the evidence of efficacy of MI

or Motivational Enhancement Therapy in terms of having a direct effect on boosting quit rates in clinical trials is not strong.[16]

Many busy clinicians now choose to ask questions designed to assess motivation to quit (e.g., "how much do you want to quit smoking?") *after* they have first of all delivered a positive statement of advice, emphasizing the importance of treatment. Here is an example of a brief, simple piece of advice that can be provided after identifying that a patient is a current tobacco smoker:[17]

> *"As your clinician, I want you to know that the single best thing you can do for your health right now is to quit smoking. Every year that you continue smoking likely reduces your healthy lifespan by around 3 months. I understand that it may not be an easy thing to do, but there are now treatments that have been shown to be effective, and I am familiar with those treatments and can help provide them. I believe it is very important for your health that we get started on this."*

When this type of accurate but encouraging advice is followed up with a question about interest in quitting, it is more likely to receive a positive response, which can lead directly to a more detailed assessment and discussion about treatment options.

36.5 "ASSESS": ASSESS FREQUENCY OF USE

Once the products being used have been identified, it is important to assess the frequency of use of every product that is currently being used, using the following questions:

> *"On how many days out of the past 30 did you use xxx product?"*
>
> *"In the past 30 days, how many cigarettes have you smoked per day, on average?"*

36.6 ASSESSING ADDICTION/DEPENDENCE

Nicotine addiction, like other psychoactive drug addictions, is characterized by continued compulsive nicotine seeking and use, which would be very difficult to control were the person to seriously try to stop using or believe that continued use may be harmful.

With regard to cigarette addiction (by far the most widely used nicotine product across the world), the question of attempting to quit, or being aware of the health risks, does not usually arise. Almost all cigarette smokers are aware that cigarette smoking can cause serious diseases like lung cancer, and the average 40-year-old smoker who started in their teens will have made more than 20 failed quit attempts.[18] Nicotine addiction differs from some other addictions in that there is often an unpleasant withdrawal syndrome on abruptly ceasing nicotine use, characterized by dysphoric mood, increased appetite, and poor concentration, that peaks in the first week and has largely resolved within three to four weeks of complete abstinence.

Some common characteristics of other addictions are less prominent for nicotine addiction because in most contexts, nicotine use is legal, and because nicotine use does not typically cause a general impairment in cognitive abilities or consciousness. For these reasons, nicotine addiction is less commonly accompanied by legal problems, loss of employment, or loss of the right to drive a motor vehicle.

With this definition, nicotine addiction can be identified by its behavioral characteristics even if the person has not yet made a serious quit attempt or has not yet experienced a serious health problem caused by their nicotine or tobacco use.

36.6.1 Assessment Using Criteria from the 5th Edition of the Diagnostic and Statistical Manual of Mental Disorders

Whereas DSM-4 required at least 3 out of 7 criteria for the diagnosis of tobacco dependence, DSM5 requires only 2 out of 11 criteria to meet diagnostic criteria for tobacco use disorder (TUD). The 11 basic criteria for DSM-5, translated into an easy-to-administer questionnaire, are shown in Table 36.1. TUD is considered of "mild" severity when two or three criteria are met, "moderate" severity when four or five criteria are met, and "severe" when six or more criteria are met.

An analysis of a representative sample of 6,793 exclusive cigarette smokers found a close relationship between cigarette smoking frequency and severity of DSM5 TUD (as assessed by the number of symptoms endorsed).[19] As shown in Figure 36.2, even among those who smoke less than weekly, 18% of those who typically smoke only one or two cigarettes on a smoking day met TUD criteria. Figure 36.2 shows a clear relationship between frequency of cigarette smoking and the proportion of cigarette smokers meeting DSM-5 TUD criteria, which becomes relatively flat above ten cigarettes per day (CPD), at around 90%. Notably, almost two-thirds of those smoking only one to four CPD met TUD criteria, as did the majority (64.1%) of those smoking on three to six days per week and a substantial minority (26.3%) of individuals who smoke less than once per week. DSM-5 states that TUD is considered of "moderate" severity when four or more criteria are met, and this study found that this is typically at ten or more cigarettes per day.

Question	Answer	Score
How soon after you wake up do you smoke your first cigarette of the day?	Within 5 minutes	3
	6–30 minutes	2
	31–60 minutes	1
	>60 minutes	0
How many cigarettes per day do you smoke?	<10	0
	11–20	1
	21–30	2
	>31	3

The most widely used questionnaire measure of cigarette dependence in smoking cessation research is the

TABLE 36.1

Questions That May Be Used to Assess DSM-5 Tobacco Use Disorder. There Are 11 Items; Each "Yes" on Items 1–10 Counts as One Criterion Met, and at Least 3 "Yes" Answers on Item 11A or a "Yes" on 11B Counts as One Criterion Met. The Total Severity Score Is Number of Criteria Met Out of 11.

The following questions are about experiences that some people have had when using cigarettes (or insert other nicotine product here). Please answer "yes" to each question if this has happened to you in the past 12 months:

1. Did you have a period when you often used your cigarettes more or longer than you intended to?
   Y N
2. Did you more than once TRY to stop or cut down on your cigarette use but found you couldn't do it?
   Y N
3. Did you have a period of time when you spent a lot of time making sure you had enough cigarettes available?
   Y N
4. Did you have a very strong desire or urge to smoke a cigarette?
   Y N
5. Did you continue to use your cigarettes even though it was causing you problems at school or home or work?
   Y N
6. Did you continue to smoke your cigarettes even though it was causing you problems in one or more relationships?
   Y N
7. Did you give up on any activities that you were interested in or that gave you pleasure because cigarettes were not permitted at the activity or because you had spent required money on cigarettes instead?
   Y N
8. Did you more than once use a cigarette in a situation that could have been dangerous, for example, driving a car, riding a motorbike, using machinery, boating, etc.?
   Y N
9. Did you continue to use cigarettes even though you knew it was causing you a health problem or making a health problem worse?
   Y N
10. Did you increase your cigarette use because the amount you used didn't give you the same effect anymore?
    Y N
11. (a) When you cut down on heavy or prolonged use of cigarettes or stopped smoking for over 24 hours did you have any of the following withdrawal symptoms:(*3 or more withdrawal symptoms required)*
    a. Irritability, frustration, or anger Y N
    b. Feeling tense or anxious Y N
    c. Difficulty concentrating Y N
    d. Increased appetite Y N
    e. Feeling restlessness Y N
    f. Feeling low or depressed Y N
    g. Had difficulty sleeping Y N
1. 11 (b) Did you continue smoking in order to avoid experiencing these types of withdrawal symptoms that may occur if you quit or cut down significantly?
   Y N

Fagerstrom Test for Cigarette Dependence (FTND). The FTND is a six-item questionnaire producing a score from 0 to 10. Numerous studies have found that a baseline FTCD score is moderately predictive of which smokers are more likely to succeed in quitting during a quit attempt (i.e., the lower the dependence score, the greater the chances of quitting smoking). The score also has significant correlations with severity of withdrawal symptoms and biochemical measures of nicotine exposure (e.g., plasma cotinine). Many studies have found that the two items in the FTND that measure the "**Heaviness of Smoking Index**" (cigarettes per day, and time to first cigarette of the day) perform about as well as the total score from six items in predicting quit success rates.[20,21]. So, a simple, practical way to assess cigarette addiction is to use the Heaviness of Smoking Index, such that a score of zero implies very low or no addiction, and a higher score implies more severe addiction.

36.6.2 Assessing Motivation to Quit

It is respectful of patient autonomy to ask about the level of interest in quitting smoking with a few straightforward questions:

> e.g., *"How much do you want to stop smoking?" (a) Not at all, (b) I am somewhat interested, (c) I am very much interested in quitting soon.*

Previous models of "stage-matched" interventions[22] have intuitive appeal to practitioners, but the strict interpretation of the model has been criticized on numerous grounds.[23] Perhaps the main problem has been the implication that if a patient states (or more commonly, checks a box implying) that they do not want to quit smoking in the next few months, then no further attempts to encourage the patient to quit should be pursued at that time. This may be an opportunity

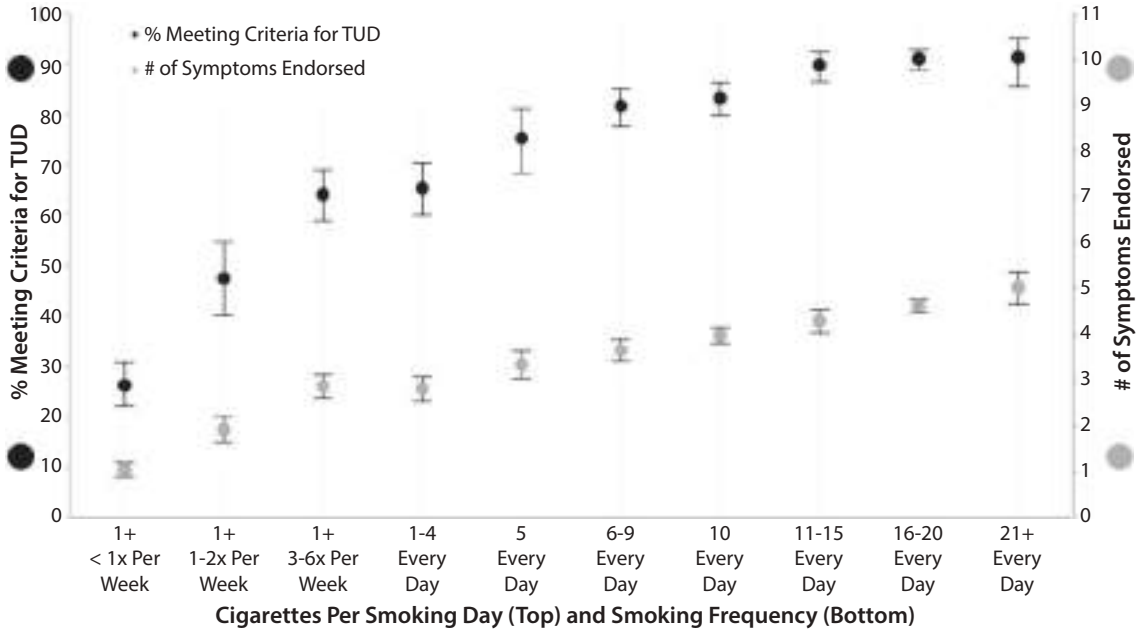

FIGURE 36.2 Percentage of smokers meeting DSM-5 criteria for Tobacco Use Disorder and mean number of DSM-5 criteria endorsed, by cigarette smoking frequency, in a large representative sample of U.S. exclusive cigarette smokers (n = 6,793). (From Oliver. J. and Foulds, J., ***Am. J. Prev. Med.***, 60(5), 726–728, 2021.)

missed, as such models do not reflect the frequent observation that people sometimes change their behavior and plans quite suddenly, and sometimes in response to seemingly small triggers.[24] So, modern models of assessment and intervention on tobacco use see it as more effective to identify motivational tools and offer evidence-based interventions that give some reasonable hope of success if an attempt at quitting or reducing smoking is to be pursued.

36.6.3 Biochemical Assessment

While numerous measures relating to tobacco use and toxicant exposure can be collected from body fluids (e.g., cotinine as a measure of nicotine exposure, or NNAL as a measure of carcinogen exposure), the most practically useful biochemical measure is assessment of exhaled carbon-monoxide (eCO). Exhaled CO can be easily measured in a few minutes using a relatively inexpensive portable device and has become a widely used method for assessing tobacco smoke exposure and validating self- reports of smoking cessation.[25] The typical eCO of smokers is around 20 ppm but can range from 5 to 80 ppm depending on the heaviness and recency of smoking. Over 90% of non-smokers in a low pollution environment have an eCO lower than 5 ppm, and most are in the range 0–3 ppm. A major advantage of routine use of eCO monitors in tobacco dependence treatment is that patients are more likely to be completely honest about their smoking behavior, as they know it will likely be measured by the CO monitor. For some people, the measurement of a high baseline eCO, then being informed that it will likely be much lower at subsequent visits after smoking cessation, can help boost motivation and attendance at treatment sessions. It can serve a similar monitoring and motivational function as measurement of blood cholesterol, blood pressure, or body weight. For example, here is a script used in one study of group smoking cessation treatment:[14]

> *"Your exhaled carbon-monoxide reading was 20. This is much higher than that of a non-smoker (typically 0–4). It means that the carbon-monoxide from inhaled cigarette smoking is binding to the red blood cells that carry oxygen in your blood and displacing oxygen. This means that your heart has to do more work to supply oxygen to your body, and it is part of the reason why smoking causes serious cardiovascular diseases such as heart attack or a stroke. It is very important to get that number down. The good news is that when you stop smoking the concentration of carbon-monoxide in your body will return to that of a never-smoker within a week. So it is really important that you attend all the stop-smoking group meetings, use the nicotine patches and succeed in stopping smoking. We will measure your CO levels at every appointment and you will be able to see the improvement when you quit smoking."*

36.7 CHRONIC CARE MODEL: TREATING TOBACCO DEPENDENCE AS A LIFE-THREATENING CHRONIC ILLNESS

An important part of modern conceptualizations of tobacco treatment is to adopt a chronic care approach. Tobacco use is seen as a chronic illness (much like asthma or diabetes), and treatment is seen as a long-term process, with the clinician offering to assist in the process for as long as it takes.[17,26] It is understood that changing the plan may be necessary at times, and every day without tobacco use is counted as a success (as compared with conceptualization of a single attempt that

either succeeds or fails in quickly resulting in complete abstinence). In this model, it is emphasized that although a target "quit date" may be arranged, the clinician explicitly expects that it may take a few months or longer before the patient feels confident in their abstinence from tobacco.

36.8 EVIDENCE-BASED INTERVENTIONS: ASSIST

The evidence is very clear that a combination of behavioral support plus pharmacologic therapy results in the highest quit rates.[15] The evidence suggests that there is a dose–response effect for the number of counseling sessions from a trained counselor (at least up to four or five sessions), and also that either varenicline or combination nicotine replacement therapy (NRT) (typically the nicotine patch plus a short acting NRT product like gum, lozenge, nasal spray, or inhaler) has the best outcomes.[27] Therefore, for smokers who have been assessed as being at least moderately dependent, they should be encouraged to use the most intensive level of counseling and pharmacotherapy available. However, in practice, many countries' healthcare systems have limitations on the counseling services available, and there may also be limitations on the types of medication the individual is willing to use, based on prior experience, cost, side effects, etc.

36.8.1 Summary of the Evidence for Various Pharmacotherapies for Smoking Cessation

Meta-analyses carried out for the 2008 U.S. Clinical Practice Guideline on Tobacco Use and Dependence[15] and subsequent updates carried out by the Cochrane Tobacco Addiction review group (and others) have confirmed a fairly consistent pattern of results from randomized clinical trials.[27]

Pharmacologic methods

Method (number of trials)	Versus placebo unless otherwise noted Risk ratio (95% CI)
First-line pharmacotherapies	
Nicotine replacement	
Any NRT product[133]	1.55 (1.49–1.61)
Combination (versus individual products(	1.25 (1.15–1.36)
Patch[51]	1.64 (1.53–1.75)
Gum[56]	1.49 (1.40–1.60)
Lozenge[8]	1.52 (1.32–1.74)
Inhaler[4]	1.90 (1.36–2.67)
Nasal spray[4]	2.02 (1.49–2.73)
Varenicline[7,27]	2.24 (2.06–2.43)
Bupropion SR[45]	1.64 (1.52–1.77)

CI: confidence interval.
Source: adapted from Rigotti et al, 2022.[27]

These studies have found that all of the Food and Drug Administration (FDA)-approved nicotine replacement therapies, as well as bupropion and varenicline, increase the chances of patients achieving long-term abstinence (6–12 months or longer) as compared with placebo or no pharmacotherapy. However, it has become clear that varenicline is the most effective single pharmacotherapy, which is approximately equal to combination pharmacotherapies (e.g., nicotine patch plus nicotine gum), which is significantly more efficacious than any other single pharmacotherapy.

The clearest evidence for the superior efficacy of varenicline versus nicotine replacement therapy or bupropion was provided from the EAGLES randomized trial.[28] This trial is by far the largest placebo-controlled, double-blind randomized clinical trial comparing different medications head-to-head (n = 8,141) and also including a large group of people with a history of mental disorders (n = 4,116). It found that within both the psychiatric and non-psychiatric cohorts, varenicline produced superior quit rates to bupropion or the nicotine patch, even though both of these therapies had significantly higher quit rates than placebo, both at the end of drug treatment (12 weeks) and after 12 weeks of medication (24 weeks), as shown in Figure 36.3.[28]

The evidence is so strong for the safety and efficacy of these FDA-approved pharmacotherapies that it would nowadays be considered sub-standard treatment not to recommend pharmacotherapy when trying to treat tobacco dependence, outside potential patient choice or population groups without clear supportive evidence (e.g., minors, pregnant women, very light smokers [e.g., <5 cigarettes per day]).

36.8.2 Summary of Evidence of Efficacy of Various Behavioral Treatments

There is clear evidence that brief advice (lasting less than 15 minutes) can improve quit rates, largely by increasing quit attempts, and that more intensive individual and group counseling can provide higher quit rates. All these proven counseling modalities tend to produce higher quit rates when added to pharmacotherapy than either counseling or pharmacotherapy alone.

Efficacy of behavioral methods

Method (number of trials)	Versus minimal or usual care unless otherwise noted Risk ratio (95% CI)
Behavioral counseling	
Individual counseling[27]	1.57 (1.40–1.77)
Group counseling[13]	1.88 (1.52–2.33)
Telephone quit line counseling[13]	1.38 (1.19–1.61)
Clinician counseling	
Brief advice[17]	1.66 (1.42–1.94)
Brief counseling[11]	1.86 (1.60–2.15)
Brief counseling (versus brief advice)	1.37 (1.20–1.56)
Counseling added to pharmacotherapy[65]	1.15 (1.08–1.22)vs. pharmacotherapy alone

Source: adapted from Rigotti et al, 2022.[27]

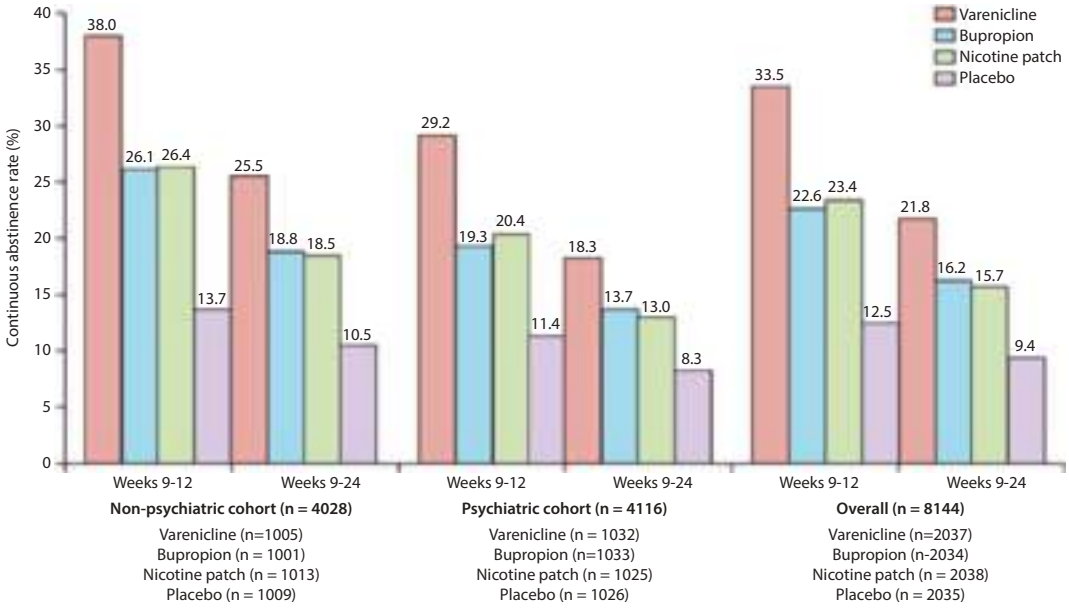

FIGURE 36.3 Continuous abstinence rates for weeks 9–12 and 9–24. Analyses based on the all-randomized population, in a randomized, double-blind, triple-dummy, placebo-controlled and active-controlled (nicotine patch; 21 mg per day with taper) trial of varenicline (1 mg twice a day) and bupropion (150 mg twice a day) for 12 weeks with 12-week non-treatment follow-up at 140 centers in 16 countries. (From Rigotti, N. et al., ***JAMA***, 327(6), 566–577, 2022.)

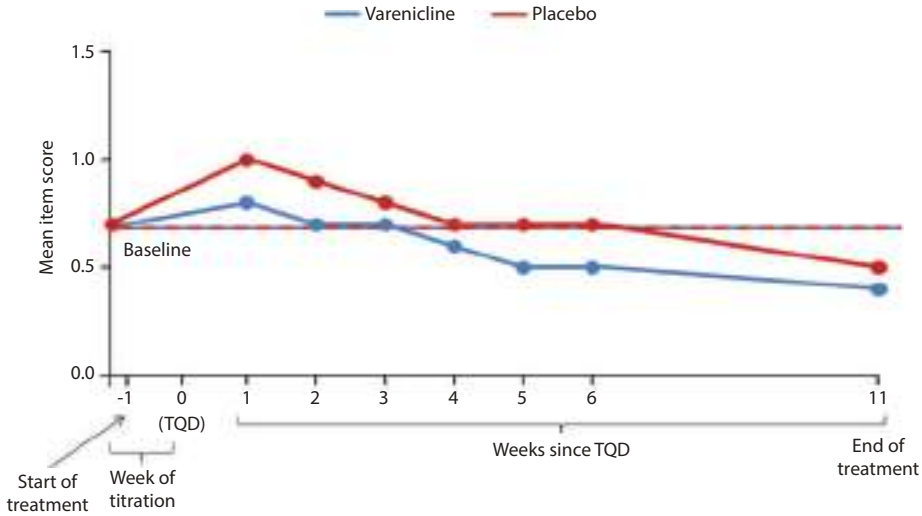
Although there are fewer studies or less clear evidence for other types of behavioral intervention, there is evidence to support the efficacy of interventions based on structured text messaging to cell-phones[29] as well as internet-based treatment[30] and real-time video counseling. There is also very solid evidence supporting the efficacy of financial incentives, although these can be practically difficult to implement.

Overall, it appears that most behavioral interventions that encourage a structured quit attempt and provide encouragement to persist with the quit attempt are likely to be helpful. Relatively intensive in-person interventions appear to result in the highest short-term quit rates (e.g. at one- to three-month follow-ups), but they also require relatively high motivation and time commitment on the part of patients, and so can be more difficult to implement in a manner that has "reach" in the sense of being able to help a large number of smokers in the local target community to quit smoking.

One aspect of smoking cessation treatment that appears to be fairly clearly supported in the literature is recommending a specific "target quit date" when the smoker will quit smoking completely, rather than having a more gradual reduction toward quitting.[31] Clinical experience also suggests that little is gained by including an extended "preparation" phase prior to attempting to quit completely, other than the allowing sufficient time for the patient to obtain and understand how to use adjunctive pharmacotherapy. While gradual reduction appeals to many smokers and makes intuitive sense, it is unclear why it appears to be less successful. It is possible that it simply delays the time frame when the individual actually quits, such that fewer smokers actually reach that point.



36.9 ADDITIONAL CONSIDERATIONS WHEN PROVIDING TOBACCO CESSATION INTERVENTIONS

There are additional components of tobacco cessation treatment that are not yet very clearly supported by evidence but are becoming more widely supported, both by the evidence and by clinical experience.

1. **Social support.** Sessions with a trained professional are a formal type of social support, as is the support provided in a formal group-based smoking cessation program. There is evidence that the more social support provided, the better the outcomes. For example, in group treatment, it appears that "group-oriented" groups, in which group members support each other and group cohesion is encouraged, do better than "class-style" smoking cessation groups, in which the therapist does most of the talking with less group interaction/support.[32] Similarly, even something as simple as seeing smokers who want to quit in pairs with a "buddy" appears to result in higher quit rates than seeing them individually.[33] Even when it is not feasible to provide within-treatment social support, it appears worthwhile to encourage smokers to consider how they might maximize the social support

in their own life (e.g., by telling supportive friends or family about their quit attempt and seeking their support).

2. **Management of withdrawal and craving**. The primary mechanism of all the pharmacotherapies is that they reduce the severity of nicotine withdrawal symptoms and also the severity and frequency of cravings for a cigarette. The dosing guidelines for each medication are based on the doses selected for the clinical trials. However, it is clear that there are large individual differences in dependence and that the standard dose of some medications, particularly the intermittently administered medicines like nicotine gum, inhaler, etc., may not be sufficient to minimize withdrawal symptoms and cravings. This is likely part of the reason why 4 mg gum often has better smoking cessation outcomes than 2 mg, and why the patch plus another NRT has better outcomes than the patch alone. So, it appears that, particularly for more addicted smokers, it is important to ensure that they are using enough pharmacotherapy to adequately treat withdrawal symptoms and cravings.
   Figure 36.4 is from Foulds et al 2013[34] and shows the severity rating of the withdrawal symptom "feeling restless" in participants in 8 randomized double-blind placebo-controlled trials of varenicline for smoking cessation, with 2,403 randomized to varenicline and 1,434 to placebo. It shows that for smokers attempting to quit on placebo, restlessness peaked at week 1 and had returned to baseline by week 4, and was significantly lower in smokers randomized to use varenicline. Similar effects were found for depressed mood, irritability, anxiety, and difficulty concentrating, and these results are consistent with other similar studies (although this is the largest placebo-controlled analysis of individual nicotine withdrawal symptoms over time).
   Given that nicotine withdrawal symptoms have largely resolved within four to six weeks after the target quit date, this is the time frame in which both pharmacological and social support should be focused. This is not to say that these treatment components are not needed after six weeks (they certainly are), but many smokers relapse and give up on their quit attempt within the first few weeks due to the severity of withdrawal and craving in those first few weeks.
3. **Novel pharmacotherapies, not yet approved by FDA for smoking cessation**. No new smoking cessation drugs have been approved in the United States for over ten years. The non-approved medication with the best evidence to date is called "Cytisine" and is actually the drug on which varenicline was originally based. Cytisine is a plant-based alkaloid with a very similar mechanism of action to varenicline and has been used for decades in Eastern Europe. Trials in Poland and New Zealand suggest a similar efficacy to varenicline,[35, 36] and a U.S. trial is ongoing.
4. **Non-smoked nicotine delivery products classified in the United States as "tobacco products."** In the U.S. regulatory system, many tobacco products are allowed on the market subject to marketing approval from the FDA – Center for Tobacco Products. These products are not allowed to make therapeutic claims (for that, they would need to

Significant difference $P<0.0001$ between varenicline and placebo at all post-baseline time points.
Figure based on observed mean values; statistical analysis based on multivariate repeated measures model controlling for baseline, visit, and treatment by visit interaction

FIGURE 36.4 Mean ratings of restlessness at baseline and then up to 11 weeks after attempting to quit smoking, while using e ither varenicline (n = 2,403) or placebo (n = 1,434) in randomized double-blind clinical trials. (From West, R. et al., ***Addiction***, 93(7), 1007–1011, 1998.)

apply via the "therapeutics" part of FDA), but once they have marketing authorization, they can then apply for "modified risk" status, which would allow them to use labeling stating that they have lower health risks than cigarettes or other products. Although these products are not allowed to make claims about smoking cessation, there is evidence that some can function in a very similar manner to nicotine replacement therapy (e.g., snus smokeless tobacco, nicotine pouches, and electronic cigarettes). The product in this category with the strongest evidence for smoking cessation efficacy is electronic cigarettes.

Electronic cigarettes (or "e-cigs") are electronic devices that transform a liquid containing nicotine into an aerosol that is inhaled via a mouthpiece. The aerosol contains chemicals such as glycerin and propylene glycol in addition to additives and nicotine. They deliver far lower levels of harmful toxicants than cigarettes, but the long-term health effects are not known.[37] A recent Cochrane review of their efficacy for smoking cessation found significant positive effects on smoking cessation as compared with NRT, placebo, and no treatment.[38] Their use for smoking cessation remains controversial, and although they are not yet considered as "first-line" treatments, a patient who wants to try them or who has already succeeded in quitting smoking by switching to an e-cig should not be strongly discouraged. They should be congratulated for quitting smoking and offered assistance to withdraw from e-cig use when they feel ready.

5. **Assessment of non-cigarette nicotine product use and dependence**

As mentioned earlier, the use of alternative tobacco products such as snus, nicotine pouches, heat-not-burn cigarettes, and electronic cigarettes is becoming more common, particularly among young people. For some of these products, the FDA has already determined that they are likely much less harmful than cigarettes and has authorized modified risk claims (e.g., General Snus, Iqos "heat-not-burn" cigarettes, and VLNC reduced nicotine cigarettes). However, for most of these products, the long-term risks are uncertain, and generally, it would be wise for users to consider quitting when they feel ready and confident that they will not relapse to combustible tobacco use. However, there may be a challenge in assessing how dependent the patient is on these alternative products. It was partly for this reason that dependence assessment questionnaires have been developed for use with any nicotine product. One example is the Penn State Nicotine Dependence Index (PSNDI),[39] which has been widely used to assess cigarette and electronic cigarette dependence and can easily be adapted for other products by simply replacing the word "cigarette" with the appropriate product name in the questions.

The cigarette version of the PSNDI was found to be at least as predictive of short-term cessation success as the Fagerstom Test for Cigarette Dependence in a controlled trial of group treatment plus NRT for smoking cessation.[14] As shown in Figure 36.5, those with a baseline PSCDI score of 0–10 were about three times as likely to be cigarette abstinent a month later as compared to those smokers with a baseline PSCDI score of 15–20.

Scores on the electronic cigarette version of this questionnaire[39] were found to be correlated with the concentration of nicotine being used in the liquid in electronic cigarettes and to predict which electronic cigarette users had quit using e-cigs a year later,[40,41] suggesting construct validity of the measure for e-cig users. Those allocated to a high dose e-cig (36 mg/ml) in a double-blind randomized controlled trial had higher Penn State Electronic Cigarette Dependence Index (PSECDI) scores after six months than those randomized to zero or 8 mg/ml, which also supports the validity of the questionnaire.[42] The PSECDI has shown good internal consistency[43] and test-retest reliability after a month (+0.78),[42] and correlates highly (around +0.7) with other measures of e-cig dependence.[44] The PSECDI questions are shown in the table.

Penn State Electronic Cigarette Dependence Index (PSECDI)

1. How many times per day do you usually use your electronic cigarette* (*assume that one "time" consists of around 15 puffs or lasts around 10 minutes*) times

(Scoring: 0–4 times/day = 0, 5–9 = 1, 10–14 = 2, 15–19 = 3, 20–29 = 4, 30+ = 5)

2. On days that you can use your electronic cigarette freely, how soon after you wake up do you first use your electronic cigarette?* minutes

(Scoring: < 5 minutes = 5, 6–15 = 4, 16–30 = 3, 31–60 = 2, 61–120 = 1, 121+ = 0)

3. Do you sometimes awaken at night to use your electronic cigarette? +

(Scoring: Yes = 1, No = 0)

4. If yes, how many nights per week do you typically awaken to use your electronic cigarette? +

(Scoring: 0-1 nights = 0, 2-3 nights = 1, 4+ nights = 2)

5. Do you use your electronic cigarette now because it is really hard to quit (using e-cigs)? ♦

(Scoring: Yes = 1, No = 0)

6. Do you ever have strong cravings to use your electronic cigarette? ♦

(Scoring: Yes = 1, No = 0)

7. Over the past week, how strong have the urges to use your electronic cigarette been? •

(Scoring: None/Slight = 0, Moderate/Strong= 1, Very Strong/Extremely Strong = 2)

8. Is it hard to keep from using your electronic cigarette in places where you are not supposed to? ♦

(Scoring: Yes = 1, No = 0)

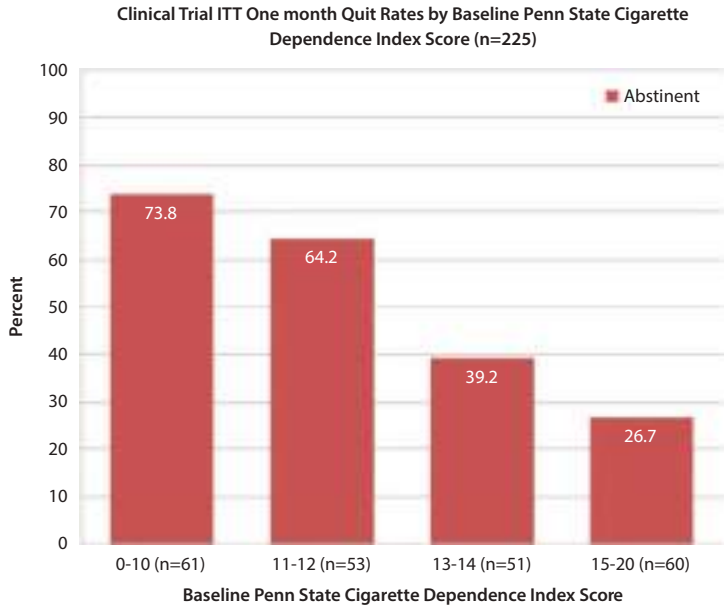


FIGURE 36.5 One-month cigarette abstinence rates (eCO-verified) in smokers participating in group treatment plus transdermal nicotine patches, by baseline score on the Penn State Cigarette Dependence Index.[14, 39]

When you haven't used an electronic cigarette for a while or when you tried to stop using.…

9. Did you feel more irritable because you couldn't use your electronic cigarette? ♦

(Scoring: Yes = 1, No = 0)

10. Did you feel nervous, restless, or anxious because you couldn't use your electronic cigarette? ♦

(Scoring: Yes = 1, No = 0)

Total score indicates dependence as follows: 0–3 = not dependent, 4–8 = low dependence, 9–12 = medium dependence, 13 or more = high dependence

While some of the older tobacco products have known health risks and can reasonably be treated much like cigarettes (e.g., cigars), for other, newer products, the picture is less clear. However, some of the large-scale smoking cessation treatment providers, such as telephone quitline vendors and other research organizations, have gained experience helping other product users to quit, and initial trials have been published. For example, Truth Initiative has recently published a large randomized trial showing efficacy of a fully automated text messaging program for vaping cessation that delivers social support and behavioral coping skills training, as compared with a no-treatment control group, among young[18–24] e-cig users (24.1% vs. 18.6% at seven months).[45]

36.10 CONCLUSION

Tobacco smoking remains the single biggest cause of premature death in high-income countries, causing an average loss of ten years of life for continuing smokers. Quitting smoking by age 35 can avoid the vast majority of the health effects from smoking. The primary reason people continue to smoke despite awareness of the health risks is addiction to nicotine. All patients should be asked about their nicotine product use and if they are smoking, provided with clear advice on the health benefits of quitting and available treatments. Dependence can be assessed with just a few questions, and smokers can be assisted to quit with counseling and evidence-based pharmacotherapy. Smokers treated with intensive pharmacotherapy and counseling are four times more likely to quit smoking long term and less likely to die in the next 15 years.[46] Non-combusted tobacco products are significantly less harmful to health than cigarettes, and switching to these from smoked products will likely reduce health risks. If a clinician does not have the time or expertise to provide tobacco counseling, then providing brief advice and referral to specialist counseling (which could include the national quitline) is still a very worthwhile intervention. These interventions should be continued and repeated as necessary within a chronic care model for tobacco dependence treatment.

KEY CLINICAL POINTS

- Tobacco dependence treatment is an extremely cost-effective, life-saving intervention.
- Every patient should be ASKed about their use of nicotine products.
- Smokers should be ADVISEd about the health benefits of quitting and offered effective treatments.
- Dependence on tobacco products can be ASSESSed with a few questions.
- Intensive counseling and pharmacotherapy quadruple the chances of long-term cessation as compared with usual care, and even brief interventions can ASSIST patients to quit.

- A chronic care model for tobacco treatment should be used, with follow-ups ARRANGEd and the intensity of the intervention increased and repeated if necessary.

37 The Role of Integrative Medicine in Cancer Prevention and Survivorship

Gabriel D. Moss, Stephanie R. Harris, and Richard T. Lee

KEY POINTS

- Understanding of Integrative, Complementary and Alternative Medicine therapies
- Regulatory and quality differences between prescription medication and dietary supplements
- Review of the clinical evidence regarding the use of dietary supplements for cancer treatment and prevention
- Summary of the clinical research on the use of mind body practices (ex. Meditation) and acupuncture, massage, music therapy, and yoga
- Acupuncture is another safe and effective therapy that has been shown to be beneficial for symptoms of pain and nausea.

37.1 INTRODUCTION

Integrative, Complementary, and Alternative Medicine (ICAM) has become increasingly popular in Western medicine. According to the National Center for Complementary and Integrative Health (NCCIH), "if a non-mainstream approach is used together with conventional medicine, it's considered complementary," while "if a non-mainstream approach is used in place of conventional medicine, it's considered alternative."[1] Meanwhile, integrative medicine intertwines complementary and conventional medicine and emphasizes the use of multimodal approaches to treat the entire person in an evidence-based manner.[1] While some people use alternative medicine alone, this is backed by very little evidence-based research. This chapter concentrates on integrative medicine, or the use of complementary medicine modalities with Western medicine, focusing solely on evidence-based clinical research. The NCCIH divides ICAM modalities into three main categories: nutrition, psychological, and physical. Nutrition approaches focus on food as medicine and encompass special diets, dietary patterns, and natural products (i.e., dietary supplements such as vitamins, minerals, herbs, and botanicals). Psychological aspects include mindfulness and spirituality, while physical modalities include massage and spinal manipulation, and increasingly popular is the combination of psychological and physical approaches known as mind and body practices, including acupuncture, massage therapy, mindfulness, meditation, music therapy, and yoga (see Figure 37.1).[1]

The use of ICAM has become increasingly popular. According to the 2012 National Health Interview Survey, 59 million Americans over the age of 4 used at least one complementary health approach, equating to 30.2 billion dollars in out-of-pocket expenses.[2] Dietary supplements and yoga appeared to be the most popular modalities in 2017, with 57.6% and 14.2% of adults reporting their usage, respectively.[3,4] Cancer patients and survivors in particular increasingly look to ICAM in attempt to decrease recurrence, manage the side effects of treatment, and manage and treat other comorbidities.[5] More specifically, approximately one-third of cancer patients reported using ICAM in the last 12 months in 2019, with herbal supplements being the most commonly used modality. Of the cancer patients using ICAM, 29.3% did not disclose their ICAM use to their physicians.[6] This high use of herbal supplements, in combination with lack of disclosure to their healthcare providers, is worrisome not only because dietary supplements are not thoroughly regulated, and thus may have quality and safety issues, but also because many have drug interactions and the potential for negative outcomes. Therefore, it is important for physicians to discuss ICAM with their patients to ensure they are using ICAM in safe and effective ways. This also requires educating physicians on the various ICAM modalities, such as their safety, efficacy, and effects on the body and on other conventional treatments. Additionally, further research needs to be done to determine the mechanisms, effectiveness, safety, side effects, and treatment interactions for each modality.[1] A list of evidence-based research sources of various ICAM modalities can be found in Table 37.1. Dietary approaches will be covered in another chapter, while this chapter will focus mainly on the dietary supplements category within nutrition and mind and body practices.

37.2 DIETARY SUPPLEMENTS

The Dietary Supplement Health and Education Act (DSHEA) of 1994 states that dietary supplements are intended to be taken by mouth, contain one or more dietary ingredients or their constituents, supplement the diet, and are clearly labeled on the front panel as being a dietary

DOI: 10.1201/9781003227793-43

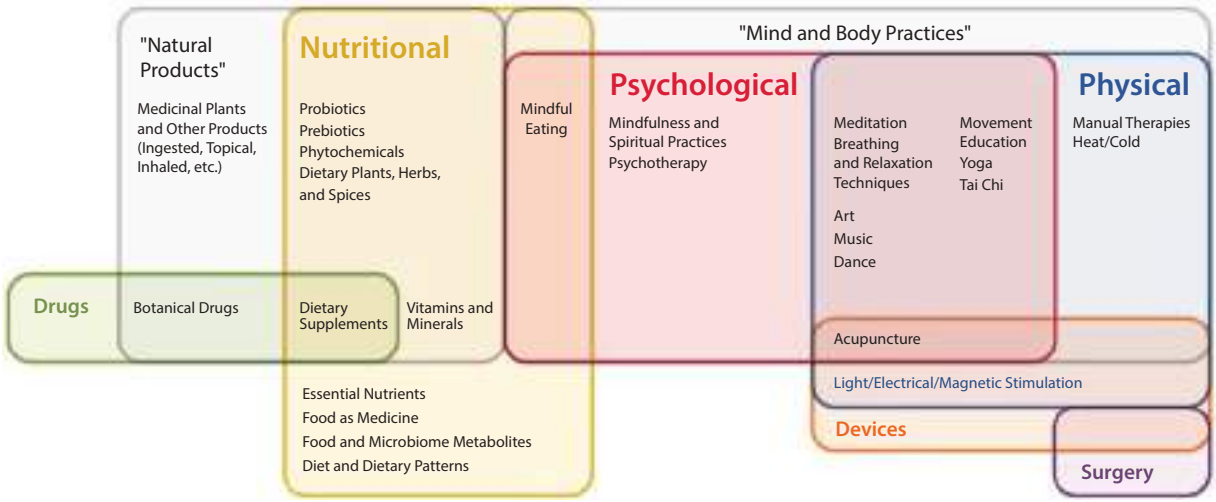

FIGURE 37.1 Examples of complementary health approaches that fall within the categories: Psychological, Physical, and Nutritional. (From Complementary, Alternative, or Integrative Health: What's In a Name? www.nccih.nih.gov/health/complementary-alternative-or-integrative-health-whats-in-a-name. Updated April 2021. supplement.[7] Unlike prescription drugs, which are marketed as disease modifying and must be proven safe and effective for intended use before being marketed, dietary supplements are not allowed to have claims of any disease modifying components and do not require the same level of premarket review and approval.[8] Under DSHEA, the federal government is not required to approve dietary supplements for safety or efficacy before they are sold on the market. Instead, the federal government is responsible for monitoring the marketplace for unsafe dietary supplements and products making misleading claims, which means that Food and Drug Administration (FDA) regulation is mostly post-market.[7,–10]

In 2019, 35.8% of cancer patients reported using herbal supplements in the last 12 months.[6] Different than many other ICAM modalities, dietary supplements run the risk of causing biological harm via potential lack of quality control of the products, metabolic and immunologic interactions, drug interactions, organ damage and toxicity, and potential tumorigenesis and cancer growth. Thus, more regulation and quality control on the dietary supplement industry needs to be instituted, in addition to further scientific research on their mechanisms of action and effects on cancer prevention, initiation, growth, and treatment. Currently, there is a lack of data, as well as mixed data, in the realm of dietary supplement research, particularly as it applies to cancer prevention and survivorship. The following section outlines dietary supplements with peer-reviewed clinical research, focusing on randomized controlled clinical trials and large meta-analyses specific to cancer outcomes.

37.2.1 Calcium

Calcium is the most widely used mineral supplement,[11] yet the data remain somewhat mixed regarding calcium and cancer prevention. One large randomized clinical trial

consisting of 2,303 women found that calcium supplementation does not significantly decrease cancer risk.[12] This is in alignment with the Women's Health Initiative, a double-blind placebo-controlled study of 36,282 postmenopausal women, which found calcium supplementation to have no significant effects on the risk of developing colorectal, breast, or total invasive cancers.[13] Conversely, two meta-analyses found calcium supplementation to lead to a decrease in colorectal adenoma (precancerous polyps) and colorectal adenoma recurrence risk.[14,15] In regard to colon cancer incidence, one meta-analysis found calcium supplementation to reduce the risk of colorectal cancer,[11] while another meta-analysis showed that calcium supplementation has a ten-year lag before intake has an effect on colorectal cancer prevention, which could contribute to the variable data.[16] Before further conclusions can be drawn, more randomized controlled clinical trials need to be done to determine calcium's role in cancer prevention, specifically as it pertains to colorectal cancer, as the data remain mixed.

37.2.2 Curcumin

Curcumin is a compound that comes from a natural root spice, turmeric (*Curcuma longa*), which is part of the ginger family. It has been associated with antioxidant and anti-inflammatory properties.[17] It has been studied for several different cancer types with variable results. A double-blind randomized controlled study of 36 patients with monoclonal gammopathy of undetermined significance (MGUS) and smoldering multiple myeloma (SMM) found that curcumin may reduce light chain proteins and random urinary protein concentrations, suggesting that it may decrease the risk of disease progression.[18] Two randomized clinical trials studied curcumin's effects on oral potentially malignant disorders. One study consisting of 223 patients with oral leukoplakia found 3.6 g/day of curcumin supplementation over six months to have a positive clinical response (67.5% vs. 55.3%),[19] while the other, consisting of 60 patients, found a positive clinical response in those receiving a combination of curcumin and green tea supplements (65%) but no significant benefits in the patients solely taking 950 mg/day of curcumin for three months (55%).[20] A prospective phase II clinical treatment trial of pancreatic cancer found that 2,000 mg of curcumin supplementation per day in addition to gemcitabine therapy produced a better response rate in advanced pancreatic cancer patients compared with historical data.[21] Another study of 25 patients with advanced pancreatic cancer found that treatment with 8 grams of daily oral curcumin generated a clinical response in 2 of the patients, in one of whom it was sustained for >18 months.[22] A randomized double-blind pilot study on muscle-invasive bladder cancer found that 180 mg/day of curcumin supplementation during chemotherapy produced no significant changes.[23] Curcumin has also been studied to reduce side effects and improve quality of life. A study of curcumin given during radiation reported a reduction in radiation-related dermatitis in breast cancer patients.[17] Another randomized double-blind placebo-controlled study of 80 patients with solid tumors undergoing chemotherapy found that 180 mg/day of curcumin supplementation over eight weeks improved quality of life and suppressed systemic inflammation.[24]

The data relating to curcumin and prostate cancer remain mixed. One random double-blind placebo-controlled study of 82 men with prostate cancer on intermittent androgen deprivation therapy found that 1,440 mg/day of curcumin supplementation over six months did not lead to significant changes in time off from androgen deprivation therapy, but did lead to fewer patients with prostate-specific antigen (PSA) elevation during curcumin therapy,[25] while another study found that 120 mg/day of curcumin supplementation three days before and during radiotherapy produced no significant differences in tumor response or in side effects.[26] Similarly, another randomized phase II study of men with metastatic castration-resistant prostate cancer found that 6 g/day of oral curcumin supplementation for seven days every three weeks, in addition to docetaxel, had no significant effects;[27] thus, more research needs to be done on curcumin and prostate cancer before conclusions can be drawn, as data remain mixed, and dosage in many of the studies is stratified. A review on curcumin found that it may cause disease stabilization in advanced pancreatic, biliary, and colon cancers.[28] Further large randomized clinical trials on curcumin's effects on cancer prevention, interaction with cancer treatments, effects on treatment-related symptoms, and dosing studies need to be done before it can be recommended.

37.2.3 Ginger

Ginger (*Zingiber officinale*) is a common spice used for culinary and medicinal purposes.[29] While there are no substantial studies demonstrating ginger's antitumor effects, it has been shown to serve an antiemetic function by increasing gastric tone, motility, and emptying;[30] thus, ginger supplements have been associated with decreased nausea and vomiting severity in breast cancer patients.[31,32] A study examining 576 adult cancer patients found 0.5–1.0 g of ginger supplementation to have the greatest reduction in acute nausea severity related to chemotherapy.[33] The American Society of Clinical Oncology (ASCO) states that based on the Society for Integrative Oncology's (SIO) guidelines, ginger can be considered as an adjunct to antiemetic pharmacology for nausea and vomiting during chemotherapy (Grade C).[34]

37.2.4 Ginseng

Korean red ginseng (KRG) is a product of ginseng (*Panax ginseng*), a vegetable root. The main therapeutic effects come from ginsenosides, a group of phytochemicals that inhibit cell proliferation and migration, as well as angiogenesis, and can reverse drug resistance.[35] In a phase III

double-blind randomized clinical trial consisting of 436 colorectal cancer patients receiving chemotherapy, cancer-related fatigue was significantly reduced in the treatment arm taking 2,000 mg/day of KRG compared with the placebo.[36] Another double-blind randomized trial of 364 fatigued cancer survivors found 2,000 mg of Wisconsin ginseng (*Panax quinquefolius*) to significantly decrease fatigue over eight weeks.[37] In a double-blind randomized clinical trial of 55 premenopausal women with gynecological cancer, 3 g/day of KRG decreased the sexual complaints after gynecological surgery but did not significantly decrease menopausal symptoms compared with the placebo group.[38] The ASCO states that based on the SIO guidelines, ginseng can be considered to improve fatigue during treatment (Grade C).[34]

37.2.5 Green Tea

The main component implicated in green tea's (*Camellia sinensis*) therapeutic effects is epigallocatechin gallate (EGCG) due to its potential to promote antioxidant activity, inhibit angiogenesis, downregulate oncogenes, and upregulate tumor suppressor genes, though molecular mechanisms remain unclear.[39] Two meta-analyses on breast cancer and green tea consumption found risk decreased by 15–27%.[39, 40]A phase II randomized controlled trial found high doses of green tea extract (750 mg/m^2 and 1,000 mg/m^2) to have higher clinical response rates in patients with high-risk oral premalignant lesions compared with the placebo arm over 12 weeks.[41]A phase II randomized controlled trial of 60 men at high risk of developing prostate cancer suggested that 3 daily treatments of 200 mg of green tea catechin capsules can have up to 90% efficacy in chemoprevention.[42] However, another phase II clinical trial found that 6 g of oral green tea per day increased PSA levels in 43% of the men studied and produced green tea–related toxicities, such as diarrhea, nausea, and insomnia, in 69% of the patients.[43] Additionally, evidence exists that EGCG may antagonize bortezomib, a chemotherapeutic used to treat myeloma and some lymphomas, as well as reports of hepatoxicity.[28, 44] While some studies have shown green tea to have promising results, data still remain inconsistent; thus, further studies examining its long-term effects, interactions with chemotherapeutics, and effects on other cancer types are needed.

37.2.6 Lycopene

Lycopene is a carotenoid and antioxidant found in some vegetables and fruits, such as tomatoes, watermelon, and papayas. Proposed mechanisms include scavenging reactive oxygen species (ROS), upregulation of detoxifying systems, disrupting the cell cycle, and altering signal transduction.[45] Supplementation has been associated with prostate cancer prevention via decreasing PSA levels and inflammatory markers,[46–49] ultimately leading to a 20–45% reduction in prostate cancer risk.[50] One phase II clinical trial of 13 men with advanced castrate-resistant adenocarcinoma of the prostate found that 30 mg/day of lycopene supplementation and 75 mg/m^2 of docetaxel every 21 days could lead to a 50% reduction in PSA levels, suggesting that lycopene can be an adjunct to chemotherapy.[51] Another double-blind randomized phase II trial of 84 men with low-risk prostate cancer found that while 30 mg/day of lycopene supplementation had no effect on prostate gene expression, it did modulate the metabolism of androgen, estrogen, and arachidonic acid, as well as modulating Nrf-2 mediated oxidative stress.[52] Another phase II randomized clinical trial of 26 men with prostate cancer found that 30 mg/day of lycopene supplementation three weeks before prostatectomy may decrease the growth of prostate cancer, though the results were not statistically significant, and the sample size was small.[53] Other phase II clinical trials have found 30 mg/day of lycopene supplementation to have no clinical benefits on prostate cancer.[54–56] Due to the relatively small sample sizes and variable results, further research needs to be done before conclusions can be drawn in order to be able to determine the therapeutic effect and mechanism of action.

37.2.7 Melatonin

Melatonin is a hormone responsible for sleep-wake cycles. A randomized double-blind clinical trial found that 20 mg of melatonin before and during the first cycle of adjuvant chemotherapy for breast cancer might have a neuroprotective effect on cognitive function in 36 women over a ten-day period.[57] One review on melatonin as an adjunct to chemotherapy found improvements in tumor remission and one-year survival, and decreases in radiation and chemotherapy side effects, such as thrombocytopenia, neurotoxicity, nausea, vomiting, and fatigue.[58] Another review included clinical trials of melatonin with chemotherapy and in supportive care scenarios.[59] However, the majority of these studies come from a single institution in Italy, and the randomized chemotherapy treatment trials have been limited in size, thus making the results difficult to interpret. More research with larger clinical trials needs to be done to determine melatonin's true efficacy.

37.2.8 Omega-3 Fatty Acids/Fish Oils

Omega-3 fatty acids are essential fatty acids that cannot be synthesized by the body and therefore, must be consumed in the diet via whole food sources or supplementation. Two specific types of long chain omega-3 fatty acids found in fish oil are eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). Some studies have shown that they may have antitumor activity. For example, one phase II double-blind randomized clinical trial consisting of 84 men with low-risk prostate cancer found that 3 g of fish oil containing EPA and DHA can modulate the metabolism of androgen, estrogen, and arachidonic acid, in addition to modulating Nrf-2 mediated oxidative stress, though it had no effect on prostate gene expression.[52] However, other

studies have shown that another omega-3 fatty acid, 16:4 (n-3) (hexadeca-4,7,10,13-tetraenoic), found in commercial fish oil supplements may antagonize platinum compounds in some chemotherapeutics.[28] Two reviews of omega-3 fatty acids and breast cancer point to an association between high omega-3 fatty acid consumption and/or a high omega-3:omega-6 fatty acid ratio in the diet and a decreased risk of breast cancer of up to 27%.[60,61] In addition, two other studies indicate that EPA and DHA may have antitumor activity in lung, breast, prostate, and colorectal cancers.[28,52] Adequate levels of omega-3 fatty acids can be achieved by including fish in the diet; thus, fish oil and EPA/DHA supplements should be avoided until more research is done.[28]

37.2.9 Pomegranate

Pomegranate (*Punica granatum*) contains polyphenols, which have been shown to have antioxidant and anti-inflammatory properites.[29] Pomegranate extract has been a major subject of study in men with prostate cancer. A phase II study involving 46 men with rising PSA after surgery or radiotherapy found that 8 ounces of daily pomegranate juice can increase the average PSA doubling times from 15 to 54 months, lead to a 12% decrease in cell proliferation, increase apoptosis by 17%, increase serum nitric oxide by 23%, and significantly reduce oxidative states, leading to overall better outcomes.[62] Similar results were found in another phase II study that found PSA doubling time to be longer in men with recurrent prostate cancer taking both low and high doses (1 g and 3 g, respectively) of pomegranate extract compared with placebo group over a six-month period.[63] This is in contrast with a phase II double-blind randomized controlled trial involving 98 men with prostate cancer that found no significant differences in PSA doubling times between men drinking 500 mL and then 250 mL of daily pomegranate juice over eight weeks and those in the control arm,[64] and with a double-blind randomized study that found no difference in PSA doubling times, oxidative stress biomarkers, and other markers of prostate cancer between men taking 2,000 mg of PomX, which contains 1,200 mg of polyphenol from pomegranate extract (equal to 16 oz of pomegranate juice), and the control arm.[65] While some studies have shown promising data for men at high risk of developing prostate cancer or those with prostate cancer, others have shown pomegranate juice and/or extract to have no effect; thus, it needs to be examined further before definitive conclusions can be drawn.

37.2.10 Probiotics

Probiotics are live organisms that can be consumed via whole food sources or supplementation. They can alter the gut microbiome and intestinal flora, strengthen the bowel epithelial barrier, change the pH of the intestines, and modulate the immune system.[66] Probiotics have been implicated in reducing post-operative side effects in patients with colorectal cancer. A randomized double-blind controlled study was stopped early due to the efficacy of LactoLevure by Unipharm, a four-strain probiotic regimen, which improved post-operative complications such as pneumonia, surgical site infections, and anastomotic leakage as well as reducing time of hospital discharge.[67] This is consistent with other controlled trials that found a three-strain eight-culture probiotic containing *Lactobacillus*, *Bifidobacterium*, and *Streptococcus thermophilus*, BIO-THREE by Toa Pharmaceuticals, and HEXBIO by B-Crobes to decrease surgical site infections,[66,68] promote normal gut function, and decrease the time in the hospital after colorectal cancer surgery.[66,69] Additionally, a randomized clinical trial of 30 metastatic renal cell carcinoma patients found that *Clostridium butyricum* may improve clinical outcomes when used as an adjunct to nivolumab and ipilimumab therapies.[70] Research regarding probiotics and colorectal cancer treatment-related side effects appears promising, though the best probiotic strain and dose remain unclear.

37.2.11 Selenium

Selenium is a trace mineral found in whole food sources, such as Brazil nuts, seafood, and organ meats, but can also be taken as a supplement.[71] SELECT, a double-blind randomized controlled trial looking at over 35,000 men for prostate cancer prevention, found 200 µg/day of oral selenium supplementation to have a 1.09 hazard ratio risk of prostate cancer, which was not statistically significant.[72] There have been no other large randomized clinical trials looking at selenium's effects on prostate cancer or any other types of cancer; thus, more research is warranted.

37.2.12 Soy

Soy, which contains isoflavones, has been widely consumed in Asian cultures for centuries and has been associated with positive health benefits, such as decreased heart disease and type 2 diabetes.[29] One phase II study of 41 men with high PSA levels found that 100 mg of oral soy isoflavone per day can lead to stabilization of PSA.[73] Meanwhile, a randomized placebo-controlled study of 140 women with early-stage breast cancer found soy protein supplementation to negatively alter gene expression of cell cycle transcripts that promote cell proliferation, thus raising concern that soy could potentially negatively impact breast cancer progression.[74] A meta-analysis of 14 cohorts or case-controlled studies on soy and soy isoflavones found a 26% decreased risk of prostate cancer in those with a high soy intake.[75] For women with breast cancer or at risk for breast cancer, current studies do not indicate any significant risk with dietary soy in moderation.[76, 77] The ASCO states that based on the SIO guidelines, soy is not recommended to improve hot flashes in breast cancer patients due to the lack of effect (Grade D).[34] Further research on soy and soy isoflavones' effects on different cancer types needs to be done, as its impacts may be cancer type specific.

37.2.13 Vitamin A/β-Carotene

β-carotene is a precursor of Vitamin A (or a provitamin A carotenoid), which is found in foods such as carrots, tomatoes, and leafy green vegetables.[78] The results of a large double-blind randomized controlled trial known as ATBC, which consisted of over 29,000 male smokers, found a higher incidence of lung cancer in those taking β-carotene supplements and an 8% increase in total mortality.[79] Similarly, CARET, a randomized double-blind controlled trial of over 18,000 smokers and workers exposed to asbestos, found those taking β-carotene and retinol (Vitamin A) supplements to have a 1.28 increased relative risk of lung cancer compared with the placebo arm and a 1.46 increase in relative risk of death from lung cancer, forcing the trial to be stopped 21 months earlier than intended.[80] One small study in pediatric leukemia and lymphomas treated with high-dose methotrexate noted a possible reduction in drug-induced D-xylose malabsorption but no other side effects.[81] Additionally, a meta-analysis of dietary supplements and primary prevention trials found that Vitamin A supplementation is associated with a 16% increased risk for overall cancer incidence.[11] However, several meta-analyses on carotenoids and breast cancer have found that high serum β-carotene levels and increased dietary intake and supplementation are associated with 17–30% reduction in breast cancer,[82–84] while others found an increased risk of disease progression and death[85] or overall inconclusiveness.[86] The U.S. Preventative Services Task Force advises against the use of β-carotene supplements for the prevention of cancer, as β-carotene is associated with a negative effect on lung cancer incidence, especially in high-risk populations.[87]

37.2.14 Vitamin B

Vitamin B is a broad term for eight B vitamins, including B6 (pyridoxine), B9 (folate), and B12 (cobalamin), which have been studied in relation to cancer. A large randomized clinical trial consisting of over 2,500 participants, known as B-PROOF, found a significant increase in colorectal cancer in patients taking B9 and B12 supplements.[88]Additionally, a large trial consisting of 1,134 breast cancer patients using B12 supplements both before and during treatment found that their use was significantly associated with poorer disease-free survival and overall survival.[89] On the other hand, a large randomized trial of 5,442 women at high risk for cardiovascular disease found no significant effect on overall risk of total invasive cancer or breast cancer in those taking combined Vitamin B6, folate, and B12 supplements.[90] A meta-analysis of Vitamin B9 found that it was associated with a 18% decreased risk in developing hormone receptor negative breast cancer, and that supplementation was associated with a 55% decreased risk in those with the *BRCA1* mutation.[78] It should also be noted that anti-folate therapies (methotrexate and pemetrexed) are commonly utilized as a cancer treatment, and supplementation with folate during such treatment would potentially impact the efficacy of these therapies. Because the data on B vitamins remain mixed and are highly specific to the different types of Vitamin B, more research needs to be done before conclusions can be drawn.

37.2.15 Vitamin C

Vitamin C, or ascorbate, is commonly found in citrus fruits and taken as a dietary supplement. Two double-blind randomized controlled trials consisting of 100 and 150 patients, respectively, looked at the effects of Vitamin C on advanced cancer. Both found high-dose (10 g) oral Vitamin C to have no effects on advanced cancer in terms of symptoms, performance status, appetite, weight, disease progression, or survival, suggesting that Vitamin C has no effect on advanced malignant cancers.[91,92] Several studies have looked at the effects of intravenous Vitamin C on cancer, though intravenous Vitamin C is not considered a dietary supplement, and the data are limited and mixed.[93,94] Thus, there is still a need for large double-blind randomized clinical trials.

37.2.16 Vitamin D

Vitamin D is a hormone that requires sunlight exposure for synthesis and is well known for its role in calcium metabolism.[28] A large randomized clinical trial of 2,303 post-menopausal women showed that Vitamin D supplementation had no effect on breast cancer risk,[12] while a meta-analysis on Vitamin D and breast cancer found Vitamin D supplementation to be associated with a decreased risk of breast cancer and that deficiency is associated with increased risk.[95] A more recent study of Vitamin D supplement, called the Vitamin D and Omega-3 Trial (VITAL), with over 25,000 participants showed no benefit in regard to cancer risk.[96] Calcitriol, the active metabolite of Vitamin D, has inconclusive data, but a summary of studies points to no effects on tumor growth.[28] However, it should be used cautiously, if at all, concurrently with chemotherapeutics like docetaxel, as the incidence of toxicity, such as gastrointestinal issues (nausea, vomiting, diarrhea, constipation, etc.), febrile neutropenia, and pneumonia, was found to be increased.[97] Further studies on Vitamin D and its metabolites need to be done before decisive conclusions can be drawn, although if patients are deficient in Vitamin D, supplementation is reasonable.

37.2.17 Vitamin E

Vitamin E, or α-tocopherol, is an antioxidant found in foods such as nuts, seeds, and plant-based oils. SELECT, a double-blind randomized controlled trial looking at prostate cancer prevention that included over 35,000 men, found Vitamin E supplementation to result in a 1.6-fold increase in relative risk of prostate cancer and a 1.17 hazard ratio, which were both statistically significant.[72] Another large double-blind randomized controlled trial involving Vitamin

E supplementation and lung cancer in over 29,000 male smokers found no reduction in incidence in lung cancer, but did find fewer cases of prostate and colorectal cancers and more cases of bladder, stomach, and other cancers in the supplementation group over the placebo, leading the group to conclude that Vitamin E has no beneficial effects on lung cancer prevention.[79] Similarly, a randomized controlled double-blind study of over 39,000 women found Vitamin E to have no significant effect on breast, lung, colon, or total cancer incidence, death, or total mortality.[98] The U.S. Preventative Services Task Force advises against the use of Vitamin E supplements for the prevention of cancer, as it has no known effects on cancer prevention.[87]

37.3 SUMMARY: DIETARY SUPPLEMENTS

In conclusion, while some dietary supplements may have the potential for cancer prevention or antitumor effects, the majority have inconclusive data, mixed data, or potentially harmful effects on tumor development and growth, as well as drug interactions that can negatively impact chemotherapy. Additionally, not all dietary supplements are created equal. Under DSHEA, manufacturers are primarily responsible for ensuring the safety, proper labeling, and truthful claims for dietary supplements.[7,9] Thus, overall compliance with DSHEA law prior to marketing a product falls on the manufacturer, which is a potential reason why there may be issues/concerns with the quality and safety of dietary supplements that have been improperly manufactured. Because of these factors, physicians should be aware of the effects of popular dietary supplements on cancer and chemotherapeutics and discuss the use of dietary supplements with their patients to prevent any potential negative outcomes, especially when referencing β-carotene, Vitamin E, and potentially Vitamin B12, as these have been shown to cause substantial harm to cancer patients.[87–89]

37.4 MIND AND BODY PRACTICES

According to the NCCIH, "Mind and body practices are a large and diverse group of procedures or techniques that are administered or taught by a trained practitioner or teacher."[99] These include massage therapy, acupuncture, yoga, and music therapy. Despite these practices having small risk profiles, the data on their effects on cancer prevention is negligible and therefore not included in the following paragraphs. While survivorship studies exist, they are somewhat limited. Their data are summarized in the remainder of this chapter, as well as grades given to each modality that are endorsed by the ASCO based on the SIO guidelines that specifically focus on breast cancer patients (Table 37.2).

Mind and body practices are mainly used to control stress and for symptom management. The reduction of stress can not only be essential to improve patients' quality of life but can also play a role in cancer growth and progression, which can be exacerbated by chronic stress via the sympathetic nervous system and hypothalamic-pituitary-adrenal axis. For example, increased levels of norepinephrine and cortisol can promote invasion, angiogenesis, inflammation, and immune dysregulation, and negatively impact chemotherapy drugs.[100] Thus, using mind and body practices to lower chronic stress levels, often associated with cancer diagnoses, can potentially impact cancer survivorship, in addition to increasing quality of life. One of the greatest obstacles to mind and body research is the difficulty of creating a "sham" group, as factors such as the impact of a healing presence cannot be discounted.

TABLE 37.2
ASCO Endorsed Grading Scale for Integrative Therapies

Grade	Definition
A	"High certainty that the net benefit is substantial"
B	"High certainty that the net benefit is moderate or there is moderate certainty that the net benefit is moderate to substantial"
C	"Evidence is equivocal or that there is at least moderate certainty that the net benefit is small"
D	"No demonstrated effect"

37.4.1 Acupuncture

The theory behind the traditional Chinese medicine practice of acupuncture is that disease disrupts the body's energy (qi), and stimulation of points via acupuncture can help restore the balance. This involves the placement of needles in the skin at specific places correlating to meridians on the body to regulate the flow of qi.[101] Proposed mechanisms of action for acupuncture's therapeutic effects include mediation through opioidergic and/or monoaminergic neurotransmission and the pituitary system.[102] Imaging studies in humans have shown that acupuncture stimulation activates numerous brain structures, including the limbic system and deep gray structures, which can potentially lead to a decrease in nociception.[103–105] When performed appropriately by a licensed practitioner, acupuncture is safe and has minimal side effects, limited to needle pain, tiredness, and bleeding.[106,107]

Its main benefits for cancer patients surround symptom management, though the outcomes are dependent on the symptom. For example, a randomized controlled trial consisting of 226 women with early-stage breast cancer showed a statistically significant reduction in aromatase inhibitor–related joint pain in patients who received 12 acupuncture sessions over six weeks, compared with the women who received sham acupuncture or no acupuncture.[108] Another large randomized clinical trial by Shen et al. focused on 104 women with high-risk breast cancer

and found electroacupuncture to significantly decrease the number of emesis episodes compared with minimal needling or antiemetic pharmacology after five days, but these differences dissipated by day 9.[109]Additionally, four reviews found that acupuncture reduces cancer-related pain,[110–113] while two other reviews found not enough statistically significant evidence to draw this conclusion,[106,114] and a review by Paley et al. found that acupuncture's effect on pain management varied by cancer type.[115] A meta-analysis by Tao et al. found that acupuncture can also increase quality of life and reduce symptoms such as pain, fatigue, sleep disturbance, and gastrointestinal discomfort,[112] while two reviews found decreases in fatigue, chemotherapy-induced nausea and vomiting, and leukopenia.[106,116]

While other studies focus on the benefits of acupuncture more generally than just cancer, many of their findings can be applied to cancer patients. For example, a randomized trial of 245 patients with migraines found acupuncture to significantly reduce the number of migraines over sham acupuncture and no acupuncture, implying that it may be beneficial for migraine prophylaxis.[117] A meta-analysis of 29 trials involving 17,922 patients with chronic pain found that acupuncture significantly decreased pain over sham acupuncture and no acupuncture.[118] ASCO/SIO guidelines state that electroacupuncture can be considered as an adjunct therapy to antiemetic pharmacology to control chemotherapy-related vomiting (Grade B), while Grade C evidence exists for treatment of anxiety, mood disturbance and depressive symptoms, post-treatment fatigue, pain, quality of life, and hot flashes.[34]

37.4.2 Massage Therapy

Massage therapy in the context of cancer patients can be used to alleviate symptoms and should be done by a licensed practitioner with training in oncology massage. It is important that the practitioner knows how to avoid vulnerable areas, such as those that have been exposed to radiation, are sites of surgery, or have lymphedema, and the importance of doing so. A randomized trial of 380 patients with advanced cancer with moderate to severe pain found that six 30-minute massage therapy sessions over 2 weeks could significantly reduce pain and mood compared with simple-touch sessions, while sustained pain, quality of life, symptom distress, and medication analgesics were not significantly different.[119] Meanwhile, other studies have shown that massage therapy can decrease pain, fatigue, anxiety, nausea, and depression from 42.9% to 59.9% in cancer patients, though the effects are relatively short term.[116,120–123] There is also evidence that massage therapy can decrease cortisol levels, which can contribute to a decline in stress.[124,125] More research needs to be done to better understand massage therapy's biological effects on cancer-related symptoms. ASCO/SIO guidelines recommend massage therapy to improve mood disturbances (Grade B) and state that it can be considered for anxiety reduction (Grade C).[34]

37.4.3 Meditation and Mindfulness

Mindfulness meditation is the practice of bringing one's attention to the present via thoughts, feelings, emotions, and physical presence with openness, which can be taught via an eight-week Mindfulness-Based Stress Reduction (MSBR) course. A clinical trial of 229 women found that MSBR significantly improved total mood, quality of life, and well-being compared with the control group in women who had undergone breast cancer treatment.[126] Another randomized controlled trial examining breast cancer survivors found mindfulness awareness practices to significantly reduce stress, pro-inflammatory gene expression, inflammatory signaling, fatigue, sleep disturbance, and vasomotor symptoms, though these effects, aside from cancer-related distress, did not persist at a three-month follow-up.[127] Six other studies found that meditation can also significantly decrease anxiety, fatigue, and depression in cancer patients,[116,128–132] as well as leading to stress reduction and improving overall quality of life.[116,133] ASCO/SIO guidelines recommend meditation to reduce anxiety (Grade A), treat mood disturbance and depressive symptoms (Grade A), and improve quality of life (Grade A).[34]

37.4.4 Music Therapy

The purpose of music therapy is to benefit from the therapeutic aspects of music, which can include stress management, decreasing pain, and expressing emotions via the nonverbal, creative, structural, and emotional qualities of music with a trained music therapist. This ideally should be an active process, where the patient creates or describes their feelings via music, rather than a passive practice where the patient just listens.[134] Music therapy has been associated with decreasing cancer-related pain, fatigue, depression, and anxiety, while increasing overall quality of life,[116,135–138] though the mechanisms of these effects are not well researched or understood. One proposed theory based on imaging studies showed music to affect the limbic and paralimbic structures that play a part in pain, anxiety, and depression.[139] ASCO/SIO guidelines recommend music therapy to reduce anxiety (Grade B) and to improve mood disturbance (Grade B), while stating that it can be considered for pain management (Grade C).[34]

37.4.5 Yoga

Yoga involves the combination of breath control, meditation, and physical movements. A randomized controlled trial of 410 cancer survivors found that two 75-minute yoga sessions per week can improve sleep, something that is often impaired in cancer survivors.[140] A randomized controlled trial of early-stage breast cancer patients found that yoga can lead to significantly lower levels of serum IgA and CD56 % post-operatively, suggesting that yoga may prevent immune suppression after surgery.[141] One meta-analysis of randomized controlled trials found that yoga significantly

decreased depression, distress, and stress in cancer patients, though the number of studies analyzed was limited to ten, which varied in quality.[142] Another review of 13 randomized controlled trials found yoga to improve cancer patients' mental health, quality of life, and treatment-related side effects, while decreasing stress, anxiety, and depression,[143] which supports a review by Greenlee et al. that also found an improvement in quality of life and decrease in distress, anxiety, and depression in cancer patients who practiced yoga.[116] Similarly, Cramer et al.'s meta-analysis of 23 randomized controlled trials found that yoga can improve quality of life and decrease fatigue and sleep disturbances in the short term, but did not affect depression or anxiety.[144] ASCO/SIO guidelines recommend yoga to reduce anxiety (Grade B), improve mood disturbance and depressive symptoms (Grade B), and improve quality of life (Grade B). They also state that yoga can be considered for post-treatment fatigue (Grade C) and that gentle yoga can be considered to improve sleep (Grade C).[34]

37.5 CONCLUSION

With an increasing number of cancer patients using a variety of ICAM modalities, it is essential that physicians discuss with their patients the benefits, safety, and efficacy of various practices. This is especially true when patients are interested in taking dietary supplements, as some can have negative effects on tumor prevention or tumorigenesis, have drug interactions, or have biological mechanisms of action that are not thoroughly researched or understood. While mind and body practices have a much lower risk profile and appear to have beneficial effects on cancer and chemotherapy-related symptoms, more research needs to be done on their biological mechanisms of action, in addition to their effects on symptom management, as the data remain mixed. It is important that healthcare providers are knowledgeable about the various ICAM modalities and can integrate evidence-based approaches into their patients' conventional care when appropriate.

CLINICAL RECOMMENDATIONS

- Herbs and supplements should be used cautiously, and some studies have shown potential harmful effects, including vitamins A, B12, and E, which should be avoided in high doses.
- Mind body practices, especially meditation, are generally safe and can be effective for the adjunct treatment of cancer-related symptoms such as stress/anxiety and sleep.
- Acupuncture is another safe and effective therapy that has been shown to be beneficial for symptoms of pain and nausea.
- Dietary supplement regulation and compliance is the responsibility of the manufacturer; thus, the quality and safety of dietary supplements vary, and therefore, physicians should be knowledgeable about the popular products and their effects. Patients should look for independent verification of quality, such as USP tested products.
- For many dietary supplements, the effects on cancer prevention, survivorship, drug interactions, and treatment-related symptoms need to be studied before further conclusions can be drawn.

38 Cancer Prevention Vaccines

Melvin Berger, MD, PhD and Nathan A. Berger, MD

KEY POINTS

- On an annual basis, there are more than two million cases of cancer attributable to infectious agents globally.
- Vaccines targeted at viral surface proteins are available to protect against infection and prevent viral mediated malignant transformation.
- Hepatitis B virus vaccine is safe, effective, prevents hepatitis B virus infection, and when administered to newborn and young children, prevents development of hepatitis B virus–mediated hepatocellular cancer.
- Human papilloma virus vaccine is safe and effective, and when given to adolescents before initiation of sexual activity, prevents high-risk HPV infection of cervix, vulva, vagina, penis, and oropharynx and prevents cancer development in these tissues.
- Many tumor cells have unique antigens, which are serving as a focus for the development of vaccines to prevent, destroy, and/or block tumor cell progression.

38.1 CANCER PREVENTION VACCINES TARGETED AT INFECTIOUS AGENTS

The International Agency for Research on Cancer (IARC) recently estimated that the worldwide annual incidence of cancer attributable to infections was 2.2 million cases for an age standardized incidence rate of 25.0 cases per 100,000 person-years.[1] The prevalence of cancers attributable to infections was greatest in East Asia and sub-Saharan Africa. On a worldwide basis, most common cancers attributable to infectious causes were due to *Helicobacter pylori*, 810,000 cases; human papilloma virus, 690,000 cases; hepatitis B virus, 360,000 cases; and hepatitis C virus, 160,000 cases. In the United States, there were 81,000 cancers attributable to infectious agents, including *Helicobacter pylori*, 18,000; human papilloma virus, 35,000; hepatitis B virus, 2,100; and hepatitis C, 20,000.[1] As discussed later, highly effective vaccines are available to prevent infections with hepatitis B virus and human papilloma viruses and eliminate their carcinogenic effects.

38.2 HEPATITIS B VIRUS–ASSOCIATED CANCERS

Hepatitis B virus (HBV) is a hepatotropic, double stranded, DNA virus, which can cause acute and chronic hepatic infections. HBV infection may be accompanied by signs of acute hepatitis, including abdominal pain, jaundice (yellowing of skin), dark urine, clay-colored stools, fever, appetite loss, and fatigue.[2] Acute HBV hepatitis is usually self-limiting and clears within six months in non-endemic areas, whereas a limited number of patients, 1–5%, may progress to chronic infection.[3] In endemic countries where neonatal HBV infection is common, the development of chronic infection is more prevalent and may occur in 20–30% of those infected.[4] HBV chronic infections may be asymptomatic or symptomatic; however, 15–40% of chronically infected persons progress to cirrhosis, liver failure, and hepatocellular cancer (HCC).[4–7]

HBV is spread through direct contact with body fluids, including blood, saliva, semen, and vaginal secretions, by way of perinatal, percutaneous, sexual, and other forms of close contact. In endemic areas such as Africa, Eastern Europe, and Asia, perinatal, vertical transmission from mother to neonate is one of the most common routes of HBV spread.[3,5,7]

In the United States, prior to the launching of the HBV vaccine in 1982, there were an estimated 200,000 new cases of HBV infection per year.[7,8] On a worldwide basis, chronic HBV infection (persisting for six months or more) is estimated to affect 257–291 million persons.[6,9] The risk of becoming a chronic carrier of HBV is increased in those infected at younger ages.[5,7]

HBV is a major cause of HCC in most parts of Asia, South America, and Africa, accounting for an estimated 60% of cases, whereas in the United States, HBV is associated with 20% of HCC.[10,11] Studies in Taiwan have shown that death from cirrhosis and/or HCC may occur in 25% of patients who become chronic HBV carriers, stemming from infections acquired during infancy or childhood.[12] The number of global deaths due to HBV-associated HCC in 1990 was estimated at 210,200, increasing to 341,400 by 2010.[13] A 2013 study estimated that HBV was associated with 680,000 deaths per year, of which 300,000 were due to HCC.[14]

HBV-induced hepatic inflammation is mediated in part by the HBV pre s protein, which distributes to the endoplasmic reticulum, where it promotes cellular and oxidative stress, leading to cellular and DNA damage. A major element of chronic HBV toxicity is due to the viral genome being incorporated into host DNA, resulting in insertional mutagenesis, chromosomal rearrangement, and oncogene activation. HBV may also produce epigenetic effects associated with aberrant DNA methylation. In addition, viral

DOI: 10.1201/9781003227793-44

protein HBx activates multiple cellular mitogen signaling genes, including Il-6, TNF, TGF-β, and EGFR. Thus, HBV promotes hepatocyte proliferation, which in the presence of viral-induced DNA damage and mutations, leads to hepatic carcinogenesis.[4,10]

The HBV genome codes for three viral surface antigens: Pre-S1, which is the large HBs antigen envelope protein; Pre-S2, the medium HBs antigen envelope protein; and S, which is the small HBs antigen envelope protein. The S protein has been used to produce several monovalent viral surface antigen vaccines (1AHBV), and the S, Pre-S1, and Pre-S2 proteins have been combined to produce a trivalent viral surface antigen vaccine (3AHBV). HBV vaccines are composed of recombinant protein molecules produced in a *Saccharomyces cerevisiae* system.[15–17] The vaccines are free of viral DNA. Three monovalent vaccines, Engerix-B®, Recombivax HB®, and Heplisav-B®, and one trivalent vaccine, PreHevbrio®, are all Food and Drug Administration (FDA) approved in the United States, and all are highly immunogenic.[18] Both monovalent and trivalent vaccines are administered by intramuscular injection, with three doses given over a six-month period. The second dose usually follows the first dose after one month, and the third dose six months after the first. In a series of 18–45-year-old healthy adults administered three vaccine doses, 94.8% of those receiving 1AHBV achieved sero-protection, whereas among those immunized with 3AHBV, 99.3% achieved sero-protection.[17]

Vaccination against HBV is associated with mild to moderate injection site reactions, including pain, tenderness, itching, redness, and swelling, which are usually of short duration and self-limiting, lasting one to two days. Site reactions were greater with 3AHBV vaccines compared with 1AHBV vaccine. Systemic effects, including limited fatigue, headaches, fever, and vertigo, were also of short duration. Among individuals receiving 3AHBV, 85% and 68%, respectively, had local and systemic reactions, whereas among those receiving 1AHBV, 65.9% and 60.1% showed local and systemic reactions.[17] HBV vaccination is not associated with long-term adverse effects. Early concerns of associated demyelinating disorders have not been substantiated.[19,20]

Because of the prevalence of neonatal and early childhood HBV infection, HBV vaccination is recommended to be initiated within 24 hours of birth for all medically stable infants, followed by administration of two additional doses within 6 months. For individuals not vaccinated in infancy, HBV vaccination is recommended for those up to 59 years of age and also for those over 60 with risk factors for HBV infections, such as contact with HBV infected people, people who inject drugs, people who have HIV, men who have sex with men, and people with end stage renal disease, especially those receiving hemodialysis.[21] Immunization provides lifelong immunity, and there are no recommendations for boosters beyond the initial three dose immunization regimen.

Since the institution of HBV vaccination of newborns in the 1980s, the incidence of HBV-associated HCC has been reduced among individuals who were vaccinated at birth compared with non-vaccinated children. Cases of HBV in the United States progressively decreased from 25,916 new cases of HBV reported in 1987, for an annual incidence of 10.7 cases per 100,000 individuals per year, to 6,212 reported cases in 2009, for an annual incidence rate of 2.1 per 100,000, to 0.9–1.1 per 100,000 in 2009, and to 0.7 per 100,000 in 2020.[3,22] The U.S. National Health and Nutrition Examination Survey (NHANES), in three different studies conducted from 1988 to 2016, estimated that chronic HBV infection remained stable at 0.3–0.35% of the U.S. population, with prevalence being greatest in foreign born persons compared with those born in the United States.[6]

Comparing the NHANES data survey from 1999–2006 with 1988–1994, there was a 68% decrease in new HBV infections and a 79% decrease in chronic HBV infections among children 6–19 years of age. In contrast, there was no statistical difference in overall or chronic HBV infection in individuals over 50 years of age.[7]

However, on a worldwide basis, as of 2019, there were still an estimated 1.5 million new cases of HBV infection per year, 296 million people with chronic HBV infection, and 820,000 deaths annually from liver cirrhosis and HCC.[23] The overall worldwide incidence of HCC is increasing at a rapid rate, stemming from multiple etiologic factors, including alcohol, aflatoxin, viruses such as HBV and HCV, and the obesity pandemic–associated non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH).[10,13,24] In 2020, there were 900,000 new cases of HCC, 632,320 in men and 273,357 in women.[25] The incidence of HBV related HCC deaths continued to increase from 210,200 in 1990 to 341,400 in 2010, presumably a reflection of chronic HBV infection acquired before the availability of HB vaccines.[13]

Although the overall incidence of HCC and even HBV-associated HCC may be increasing in many countries, those that have shown early uptake of neonatal HBV vaccination are beginning to show signs of a decrease or stabilization of HBV-associated HCC. For example, in Singapore, where perinatal HBV vaccination was introduced in 1984, liver cancer decreased from 27.1 per 100,000 population members in a 1993–1997 cohort to 17 cases per 100,000 population in a 2006–2012 group.[26] In the United States, age standardized death rates for HBV-associated HCC decreased by 0.2% annually from 2.35 cases per 100,000 population to 2.31 cases in 2019.[27] While the overall incidence of HCC is continuing to increase, it is expected that the contribution of HBV will continue decreasing as children vaccinated in the perinatal period progress into adulthood.[9]

38.3 HUMAN PAPILLOMA VIRUS–ASSOCIATED CANCERS

Human papilloma viruses (HPV) are a family of over 200 double stranded DNA viruses that are epithelial tropic, infecting both cutaneous and mucosal tissues. Acute

infections are usually asymptomatic and clear spontaneously. HPV may become persistent, either in an extrachromosomal, nuclear episomal form or integrated into host DNA.[28–30] Chronic HPV cutaneous infections may lead to common skin warts, whereas chronic infections of mucosal tissue with HPV may lead to diseases such as anogenital warts and malignancies, including cervical, vaginal, vulvar, anal, and oropharyngeal cancers.[31] Although 14 types of HPV are considered high risk for anogenital warts and malignancies in humans, HPV 16 and HPV 18 are most frequently associated with human cancers.[32,33]

HPV infection is most commonly transmitted through sexual contact, including vaginal, penile, anal, and oral sex, as well as by other forms of intimate skin contact.[30] Although HPV infection may occur before initiation of sexual activity, it increases rapidly thereafter. A study in Tanzania showed 11.6% HPV positivity among 15–16-year-old girls who reported having had no sexual activity.[34] Among 15–16-year-old unvaccinated girls, the median time from initiation of sexual activity to first HPV infection was found to be 4.9 months, and 9.3 months to first infection with high-risk HPV. The median duration of new HPV infections was 6 months.[35] A prospective study of U.S. college women showed that the cumulative incidence of HPV infection reached 38.9% within 24 months after first sexual intercourse, with 10.4% of the infections being caused by HPV 16.[36]

Prior to the introduction of HPV vaccines, the prevalence of infections in the United States was estimated at 79 million persons, with 14 million new cases annually, almost half of which occurred in individuals 15–24 years old.[37]

In a NHANES U.S. population based national study conducted from 2003 to 2008, using self-collected cervical-vaginal smears obtained from 1,921 women, the overall HPV prevalence among 14–59-year-old women was 26.8%. The prevalence was 33.8% among 14–34-year-olds and was highest at 44.8% among those women 20-–24 years old. Sexually active women were 39.6% positive among 14–19-year-olds and 49.3% among 20–30-year-olds. High-risk HPV types were identified in 15.2% of women. HPV 16 was detected in 1.6% and HPV 18 in 0.8% of women aged 14–59.[38] These studies confirm that genital HPV infection is common in women, even among adolescents, and increases when individuals become sexually active.

A subsequent NHANES study was conducted in 2013–2014 to identify the prevalence of genital HPV among adult men aged 18–59 years old. Analysis of self-collected penile swabs from 1,868 men identified HPV infection prevalence of 45.2%, with 25.1% showing at least one high-risk HPV type; 4.3% were positive for HPV 16 and 1.7% for HPV 18. On a population basis, these numbers extrapolated to 3.3 million men infected with HPV 16 in the United States and 1.3 million with HPV 18.[37]

A NHANES study of U.S. adults aged 18–69 years old from 2011 to 2014 showed a 7.3% prevalence of oral HPV, 11.5% among men and 3.3% among women. The prevalence of high-risk oral HPV was 4.0% overall, 6.8% among men and 1.2% among women.[30]

The U.S. Centers for Disease Control (CDC), using data from 2015–2019, reported an average of 47,199 HPV-associated cancers annually, of which 26,177 occurred in women and 21,022 in men. In the United States, HPV is considered to be responsible for 91% of cervical cancer, 91% of anal cancer, 69% of vulvar cancer, 75% of vaginal cancer, 63% of penile cancer, and 70% of oropharyngeal cancer.[39] In 2019, 300,000 women died of cervical cancer on a worldwide basis.[40]

Integration of the HPV virus into host DNA drives expression of two viral early genes, E-6 and E-7.[28] These viral early genes are expressed in cervical tissues from women with chronic infections, in cervical carcinoma cell lines, and in clinical samples of cervical carcinoma, where they promote cancer by inactivating the two tumor suppressor proteins, p53 and Rb[41] and by increasing telomerase, which promotes tumor cell survival.[42]

HPV vaccines have been developed to protect against HPV 16 and 18, which are responsible for 70% of cervical cancers, and against HPV 31, 33, 45, 52, and 58, which are responsible for 20% of cervical cancers. HPV 6 and 11 are responsible for anogenital warts. A bivalent vaccine, 2vHPV, Cervarix®, was developed to protect against HPV 16 and 18. A quadrivalent vaccine, 4vHPV, Gardasil®, was developed against HPV 6, 11, 16, and 18. Following up on the success of these vaccines, the nine-valent (9vHPV) Gardasil9® was developed against HPV types 6, 11, 16, 18, 31, 33, 45, 52, and 58 to provide more comprehensive protection against all HPV types associated with cervical, vaginal, vulvar, penile, and oropharyngeal cancers.[33]

HPV vaccines consist of recombinant proteins that form the outer viral capsid layer of the HPV, which self-assemble into virus like particles. The vaccines are free of any DNA that could cause infection or development of cancer. Vaccines are produced using *Saccharomyces cerevisiae* systems and contain yeast proteins. Immunization with the viral proteins stimulates antibody production capable of preventing HPV infection. Immunization with the 4vHPV vaccine provided 100% protection against HPV 16 and 18 infection. The 9vHPV vaccine, Gardasil9®, protects against the nine HPV types included in the vaccine.[33,43]

Clinical trials demonstrate strong safety profiles for both Gardasil® and Cervarix® vaccines, with transient symptoms of injection site pain, swelling, and/or redness along with systemic symptoms of headache and fatigue. Pregnant women who receive Cervarix® treatment compared with Gardasil® showed no significant increase in miscarriages. However, a non-significant increase in miscarriages was noted in pregnancies conceived within three months of Cervarix® vaccination. Immunization with Gardasil® compared with control vaccine resulted in no differences in live births, spontaneous abortion, or congenital abnormalities.[43]

Gardasil9® was subsequently shown to be immunologically non-inferior to Gardasil® in eliciting antibody response among women who were not infected at the time of vaccination.[43] Mild, transient pain, swelling, redness, and itching at the injection site were more common with

Gardasil9® than with Gardasil®. Adverse systemic effects from the two agents were similar.[43] Gardasil9® was more effective than Gardasil® at protecting against cervical, vaginal, or vulvar cancer.[33]

HPV vaccine is administered by intramuscular injection. In the United States, Gardasil9® is now the only HPV vaccine available and is recommended for routine immunization of both sexes by ages 11–12 years, before initiation of sexual activity, to protect against HPV infection. Gardasil9® should be administered as two doses separated by six months. A third dose is required if the first two doses are given at less than six-month intervals. The CDC further recommends vaccination for everyone up to 26 years of age, with three doses given for those who start vaccination after age 15. Vaccination may be given to adults 27–45 years of age who have not been previously vaccinated and who are at high-risk for infection. Pregnant women should not be vaccinated.[29,44]

In a NHANES study of 4,727 women who were 26 years old or younger in 2006, of whom 38% were vaccinated by 2018, the prevalence of HPV 16 and HPV 18 was reduced from 5% in unvaccinated women to 3.4% in women who were vaccinated after initiation of sexual activity, and to less than 1% in women vaccinated before initiation of sexual activity. These studies clearly show the importance of vaccination before initiation of sexual activity to prevent HPV infection.[45] The prevalence of HPV 6, 11, 16, and 18 decreased by 88% among women aged 14–19 years old and by 71% among those 20–24 years old within one decade after the quadrivalent vaccine introduction.[46] Similar studies have shown that vaccination before initiation of sexual activity prevents cervical cancer caused by HPV 16 and HPV 18. However, vaccine efficacy in preventing cancer decreases as vaccination age increases to 19.[47] Emphasizing the need for early age vaccination, estimates based on model studies predict that the lifetime risk of cervical cancer can be decreased by 55% for women vaccinated by age 9, but only by 6% among women vaccinated at age 45.[47]

A 2017 review of the first decade of experience with HPV vaccine showed significant immunogenicity and improvement in HPV infections and related pathologies.[48,49]. Cervarix®, Gardasil®, and Gardasil9® were each shown to produce high antibody titers to the specific HPV type virus like particle contained in the vaccine. Antibody titers have been shown to be persistent after five to ten years, and both Gardasil® and Cervarix® have been shown to extend protection against HPV 16 and HPV 18 infections for at least five to ten years, respectively.[49] Immunization with type specific vaccine did not induce clearance of already infected women.[49] In a 2011–2014 NHANES study of men and women, oropharyngeal HPV infection with HPV 6, 11, 16, and 18 was reduced by 88% in vaccinated versus unvaccinated individuals.[50]

Among women 15/16–26 years old, Gardasil® and Cervarix® have been shown to be 98% protective against development of HPV 16/18-associated grade 2 cervical intra-epithelial neoplasia (CIN 2). Gardasil9® was shown to be further 100% protective against CIN 2 associated with HPV 31, 38, and 55, as well as 53% protective against CIN 2 due to any HPV type. Gardasil® and Cervarix® are 43% and 83% protective against grade 3 CIN caused by any HPV type.[33,43]

In an international trial of 14,215 women 16–26 years of age, randomized to immunization with three injections of either Gardasil® or Gardasil9® and then followed for 48 months, Gardasil9® was shown to be non-inferior to Gardasil® for preventing high-grade intra-epithelial neoplasms and malignant cervical, vulvar, and vaginal disease related to HPV 16 and 18. Among women immunized with Gardasil®, there were 30 cases of high-grade CIN and 27 cases of cervical cancer related to HPV 31, 33, 45, 52, and 58 compared with 1 case of high-grade CIN and only 1 case of cancer in women receiving Gardasil9®. Risk reduction was 96.7% and 96.3%, respectively, for high-grade disease and cancer related to HPV 31, 33, 45, 52, and 58. This study clearly showed that prophylactic administration of Gardasil9® protected against development of high-grade intra-epithelial neoplasms and cancer caused by the HPV types included in the vaccine over a 48-month period.[33] A Swedish national registry study composed of nearly 1.7 million women 16–30 years of age compared 527,871 who received at least one dose of quadrivalent HPV vaccine with 1,145,112 unvaccinated women of the same age. Women were followed for 11 years from 2006 to 2017 or until they reached 31 years of age. There were 538 cases of invasive cervical cancer, for an incidence rate of 5.27 cases per 100,000 person-years, among unvaccinated women compared with 19 cases in vaccinated women, for an incidence rate of 0.73 cases per 100,000 person-years in the latter. Of the cases that occurred in vaccinated women, only 2 were in those vaccinated before age 17, while 17 occurred in women vaccinated between 17 and 30 years of age. Overall, there was an 86% reduction in invasive cervical cancer in women receiving quadrivalent vaccine, with best results when those vaccines were given at younger ages.[51] Studies have not yet been reported demonstrating that HPV vaccination protects against oropharyngeal cancer; however, since the vaccine protects against the virus types associated with these malignancies, it is expected that they will be shown to prevent development of the cancers as well.[52]

Overall, HPV vaccines have been shown to be highly immunogenic, to produce long lasting seropositivity of antibodies to effectively reduce HPV vaccine type specific infections of cervix, vulva, vagina, penis, and oropharynx, and to further protect against development of cervical intra-epithelial neoplasia and invasive carcinoma. Long-term protection by these vaccines against HPV infection, resultant high-grade disease, and cancer remains to be determined. Thus, although HPV- and HBV-related cancers are preventable, strategies to increase uptake of the vaccines and eliminate these diseases need to be improved.

In the United States, 86.3% of U.S. born children are vaccinated against HBV, while 40.3% of adults aged 19–49 and 19.1% of adults over 50 are vaccinated.[53,21] HBV

vaccination rates vary by country, with an overall global estimate of 42% vaccination.[23] Only 58.6% of U.S. adolescents have completed HPV vaccination, while worldwide, fewer than 15% of girls have been vaccinated.[54,55] Thus, we have witnessed the contribution of vaccines to the control of two major cancer classes attributable to infectious agents, with great promise if more cancer preventive vaccines were to be targeted at both infectious agents and unique tumor cell antigens.

38.4 STATUS OF CANCER PREVENTION VACCINES TARGETED AT TUMOR CELL ANTIGENS

It has long been recognized that tumor cells express unique or mutated "neo"-antigens and/or over-express surface structures that are only minimally present on normal, non-malignant cells. Thus, it was hypothesized that the immune system provided continuous surveillance that could detect neoantigens and eradicate neoplastic cells before they became actual tumors,[56] and that when this "immune surveillance" was weakened in patients who were iatrogenically immunosuppressed to prevent rejection of transplanted organs[57] and in those with intrinsic immune deficiencies, higher incidences of cancers resulted.[58] It became apparent, therefore, that tumors somehow protected themselves from immune attack, but the mechanisms by which they evaded the immune system were unknown. Early attempts to stimulate immune eradication of tumors involved non-specific inflammatory stimuli such as bacterial toxins;[59] cross-immunization with tumor cells from different individuals;[60] isolation, amplification, and stimulation *in vitro* of tumor infiltrating lymphocytes;[61] and administration of stimulatory cytokines such as IL-2 *in vivo*.[62] With improved understanding of the induction and regulation of immune responses, research in the 1970s began to focus on dendritic cells and attempts to stimulate antigen presentation for induction of helper and cytotoxic T-cells. To avoid tumor microenvironments, which may be immunosuppressive or tolerogenic *in vivo*, *ex vivo* conditions were developed in which peripheral blood monocytes could be differentiated into activated antigen-presenting dendritic cells by culturing with toll-like receptor agonists and/or immunostimulating cytokines, together with tumor antigens, to activate and induce proliferation of tumor-specific T-cells. This approach is exemplified by Provenge® (Sipuleucel-T), approved in the United States in 2010, in which autologous peripheral blood cells are collected by leukapheresis and cultured *in vitro* with a proprietary recombinant fusion protein consisting of prostatic acid phosphatase and GM-CSF (Prescribing Information, Dendreon Inc., Seal Beach, CA). In this case, the tumor antigen, prostatic acid phosphatase, is expressed by 95% of all prostate cancers. However, this and other attempts at immunotherapy had only limited success because besides developing defenses that enable them to evade immune detection, tumor microenvironments may also inhibit T-cell proliferation and cytotoxic lymphocyte attack. As tumors grow, they often develop progressively immunosuppressive microenvironments due to hypoxic and other metabolic stresses, shedding of exosomes and cell fragments, and chronic inflammation with prolonged NF-κB activation. These changes favor differentiation of macrophages into the M2 phenotype with diminished antigen-presenting activity, increased concentrations of suppressive cytokines such as interleukin (IL)-10 and transforming growth factor beta (TGF-β), and exhaustion and apoptosis of T-cells.[63]

Research in the 1990s led to elucidation of the need for co-stimulation to induce T-cell responses and the discovery that in addition to co-stimulatory molecules, there were also inhibitory surface proteins on T-cells, antigen-presenting cells, and target cells. It soon became apparent that integration of these various stimulatory and inhibitory (so-called "check-point") signals determined the extent of T-cell activation, and that using antibodies to block inhibitory molecules such as CTLA-4 could unleash potent anti-tumor immune responses.[64] Thus, tumors can become established and grow when co-stimulatory molecules are down-regulated and/or inhibitory molecule expression is increased. This realization led to the introduction and increasing use of "check-point inhibitors" such as ipilimumab (anti-CTLA-4), pembrolizumab (anti-PD1), nivolimumab (anti-PD1), and atezolimumab (anti-PD-L1) as immunotherapeutics for a wide variety of cancers. In turn, the success of check-point inhibitor immunotherapy has led to increased interest in the use of vaccines, now in combination with check-point inhibitors, to focus the immune response on tumor-specific antigens and to unleash its effectors. Development of autoimmune complications is one risk of this and other immunotherapy approaches.[65]

Considerable evidence suggests that many nascent tumors are eliminated by immune surveillance before they become clinically apparent.[58] Demonstration that mice with targeted knockouts of important immune effector genes such as interferon-γ and perforin have an increased incidence of spontaneous and carcinogen-induced tumors supports the importance and highlights the mechanisms of immune surveillance.[66] Many individuals without cancer have been found to have established T-cell memory and/or pre-existing antibodies against tumor antigens, which can effectively inhibit tumor growth in animal models.[67] Such antigens include mutated and/or over-expressed cell surface growth factor receptors, mucins and adherence proteins, and even intracellular growth-regulating proteins such as cyclins and transcription factors, which actually drive tumor growth.[68–70] The latter types of intracellular proteins may be processed through proteosomes into peptides, which can be presented on class I MHC molecules as targets for CD8-effector lymphocytes,[71] but may require phagocytosis of tumor cells or their fragments by macrophages in order to be presented on class II molecules to stimulate CD4 T-helper cells—a process that is often impaired in the tumor microenvironment.[72] Several

studies suggest that the presence of activated T-cells and other immunologic reactants in and/or adjacent to premalignant lesions is associated with decreased incidence of tumor formation and better long-term prognosis if cancer does develop. Immunization with HPV antigens in Freund's adjuvant led to regression of premalignant intraepithelial vulvar lesions.[73] Similarly, the presence of autoantibodies against MUC1 in heavy smokers and others who are at risk for, but have not yet been diagnosed with, carcinomas also suggests that active immune surveillance is effective in preventing or delaying the development of malignancies.[68]

Thus, current efforts in the immunoprevention of non-virally induced cancers focus on the detection of premalignant lesions and blocking their progression to invasive malignant tumors.[74–76] Two main avenues of attack include identification of appropriate neoantigens and optimizing presentation to achieve effective responses. Approaches to antigen identification include characterizing and cataloging shared proteins and epitopes on premalignant tissues through such efforts as the "Precancer Genome Atlas"[77,78] and the "Cancer Epitope Database and Analysis Resource (CEDAR)."[79] It is hoped that this could yield off-the shelf vaccines useful for many patients and potentially, multiple types of tumors that share common mutations or over-expressed antigens. For example, detection of microsatellite instability and proteins with frame-shift mutations (i.e., in Lynch Syndrome patients) could potentially identify frequently occurring neoantigens, which could be targeted.[80] A potentially important approach toward personalized vaccines tailored for presentation on a patient's own HLA molecules includes subtraction of whole exome sequences of a patient's healthy cells from sequences of that patient's own tumor, accompanied by informatic/machine learning tools to optimize tumor-specific, HLA-binding sequences.

The success of mRNA vaccines against the SARS-coronavirus responsible for the COVID-19 pandemic has suggested that individual epitope sequences or sequences for multiple epitopes could be linked together and incorporated into optimized nucleic acid–based vaccines[71,75,81] rather than translated into peptides or fusion proteins with different solubility and administration requirements. The injection of stabilized and adjuvanted nucleic acid–based vaccines remotely from the tumor microenvironment should stimulate and expand T-cells to prevent progression of premalignant lesions and in patients with established disease, eradicate residual tumor cells and prevent metastases and recurrence.[82,83] Other approaches to increase the antigenicity of tumor vaccines include the use of extracellular vesicles bearing tumor antigens, incorporation of tumor lysate antigens into nanoparticles comprised of yeast or bacterial cell walls, and other strategies designed to promote phagocytosis and stimulate antigen presentation.[84] These strategies are often used in combination with cytokines intended to further stimulate T-cell activation by dendritic cells.

Thus, advances in basic immunology, tumor biology, and vaccine technology have come together to illuminate a bright future in immunologic approaches to the prevention and treatment of cancer.

KEY CLINICAL POINTS

- Hepatitis B vaccine should be administered to prevent infection with HBV and consequent hepatocellular cancer.
- Hepatitis B vaccine should be administered according to the following CDC guidelines:[21]
  - All newborns
  - All persons under 19 years of age who have not been vaccinated
  - Adults 19–59 years old
  - Adults 60 years and older with risk factors for hepatitis B virus infection
- Human papilloma vaccine is recommended to prevent human papilloma virus infection and consequent anogenital warts as well as cervical, vaginal, vulvar, penile, and oropharyngeal cancers.
- Human papilloma vaccine should be administered according to the following CDC guidelines:[29]
  - All children, boys and girls, by 11–12 years of age, starting at age 9 to ensure vaccination before exposure to HPV through sexual activity.
  - Catch-up vaccination is recommended up to age 26 years.
  - Vaccination may be of benefit to individuals 27–45 years old who are not adequately vaccinated and who have not been exposed to HPV infection.
- HBV and HPV vaccines are not effective for treating acquired infections or virus-attributable cancers.

39 Lifestyle Approaches To Obesity Management for Cancer Control

Debora S. Bruno, MD, MS and Nathan A. Berger, MD

KEY POINTS

- Overweight and obesity are at pandemic proportions in the United States and worldwide.
- Overweight and obesity promote, accelerate, and worsen the prognosis of multiple malignancies.
- Overweight and obesity account for 14% of all cancer deaths in men and 20% in women.
- Obesity control can prevent and/or reduce incidence of many cancers.
- Metabolic-bariatric surgery is the most effective and durable approach to weight loss in markedly obese patients. Its role in cancer prevention will be reviewed.

39.1 INTRODUCTION

Obesity is a major health problem in the United States and worldwide.[1,2] On a global basis, obesity has reached pandemic proportions, with an estimated 650 million obese adults and more than 110 million obese children.[3–5] Successive reports by the U.S. National Health and Nutrition Examination Survey (NHANES) from 1960–1962 through 2017–2018 indicate that obesity in the United States has increased more than threefold among women and more than fourfold among men.[6] In the United States, 42.5% of adults have obesity, another 31.1% are overweight, and almost 10% have severe obesity.[6] Childhood obesity is also increasing, affecting over 17% of U.S. children in 2018.[7]. These figures are alarming in that overweight and obesity are associated with increased risk for many health problems, including heart disease, stroke, Type II diabetes mellitus, musculoskeletal disorders, cancer, and many others.[5] In addition, each year, there are 2.8 million deaths worldwide, and over 300,000 in the United States, as a result of overweight or obesity.[8–10] Thus, obesity and its consequences are a major cause of morbidity and mortality. Further cause for alarm is the cost of obesity-associated diseases, which in the United States has been estimated at $173 billion annually, or an increase per individual of $1,861 per year above average healthcare costs.[11].

The terms "overweight" and "obesity" are used to describe the condition where an individual carries more weight, usually as fat mass, than the average normal person of the same height and gender. These weight comparisons are commonly expressed using the term "body mass index" (BMI), calculated as weight in kilograms divided by height in meters squared (BMI = weight [kg] ÷ height [m]$^{2)}$). BMI can be easily determined using readily available websites.[12]. Individuals with a BMI lower than 18.5 kg/m2 are considered underweight and may be subject to unique health problems associated with malnutrition and nutritional deficiencies.[13–15] Individuals with a BMI of 18.5 to 24.9 are considered normal and usually serve as the reference range for conditions associated with elevated BMI. Individuals with a BMI of 25–29.9 are considered overweight, and those with a BMI of 30 or over are considered obese. Obesity is sometimes further divided into BMI 30.0–34.9 kg/m^2 as type 1 obesity, BMI 35–39.9 kg/m^2 as type 2 obesity, and BMI ≥40 kg/m^2 as severe or morbid obesity.

Prior to 1962, only 14.3% of the U.S. adult population was estimated to be obese.[16] More recent U.S. data indicate the prevalence of obesity to be 42.5% in adults and 19.7% in those under 20, with no differences noted between adult men and women.[6,17,18] Obesity rates in the United States show a regional distribution, with higher prevalence in the eastern United States and even higher rates in the south, reaching greater than 38% in the Mississippi Delta states of Alabama, Louisiana, and Mississippi; and in Appalachia, where the prevalence of obesity is greater than 40% in Kentucky and West Virginia. Obesity likewise has an ethnic distribution, with the highest prevalence in non-Hispanic Black Americans (49.9%), followed by Hispanics (45.6%) and non-Hispanic Whites (41.4%), and is lowest among non-Hispanic Asians (16.1%).[18]

Although the United States is in the unenviable position of leading the world in prevalence of overweight and obesity, similar trends occur in countries throughout Europe, Australia, and the Middle East. In contrast, the prevalence of obesity in sub-Saharan Africa, India, and China is significantly lower; however, these countries are showing marked increases in the incidence of obesity, especially in urban areas where residents acquire Western lifestyles.[4]

The public is well aware of the impact of obesity on heart disease, stroke, and diabetes and engaged in multiple strategies to reduce these comorbidities. However, a 2017 report from the American Institute of Cancer Research (AICR) indicated that only 50% of Americans were aware that obesity stimulates cancer growth.[19] An important alert and awakening subsequently came from the American

DOI: 10.1201/9781003227793-45

Cancer Society, which in a series of landmark reports based on a prospective observational study of more than one million U.S. adults, showed that overweight and obesity were associated with increased cancer incidence and deaths. They identified that obesity-associated cancers accounted for 14% of all cancer deaths in men and 20% in women.[20–22] The International Agency for Cancer Research (IACR) subsequently convened an expert panel, which upon review of extensive epidemiologic data, concluded there was sufficient evidence to link 13 human malignancies to excess body fatness.[23] These obesity-associated cancers include esophageal adenocarcinoma, gastric cardia cancer, colon and rectal cancer, liver cancer, gall bladder and pancreatic cancer, post-menopausal breast, corpus uteri, ovarian, renal cell, and thyroid cancers, meningioma, and multiple myeloma.[23] In addition, there is suggestive but not conclusive evidence that other malignancies, including prostate cancer, lung cancer, and some hematologic malignancies, especially acute promyelocytic leukemia, may be associated with obesity.[24–28]

A more recent report, using Mendelian randomization studies of germline genetic determinants of lifetime expectancy of body fatness, reported causal association of adult obesity with six cancers, including esophageal adenocarcinoma, colorectal cancer, and cancers of endometrium, ovary, kidney and pancreas.[29,30] These studies also suggested a potential link of obesity to lung cancer, which may be obfuscated by tobacco use, and development of cachexia in association with disease development and progression. Studies of association with breast cancer were mixed because of pre- and post-menopausal breast cancer. Mendelian randomization studies had insufficient data to link obesity with cancers of gall bladder, gastrocardia, or multiple myeloma.[29,30]

Improved awareness and understanding of how excess fat, overweight, and obesity as well as high fat diets promote cancer development and progression should contribute to improved lifestyle efforts to control obesity, reduce cancer risk, and mitigate some of its effects on prognosis. Adipose tissue was once considered a storage depot where reserve energy was maintained in the form of fats (triglycerides) to be released and utilized by peripheral tissues in times of energy demand or periods of restricted food availability. However, it was shown that adipose tissue, composed of adipocytes, stromal fibroblasts, and vascular, immune, and hematopoietic cells, is intensely metabolic, with multiple physiologic functions, including appetite regulation, inflammation, modulation of insulin sensitivity, nutrient uptake and storage, and other processes as well.[31–34] Obesity-associated aberrations in these physiologic functions result in multiple and overlapping pathophysiologic mechanisms by which obesity promotes cancer.[3536]

39.2 MECHANISMS OF OBESITY'S IMPACT ON CANCER

In considering the multiple mechanisms by which obesity affects cancer (Figure 39.1), it is important to note that obesity does not initiate the carcinogenic process, but rather, obesity promotes and accelerates cancer progression.[36,37] As adipose tissue expands in association with overweight and

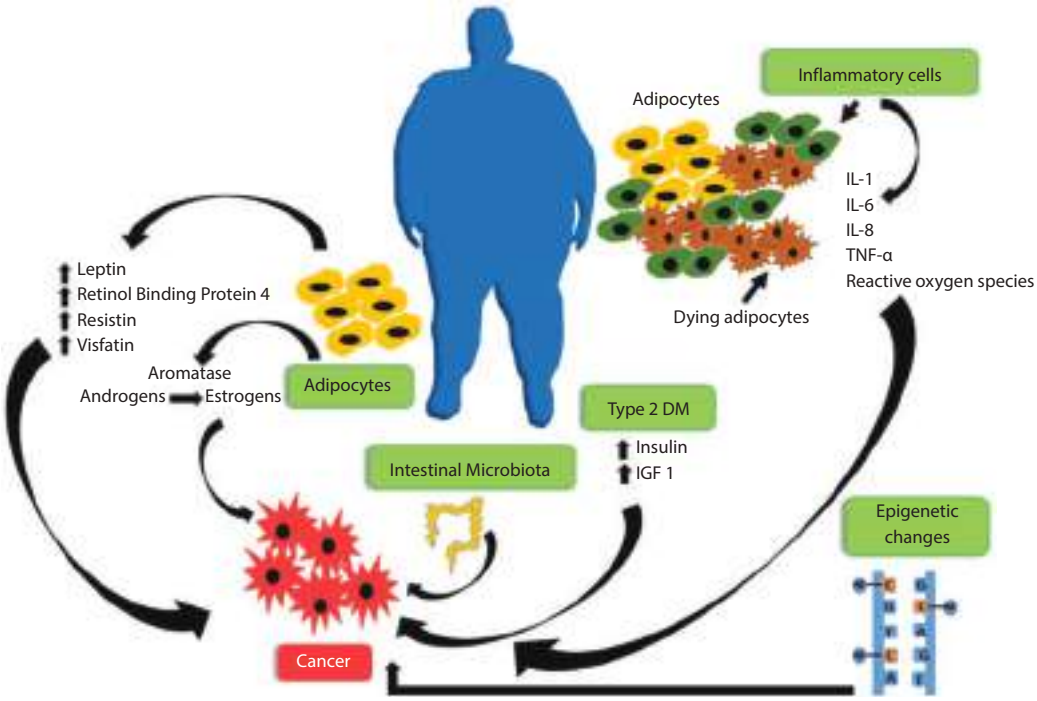

FIGURE 39.1 Mechanisms of cancer obesity. (From Bruno, D.S. and Berger, N.A., ***Ann. Transl. Med.***, 8(Suppl 1), S13, 2020. doi: 10.21037/atm.2019.09.26. PMID: 32309417; PMCID: PMC7154324. Used with permission from the author.)

obesity, adipocytes, the fat containing cells, enlarge, and some undergo cell death and become surrounded by pro-inflammatory macrophages to form crown-like structures (CLS), which generate cellular and humoral pro-inflammatory factors, including lipids, cytokines, interleukin (IL)-6, IL-1, and tumor necrosis factor alpha (TNFα).[38] These in turn further act to provide cellular and humoral growth-promoting microenvironments that lead to insulin resistance.[32,33] In addition, adipose tissue is responsible for the synthesis and secretion of a number of adipokines, proteins that under normal conditions have a variety of physiologic functions.[34,39].These include leptin, which under normal conditions increases in proportion to fat cell mass and has an anorexigenic effect, that is, it down-regulates appetite;[40] adiponectin, which increases in response to calorie restriction and has an orexogenic or appetite stimulating function;[41] and retinol binding protein 4 (RBP4), which facilitates vitamin A uptake and transport.[42] Increased levels of these adipokines, such as leptin and RBP4, promote tumor cell growth by stimulating cell proliferation, survival, and invasion.[43,44]. In contrast, adiponectin, which suppresses cell proliferation and stimulates apoptotic cell death, is decreased in obesity.[41]

Levels of insulin and insulin like growth factor (IGF-1) are usually increased in obesity, where they may contribute to tumor growth.[33,34] While the normal physiologic function of insulin is to stimulate cellular glucose uptake and utilization, insulin can also stimulate cell growth.[45,46] Thus, elevated levels of insulin secreted by the pancreas in response to insulin resistance may have the pathophysiologic effect of promoting tumor cell growth and cancer progression.[45,46]. IGF-1, synthesized mostly by the liver, has a structure similar to insulin and commonly functions to stimulate normal tissue growth. [46] Elevated levels of IGF-1 may likewise contribute to the pathophysiologic mechanism by which obesity promotes tumor cell growth and cancer progression.[46]

Aromatase, the enzyme responsible for converting androstenedione to estrone and estrogen, is found in many organs, including adipose tissue. As a result of the increased adipose tissue associated with obesity, increased aromatase produces increased estrogen, which promotes the growth of breast cancer.[47,48] Another process by which obesity promotes tumor growth is mediated by the intestinal microbiome, which harbors a great number and extensive variety of bacteria whose concentration and metabolic products are highly dependent on both the composition and quantity of our dietary intake and nutritional status. Shifts in these populations, such as increases in bacteroidetes or decreases in firmicutes, promoted by high fat diets, may lead to metabolic changes and circulating toxins that promote cancer growth.[49] Obesity may also predispose to cancer by mechanical factors, such as stretching of diaphragmatic muscles, leading to hiatal hernia and gastro-esophageal reflux disease, thereby predisposing to esophageal adenocarcinoma.[50–52] It has recently been shown that adipocytes (fat cells) can take up and metabolize cancer chemotherapeutic agents, thereby reducing available chemotherapy in the tumor microenvironment. Thus, the increase in adipocyte number and size associated with obesity, along with their ability to reduce tumor exposure to chemotherapeutic agents, provides a mechanism for tumor cells to escape and survive chemotherapy.[53]

Many of the effects just described are the result of alterations in metabolic, hormonal, or pro-inflammatory signaling pathways associated with obesity. These pathways may be regulated in relatively rapid response to changes in nutritional status. Obesity may also alter cellular messaging by more stable epigenetic processes in which modification of the DNA or its supporting chromatin proteins changes the genetic readout without altering the genetic sequence.[54–56] Such alterations include chemical modifications like methylation of DNA or methylation, acetylation, or other changes in chromosomal proteins that alter their structure and function.[54–56] Epigenetic changes that shift cellular metabolism to fatty acid synthesis and oxidation for generation of energy and cellular building blocks to promote growth in tissues with predisposing genetic mutations have been shown to occur after as little as three days of high fat diet feeding.[57],[58] Studies also suggest that high fat obesogenic diets may contribute to epigenetic suppression of immune responses to tumors.[58, 59]

Epigenetic changes may persist after nutritional status changes.[60,61] They may become heritable, through multiple generations of cell division, and may even become transgenerational, passing from parent to offspring.[60–62] It is now becoming apparent that lifestyle phenomena such as starvation, obesity, and physical activity may alter epigenetic factors that affect individuals and the ,pathophysiology of chronic conditions like obesity, diabetes and cancer.[55,63,64] For example, obesity has been shown to induce epigenetic, structural changes in the organization and structure of chromatin in colon epithelium that alter the binding of transcription factors promoting colon development and growth.[65] While these changes do not directly promote tumor growth, they induce chromatin structural remodeling that enhanced cell-signaling pathways driving cancer progression.[65] The sustainability of these epigenetic changes suggested the possibility that the tumor promoting effects of obesity, at any stage of life, may contribute to cancer progression at later ages, leading to the need for epigenetic targeted therapy.[56] The importance of considering both the metabolic, hormonal, and pro-inflammatory effects of obesity and the epigenetic effects is that the former may be largely eliminated or reversed with weight loss, whereas the latter may be more durable. Thus, while elimination of obesity and restoration of normal body weight is desirable at any time of life, it may not always reverse all cancer promoting consequences of obesity. Moreover, the rapid onset of epigenetic changes following initiation of obesogenic diets and their durability indicate potential problems with weight cycling, that is, recurrent weight loss and weight gain; also known as yo-yo dieting.

In studies on the effects of obesity on adverse health outcomes, it is noteworthy that not all adipose tissue has

the same metabolic, hormonal, or pro-inflammatory activity, and likewise, not all adipose tissue has the same tumor promoting activities. Visceral fat, consisting of the fat in and around abdominal organs, is more intensely metabolic and pro-inflammatory, produces more pro-inflammatory cytokines such as TNFα and IL-6, and is more likely to stimulate insulin resistance, diabetes, and cardiovascular disease than subcutaneous fat, which lies directly under the skin.[66–68] Visceral fat has been epidemiologically linked to tumor promotion in humans.[69,70] In mouse models, surgery to remove visceral fat depots has been shown to reduce development of the intestinal tumors[71] and ultraviolet light induced skin carcinogenesis.[72] However, this surgery is not practical in humans. Although liposuction removes subcutaneous fat, it has been used primarily for cosmetic body contouring[73] but has not been shown to produce sustained body weight loss or to reduce risk for many of the pathophysiologic consequences of obesity. Caloric restriction, on the other hand, is likely to reduce both subcutaneous and visceral adipose mass and to reduce risk of obesity-associated comorbidities. In preclinical animal model studies, prevention of obesity by calorie control or weight loss after calorie restriction, following diet-induced obesity, has been shown to reduce or delay the incidence of tumors.[74]

Other studies demonstrate that the tumor promoting effects of obesity can be reduced by pharmacologic interference with obesity-mediated growth promotion and pro-inflammatory pathways. For example, blockade of insulin or IGF-1 receptors[75] and molecular interference with leptin receptor[76] counteract the promotion of breast cancer by obesity. Likewise, both genetic and pharmacologic interference with pro-inflammatory activity of the complement system counteracts obesity-mediated progression of colorectal tumors.[57]

While obesity itself is associated with an increased risk for cancer, it is also clear that different dietary fats may have different effects on cancer development. Murine models and human epidemiologic studies indicate that not all dietary fat is equal in influencing obesity and cancer risk. For example, saturated coconut oil and corn oil promote tumor growth, while equal amounts of olive oil promote obesity but not tumor growth.[57] Further, high fat lard-based diets fed to obesity resistant BALB/C mice promoted the growth and metastasis of mammary carcinoma.[77] In general, tumor promoting fatty acids include medium chain saturated fatty acids, such as lauric and myristic acids; long chain saturated fatty acids, including palmitic and stearic acid; and ω6 polyunsaturated fatty acids, linoleic and arachidonic acids. In contrast, unsaturated fatty acids, including oleic and conjugated linoleic acid, and ω3 polyunsaturated fatty acids, including eicosapentaenoic, docosahexaenoic, and α-linolenic acid, have anti-inflammatory properties that function as tumor suppressors.[78]

Studies with animal models indicating that different types of dietary fat may impact tumor growth have been shown to be clinically relevant. For example, consumption of high quantities of olive oil was associated with decreased risk of upper aerodigestive and breast cancer.[79] Increasing ω-3 PUFAs has been shown to alter the risk of several malignancies, including breast, colon, lung, and prostate cancer.[80,81] A high fat walnut-based diet decreased risk for pancreatic cancer and cancer metastasis.[82, 83]

High carbohydrate diets leading to hyperglycemia and insulin resistance, especially in obese and/or diabetic individuals, have been shown in model, epidemiologic, and clinical studies to contribute to cancer progression and its adverse effects.[84–86] While obesity is associated with the increasing incidence of esophageal adenocarcinoma, increased carbohydrate consumption appears to be a contributing factor.[85] Recent studies further indicate that the consumption of high-fructose corn syrup drinks may contribute to the development of obesity and colorectal tumor growth.[87,88] At the clinical level, in patients with stage III colon cancer and elevated BMI who had failed adjuvant chemotherapy, increased glycemic and carbohydrate loads led to shorter overall survival.[86]

39.3 STRATEGIES TO DISRUPT THE OBESITY–CANCER LINKAGE

From a clinical perspective, the most effective way to prevent the increased cancer risk associated with obesity is by maintaining a lean body mass throughout life, using prudent lifestyle practices of dietary regulation and regular physical activity. For individuals who are overweight or obese, reducing the excess obesity-associated comorbid risk factors should primarily be addressed by lifestyle modifications to lose weight and restore normal body mass. Studies to demonstrate the clinical effectiveness of this approach are limited; however, they do indicate that intentional weight reduction by lifestyle modification, in morbidly obese patients, is associated with normalization of circulating cancer risk factors, including estrogens, insulins, IGF-1, and inflammatory markers such as IL-6, TNFα, and others.[89–91] It is noteworthy that these effects occurred with sustained weight loss. As noted earlier, in discussion of diet-induced epigenetic changes, weight cycling, repeated cycles of loss then regain of excess weight, has not been shown to effectively reduce obesity-associated cancer risk. It may in fact have the opposite effect of increasing risk for breast cancer, renal cell cancer, and non-Hodgkin lymphoma in post-menopausal women.[92]

While studies indicate that intentional weight loss can reduce obesity-associated biomarkers, there have been limited randomized controlled studies to evaluate whether dietary interventions can improve cancer risks or outcomes. In general, studies to alter dietary composition have not been effective at primary prevention of breast cancer occurrence or secondary prevention of tumor recurrence except when interventions were accompanied by weight loss.[93–99] In the prospective Woman's Health Initiative, an

observational study of 61,395 women ≥50 years old, followed for a median 11.4 years, weight loss ≥5% was associated with 12% lower risk of breast cancer, hazard ratio (HR) = 0.88 (95% confidence interval [CI]: 0.78–0.98).[100] The Pooling Project of Prospective Studies on diet and cancer examined the impact of weight loss on the incidence of breast cancer in 180,855 women over age 50, reported in ten studies from the United States, Australia, and Japan. For women not taking post-menopausal hormones, with weight loss and maintenance of greater than or equal to 9 kg, there was a 32% lower incidence of breast cancer, HR = 0.68 (95% CI: 0.50–0.93). A trend to reduced cancer incidence was even noted with sustained weight loss of 2–4.5 kg, HR = 0.82 (95% CI: 0.70–0.96).[101] Although demonstrating a decreased risk of breast cancer associated with weight loss, these studies did not provide comparisons to randomized groups of control patients.

In the LookAHEAD randomized clinical trial, 4,859 patients with obesity, mean BMI 36 kg/m^2, and Type II diabetes mellitus, mean age 58 years old, were divided into either an intensive lifestyle intervention (ILI) targeted at 7% weight loss and maintenance or a diabetic support and education (DSE) control group.[102, 103] After median 11-year follow-up, the cumulative incidence of obesity-associated cancers was 6.1 cases per 1,000 person-years in the ILI group compared with 7.3 cases per 1,000 person-years in the DSE group for HR = 0.84 (95% CI: 0.68–1.04). The 16% reduction in cancer risk for ILI, however, did not reach statistical significance. There were no differences between male and female patients, no specific differences in any tumor type, and no differences in overall or non-obesity-associated cancers. Although not statistically significant, the trend of 16% reduction was considered to provide important evidence that obesity-associated cancer promotion may be reversed by weight loss. The marginal effect resulting from this RCT involving 4,859 patients at 16 institutions with 11-year median follow-up, coupled with the difficulty of monitoring weight regulation by behavioral alterations ,illustrates the problems in conducting large-scale randomized control studies of cancer impact associated with lifestyle approaches to weight loss.[102,103]

The beneficial consequences of intentional weight loss have been most successfully demonstrated by bariatric surgery, in which obese patients undergo one of several surgical procedures to reduce and/or bypass gastric function and capacity.[104,105] Because of the profound metabolic changes associated with these procedures, they have more recently been referred to as metabolic-bariatric surgery (MBS).[105,106] With appropriate post-surgical management, these procedures are among the most successful in achieving sustained weight loss and reduction of comorbidities associated with obesity.[107–110] In the Swedish Obese Subject (SOS) prospective study, comparing the outcomes in 2,010 MBS treated patients with 2,036 controls, surgery was associated with 40% reduction in cancer incidence after 10.9 years' follow-up.[107,108] In a retrospective single practice study from Utah of 7,925 patients who underwent gastric bypass surgery, the surgical intervention showed a 60% decrease in cancer mortality compared with 7,955 controls.[111]

In a follow-up period of 16 years, overall mortality in the SOS study was reduced in patients undergoing surgery compared with medically managed obese patients. Cancer was noted to be the most common cause of death, with 47 cancer deaths in the control group compared with 29 in the surgery group. The number of first-time cancer diagnoses, 117 in the surgery group, was lower than in the controls 169.[108] MBS has been shown to reduce risk of endometrial cancer in severely obese patients.[112] In a recent retrospective study of 22,198 subjects who had MBS for severe obesity compared with 66,427 matched controls, surgically treated patients had a 33% lower incidence of new cancers over a three-year follow-up period compared with controls.[113] The risk reduction was greater for obesity-associated cancers, including post-menopausal breast, colon, endometrial, and pancreatic cancer.[113]

The recently reported SPLENDID (Surgical Procedures and Long Term Effectiveness in Neoplastic Disease Incidence and Death) trial describes a single-institution (Cleveland Clinic) retrospective observational cohort study that provides important new insights regarding the contribution of MBS to protection against cancer development and further demonstrates the importance of weight loss in the process.[114] Among 30,318 patients, 18–80 years old, BMI 35–80 kg/m^2, 5,383 who underwent MBS between 2004 and 2017 were matched 1:5 with 25,265 patients subject to conventional non-surgical obesity management. Among patients followed for median 6.1 years, there were 93 cases of obesity-associated cancers among MBS patients, for an incidence of 3.0 per 1,000 person-years, compared with 780 cases of obesity-associated cancers among controls, for an incidence of 4.6 per 1,000 person-years. The cumulative ten-year incidence for obesity-associated cancers was 2.9% among MBS patients compared with 4.9% in non-surgical controls, for adjusted HR = 0.68 (95% CI: 0.53–0.87) for obesity-associated cancers. The ten-year cumulative incidence for all cancers was 6.8% with MBS, compared with 8.3% in controls, for adjusted HR = 0.83 (95% CI: 0.69–0.99) for all cancers. There were 21 cancer deaths, 0.8% ten-year mortality, among MBS patients compared with 205 deaths in controls, 1.4% ten-year mortality, for adjusted HR = 0.52 (95% CI: 0.31–0.88). Reduced risk of cancer incidence with MBS was noted for both Black patients, adjusted HR = 0.47 (95% CI: 0.27–0.84) and White patients, adjusted HR = 0.71 (95% CI: 0.55–0.93). The study found similar cancer protective effects of sleeve gastrectomy and Roux-en-Y gastric bypass (RYGB). MBS was associated with a decrease in most types of obesity-associated cancers and showed a statistically significant reduction in endometrial cancer. An important aspect of the SPLENDID study was that it provided strong evidence that protection against cancer was associated with degree of weight loss, with those achieving less than 24% weight loss showing the highest cumulative cancer incidence (6%), while those with greater than 39% weight reduction showed the lowest (1%) cancer incidence.

In summary, the SPLENDID study provides strong evidence that MBS is associated with a significantly lower incidence of obesity-associated cancers and all cancers, as well as decreased cancer-related deaths. The cancer protective effects extended to both Black and White patients and were clearly demonstrated to be associated with degree of weight loss.[114]

In more recent years, several programs have focused on the potential role of MBS to prevent specific cancers. Liver cancer has been a particular interest, since the obesity pandemic has been accompanied by a rapid increase in non-alcoholic fatty liver disease (NAFLD), non-alcoholic steatohepatitis (NASH), and cirrhosis, all of which function as precursors to liver cancer and more specifically, to hepatocellular cancer. Importantly, NAFLD, NASH, and cirrhosis are important precursors of liver cancer that can be evaluated in response to MBS.[115–117]

In 2017, a consortium of 110 academic medical centers and their 338 affiliated hospitals in the United States conducted a retrospective administrative database study comparing the presence of liver cancer among hospital admissions with and without MBS over a three-year period, 2011–2015.[118] Among 15,534,065 patients who never had MBS, there were 74,404 patients with liver cancer, for a prevalence of 477.72 cases per 100,000 admissions, compared with 336 diagnoses of liver cancer among 178,192 patients who had MBS, for a prevalence of 188.56 cases per 100,000 admissions. The reported prevalence ratio (PR) = 0.39 (95% CI: 0.35–0.44) suggests a 61% decrease in prevalence of liver cancer in patients who had undergone MBS. The association persisted for sex, race, and ethnicity.[118] In a retrospective survey of 2,881,414 patients with morbid obesity in the United States, the Nationwide Inpatient Sample (NIS) database, sponsored by the U.S. Agency for Healthcare Research and Quality (AHRQ) from 2004 to 2014, 230,956 patients who had undergone MBS were propensity matched with same number of non-surgical patients.[119] Compared to non-surgical patients, where there were 18 cases of hepatocellular carcinoma (HCC), those with MBS had 10 or fewer cases of HCC, for PR = 0.11 (95% CI: 0.63–0.48), accounting for an 89% decrease in the prevalence of HCC associated with MBS. Patients with MBS compared with non-surgical patients were also noted to have 75% decreased hospital mortality.[119] In another retrospective review from a single institution, University of Virginia, in which patients with obesity were followed for up to 12 years, 2,052 MBS patients were compared with 2,055 propensity matched non-surgical patients. MBS was associated with the development of a lower incidence of NASH, from 212 cases (10%) in non-surgical controls to 123 cases (6%) in MBS patients, odds ratio (OR) = 0.52 (95% CI: 0.40–0.68), for 48% reduction in NASH. The incidence of HCC decreased from seven cases (0.3%) in controls to one case (0.05%) in MBS patients.[120] In a meta-analysis of 9 reported MBS studies among patients with NALFD, NASH, and general obesity, BMI 40–47 kg/m^2, with a maximum 24-year follow-up, the incidence of HCC among 239,924 patients who had NALFD and underwent MBS was 0.051 cases/1,000 person-years compared with non-surgical controls, 0.34 cases/1,000 person-years, for a pooled adjusted OR = 0.63 (95% CI: 0.53–0.75), indicating that MBS decreased HCC incidence by 37%.[121]

To evaluate the impact of obesity and NAFLD and subsequent cancer outcomes and protective effects of MBS, a survey was performed of over 230 million unique patient medical records in the IBM Watson Health Market Scans Commercial Claims and Encounters Database from 2005 to 2014. A total of 98,090 patients were identified, 18–64 years old, with severe obesity, BMI $\geq$ 40 kg/m^2 and NAFLD, of whom 33,435 underwent MBS. After 96 months' follow-up, there were 1,898 incident cases cancer among 64,655 non-surgical patients and 925 incident cancers among 33,435 MBS patients, adjusted HR = 0.82 (95% CI: 0.76–0.89) for an 18% reduction in incidence for all cancers and adjusted HR = 0.65 (95% CI: 0.57–0.77) for a 25% reduction in obesity-associated cancers. There were 49 cases in total of HCC, resulting in adjusted HR = 0.48 (95% CI: 0.24–0.89) for 52% reduction. Reductions were also reported for colon cancer, pancreatic cancer, thyroid cancer, multiple myeloma, and endometrial cancer. Of all cancers in this group, endometrial cancer showed the greatest adjusted risk reduction of 52%, adjusted HR = 0.48 (95% CI: 0.31–0.73). Interestingly, risk reduction was greater in patients with cirrhosis compared with those without.[122]

Collectively, these five retrospective database surveys and meta-analysis indicate that in patients with obesity, MBS, compared with non-surgical controls, is associated with 37–89% decreased occurrence of HCC and/or liver cancer as well as a 48% reduction in NASH. The decrease in development of NASH appears to be a major benefit of MBS. While the actual case numbers of HCC and liver cancers are small, their prevention by MBS may become increasingly important, as the incidence of NASH and NAFLD and consequent liver cancer are expected to continue to increase in association with the obesity pandemic.[123]

The prevention of obesity-associated female cancers by MBS has also been an important area of inquiry. In a follow-up to earlier reports in which the SOS study indicated predominant cancer protective effects of MBS in women but not in men, the investigators reported an extended follow-up of 18.1 years median, 26 years maximum for female-specific cancers, including breast, endometrial, ovarian, cervix, and other gynecologic malignancies, among 1,420 women from the SOS surgical cohort and 1,442 contemporaneously matched controls.[124] The MBS group had an incidence of 205 new cancers compared with 267 in the control group, for adjusted HR = 0.71 (95% CI: 0.5–0.85), 29% protection. For female-specific cancers, there were 97 cases in the MBS group compared with 135 in controls, for adjusted HR = 0.68 (95% CI: 0.52–0.88). The MBS group compared with controls showed a decrease in breast, endometrial, and

ovarian cancer. However, only the decrease in endometrial cancer reached statistical significance: adjusted HR = 0.56 (95% CI: 0.35–0.89), 44% reduction in risk. Thus, multiple studies have now shown reduction in endometrial cancer in patients undergoing MBS.[110,112,114,122,124] Interestingly, the reduction in female-specific cancers in the SOS study was associated with elevated baseline insulin levels. Based on a number needed to treat (NNT) analysis, the authors determined the need to conduct MBS surgery in 56 patients to prevent the occurrence of 1 female-specific case of cancer over ten years[124].

Bariatric surgery has also been successful in achieving weight loss in cancer survivors[125] following primary treatment of malignancy, but long-term effects on recurrence and on overall or disease related survival have not yet been reported. Bariatric surgery to reduce weight during active treatment of malignancy has not been reported in enough numbers to evaluate its potential for mitigating adverse prognostic effects in patients with cancer.

In summary, dietary interventions have resulted in modest weight loss, improvement in cancer biomarkers, decrease in incidence of several cancers, and extended overall survival.[89–93,95–99] In an RCT of ILI weight loss, there was a trend to reduced cancer incidence that did not reach statistical significance.[102,103] In contrast, MBS has produced greater and more sustained weight loss and greater reduction in cancer risk.[107–114] The limited benefits of dietary interventions compared with MBS serve to emphasize the importance of significant and sustained weight loss and restoration of lean body mass to reduce cancer incidence among overweight and obese patients. Cancer prevention associated with MBS has been most notably, and most consistently, demonstrated for endometrial and hepatocellular cancers.[112–114,118,119,121,122,124] The persistence of some degree of elevated cancer risk after weight loss may be associated with lasting epigenetic consequences of obesity and may require specific targeted therapy to reverse. While those possibilities are in development, increased cancer risk associated with overweight and obesity is most effectively prevented by maintaining lean body mass throughout life and by emphasizing the necessity for adopting prudent lifestyle practices, including diet modulation, avoidance of pro-inflammatory foods, and regular physical activity.

39.4 LIFESTYLE RECOMMENDATIONS TO DISRUPT THE OBESITY–CANCER LINKAGE

39.4.1 Recommendations for Lifestyle Modifications for Primary Cancer Prevention

As previously discussed, maintaining a healthy BMI (18.5 to 24.9 kg/m^2) throughout life is as important to prevent certain common types of cancer as is avoidance of tobacco consumption. While there are multiple guidelines and recommendations on what constitutes a healthy approach to weight management, the most important behaviors focus on diet and physical activity. As any excessive energy consumption will be stored as fat, it is fundamental for successful weight loss to decrease the number of calories ingested while increasing physical activity. For persons striving to keep their current weight, expenditure and consumption of calories should be relatively balanced. Provided that endocrine disorders affecting basal metabolic rate do not play a role in one's health (i.e., hypothyroidism), the simple math of keeping energy expenditure greater than energy consumption should suffice as a rough guide.

A number of guidelines on physical activity and diet for cancer prevention are accessible to the general public and health practitioners (Table 39.1). Further descriptions are available in the accompanying chapters on the Importance of Nutrition in Cancer (Chapter 40) and in the chapter on Exercise Oncology (Chapter 35). The vast majority of recommendations focus on maintaining a lean body weight and avoiding obesity and were created using the best currently available data and a multitude of studies of mostly cohort nature that have validated the benefits of adhering to such guidelines for cancer prevention. In this section, we provide a compilation of current guidelines while adding personal recommendations on nutrition and physical activity to decrease cancer risk.

39.4.1.1 Achieve and Maintain a Lean Weight across Life Span

A BMI between 18.5 and 24.9 is considered healthy, as it is associated with decreased risk for developing many diseases, such as type 2 diabetes mellitus (DM), hypertension,

coronary artery disease, strokes, and of course, many cancers.[4,126,127] As previously noted, individuals should strive to achieve and keep a lean body weight throughout life, including childhood and elderly years, since increased weight at any time of life may result in obesity at later stages and may also have long lasting epigenetic effects. In a recent meta-analysis of 50 prospective studies, adult weight gain was significantly associated with increased risk for post-menopausal breast cancer, endometrial and ovarian cancers, as well as colon cancer in men.[128] In adolescents, overweight and obesity have been associated with increased risk for colon cancer[129] and colon cancer–related death.[130] And even though the overall incidence of colon cancer has decreased since the late 1990s, colorectal cancer rates have actually increased among younger patients ages 20 to 49.[131]

In adolescents and children over age 2, a BMI between the 5th and 85th percentiles is considered healthy. BMIs between the 85th and 95th percentiles are considered overweight, and above the 95th percentile obese. Childhood obesity predicts not only adulthood obesity but also type 2 DM and abdominal obesity.[132] For the overweight or obese, controversy exists as to which is more effective, rapid or gradual weight loss; however, whichever approach is taken, it is quite clear that long-term management is essential for maintenance.[133,134]

Since 1 pound is equal to 3,500 calories, in order to lose 1–2 pounds in one week, one must decrease the ingestion of calories by 500–1,000 calories per day on average. Making lifelong lifestyle changes is recommended by all national guidelines and leading experts to modify energy balance and maintain a healthy weight.

39.4.1.2 Avoid High-Calorie Foods and Sugary Drinks

A major contributor to the obesity epidemic is the availability and appeal of energy-dense foods, which are defined as having an energy content of at least 225 kcal per 100 grams. The densest micronutrient is fat, as each gram of fat = 9 calories. Each gram of protein and carbohydrate, on the other hand, corresponds to 4 calories.[135] Naturally, for the same amount of calories, a person can consume a much larger portion of food lower in energy density than a food higher in energy density. As an example, oranges have one-quarter of the energy density of one fried egg. In general, foods with the lowest energy density tend to be high in water and fiber content and very low in fat (fruits and vegetables). The consumption of energy-dense foods should be done sparingly.[136] Sugary drinks should be avoided completely, and so should fast foods. Fruit juices should also be limited. Fruits are best eaten whole.[136]

39.4.1.3 Prioritize Healthy Eating Patterns—Rich in Whole Foods, Plant-Based Elements

Because vegetables, legumes, whole grains, and fruits are very high in fiber and water and overall low in fat, they are the perfect example of low energy dense foods that promote healthy weight loss or weight maintenance. They should be consumed mostly whole, with minimal if any processing, including juicing. Processing such as juicing reduces the fiber content that promotes gastric stretching and feeling of satisfaction after eating while concentrating carbohydrates and calories.

39.4.1.4 Physical Activity

Physical activity has many health benefits. Not only does it "burn calories," but also, exercise can enhance muscle mass, leading to increased baseline metabolic rate, aiding in weight loss maintenance. It can also decrease levels of growth factor hormones such as insulin and IGF-1, improve lipid profile, and increase bone mineral density. Many studies have validated a protective effect of exercise in breast cancer,[137] even more so with vigorous activity.[138] Similar associations have been reported for colon[139] and endometrial cancers.[140] For more information, see Chapter 35.

39.4.1.5 Maintain Good Sleep Hygiene

Sleep may play a more important role in weight management than is credited. For natural successful sleep to occur, a highly structured circadian interplay of biological mechanisms, such as melatonin release in response to environmental cues such as dimming of lights/darkening, needs to occur. Lack of adequate sleep has been associated with many diseases, including obesity. Recently, it has been demonstrated that sleep restriction can in fact activate the endocannabinoid system, which modulates appetite and food intake,[141] as well as other appetite stimulating hormones such as ghrelin,[142] leading to an increase in BMI.[143] Sleep deprivation also worsens insulin sensitivity and is a risk factor for type 2 DM.[144] Short sleep duration has been associated with colorectal adenomas[145] and cancer.[146] In breast cancer patients with hormone receptor positive tumors, shorter sleep correlated with higher likelihood for systemic relapse.[147] The initial recommended approach to chronic insomnia is cognitive behavioral therapy, which mostly addresses healthy sleep practices and relaxation training.[148] It can lead to significant and durable symptom control.[149] It may be necessary to address an existing psychiatric disorder and to use pharmacotherapy when cognitive behavioral therapy alone does not effectively control insomnia.[150]

39.4.1.6 Lose Weight If You Are Overweight or Obese

As previously discussed, weight loss is achieved if a caloric deficit is created by restricting the intake of calories with or without increasing the energy expenditure with exercise. Clinicians should screen all adults for overweight and obesity and counsel on weight loss, referring patients to weight management programs if needed. It is important to stress that even 5–10% weight loss is already associated with substantial health benefits.[151] Also, small but meaningful weight loss can boost energy levels and improve mobility, self-esteem, and mood, leading to greater adherence to lifestyle modifications.

39.4.1.6.1 Weight Management Programs

Typically focusing on behavioral treatment, weight management programs offer a comprehensive approach to obesity and overweight, including a large element of coaching. Following individualized assessment, subjects commonly engage in both individual and group sessions aiming to educate and develop strategies to overcome barriers to lifestyle modifications. Patients are encouraged to establish weight loss goals and to develop a plan for reduced caloric intake and increased physical activity as well as self-monitoring strategies. Individuals are encouraged to engage in a steady and slow weight-loss process of 1–2 pounds per week, as very rapid weight loss (more than 3 pounds per week) can be associated with health hazards such as gallstones.

39.4.1.6.2 Metabolic-Bariatric Surgery

Morbidly obese individuals (BMI $\geq$ 40 kg/m^2) or obese subjects with a BMI $\geq$ 35 kg/m^2 who also have comorbidities (type 2 DM, for instance) and despite behavioral treatment cannot achieve target health outcomes are typically referred for a consultation with a bariatric surgeon.[152] Compared with lifestyle modifications, MBS leads to greater weight loss and higher rates of successful control of metabolic syndrome indicators, such as glucose intolerance/type 2 DM.[153] MBS also reduces development of NASH. On average, patients undergoing MBS lose 60% of excess body weight, with more than 80% of patients achieving either complete resolution or improvement of type 2 DM.[154]

There are different types of operations, with different technical challenges, complications, and morbidity.[104] The RYGB and the sleeve gastrectomy procedures typically have higher success rates when compared with gastric banding.[155,156] As with any medical intervention, failures can also occur, and re-operation may be required. For individuals undergoing operations leading to significant anatomical changes, such as the RYGB surgery, vitamin deficiencies can develop,[157] and monitoring and replacement for life (vitamin B12, iron, vitamin D) may be indicated.

Existing data are still conflicting in regard to whether bariatric surgery affects cancer-related mortality, in part due to the limitations of the studies reported, which are mostly of cohort nature and with short follow-ups. Some studies have demonstrated at least a 50–60% reduction in cancer-related deaths,[111,114,158,159] while others have found no effects.[160] In contrast, several Swedish studies suggest that MBS patients may have a higher incidence of colon cancer especially at ten years following surgery.[161,162] In these studies, it is noteworthy that the reported increased incidence of colon cancer is for obese patients who underwent MBS compared with the overall background population calculated by standardized incidence ratios (SIR).[163] In a follow-up study of five Nordic countries, Denmark, Finland, Iceland, Norway and Sweden, the same group using the SIR comparison approach found that patients with obesity, with or without MBS, showed increased colon cancer relative to the background population. However, when patients with obesity who underwent MBS were compared with control patients with obesity but no surgery, there was no significant increase in colon or rectal cancer after ten-year follow-up. A trend to increase in colon cancer was noted 14 years after surgery. Of interest, this study showed a marked reduction in uterine cancer in MBS patients compared with controls, HR = 0.69 (95% CI: 0.56–0.84).[163] In contrast, in a long-term, 22.2-year median follow-up of 4,047 patients (2,007 MBS and 2,040 contemporaneous controls) in the SOS study, there were 58 cases of colorectal cancer in the surgery group compared with 67 cases in the control group, adjusted HR = 0.89 (95% CI: 0.62–1.29), demonstrating that bariatric surgery was not associated with altered colorectal cancer risk.[164]

In summary, MBS provides proof of principle that significant and sustained weight loss can reduce cancer risk, particularly endometrial and hepatocellular cancers. However, because of the radical nature, high cost, and intensive follow-up care for those undergoing the procedure, there remains insufficient evidence to recommend for or against MBS primarily for cancer risk reduction. Moreover, the need to treat more than 50 patients to prevent 1 case of cancer is prohibitive.[124] Nevertheless, MBS actually constitutes an important option for treatment of severe and refractory obesity and its associated metabolic conditions,[107,109,110,114] with the potential for cancer risk reduction as an added incentive.

39.4.1.7 Follow Cancer Screening Guidelines

While people who are overweight or obese have a tendency to avoid cancer screening, it is important to remember that obesity increases the risk for cancer occurrence and that early detection increases the chance of cure and decreases the need for more extensive therapies that can cause unwanted side effects and complications. Moreover, patients with obesity who successfully undergo and maintain weight loss still remain susceptible to common causes of cancer. Accordingly, it is important that all individuals, especially those who are overweight or obese, follow recommended screening guidelines for breast, colorectal, lung, and gynecologic cancers.[165–171]

39.4.2 Guidelines for Secondary Prevention in Cancer Survivors

Cancer survivorship is, by definition, life after a diagnosis of cancer. From the time of diagnosis onward, treatment goals should focus not only on cure or lengthening survival, but also on decreasing and treating complications related to therapy, surveying for progression or recurrence of the original cancer, as well as preventing and detecting new primary cancers. With improvement in screening and treatment of different types of malignancies, the numbers of cancer survivors have increased substantially over the past decades. Currently, there are more than 18.1 million survivors in

the United States. They are projected to increase to 22.5 million by 2032.[172,173]. Two-thirds of cancer survivors are over 65, and many of them potentially face substantial challenges not only in recovering and living with sequelae from their diagnosis and treatment but also working on instituting and maintaining lifestyle modifications that can lead to improved health outcomes. In this section, we focus on the impact of obesity in cancer survivorship and potential strategies to address this health problem.

39.4.2.1 Secondary Prevention of Cancers

Obesity is a risk factor for cancer recurrence after initial diagnosis and treatment and can lead to worse outcomes.[174–176] Obese cancer survivors are more likely to develop complications from cancer treatment,[177–179] including lymphedema and post-operative complications. They are also more likely to develop new primary malignancies.[180] Therefore, following an initial cancer diagnosis, obesity should be aggressively treated as a risk factor that needs to be controlled as much as tobacco use.

39.4.2.2 Avoid Weight Gain After Cancer Diagnosis

Many interventions aiming to control and treat cancers can lead to deleterious weight gain. The etiology of weight gain following cancer diagnosis is multifactorial. It includes:

- Use of medications to prevent nausea and reactions to chemotherapy that are notorious for inducing increased appetite and weight gain (corticosteroids).
- Development of fatigue as a cancer symptom or a side effect of the treatments provided (chemotherapy, hormonal therapy, and radiotherapy) that decreases physical mobility and ability to exercise.
- Development of side effects such as neuropathy, myalgia, and arthralgia that can make regular forms of exercise a painful and challenging endeavor.
- Use of hormonal manipulation (especially in the case of breast and prostate cancers) leading to decrease in muscle mass and sarcopenic obesity (obesity with depleted muscle mass).
- Gastrointestinal side effects such as dysgeusia (taste bud changes), nausea, diarrhea, and constipation that lead to perversion of natural food choices and may skew food intake toward unhealthy food groups.
- Sleep dysfunction is a common manifestation of cancer and/or side effect from treatment, and as previously discussed, can contribute to weight gain.

The authors recommend that following a diagnosis of cancer, all the aforementioned strategies to control weight and obtain/keep lean body weight are developed and/or strengthened. Some other considerations specific to cancer survivorship include the following.

39.4.2.3 Use Exercise as a Tool to Decrease Obesity

Different forms of exercise activity have been studied in cancer survivors to combat side effects from treatment.[181,182]. While in the recent past, oncology patients were frequently told to rest and conserve energy, currently, they are told to be as active as possible. It is best to combine and diversify aerobic, resistance, and mindfulness-based exercise to achieve maximal health benefits and fight side effects. There is no single exercise prescription that fits all cases, and the type and level of activity should be tailored to individual needs and limitations.

Both aerobic and resistance training exercise can improve cancer-related fatigue,[183–186] a highly prevalent symptom that often persists after cancer-directed therapy is complete.[187] Positive effects of physical activity seem to be dose-related, with moderate- or vigorous-intensity exercise displaying a more pronounced impact.[188]

39.4.2.4 Use Exercise to Increase Cancer Survival Odds

The biological reasons for the protective effects of exercise may be more complex than simply weight management. For instance, there is evidence that exercise can modulate circulating levels of growth factors such as IGF-1[189] and insulin[190] as well as endogenous hormones such as estradiol.[191] For a detailed review on exercise for cancer prevention, refer to Chapter 35 on Exercise Oncology.

39.4.2.5 Make Dietary Changes to Achieve Weight Loss

Two clinical studies in breast cancer survivors have addressed the impact of dietary intervention on breast cancer recurrence and overall survival. The Women's Healthy Eating and Living (WHEL) study looked at the effects on breast cancer outcomes and overall survival of increasing the consumption of fruits and vegetables and decreasing the consumption of dietary fat. In this cohort of pre- and post-menopausal women, there were no differences in outcomes between the intervention and the control group[96] in terms of weight loss, progression free survival, or overall mortality. It is noteworthy, however, that the WHEL study was not designed to achieve weight loss. In contrast, the Women's Initiative in Nutrition Study (WINS) addressed the impact of decreasing all dietary fat to 15% of total energy intake and found a 24% lower risk of breast cancer recurrence; however, this was not statistically significant. Nonetheless, a secondary analysis found a 42% lower recurrence risk in the hormonal receptor negative breast cancer patients. Of note, even though the study did not target weight reduction, there was nonetheless a mean weight loss of 6 pounds in the intervention group.[98] These studies suggest that while dietary change alone was not sufficient to reduce the risk for breast cancer, risk may be reduced when diet change is accompanied by weight loss. The contrasting results in the WINS and WHEL studies may also be attributable, in part, to the fact that WINS focused on post-menopausal

women, while WHEL studied both pre-and post-menopausal women, along with other differences.[94] An ongoing initiative, the Breast Cancer Weight Loss (BWEL) study, is a randomized controlled study to specifically evaluate caloric restriction and exercise initiated after a diagnosis of breast cancer, targeted at achieving and maintaining ≥10% weight loss to decrease the risk of reoccurrence in overweight or obese pre- and post-menopausal women with early stage breast cancer.[192] Results of the BWEL study are anxiously awaited. Nonetheless, a recent expert panel convened by the American Society of Clinical Oncology concluded that there was an insufficient amount of evidence based on RCTs to recommend for or against intentional weight loss to improve outcomes. Accordingly, they recommend that patients with cancer should follow guidelines to support general health for patients undergoing active cancer therapy.[193]

39.4.2.6 Invest in Sleep Hygiene

Insomnia is an often-non-recognized symptom in cancer survivors. While many patients are insomniacs by the time of cancer diagnosis, many develop this symptom as a consequence of adjusting to the diagnosis, side effects from therapy, or cancer-related symptoms. As such, insomnia should be addressed in every cancer survivor and treated.

39.4.3 Type 2 Diabetes Mellitus and Cancer Risk

Obesity is a major risk factor for the development of type 2 DM. Type 2 DM is a condition defined by resistance to insulin, leading to sustained hyperinsulinemia and hyperglycemia, and it has been associated with an increased risk for different types of malignancies, including pancreatic, colon, endometrial, breast, and hepatobiliary cancers.[194] One of the working hypotheses for the increased cancer risk seen in diabetics is the cancer promoting effect of insulin and IGF-1, the levels of which are typically elevated in this population. These hormones can activate mitogenic pathways, affecting tumor microenvironment and cell-signaling pathways that lead to tumor growth and progression.[195] Type 2 DM is associated with excess mortality in a multitude of cancer types, including colorectal, breast, pancreatic, gastric, liver, endometrial, and even lung cancers.[196–198]

Metformin is commonly the first drug used for treatment of type 2 DM. Through activation of the AMP-activated protein kinase (AMPK) pathway,[199] it can decrease the production of glucose in the liver. It also increases insulin sensitivity and lowers its circulating levels. AMPK regulates cell metabolism and becomes activated when there is shortage of energy, and also acts as a tumor suppressor.[200] Through AMPK activation, metformin may exert cancer prevention properties and has been implicated in reducing the incidence of certain types of cancers in diabetics, including pancreatic, breast, and liver cancers.[201, 202] Many prospective studies were conducted to explore the chemopreventive properties of this drug. In the MA32 randomized, placebo controlled, double blind trial, involving 3,649 nondiabetic women undergoing usual treatment for breast cancer and followed for eight years, there was no statistically significant difference based on adjuvant therapy with Metformin versus placebo for disease free survival, overall survival, distant relapse free survival, or breast cancer free survival.[203] In an earlier trial of Metformin versus placebo in patients with Barrett's Esophagus, a precursor to esophageal adenocarcinoma, Metformin had no significant impact on cell proliferation, apoptosis, or phosphorylated S6 kinase, a biomarker of insulin pathway activation.[204] Thus, while Metformin has lost its apparent promise as a cancer preventive agent, it remains an important asset for managing type 2 DM in patients with or without cancer.

39.4.4 Special Considerations

The doses of most antineoplastic agents are traditionally calculated based on the body surface area (BSA), using the weight and height of the individual. Deviating from standard dosing and dose-intensity can compromise long-term outcomes and survival of cancer patients, particularly when treating with curative intent. In that regard, the American Society of Clinical Oncology (ASCO) has issued guidelines for treating oncologists on how to dose chemotherapy agents in the ever-growing obese population. ASCO recommends that chemotherapy agents are dosed on a full weight basis, and that ideal body weight or adjusted body weight are not used for dosing.[205] Obese cancer patients should be aware of this recommendation and ensure that treating oncologists are knowledgeable in this regard.

39.5 CONCLUSIONS

Obesity is a risk factor for many types of malignancies, including the highly prevalent post-menopausal breast and colorectal cancers. Excessive adipose tissue can contribute to tumor progression through a variety of mechanisms, including inflammatory, hormonal, and epigenetic alterations. Therefore, maintaining a healthy BMI across the lifespan is essential for cancer prevention. This can be achieved by adherence to national guidelines on diet and physical exercise. Since even after an initial cancer diagnosis, obesity may impact cancer-related outcomes, achieving and keeping a healthy weight constitutes a key priority in cancer survivorship.

39.6 RECOMMENDATIONS FOR LIFESTYLE MODIFICATIONS FOR CANCER PREVENTION

- Achieve and maintain a lean weight across the lifespan
  - Healthy BMI for adults: 18.5–24.9 kg/m^2
  - Adolescents and children over age 2: BMI between 5th and 85th percentile for the age

- If overweight or obese, lose weight gradually.
  - Weight loss goal: 1–2 pounds per week
- Avoid calorie-dense foods and sugary drinks.
  - Drink more water and avoid high glycemic foods such as desserts, sodas, white breads.
  - Prioritize healthy eating patterns, eating plant-based whole foods that are not calorie- but nutrient-dense (high in vitamins and minerals) and high in fiber content.
  - Consume at least five portions of vegetables and fruits of different colors (dark leafy greens, orange, red, yellow, and purple) daily.
  - Use legumes (beans) as a major source of protein.
- Limit the amount of certain animal-derived foods.
  - Red meat (beef, pork, lamb, goat) should be limited to <500 grams/week. If consuming animal protein, prioritize fish and poultry.
- Consider adopting a well-balanced vegetarian or vegan (whole foods, completely plant-based) diet.
  - Whole foods and a plant-based diet aid in weight loss and maintenance of healthy weight through avoidance of calorie-dense foods while providing ample amounts of protein, minerals, and vitamins.
- Engage in physical exercise.
  - Aim for at least 150 minutes of moderate exercise (brisk walk, biking, yoga) or 75 minutes of vigorous exercise (swimming, running/jogging) per week.
- Avoid completely the use of tobacco and if drinking alcohol, use in moderation.
  - Men should limit alcohol intake to up to two drinks per day and women to less than one drink per day.
  - One standard drink = 5 oz. glass of wine, 1.5 oz. hard liquor, 12 oz. beer.
  - Alcohol is a calorie-dense drink and can lead to weight gain.
- Prioritize sleep.
  - Aim for seven to eight hours of sleep every night.
- Avoid dietary supplements unless prescribed by a physician.
  - Obtain all vitamins and minerals from your diet. People following a strict plant-based diet (vegan diet) require oral B12 supplementation.
- If unable to lose weight by making all the aforementioned recommendations, consider joining a weight management program.
  - Achieving and keeping a healthy BMI should be a priority.
  - Discuss with primary care provider metabolic-bariatric surgery evaluation if behavior modifications fail to promote meaningful weight loss.

40 The Importance of Nutrition in Cancer Prevention

Elizabeth R. M. Zunica, PhD and L. Anne Gilmore, PhD, RD

KEY POINTS

- Eat a plant-based diet rich in a variety of vegetables, fruits, whole grains, pulses, legumes, roots, and tubers.
- Limit or avoid the consumption of red and processed meat, alcohol, foods preserved by salting, and foods that are energy dense and nutrient poor.
- Eat a varied and balanced diet, eating foods from across all food groups rather than relying on supplements to protect against cancer.

40.1 INTRODUCTION

Cancer is the leading cause of death worldwide, accounting for one in six deaths in 2020.[1] Some cancers are found to be hereditary, but most are influenced by age, environmental, and lifestyle factors, accounting for up to 90% of the lifetime risk of developing cancer.[2] This large non-hereditary influence on risk indicates that primary risk factors associated with carcinogenesis are potentially modifiable for most cancers. Doll and Peto's seminal 1981 publication "The Causes of Cancer" introduced a framework of studying cancer prevention through modifiable environmental and lifestyle interventions, estimating that at least 35% of the cancer burden at the time was attributable to dietary factors.[3] They highlighted dietary factors hypothesized as protective against cancer and those, such as overnutrition and alcohol, that could increase risk.

The association between nutrition and cancer has been hypothesized since at least the 1800s.[4] Data have shown that nutrition is highly associated with cancer risk and that dietary patterns can either increase or decrease this risk. The National Academy of Sciences (NAS) published the first major institutional report on diet, nutrition, and cancer. This report provided the first evidence-based dietary guidelines for the prevention of cancer, recommending a decrease in dietary fat intake, an increase in plant-based foods, and not consuming nutrients through supplements.[5] Food groups and macronutrients such as protein, carbohydrates, and fats have been a focus in studying the impact of diet on cancer. Additionally, observational and prospective epidemiological studies have shown associations of individual micronutrients such as vitamins, minerals, and phytochemicals (defined here as chemicals from plants that may impact health but are not essential nutrients) with decreasing cancer risk, leading to several seminal clinical trials investigating the effects of supplements. However, many of the clinical trials investigating the potential anticancer effect of specific supplements or dietary components have yielded mixed results.[6] Understanding that foods and nutrients are consumed in combination and not in isolation, there has been a more recent shift to investigating the effect of diet as a whole, or dietary patterns, and cancer risk. Studying dietary patterns aims to dynamically capture food consumption over time and study interventions based on the concerted effect of nutrition. This can include measuring what and how much is consumed as well as when and how often.

There are current limitations in regard to making general evidence-based dietary recommendations for cancer prevention due to robust heterogeneity in cancer incidence, methodology for data collection, and shifts in dietary patterns over time. The influence of nutrition for the prevention of cancer can vary by cancer type. Additionally, dietary patterns are typically assessed through either an *a-priori* approach, using a dietary hypothesis and a standardized scoring system to evaluate adherence to the pattern, or an *a-posteriori* approach, by collecting dietary data, which are statistically analyzed to generate groupings of patterns observed.[7] In research assessing dietary patterns, individual dietary components are not evaluated for contribution to cancer risk. Dietary pattern research holds both potential for clinical effectiveness as well as challenges for well-defined intervention research. Gold standard dietary intervention studies are randomized, double-blinded, provision-controlled trials in which all foods and liquids are provided to participants for the duration of the study, which can be very difficult to carry out.

There now exist multiple national and international tools for researching dietary recommendations and making guidelines for cancer prevention as well as application tools to aid in public health messaging and adherence to guidelines. In the United States, the Dietary Guidelines for Americans is released every five years and now includes a section for cancer risk reduction. The National Cancer Institute (NCI) has created dietary assessment resources for research, which includes the commonly used Healthy Eating Index (HEI-2015) to evaluate dietary patterns, updated in 2015 in collaboration with the United States

DOI: 10.1201/9781003227793-46

Department of Agriculture (USDA).[8] One of the most impactful research and public health messaging efforts on nutrition and cancer prevention was established by the World Cancer Research Fund International (WCRF), a not-for-profit organization network between the American Institute for Cancer Research in the US (AICR), World Cancer Research Fund United Kingdom, Wereld Kanker Onderzoek Fonds in the Netherlands, and World Cancer Research Fund Hong Kong. The WCRF established the Global Cancer Update Programme (CUP) to analyze how diet, nutrition, and physical activity impact cancer risk and survival. The CUP has now published three expert reports (1997, 2007, and 2018) comprising comprehensive analyses and leading to the development of the WCRF/AICR Cancer Prevention Recommendations.[9] These recommendations emphasize increased consumption of plant-based foods and limitation of certain foods and fluids to decrease cancer risk (Figure 40.1). In 2019, NCI also developed a standardized 2018 WCRF/AICR score that can be used by researchers to evaluate adherence to the recommendations and associations with cancer-related outcomes.[10] Recent use of this scoring system demonstrated that adherence to the 2018 WCRF/AICR recommendations substantially reduces total cancer risk. However, a high percentage of the study population had a low adherence score, indicating a significant opportunity to improve cancer prevention.[11]

40.2 SUPPLEMENTS

The 2018 WCRF/AICR Cancer Prevention Recommendations state directly: Do not use supplements for cancer prevention, consistently with the messaging recommended by the NAS in 1982. In the United States, supplement use is common and has increased over the past ten years in all adult age groups.[12] According to the National Health and Nutrition Examination Survey, over 57% of adults and 80% of women aged 60 and over use dietary supplements, most commonly multivitamin-mineral supplements, vitamin D, and omega-3 fatty acid supplements.[12] Dietary supplements are critical tools for the treatment of nutrient deficiencies and related conditions, but in the context of sufficiency, could lead to negative outcomes related to excessive and isolated intake.

Observational epidemiological studies among some human populations have generated hypotheses regarding the potential relationships between nutrients and cancer outcomes. The direct testing of these hypotheses to assess the impact of dietary supplements in cancer prevention is mostly limited to *in vitro* cell and preclinical animal studies. Specific micronutrients and phytochemicals are capable of modifying aspects of carcinogenesis in some cancers. There have been a variety of randomized control trials (RCTs) investigating dietary supplements, mainly antioxidants, folic acid and/or vitamin B, and vitamin D and/or

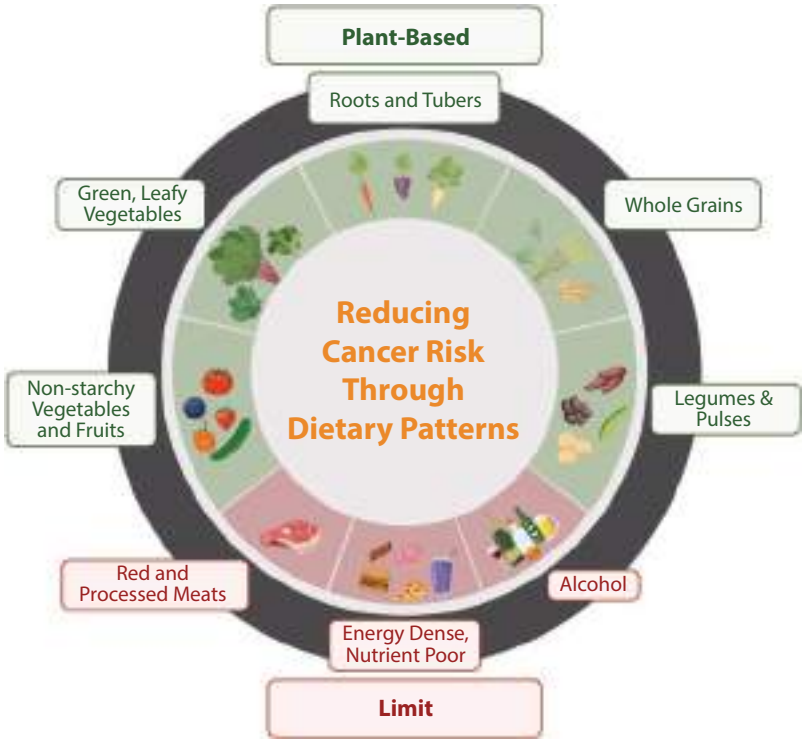

FIGURE 40.1 Nutrition is a key strategy for cancer prevention. Current recommendations encourage reducing cancer risk through dietary patterns that incorporate a plant-based diet and limit intake of components identified as increasing cancer risk. Multiple components of a plant-based diet have been identified in decreasing cancer risk, such as non-starchy vegetables and fruits, green, leafy vegetables, roots and tubers, whole grains, and legumes and pulses. Components recommended to limit include red and processed meats, energy, dense nutrient-poor items, and alcohol. Figure 40.1 was created using Biorender.com.

calcium, for the prevention of certain cancers. These studies have generally produced null results, with some even showing increased risk of certain cancers with supplement use.

In the case of antioxidants, β-carotene/retinoids, α-tocopherol/vitamin E, vitamin C, vitamin A, and selenium have been used in several cancer prevention clinical trials over the past 30 years.[13–28] The data from nearly all these studies showed that the supplement and/or combination of supplements did not protect against the incidence of the cancer being investigated. Furthermore, several of the studies reported increased risks with supplementation. There were some surprising results in which initial trials indicated potential protection against cancer incidence and mortality when studied as secondary endpoints, but when those were directly tested in follow-up studies, the effect was not seen. Further investigations have found that the initial trials were more successful because there were baseline deficiencies within the populations and that supplementation on top of sufficiency had no additional benefit.[29]

There have been only a few RCTs evaluating the effect of folic acid/vitamin B supplementation or vitamin D and/or calcium supplementation in the prevention of cancer. Clinical trials using folic acid supplementation with or without other B vitamins with cancer prevention as a primary endpoint or in a secondary analysis have mostly shown that the supplementation was not protective and in some cases, may have tumor-promoting effects.[30–34] Short-term RCTs using vitamin D and/or calcium supplementation have shown mixed results regarding cancer outcomes,[35–40] and given the short study period and sample size, there is insufficient evidence to draw cancer prevention conclusions. Overall, the potential effects of supplementation on cancer risk have been difficult to identify given the variable baseline nutrient status and dietary backgrounds of individuals, variation in supplement formulations and doses, study duration, and differential effects between tissue and cancer types.

40.3 PLANT-BASED DIETARY PATTERNS

Plant-based dietary patterns emphasize the consumption of a variety of fruits, vegetables, whole grains and cereals, nuts, seeds, legumes, herbs, and spices. Additionally, plant-based dietary patterns may encompass diverse constellations of a variety of plants as well as quantity. They are vaguely described as infrequent consumption of animal products along with frequent consumption of plant-based foods. Plants are rich in bioactive compounds, including fibers, vitamins, minerals, and polyphenols, that have been associated with anti-cancer properties and/or reduced cancer incidence as individual compounds, food components, and whole foods. As noted in the previous section, multiple expert panels/reports have concluded over the years that these bioactive compounds are most beneficial when consumed as whole foods.

Whole grains are grains and grain products that include the bran, endosperm, and germ layers, contributing soluble and insoluble fibers, protein, starch (carbohydrate), fats, and micronutrients, particularly B vitamins (e.g., thiamin, niacin, and folate), and phytochemicals to the diet. Conversely, refined grains have been processed in a way that removes some or all the nutrient-rich outer bran layer and inner germ core, to isolate the starchy carbohydrate middle endosperm layer. Notably, refined grains are often enriched with B vitamins and iron and may have variable nutrient and fiber status depending on the degree of processing. Whole grain and fiber intake are consistently associated with a reduced risk of gastrointestinal cancers. including colorectal,[41] colon, gastric, pancreatic, and esophageal cancers.[42,43] Investigations assessing the risk of cancer with high intake of refined grains are currently limited and potentially biased by the definition and types of refined grains studied. There have only been a few meta-analyses investigating the association of refined grain intake and cancer, yielding mixed results.[42] Importantly, there have not been studies to distinguish between refined grains that also contain high amounts of fat and/or sugar, such as cookies, doughnuts, and pizza, versus those that are considered staple foods, such as bread, non-sugary cereals, and pastas.[42]

Fruits and vegetables also contain varying levels and types of soluble and insoluble fibers, macronutrients, micronutrients, and phytochemicals. Fruits and vegetables can be classified using a botanical definition, where a fruit is precisely the mature ovary of a seed from the flower of a plant, or a culinary definition, in which fruits are considered to be sweet or sour while vegetables are non-sweet or more savory. Like the Continuous Update Project, this chapter will discuss fruits and vegetables from a culinary perspective that is commonly understood by consumers. In addition, vegetables are often discussed in dietary recommendations as starchy (e.g., corn, potatoes, acorn and butternut squash) or non-starchy vegetables (e.g., leafy greens, eggplant, tomatoes, peppers, onions, summer squash, asparagus). Starchy vegetables contain higher amounts of carbohydrate and less fiber, but still contain various micronutrients and phytochemicals. Like whole grains, a higher intake of non-starchy vegetables and fruit is associated with a decreased risk of gastrointestinal cancers.[9] Additionally, non-starchy vegetables and fruit intake are associated with a decreased risk of lung cancer, breast cancer, and bladder cancer. However, higher intakes of vegetables preserved by salting (e.g., kimchi, olives, cucumbers, canned vegetables with salt) are associated with an increased risk of gastric and possibly nasopharynx cancers.[9]

In plant-based diets, soybeans and other legumes such as beans, nuts, peas, and lentils are major protein sources. Like whole grains, vegetables, fruits, and legumes contribute various levels of macronutrients, micronutrients, fiber, and phytochemicals. Thus, higher intakes of these fiber-containing foods are associated with decreased gastrointestinal cancer risk.[9,41,44,45] Soybeans and soy-containing products contain naturally occurring isoflavonoids

that act as phytoestrogens and antioxidants in mammals. Due to their similarity to estrogen and differences in how rodents, a common preclinical research model, metabolize phytoestrogens compared with humans, there is a common misconception that soy may increase the risk of certain types of cancers, including hormone sensitive breast and prostate cancer. However, moderate intakes of soy and soy-containing products are associated with a decreased risk of breast cancer and do not increase the risk of recurrence of breast cancer.[46–48] Nuts, seeds, and legumes also contribute mono- and polyunsaturated fatty acids to the diet. Diets with a higher ratio of omega-3 to omega-6 polyunsaturated fatty acids have been associated with a lower risk of cancer than diets higher in omega-6 and saturated fats.[49]

Due to the differences in nutrient profiles, plant-based diets encourage intake of a variety of whole grains, vegetables, fruits, legumes, nuts, and seeds to constitute most of one's food intake. Plant-based dietary patterns can be achieved by following several different diets, including vegan diets that are free of animal products or vegetarian diets that may include animal products such as eggs and dairy (i.e., lacto-ovo vegetarian) or fish (i.e., pescatarian). Additionally, flexible vegetarian (i.e., flexitarian), Mediterranean diets, and other dietary patterns such as The New American Plate recommended by the AICR contain more animal products than vegan diets but still encourage a plant-based diet, with the majority of dietary intake coming from whole grains, vegetables, fruit, legumes, nuts, and seeds. In a recent meta-analysis, the highest adherence to a Mediterranean diet was inversely associated with a lower risk of cancer mortality and in the incidence of several cancers, including colorectal, liver, gastric, breast, head and neck, and prostate.[50] To date, the scientific evidence does not support one specific plant-based diet over the other for reduction in cancer risk. Individuals should be encouraged to follow the plant-based dietary pattern that fits their lifestyle and personal preferences and to which they can routinely adhere.

40.4 ENERGY BALANCE

Plant-based diets are typically more nutrient dense and less calorically dense (kcal per unit weight of food) than other dietary patterns. Thus, in addition to the nutrients provided, plant-based diets may facilitate a reduction in cancer risk by aiding in maintaining a healthy body weight. The first 2018 WCRF/AICR Cancer Prevention Recommendation is to be a healthy weight. Six of the other recommendations (be physically active, eat a plant-based diet, limit fast foods, limit red and processed meats, cut down on sugary drinks, and limit alcohol consumption) can influence energy balance and the healthy weight recommendation.

Overweight and obesity describe increasing states of the amount and/or distribution of body fat above a recommended range identified with improved health outcomes. Chronic positive energy balance due to an excess of energy intake from foods and drinks results in increased body fatness, obesity, and metabolic alterations. The mechanisms linking obesity and cancer are multifactorial and are not yet fully elucidated. Obesity induces chronic inflammation and insulin resistance, leading to increased levels of cytokines and growth hormones promoting cancer initiation and progression. Indeed, overweight, obesity, and metabolic syndrome are associated with increased incidence of at least 13 cancers.[51] According to the 2018 WCRF/AICR report, there is convincing evidence to support a causal relationship with increased adult weight gain and body fatness and the incidence of esophagus, pancreas, liver, colorectal, postmenopausal breast, endometrial, and kidney cancers,[52] Furthermore, their investigations have found strong evidence to support a probable causal relationship between adult body fatness and the risk of mouth, pharynx, larynx, stomach, gallbladder, ovary, and prostate cancers.[52] In contrast, the effect of body fatness in premenopausal breast cancer may lower risk. This paradoxical relationship is likely multifactorial and related to circulating estrogen concentrations, adipocytokines, inflammatory status, and insulin-signaling pathway activation.[53]

A Western diet or Standard American Diet dietary pattern is typically energy dense, consisting of large portions of processed foods, red and processed meats, and high fat and high sugar foods. In contrast to plant-based diets, the Standard American Diet is typically lower in whole grains, vegetables, and fruit. Thus, these dietary patterns are often associated with increased body fatness and increased risk of cancer, including colorectal cancer and hormone sensitive, postmenopausal breast cancer.[54]

40.5 PROCESSED FOODS

Food processing is a critical tool for providing foods to consumers—this tool can be used minimally or extensively, with a wide range of approaches. In general, processed foods are often criticized and their nutritious contributions called into question, but as defined by multiple regulatory systems and food science teachings, processed foods encompass a wide range of products. The U.S. Department of Agriculture defines a processed food as one that has undergone any changes from its natural state.[55] This could include milling, cutting, pasteurizing, cooking, canning, drying, fermenting, packaging, and addition of other ingredients. Thus, most of the foods within our food supply have been processed to some degree, and not all foods with some processing are unhealthy. Food processing can increase food safety and extend the shelf life of foods. Some food processing methods can preserve (e.g., freezing) or enhance (e.g., enrichment and fortification) the nutritional properties of foods. Other food processing methods can decrease the nutritional properties of foods and incorporate less nutritionally desirable ingredients such as added salt, sugars, and saturated and trans fats.

Multiple classification systems have been developed to describe the type and extent of food processing in

order to study the relationship between food processing and health. Currently, these frameworks vary in what is defined as processed and how the level of processing may influence health outcomes, but most do not include nutrient profiling parameters. One framework was developed as a part of the large multi-center European Prospective Investigation into Cancer and Nutrition (EPIC) in connection with the International Agency for Research on Cancer, referred to as the IARC-EPIC system.[56] The IARC-EPIC system bases food processing on the level of physical change made to the food per type of food and not the technique used, including how food is modified and prepared in the home. Conversely, the NOVA system, originally described in 2010[57] and revised over the years, classifies food based on the extent and purpose of the industrial processing.

Processed foods can be made by adding salt, oil, sugar, or other processed culinary ingredients. Processed food also includes preservation methods such as canning, curing, smoking, bottling, and non-alcoholic fermentation. Intake of foods preserved by salting, including pickled and/or fermented vegetables and salted fish, is associated with an increased risk of nasopharynx and stomach cancers.[9,58] Ultra-processed foods or highly processed foods are processed in such a way that nutrient density decreases and energy density increases through the addition of sugars and fats. Typically, these foods are ready-to-eat, such as sugar sweetened beverages, cookies and package baked goods, salty snacks, fast food, and frozen dinners. The consumption of ultra-processed foods is inversely related to diet quality. It is estimated that on average, Americans consume more than half of their calories from ultra-processed foods.[59] Due to increased energy density, habitual consumption of ultra-processed foods contributes to positive energy balance, weight gain, and increased body fatness. Ultra-processed food intake is associated with higher overall cancer risk and breast cancer risk.[60]

40.6 RED AND PROCESSED MEATS

Epidemiological data has long supported the association between red and processed meat intake and colorectal cancer.[61] In 2015, the IARC classified processed meat as a carcinogen.[62] A critical evaluation of the epidemiological studies investigating processed meat intake and cancer risk cautions such associations due to lack of scientific rigor. The 2018 WCRF/AICR report acknowledged the methodological limitations of the epidemiological studies and therefore considered the available mechanistic evidence as well in their recommendations regarding processed meat. Processed meat intake is strongly associated with an increase in colorectal cancer and may be associated with an increased risk of nasopharynx, esophageal, lung, stomach, and pancreatic cancers.[9,63,64] Additional controversy has emerged based on regional differences, in which investigations in some populations of Asian countries have not shown significant increases in colorectal cancer risk with red and processed meat intake.[65]

The associations between red meat, its specific components, and cancer risk indicate potential complexity.[66] Consumption of red meat, including beef, pork, sheep, horse, and goat, is probably a cause of colorectal cancer. One suggested mechanism is that red meat is higher in heme iron than poultry or seafood. Heme iron can increase the production of reactive oxygen species and formation of nitroso compounds that can lead to DNA damage within the gastrointestinal tract. Additionally, gastrointestinal carcinogens, including heterocyclic amines and polycyclic aromatic hydrocarbons, can be formed when meat is cooked well-done at high temperatures. However, these compounds can be formed in red and white meats and may not explain the association of red meat consumption and colorectal cancer. Most preclinical studies testing these potential mechanisms used concentrations of these compounds in excess of those found in human diets. Also, the semi-purified animal diets that were used did not include potentially protective compounds present in a variety of whole foods.[67] Another potential mechanism focuses on the interaction of red and processed meats with the gut microbiota and the impact on colorectal cancer.[68] From these data, it remains unclear whether red and processed meats are causes of dysbiosis of the microbe–host relationship or only increase risk if a pre-existing dysbiosis exists,[68] potentially indicating why there could be dramatic regional differences in the association of red and processed meats and cancer.[65] More evidence from rigorously designed studies is needed to fully understand the relationship between red meat consumption and cancer risk. In addition to iron, red meat is an excellent source of protein, vitamin B12 (almost exclusively found in animal products), niacin, vitamin B6, zinc, and phosphorus.[69] To balance risk versus benefit, the 2018 AICR/WCRF recommends limiting intake of red meat to 12 to 18 ounces (or three portions) per week in conjunction with a plant-based diet.

40.7 ALCOHOL

Alcoholic drinks include beers, wine, spirits, fermented milks, mead, and cider. On average, worldwide, adults consume one alcoholic drink per day (~14 grams of pure alcohol); however, alcohol consumption varies widely between and within different populations across the world. The National Toxicology Program of the U.S. Department of Health and Human Services classifies alcohol as a known human carcinogen.[70] Ethanol increases reactive oxygen species production in cells, and ethanol is metabolized to acetaldehyde. Both reactive oxygen species and acetaldehyde can damage DNA and proteins, increasing carcinogenic potential. Alcohol also decreases the absorption and utilization of several micronutrients associated with cancer risk (e.g., vitamin A, B complex, C, D, and E) and increases estrogen levels.[71] Although alcohol intake is often confounded with tobacco use, there is strong

TABLE 40.1
Clinical Nutrition Recommendations for Cancer Prevention and Control

Recommendation	Strategies for Implementation
Use a patient-centered treatment approach	• Use SMART (Specific, Measurable, Achievable, Relevant, and Time-Bound) goals; set personalized goals for each individual • Consider and address socio-economic barriers • Treat emotional or disordered eating behaviors • Consider consultation with or referral to other healthcare providers or agencies that can assist in treating or managing nutrition-related problems
Achieve and maintain a healthy weight throughout the lifecycle	• Consume a nutrient-dense, balanced diet • Participate in physical activity or exercise most days of the week • Follow obesity treatment guidelines considering lifestyle, pharmacological, and surgical treatment options as appropriate[78–80]

Eat a plant-based diet	• Balance meals and snacks according to The New American Plate with at least two-thirds of the plate being vegetables, fruits, whole grains, and beans and one-third or less animal protein
	• Follow a vegan, vegetarian, or Mediterranean dietary pattern
	• Consume 30 g/d of fiber from food sources
	• Eat a variety of:
	  • fruits (e.g., berries, oranges, apples, avocado)
	  • non-starchy vegetables (e.g., broccoli, okra, asparagus, peppers, cabbage)
	  • green, leafy vegetables (e.g., spinach, lettuce, kale)
	  • roots and tubers (e.g., carrots, sweet potatoes, turnips, beets)
	  • whole grains (e.g., brown rice, wheats, oats, barley, and rye)
	  • legumes and pulses (e.g., beans and lentils)

Limit consumption of red and processed meat	• Limit intake of red meat (e.g., beef, pork, lamb) to 12 to 18 ounces (or three portions) per week • Eat little, if any, processed meat (e.g., bacon, hot dog, sausage, pepperoni, deli meats)
Limit consumption of sugar sweetened beverages (e.g., soda, sweet tea, juices)	• Enjoy mostly low-calorie beverages such as water, sparkling water, and unsweet tea
Limit or avoid alcohol consumption	• It is best not to drink alcohol
Limit consumption of processed foods high in fat, starches, or sugars	• Limit consumption of "fast foods," many pre- prepared or packaged foods, baked goods, desserts, and candy • Consume fresh, frozen, or no salt added vegetable options • Prepare more meals at home and avoid adding fat, sugar, and salt during and after cooking • When eating out, choose foods lower in fat and sugar • Eat fruit or yogurt as a sweet food option
Do not use supplements for cancer prevention	• Aim to meet nutritional needs through diet alone • Use macro- and micro-nutrient supplementation to correct known deficiencies • Do not mega-dose or use high-dose dietary supplements

evidence supporting the positive association between alcohol intake and the risk of mouth, pharynx, larynx, esophagus, liver, colorectal, and postmenopausal breast cancer.[9,72,73] Alcohol may also increase the risk of lung, pancreas, and skin cancers, although current evidence is limited.[9] Although the consumption of up to two alcoholic drinks per day may be protective against kidney cancers, most cancer prevention dietary recommendations endorse limiting or complete avoidance of alcohol.[9,74] In the United States, most alcohol related policies are regulated at the state level. More restrictive policy environments are associated with lower rates of most alcohol-attributable cancers.[71]

CLINICAL APPLICATIONS

There are important aspects regarding the incorporation of changes in dietary patterns to reduce cancer risk. While increased adherence to recommendations corresponds to decreased risk, adherence needs to be considered on a continuous scale with a goal of identifying what can be manageably changed in a sustainable way for an individual. Health and eating behaviors are multifactorial and are influenced at the individual, interpersonal, organizational, community, and public policy levels. Such factors include health status, knowledge, skills, motivation, preferences, social support, time constraints, food availability and accessibility, cultural

and societal norms, food environment, food pricing, media advertising, and public policy. Notably, over half of patients with obesity experience weight discrimination and bias, significantly reducing their access to quality healthcare and inducing additional barriers to improving health.[75] Additionally, there is a complex influence of economic and social injustices on dietary patterns and health status. The USDA found that the prevalence of cancer increases as the severity of food insecurity increases.[76] Often, food insecurity limits access to affordable, nutritious foods while incentivizing energy-dense, nutrient-poor foods.

Understanding the psychosocial aspects of food choices and behavioral changes is important. Many behaviors cannot be addressed in a single session or by solely providing a written handout, as knowledge alone is a poor predictor of behavior.[77] Patients are likely to benefit from a multidisciplinary treatment team (e.g., physician or advanced practice provider, dietitian, social worker, and/or psychologist) to meet their needs. Together, patients can make incremental, realistic, and sustainable changes building toward a lifestyle that contributes to overall cancer risk reduction. Furthermore, organizations and individuals at national, state, and local levels should work collaboratively to advocate for, develop, and implement policies to increase access to affordable healthy foods for all individuals throughout the lifecycle.

The diverse field of nutrition and cancer progression is burgeoning. The understanding of the pathology of carcinogenesis for different cancer types has improved, and the appreciation for the interaction between dietary components and health and disease has widened. There remains a need for RCTs that incorporate robust dietary information and the effect on specific cancers to offer evidence for the potential causative relationship between dietary patterns and different types of cancers. This effort will be made possible with improved tools and technologies to capture food intake and dietary patterns. Investigations into the nutritional components and quality of food between different sources and levels of processing and preparation offer insights into how we can make healthier choices even within the same types of foods. Efforts to highlight food insecurity and weight and health stigma bring to light the structural barriers people face regarding their nutrition and health. A person-centered approach to find ways to shift dietary patterns toward plant-based incorporation and limited intake of alcohol, nutrient-poor/energy-dense foods, and red and processed meats are recommended for reducing cancer risk (Table 40.1 and Figure 40.1).

41 Exercise Management for the Patient with Obesity

John M. Jakicic, PhD

KEY POINTS

- Physical activity contributes to the prevention of weight gain and a lower risk of developing obesity as an adult. Thus, physical activity should be emphasized in efforts focused on the primary prevention of weight gain and obesity.
- Physical activity can result in weight loss, even without a concurrent reduction in energy intake, and the magnitude of weight loss is dependent on the dose of physical activity.
- Physical activity is a key contributor to enhancing weight loss maintenance and the prevention of weight regain, which supports the need for intervention efforts focused on continued engagement in an adequate dose of physical activity for these outcomes.
- Moderate-to-vigorous-intensity physical activity is most strongly associated with weight loss and prevention of weight regain; however, a concurrent increase in light-intensity physical activity may result in additional weight control benefits.
- Physical activity is an important lifestyle behavior to include within medical-based treatments of obesity, which may include bariatric surgery and pharmacotherapy.
- Independently of body weight and obesity status, physical activity contributes to a variety of health benefits, which justifies its importance as a key lifestyle behavior for health in patients of optimal body weight and in patients with overweight or obesity.

41.1 INTRODUCTION

Overweight and obesity are significant public health problems, given the association between excess body weight and many chronic diseases, which include cardiovascular disease, diabetes, some forms of cancer, musculoskeletal disorders, and others.[1,2] Thus, public health approaches and interventions are needed to prevent overweight and obesity, and to reduce body weight in adults who are already diagnosed with overweight or obesity. The cornerstone of these approaches is lifestyle factors that contribute to optimal energy balance to prevent weight gain, and energy imbalance that results in an energy deficit to promote weight loss. One of the key lifestyle factors that have been implicated in these prevention and treatment efforts is physical activity.[3–5] This may result in important health benefits to patients.

41.2 EFFECT OF PHYSICAL ACTIVITY ON PREVENTION OF WEIGHT GAIN

Given the high prevalence of overweight and obesity in adults, much of the clinical emphasis is typically on effective treatments for weight loss. However, from a public health perspective, it is also important to consider effective approaches to prevent weight gain in order to reduce the onset of overweight and obesity.

There is evidence that physical activity may be an important lifestyle behavior that can contribute to these prevention efforts.[3,4,6] For example, there is cross-sectional evidence to support that an inverse relationship exists between physical activity and both body mass index (BMI)[7–13] and body fatness.[7,9,11–14] There are also prospective data from the NHANES-I Epidemiology Follow-Up Study,[15] Aerobics Center Longitudinal Study,[16] Women's Health Study,[17] and Harvard Alumni Study[18] to support the importance of physical activity for the prevention of weight gain. Others have also demonstrated that physical activity is important for maintaining a healthy body weight, defined as a BMI of $\geq$18.5 to <25 kg m^2,[19] and for reducing the odds of developing obesity.[20] Moreover, there may be a threshold of physical activity that is needed to prevent significant weight gain, defined as a weight gain of at least 3% of current body weight, with this threshold ranging from 150 to 250 minutes per week.[21]

The findings from prospective and randomized studies that were at least one year in duration to support that physical activity contributes to the prevention of weight gain were reviewed by the U.S. Department of Health and Human Services 2018 Physical Activity Guidelines Advisory Committee.[3,4] This review concluded that "there is strong evidence to demonstrate a relationship between greater amounts of physical activity and attenuation of weight gain in adults."[3,4] This review also supported that the evidence for the association and attenuation of weight gain in adults was most pronounced when physical activity exceeds 150 minutes per week, and when physical activity

DOI: 10.1201/9781003227793-48

is at a moderate-to-vigorous intensity compared with less intense physical activity (e.g., light-intensity physical activity).[3,4] Moreover, despite the increased public health emphasis on reducing sedentary behavior, there is limited evidence to support that reducing sedentary behavior, without a concurrent increase in moderate-to-vigorous physical activity, will impact efforts to prevent weight gain.[22]

41.3 EFFECT OF PHYSICAL ACTIVITY ON WEIGHT LOSS

41.3.1 Physical Activity without a Concurrent Prescribed Reduction in Energy Intake

Physical activity has been recommended as a key behavior within interventions that target overweight and obesity.[2] However, the effects of physical activity on weight loss, when not coupled with a concurrent reduction in energy intake, appear to be on average quite modest.[23,24] For example, average weight loss of 2% at 6 months and 1% at 18 months was reported in a study of overweight adults who were prescribed home-based physical activity without a prescribed reduction in energy intake.[25] This is also consistent with the 0.5–3.0-kg weight loss in response to 180–270 minutes per week of physical activity that was reported based on a systematic review in the 2008 Physical Activity Guidelines Advisory Committee Report.[26] This systematic review also reported that weight loss did not occur when physical activity was reported to be less than 150 minutes per week.

Despite the modest average effect of physical activity on weight loss, there may be a dose–response effect, with the magnitude of weight loss increasing as the dose of physical activity increases. For example, a systematic review of the literature conducted for the 2009 Position Stand of the American College of Sports Medicine (ACSM)[21] concluded that there was no significant change in body weight in response to <150 minutes per week of physical activity, whereas a change of 2.0–3.0 kg and 5.0–7.5 kg was observed with >150 and 225–420 minutes per week of physical activity, respectively.

Donnelly et al. also reported on the findings from a randomized study that was 10 months in duration, with 5 days per week of supervised aerobic exercise that progressed to either 400 or 600 kcal per session. Results showed that weight loss was 3.9 ± 4.9 kg and 5.2 ± 5.6 kg in the 400 and 600 kcal per session conditions, respectively, with the no exercise control group showing a small weight gain (0.5 ± 3.5 kg).[27] A similar pattern was observed in this study for reduction in body fat. However, the additional weight or fat loss achieved within the 600 kcal per session condition was not statistically greater than the weight and fat loss achieved within the 400 kcal per session condition. These findings may suggest that significant weight loss can be achieved with progressively increasing engagement in aerobic physical activity to 400 kcal per session (equivalent to approximately 30–50 minutes per session at a moderate-to-vigorous intensity); however, increasing the energy expenditure to 600 kcal per session (approximately 45–65 minutes per session) may result in modest additional weight and fat loss.

41.3.2 Physical Activity Combined with a Prescribed Reduction in Energy Intake

It is recommended that within the context of a comprehensive behavioral weight loss intervention, a diet focused on reduced energy intake be coupled with an increase in physical activity.[1,2] There is an abundance of studies to support that physical activity, when added to a modest energy restricted diet, will result in greater weight loss than a modest energy restricted diet that does not also include physical activity. For example, results from a six-month weight loss intervention showed that the combination of both reduced energy intake and increased physical activity was associated with an increase in weight loss.[28] Moreover, findings from the multi-center Look AHEAD Study showed that within a comprehensive behavioral weight loss intervention, physical activity was a significant predictor of weight loss achieved at one year.[29] Examination of the scientific evidence further suggests that the addition of physical activity to an energy restricted diet will result in an additional 1.0–3.0 kg beyond what is achieved with an energy restricted diet alone.[23,24,30] While this magnitude of additional weight loss appears to be modest, Curioni and Lourenco[31] have suggested that the combination of physical activity and an energy restricted diet results in approximately 20% greater weight loss than the weight loss achieved with an energy restricted diet alone.

Despite the findings that behavioral interventions, on average, are effective for initial weight loss, the maintenance of weight loss is less than optimal.[32] Thus, there is a clinical and public health need for interventions targeting weight loss maintenance to be more effective. This is a particularly important health-related area that may highlight the important of physical activity, as physical activity appears to be important for enhancing weight loss beyond the initial six months of treatment, improving long-term weight loss maintenance, and minimizing weight regain.[21,33] An important observation is that relatively high levels of physical activity may be necessary to improve long-term weight loss,[34–41] and the magnitude of physical activity to enhance long-term weight loss and to minimize weight regain is recommended to be 200–300 minutes per week at a moderate-to-vigorous intensity.[21,33] The higher level of physical activity may be a particularly important behavior to achieve an initial weight loss of ≥10% at six months and to sustain this magnitude of weight loss at the conclusion of the 24-month intervention period.[42]

It is important to highlight a few important considerations that are pertinent to the association between physical activity and long-term weight loss and weight loss maintenance. First, most of the evidence for this association is supported

by data from secondary analyses or observational studies.[34–42] However, randomized studies do not necessarily support that the higher dose of physical activity contributes to improved long-term weight loss. For example, Washburn et al. reported that following a 3-month intervention, weight loss after an additional 12-month period did not differ when physical activity was prescribed at 150, 225, or 300 minutes per week.[43] Moreover, recent findings from a randomized study conducted in our laboratory showed that weight loss at 12 months did not differ when a reduced energy diet was combined with prescribed physical activity of either 150 minutes per week (−10.1 [95% confidence interval, CI: −11.5 to −8.8] kg) or 250 minutes per week (−9.4 [95% CI: −10.8 to −8.0] kg), and neither of these differed from weight loss achieved with a reduced energy diet without prescribed physical activity (−9.4 [95% CI: −10.8 to −8.0] kg).[44] These findings may suggest that the influence of physical activity on long-term weight loss and weight loss maintenance is observed when interventions exceed 12 months in duration. Moreover, this may support the need for effective intervention strategies that enhance initial engagement in physical activity and support continued physical activity beyond 12 months in adults with overweight or obesity.

41.4 ALTERNATIVE TYPES OF PHYSICAL ACTIVITY

41.4.1 Daily Steps of Physical Activity

There has been a proliferation of wearable devices that monitor and provide feedback on physical activity, and a common metric included in these devices is steps of daily movement. These devices are upgrades to the simple technology included in pedometers, which also monitor and provide feedback on steps of physical activity. It has been shown that providing a device, similar to a pedometer, to monitor and provide feedback on steps of activity resulted in an increase of 2,100 to 3,000 steps per day.[21,45] This increase in steps per day resulted in modest weight loss equivalent to 2–3 kg[21] or a reduction in waist circumference.[45] These findings were observed in studies where there was no concurrent prescription to decrease energy intake.

Creasy et al.[46] examined the effect of prescribing physical activity as steps per day within the context of a comprehensive behavioral weight loss intervention. Steps per day was the prescribed physical activity, to progress to 10,000 steps per day, with a target of at least 25% of those steps accumulated in bouts that were at least 10 minutes in duration at a moderate-to-vigorous intensity. Results after 12 weeks showed that participants achieved 10,323 ± 2,538 steps per day, with 36% of daily steps performed in bouts of at least 10 minutes in duration and at a moderate-to-vigorous intensity. Moreover, there was no difference in short-term weight loss achieved with the step-based physical activity prescription compared with a traditional structured physical activity prescription. There is also evidence to support that 10,000 steps per day, with at least 35% of the steps performed in bouts of at least 10 minutes and at a moderate-to-vigorous intensity, is associated with enhanced long-term weight loss and weight loss maintenance.[47] This may suggest that a step-based physical activity prescription is a viable method of prescribing physical activity for adults with overweight or obesity.

41.4.2 Resistance Exercise

While most of the research related to the effect of physical activity, in the absence of restrictions in energy intake, has focused on cardiovascular (aerobic) forms of physical activity, there is a body of literature on the effects of resistance exercise on weight loss. It has been proposed that the pathway by which resistance exercise may influence body weight is through an increase in lean mass, which may increase resting metabolic rate and also increase strength, which will result in an increase in free-living physical activity.[21] In combination, these may result in an increase in total daily energy expenditure, which may then have an effect on body weight regulation.[21]

There is evidence from studies of resistance exercise of a modest, but significant, increase in lean mass when this form of activity is not coupled with a concurrent reduction in energy intake.[48] However, this increase in lean mass is not observed when resistance exercise is coupled with a concurrent reduction in energy intake.[49, 50] Nonetheless, even in the presence of a concurrent reduction in energy intake, resistance exercise has been shown to increase muscular strength,[49] and it may also result in beneficial enhancements in the structure of skeletal muscle.[51] This may suggest that resistance exercise can be beneficial in enhancing strength and function in adults with overweight or obesity.

Despite the potential benefits of resistance exercise, systematic reviews have shown that this form of physical activity has modest effects on weight loss without a concurrent reduction in energy intake.[21, 52]. Moreover, within the context of dietary restriction, resistance exercise is not superior to aerobic forms of physical activity for weight loss.[52] There are few long-term trials of the effects of resistance exercise on weight loss,[52] and the inclusion of resistance exercise may not enhance the maintenance of diet-induced weight loss.[53]

Despite the above-mentioned potential benefits of resistance exercise, systematic reviews have concluded that resistance exercise has a modest influence on weight loss when performed in the absence of reductions in energy intake.[21, 52] One potential explanation for this lack of an effect of resistance exercise on weight loss is that the potential increase in lean mass may offset the reduction in the loss of fat mass, and this may result in absolute body weight remaining unchanged.[54–57] Moreover, it has been suggested that the energy expenditure resulting from resistance exercise may have been insufficient to result in weight loss in studies that have been relatively short in duration (e.g., six months or less).[21,26] There are limited data available from longer-term studies,[52] and the limited data available do not

support that resistance exercise enhances the maintenance of weight loss resulting from an energy restricted diet.[53]

The evidence does not support that resistance exercise is superior to aerobic forms of physical activity for either short-term or long-term weight loss, either without energy restriction or when coupled with energy restriction.[52] However, there is evidence to support that resistance exercise may reduce subcutaneous abdominal adiposity,[58] which has been shown to be associated with reduced cardiometabolic health risk.

41.4.3 Yoga

Yoga participation is a form of physical activity that may have the potential to contribute to weight loss and the treatment of obesity. Within the context of yoga, there are many styles and components that may need to be considered when determining if this is a form of physical activity that can impact body weight regulation.

A major aspect of yoga practice is the asanas (poses), and how these asanas are performed can impact energy expenditure, which may then also have implications for body weight control. Some styles of yoga perform the asanas in a manner that holds the body in a static manner prior to moving to the next asana, and this style of yoga typically elicits energy expenditure that is consistent with light-intensity physical activity (1.5 to 3.0 metabolic equivalents [METs]).[59] An alternative style of yoga is one in which the asanas flow from movement to movement in a continuous manner, rather than being held statically, and this stye of yoga elicits an energy expenditure that consistent with moderate-to-vigorous-intensity physical activity (e.g., ≥3.0 METs).[60] Thus, given these differences in energy expenditure, the style of yoga may have different effects on body weight.

There have been few studies that have examined the effects of different styles of yoga, within the context of a comprehensive intervention program that includes a prescribed energy-reduced diet, on weight loss in adults with overweight or obesity. A study conducted in our laboratory compared a restorative hatha style of yoga with a vinyasa style of yoga within the context of a six-month comprehensive behavioral weight loss intervention.[61] There was no significant difference in weight loss between these styles of yoga. However, as expected, participants reported that vinyasa yoga rather than the restorative hatha style of yoga was more likely to elicit an effort similar to brisk walking.

Another recent study examined whether adding 12 weeks of yoga following an initial 12 weeks of a behavioral weight loss intervention enhanced weight loss that was observed at 6 months.[62] This study showed that the additional yoga at 12 weeks to a behavioral weight loss intervention resulted in greater weight loss at 6 months (9.0 kg vs. 6.7 kg) compared with not receiving the addition of yoga. However, these findings need to be interpreted with caution, given that the comparison group was not provided with an additional physical activity intervention at 12 weeks. This is a limitation, given that other studies have shown that the addition of other forms of physical activity after initial weight loss can also enhance subsequent measures of weight loss.[30] Thus, it is unclear whether the additional weight loss observed is a result of specifically adding yoga to the intervention or whether adding any form of physical activity would have resulted in a similar finding. Thus, the effects of yoga on weight loss are currently inconclusive. Moreover, there is a lack of evidence supporting the efficacy of yoga for weight loss beyond a six-month intervention.

41.5 PHYSICAL ACTIVITY INTENSITY

Within the context of interventions for weight loss, physical activity has typically been prescribed at a moderate-to-vigorous intensity. Greater improvements in cardiorespiratory fitness are observed with vigorous compared with moderate-intensity physical activity.[37,63] However, when controlling for energy expenditure, there does not appear to be a difference in weight loss achieved with the inclusion of moderate-intensity compared with vigorous-intensity physical activity.[37,63] This suggests that physical activity energy expenditure, rather than physical activity intensity, makes the greatest contribution to weight loss. Thus, strategies to enhance physical activity energy expenditure may need to be the emphasis of interventions focused on weight loss and the treatment of obesity.

An alternative form of physical activity that has gained popularity is high-intensity interval training (HIIT). This has been defined as "episodic short bouts of high intensity exercise separated by short periods of recovery at a lower intensity."[64] Studies have shown that HIIT is not superior to other forms of moderate-to-vigorous-intensity physical activity for changes in weight, body fatness, or lean mass.[64–66] Thus, provided that it is not contraindicated, HIIT may provide an alternative to traditional physical activity prescriptions for adults with overweight or obesity.

The term "nonexercise activity thermogenesis" (NEAT) is used to describe energy expenditure that does not result from sleeping, eating, or structured periods of exercise.[67] This form of physical activity may be comprised mostly of light-intensity physical activity rather than moderate-to-vigorous physical activity. Within the context of obesity treatment and weight loss, light-intensity physical activity may provide weight loss benefits in addition to what is achieved with moderate-to-vigorous physical activity. For example, Jakicic et al.[28] found that the amount of light-intensity physical activity, in combination with moderate-to-vigorous physical activity and reduced energy intake, was predictive of weight loss achieved during a six-month behavioral weight loss intervention. Secondary data analysis also showed that light-intensity physical activity, in combination with moderate-to-vigorous physical activity, was associated with long-term weight loss and enhanced weight loss maintenance.[39] In an additional study conducted in our laboratory, we again have shown that light-intensity physical activity, in combination with

moderate-to-vigorous intensity physical activity, is associated with weight loss achieved at both 6 and 12 months of a comprehensive behavioral weight loss intervention.[68] These findings suggest that interventions for weight loss should emphasize the need for moderate-to-vigorous intensity physical activity, and there should also be an emphases on increasing participation in lifestyle forms of light-intensity physical activity.

Within the context of physical activity intensity, consideration of the influence of reducing sedentary behavior warrants consideration. The reduction in sedentary behavior has gained considerable attention relative to its association with enhancing a variety of health-related outcomes.[22,26,69] Despite the potential health benefits of reducing sedentary behavior, there is limited evidence to support that reducing sedentary behavior alone will have a positive impact on measures of weight control or obesity.[70–72] Studies that have examined sedentary behavior within the context of a comprehensive behavioral weight loss intervention have also not shown an association between reduced sedentary behavior and weight loss.[28] This may be a result of a minimal increase in energy expenditure with the change in posture from sedentary (lying or sitting) to non-sedentary (standing), whereas changing from sedentary to movement (walking) results in a substantial increase in energy expenditure.[73] Thus, for weight loss, reducing sedentary behavior in combination with increasing movement appears to be needed and should be recommended for patients with overweight or obesity.

41.6 DURATION OF PHYSICAL ACTIVITY BOUTS

Until recently, public health guidelines have recommended that physical activity be accumulated in bouts of 8-–10 minutes to have favorable benefits on a variety of health-related outcomes.[26, 74] However, evidence reported in the 2018 Physical Activity Guidelines Advisory Committee Report support that bouts even shorter than 8–10 minutes in duration are associated with a variety of health benefits.[4,75] Included in these health benefits are measures of obesity that include BMI,[7–9,11] and body fatness.[7,9,11–13] However, these findings may need to be interpreted with caution, given that they are supported primarily by evidence from cross-sectional studies. When prospective studies are examined, the evidence supports that physical activity accumulated in bouts of at least 10 minutes is associated with a lower incidence of obesity, whereas this finding was not supported when examining physical activity accumulated in bouts of a shorter duration.[76] Moreover, secondary data analysis from an intervention study supports that moderate-to-vigorous physical activity performed in bouts of at least 10 minutes in duration was associated with greater weight loss at 18 months, with physical activity accumulated in bouts less than 10 minutes in duration not being associated with weight loss.[39,47] These findings may suggest that adults with overweight or obesity can realize health benefits with physical activity accumulated in bouts less than 10 minutes in duration; however, to enhance weight loss, physical activity may need to be accumulated in bouts of at least 10 minutes.

41.7 THE TIMING OF PHYSICAL ACTIVITY BOUTS

Evidence has started to emerge related to the time of day when physical activity occurs and its relationship with obesity-related outcomes. There is a circadian clock in muscle tissue, and it has been suggested that physical activity may impact this pathway, which may further impact substrate metabolism.[77] This potential influence on substrate metabolism, along with other potential pathways that have yet to be determined, may provide a variety of biological pathways by which the time of day when physical activity is performed may influence body weight. There are few studies that have specifically examined whether the timing of physical activity influences weight loss, with the limited data results primarily from secondary data analyses.[78] In the context of a 10-month supervised physical activity study, when the majority of physical activity was performed between 7:00 and 11:59 AM, the weight loss was 7.2 kg, whereas when the majority of physical activity was performed between 3:00 and 7:00 PM, the weight loss was 2.1 kg. Given that this was a supervised physical activity study, sessions were not offered after 7:00 PM, so it is unclear how structured periods of physical activity performed after 7:00 PM would influence weight loss. Moreover, this study did not include measures of potential mechanisms that may have contributed to these findings.

Schumacher et al. examined whether consistency of the time of day when physical activity was performed was associated with greater physical activity participation in participants in the National Weight Control Registry.[79] This study showed that regardless of the time of day when physical activity was performed, being consistent with that time of day resulted in greater physical activity compared with participants who were not consistent with the time of day of their physical activity. Creasy et al. reported that patients defined as weight loss maintainers engaged in higher amounts of moderate-to-vigorous physical activity, with more of this occurring in the morning hours, compared with control participants with obesity or without obesity.[80] In adults who had bariatric surgery, a greater amount of physical activity performed in the morning hours was associated with greater overall physical activity.[81] This greater amount of physical activity, which may be influenced by the time of day or consistency of when physical activity is performed, may contribute to increased energy expenditure, which may influence body weight regulation. These findings may support that there is a behavioral influence, and not only a biological influence, for how the time of day when physical activity is performed may contribute to the effects of physical activity on body weight regulation and the treatment of obesity.

From a clinical perspective, these findings may suggest that consistency of when physical activity is performed should be an important behavioral target that can enhance physical activity participation and result in greater energy expenditure. Moreover, when feasible, there may be some additional benefit from physical activity being consistently performed in the early hours of the day. However, the specific mechanisms by which physical activity timing may influence body weight regulation have not been confirmed, and the findings from the observational studies warrant confirmation from appropriately designed and rigorous research studies.

41.8 THE ROLE OF PHYSICAL ACTIVITY IN THE MEDICAL TREATMENT OF OBESITY

41.8.1 The Role of Physical Activity in Surgically Induced Weight Loss

Bariatric surgery has become a more common treatment for obesity[82] and results in highly significant weight loss compared with nonsurgical interventions for weight loss.[83] While there is limited additional weight loss observed in the short term (<6 months) following bariatric surgery with the addition of physical activity,[84,85] the existing evidence does support that surgically induced weight loss is enhanced with physical activity at 12 months and beyond.[85–88] Thus, patients who undergo bariatric surgery may benefit from physical activity to enhance long-term weight loss, and therefore, physical activity should be included within a treatment plan for these patients.

41.8.2 The Role of Physical Activity in Pharmaceutically Induced Weight Loss

There is a pipeline of pharmaceutical agents focused on weight loss for the treatment of obesity. These medications have varying degrees of effectiveness; however, recent trials have shown that current pharmaceutical agents can be highly effective for weight loss. For example, liraglutide and semaglutide are glucagon-like peptide-1 analogues that are currently approved for weight loss, and 68 weeks of liraglutide resulted in mean weight loss of 6.4%, while semaglutide resulted in mean weight loss of 15.8%, from baseline body weight.[89] Within these pharmaceutical approaches for weight loss, patients were also prescribed an energy restricted diet and a prescription to engage in physical activity of at least 150 minutes per week. While most of these pharmaceutical trials do not specifically report on the adherence to the physical activity recommendation or how adherence to the physical activity recommendation may be associated with weight loss, it is important to highlight that physical activity is a component of the comprehensive treatment plan. Moreover, regardless of whether physical activity significantly contributes to the weight loss observed in response to these pharmaceutical agents, as highlighted later, physical activity may contribute to other health-related outcomes in patients with obesity, and these health benefits may be independent of weight loss.

41.9 WEIGHT LOSS VARIABILITY IN RESPONSE TO PHYSICAL ACTIVITY

There is a high degree of individual variability in weight loss in response to physical activity,[90] and this has been observed even in studies that included structured periods of highly controlled exercise.[91] There are a variety of factors that may contribute to this variability in weight loss with physical activity. There may be biological factors that contribute to this variability, and this is supported in studies of twins, in which there was small variability within a pair of biological twins but greater variability within non-biological pairs of twins.[92] There is evidence of inter-individual variability in energy intake in response to physical activity, with some individuals experiencing an increase in energy intake and others experiencing a reduction in energy intake in response to physical activity, which can contribute to variability in energy balance.[93,94] There are also genetic[95–97] and psychosocial factors[98,99] that are associated with physical activity engagement, and these may further contribute to weight loss response with physical activity. These factors are important to consider when there is less than the expected weight loss in response to physical activity in adults with overweight or obesity, and clinicians should be cautious about attributing this lack of weight loss response solely to the possibility of lack of compliance by the patient. Rather, exploring potential causes of this lack of weight loss response to physical activity warrants careful consideration on behalf of the clinician.

41.10 PHYSICAL ACTIVITY, FITNESS, AND HEALTH OUTCOMES

41.10.1 Effects on Mortality and Cardiovascular Disease

There is a substantial body of evidence to support that a higher level of cardiorespiratory fitness is associated with reduced risk of mortality. This association between cardiorespiratory fitness and reduced risk of mortality may be present even when adjusting for body mass index[100–104] or body fatness.[105,106] However, there is also evidence to support that fitness will not completely ameliorate the risk of a higher level of BMI or body fatness on these outcomes.[107–109] Thus, to maximize the reduction in mortality and cardiovascular disease, public health and clinical approaches should focus on both weight loss and enhancing cardiorespiratory fitness in adults with overweight or obesity.

More recently, secondary analyses examining the association between physical activity and cardiovascular disease outcomes from the Look AHEAD Study have been reported.[110] These result showed a significant inverse

association between objectively measured physical activity and outcomes of cardiovascular disease in patients with type 2 diabetes, and these results remained significant after controlling for a variety of covariates that included weight loss. However, an important finding from these analyses was that the association between change in physical activity and cardiovascular disease was not present after one year of observation but was present after four years of observation. Other studies have also shown that the association between physical activity and cardiovascular disease in prospective studies was observed for periods beyond one year.[111] These findings may suggest that for physical activity to reduce the onset of cardiovascular disease, physical activity needs to be sustained for relatively long periods (e.g., more than one year), and therefore, strategies to enhance long-term engagement in physical activity are needed.

41.10.2 Effects on Risk Factors for Cardiovascular Disease

41.10.2.1 Left Ventricular Mass

A clinically prognostic indicator of cardiovascular disease is the left ventricular mass of the cardiac tissue.[112,113] When measured by either echocardiography[114] or cardiac magnetic resonance imaging,[115, 116] BMI is positively associated with left ventricular mass. This association between BMI and left ventricular mass may reflect a maladaptive response that contributes to the association between obesity and cardiovascular disease. Jakicic et al. recently reported that weight loss induced by an energy restricted diet resulted in significant reduction in left ventricular mass in middle-aged adults.[44] However, when physical activity was combined with the energy restricted diet, there was a blunting of the reduction in the left ventricular mass. Moreover, cross-sectional evidence from this same study showed that cardiorespiratory fitness was associated with greater left ventricular mass in adults with overweight or obesity.[116] Thus, combining physical activity with weight loss that results in an increase in cardiorespiratory fitness, which is associated with a greater left ventricular mass, may reflect a clinically adaptive response that indicates an improvement in cardiac structure and function. This may provide an explanation of why both weight loss and physical activity, in combination, contribute to reduced risk of cardiovascular disease.

41.10.2.2 Blood Pressure

Hypertension is a risk factor for cardiovascular disease. Whether interventions should target treatment of obesity, low fitness, or the combination of obesity and low fitness to reduce resting blood pressure is an important clinical question. Some studies have reported that both obesity and low cardiorespiratory fitness are significantly associated with the risk of developing hypertenstion.[117] However, other studies report that when both a measure of obesity and cardiorespiratory fitness are considered in the same analysis, the measure of obesity and not cardiorespiratory fitness is associated with systolic blood pressure.[118,119] In response to a 12-month weight loss intervention in adults with overweight or obesity, a reduction in systolic blood pressure was reported, and a similar reduction was observed with weight loss induced by an energy restricted diet alone or when this same diet was combined with physical activity.[44] However, there is also evidence to support that structured periods of physical activity can significantly decrease blood pressure.[120] Thus, collectively, it may be important to target both weight loss and physical activity, which elicits an increase in cardiorespiratory fitness, to maximize reduction in blood pressure.

41.10.2.3 Lipids

Abnormal blood lipids are risk factors for cardiovascular disease, and there is an association between obesity and blood lipids.[2] Thus, interventions that target the treatment of obesity may contribute to improved lipid profiles, which are associated with reduced risk for cardiovascular disease. However, there are inconsistent results regarding the potential effect of physical activity on changes in blood lipids. For example, weight loss induced by an energy restricted diet resulted in favorable improvements in blood lipids; however, the addition of physical activity to the same diet did not result in further improvements in blood lipids in adults with overweight or obesity.[44] Similar results have been shown in other studies of weight loss and physical activity.[30] However, these findings are in contrast to the results from the CALERIE Study, which reported that the addition of physical activity to calorie restriction resulted in reductions in total cholesterol and low-density lipoprotein (LDL), and these reductions were not reported with calorie restriction that did not include physical activity.[121] Moreover, in the absence of dietary restriction or weight loss, physical activity has a modest effect on blood lipids,[122,123] while other studies have reported no influence of physical activity on changes in blood lipids.[128]

41.10.2.4 Inflammatory Markers

Biomarkers of inflammation and anti-inflammation contribute to the processes of atherosclerosis.[124] Studies have shown that physical activity is not associated with improvements in markers of inflammation,[123, 125] and cardiorespiratory fitness has also been shown not to be associated with markers of inflammation.[126] These findings support that physical activity may not be the preferred therapy for improving measures of inflammation in adults with overweight or obesity.

41.10.2.5 Cardiorespiratory Fitness

As highlighted in the preceding sections, cardiorespiratory fitness may be a clinically meaningful correlate of a variety of health-related outcomes, and some evidence supports that these benefits are observed even when excess body weight is present. Thus, engagement in physical activity is needed to realize improvements in cardiorespiratory fitness, and this is also observed in adults with overweight or obesity.[25,127]

Improvement in cardiorespiratory fitness is seen in response to a sufficient dose of physical activity regardless of whether that dose of physical activity also results in weight loss.[128] However, an important clinical observation is that cardiorespiratory fitness does not improve significantly with weight loss in the absence of physical activity.[49,128] These findings support the need for clinicians to prescribe engagement in physical activity to enhance cardiorespiratory fitness in adults with overweight or obesity, regardless of whether physical activity contributes to weight loss.

SUMMARY AND CLINICAL APPLICATIONS

Physical activity is a key lifestyle behavior that contributes to numerous health-related benefits.[70] These health-related benefits include prevention of weight gain, weight loss in the presence of overweight or obesity, and additional health-related benefits even in the presence of excess body weight or when weight loss is not achieved. The summary of the evidence presented supports the following:

- Physical activity contributes to the prevention of weight gain and can also contribute to a reduced incidence of developing obesity, and these benefits are typically observed when physical activity is at least 150 minutes per week and performed at a moderate-to-vigorous intensity.
- Physical activity, when not combined with a prescribed energy restricted diet, results in an average short-term weight loss (typically less than six months) of approximately 0.5–3.0 kg; however, the magnitude of weight loss occurs in a dose–response manner and is dependent on the dose of physical activity.
- When combined with a reduction in energy intake, physical activity can enhance weight loss by approximately 20% beyond the magnitude of weight loss achieved through a reduction in energy intake alone.
- Physical activity engagement at a sufficient dose is an important contributor to enhancing long-term weight loss and prevention of weight regain following initial weight loss.
- The evidence supports that moderate-to-vigorous-intensity physical activity is most strongly associated with weight loss and prevention of weight regain; however, the addition of light-intensity physical activity can further contribute to weight loss or weight loss maintenance.
- While there is some evidence that moderate-to-vigorous physical activity that is accumulated in bouts of less than 10 minutes per bout may contribute to effective weight control, the scientific evidence supports accumulation of physical activity performed in at least 10 minutes per bout is more strongly associated with enhance weight loss and weight loss maintenance.
- It is important that physical activity be included within medical treatments for obesity, which include bariatric surgery and pharmacotherapy.
- Physical activity contributes additional health benefits beyond weight loss, and many of these benefits can be realized in adults with overweight or obesity, even without a significant reduction in body weight.

Given these findings, physical activity should be included in the treatment plan for obesity and related health conditions. Physicians, other healthcare providers, public health professionals, and health-fitness professionals should prioritize the inclusion of physical activity within the treatment of patients with overweight or obesity to optimize health-related benefits.

42 Dietary Management of Overweight and Obesity

Nina Crowley, PhD, RDN, LD and Katherine R. Arlinghaus PhD, RDN

KEY POINTS

- Behavioral intervention is the cornerstone of treatment plans for people with overweight or obesity; Registered Dietitian Nutritionists (RDNs) use an ongoing, dynamic process to collect data and continually analyze the patient during medical nutrition therapy.
- Nutrition assessment includes the use of equations and tools to estimate resting energy expenditure and energy intake balanced with an understanding of patient-specific environmental and behavioral factors.
- Evidence for particular dietary interventions varies and includes various ways to reduce energy intake while maintaining realistic expectations and enjoyment; there is no one-size-fits-all approach, so individual interventions can be tailored based on assessment and then monitored and adjusted accordingly.
- The chronic, relapsing nature of the disease of obesity requires long-term strategies and a commitment to shared decision making and a trusting partnership between each patient and their healthcare team.

42.1 INTRODUCTION

As the majority of American adults today live with overweight or obesity, managing obesity, or abnormal/excess body fat, as a chronic disease is one of today's greatest healthcare challenges. Rates of obesity and associated health conditions and healthcare costs continue to impact society. Obesity has been described as a chronic, relapsing disease process that is rarely, if ever, cured.[1] While target outcomes for weight management vary across individuals, modest weight losses of 5–10% are associated with improvements in cardiovascular risk factors.[2] As described in other chapters of this text, surgery and medications are important tools in the treatment of obesity. However, behavioral intervention remains a cornerstone of obesity care and plays a role in all treatment plans, irrespective of the severity of obesity or treatment modality. Dietary modification is a key component of behavioral intervention for weight management. While there is no one-size-fits-all dietary pattern for weight management, appropriate dietary patterns provide essential nutrients to achieve and maintain optimal nutritional status while simultaneously producing an energy deficit to yield a weight loss consistent with patients' goals. Importantly, appropriate dietary modifications also balance eating enjoyment with reductions in energy consumption to promote sustainable eating patterns. This chapter will help guide clinicians through the dietary assessment, intervention, monitoring, and evaluation of patients with overweight and obesity.

42.2 MEDICAL ASSESSMENT

Accurate assessment of weight status requires an office environment sensitive to the unique needs of patients with obesity. This includes having appropriately sized furniture, equipment, gowns, and scales that can weigh patients of all sizes. The assessment of overweight or obesity involves annual measurement of anthropometrics, including height, weight, and calculation of body mass index (BMI; calculated as kg/m^2), to classify overweight and obesity using current classification methods. Weight and height are measured with the patient wearing light clothing or an examination gown and no shoes. Patients identified as having overweight (BMI >25 kg/m^2) or obesity (BMI >30 kg/m^2), as well as those who may benefit from nutrition counseling, should be referred to a Registered Dietitian Nutritionist (RDN) for medical nutrition therapy (MNT).[3]

Measuring waist circumference in patients with BMI ≤35 kg/m^2 is recommended to provide additional information about other medical conditions associated with obesity, such as cardiovascular risk (>88 cm or >35 in for women; >102 cm or >40 in for men).[4] A medical history and exam should query for cardiovascular risk factors like high blood pressure, hyperlipidemia, and hyperglycemia. The measurement of blood pressure, lipids, and glucose to assess for cardiovascular risk enables treatment to be matched to risk profile.[4] These markers are also critical to assess because they provide additional baseline measures besides weight from which patients' progress can be monitored and evaluated. This is important to help patients remain adherent to treatment plans during times of weight plateaus or when weight changes are not as expected.

During the medical examination and history, genetic syndromes as well as endocrine disorders such as

DOI: 10.1201/9781003227793-49

hypothyroidism, Cushing's disease, polycystic ovary syndrome, and other metabolic conditions should be ruled out as contributing reasons for a patient's weight status. Acquiring medication history is also essential in identifying if any drugs are associated with weight gain and can be modified. For female patients, it is also important to inquire about the possibility of pregnancy before making weight loss recommendations. The Institute of Medicine has set guidelines for total and rate of weight gain during pregnancy by pre-pregnancy BMI.[5] Recommendations for weight gain during pregnancy should be individualized based on pre-pregnancy BMI to improve pregnancy outcome, avoid excessive maternal postpartum weight retention, and reduce risk of the child acquiring chronic disease later in life.[6]

42.3 NUTRITION ASSESSMENT

MNT by the RDN will include a comprehensive nutrition assessment to obtain, verify, and interpret data needed to identify nutrition-related problems, their causes, and their significance. It is an ongoing, nonlinear and dynamic process that involves data collection and continual analysis of the patient's status compared with specified criteria.[7] The RDN should assess food- and nutrition-related history, anthropometric measurements, biochemical data, medical tests and procedures, nutrition-focused physical findings, and client history in order to individualize the comprehensive weight management treatment.[8]

Assessment of food and nutrition-related history includes asking questions about beliefs and attitudes, including food preferences and motivation, food environment, access to fruits and vegetables, dietary behaviors, eating out, screen time, past dieting history, food allergies, medications, dietary supplements, and physical activity. The patient's weight history, family medical and health history, social history, living situation, and socio-economic status are all factors to consider in a thorough assessment. Weight history includes questions about highest and lowest adult body weight, usual body weight (within the last six months), body composition assessments, and finally, the individuals' stated preferred or desired body weight. Consideration of individual factors such as eating disorders or disordered eating behaviors, dieting history, pregnancy, and if a patient is receiving treatment for other health conditions that impact diet (e.g., chemotherapy, management of diabetes, renal disease) are part of determining the appropriateness of a weight management plan.

Many RDNs are becoming proficient in performing nutrition-focused physical assessment,[9] an examination of the body and physical function to help determine nutritional status, signs of malnutrition, and nutrient deficiencies. A systems-based exam of regions of the body (i.e., skin, nails, hair/head, eyes, mouth, neck/chest) can help identify declining nutrition status and micronutrient deficiencies even when malnutrition is not present.[9] Assessment of body composition (fat mass and fat-free mass) can further help individualize the dietary intervention for weight loss. Because interventions aim to reduce fat mass while preserving fat-free mass, periodic assessment of body composition changes can help to measure changes during the intervention. Body composition testing can help provide additional, objective data beyond weight/BMI to reinforce effectiveness and encourage patients to continue with their eating pattern. Available technology or devices may vary based on availability, cost, and accessibility, but include dual energy X-ray absorptiometry (DEXA) and bioelectrical impedance analysis (BIA).

42.4 DIETARY ASSESSMENT

42.4.1 Determining Energy Expenditure

Determining a patient's energy needs is a critical first step to creating a personalized dietary plan that creates the energy deficit needed for weight loss. Typically, an energy deficit of 500–750 kcal/day is recommended.[3] Energy needs can be determined by first assessing total energy expenditure. An individual's total energy expenditure consists of three components: basal energy expenditure, thermic effect of food, and an adjustment factor for the physical activity level. The assessment of energy expended in the basal state is impractical. Resting energy expenditure (REE), or resting metabolic rate (RMR), however, is practical to assess. REE is considered to be ~10% above the basal state. This substitution works well in practice because the thermal effect of food, which is also difficult to measure, is approximately 10% of total energy expenditure. The overestimation of REE compared with basal energy expenditure can be substituted for the thermic effect of food. Therefore, determining energy expenditure requires assessment or estimation of both RMR and energy expended through physical activity.

RMR should be measured through indirect calorimetry whenever possible.[3] Although reasonably priced, handheld medical devices enable measurement of RMR in the primary care setting; however, there are often times when measurement is not possible. The Mifflin-St. Jeor Equation (MSJE) is the most accurate predictive formula available for adults and has been found to predict RMR within 10% of measured in most individuals.[3,10,11] Online and mobile applications utilizing the MSJE make the calculation of energy needs particularly convenient and accessible. The simplified MSJE for males and females[11] is as follows:

$$\text{For females, REE} = 10 \times \text{weight (kg)} + 6.25 \times \text{height (cm)} - 5 \times \text{age (y)} - 161$$

$$\text{For males, REE} = 10 \times \text{weight (kg)} + 6.25 \times \text{height (cm)} - 5 \times \text{age (y)} + 5$$

To complete the estimation of total energy expenditure, physical activity level must be estimated. Assess the patient's current activity level and apply the appropriate activity factor of REE × 1.2 (sedentary), × 1.4 (low active to moderate), and × 1.6 (active). Subsequent adjustments for intentional activity or exercise (such as walking, biking, dancing, exercise routines, etc.) are added as individuals

engage in these activities and can be adjusted per day or averaged per week.

Given the depth of the physical activity and nutrition fields, separate examination of each of these areas is necessitated, and the specific role of physical activity in weight management will be discussed in more detail in other chapters. However, it is important to recognize that as the most modifiable components of energy balance, both physical activity and diet are inherent components of weight management that complement each other to create an energy deficit. In practice, the lines between physical activity and eating habits are more blurred. and clinicians must assess both areas. The assessment of energy expenditure is a natural opportunity for the RDN to assess a patient's physical activity and sedentary behaviors. The assessment of activity patterns is crucial to being able to tailor recommendations. Although it is difficult to lose weight through increased physical activity alone, physical activity is a critical factor in the maintenance of weight loss.[12] Additionally, inactivity is predictive of cardiovascular outcomes, and physical activity has many other benefits outside a simple "calories in, calories out" equation. As such, establishing regular physical activity routines is important at all weight management stages and levels of health and fitness.

42.4.2 Determining Energy Intake

Once energy needs are determined, it is important to assess an individual's total energy intake and dietary composition. There are multiple ways to assess this, including 24-hour recall, food frequency questionnaires, food records, and digital photography. Strengths and limitations of these methods are listed in Table 42.1.

Regardless of the method of dietary assessment, the goal is to determine a representative pattern from which dietary interventions and recommendations can be made. The establishment of such a pattern requires inquiry into not just what patients eat, but the time, place, and occasion of eating, as well as the method of preparation and portion size of foods eaten. These are important factors to determine sustainable changes. Mobile applications are now widely available for assessment and self-monitoring of dietary intake. Patients may find tracking their intake more sustainable when using technology to assist in collection and monitoring. Some apps are also able to seamlessly connect with electronic medical records or portals, which can provide real-time data from which providers can work with patients to utilize to tailor treatment plans. Real-time data are also helpful in overcoming limitations of self-report methods, which can be prone to error.

42.4.3 Determining Eating Environment and Readiness for Intervention

The practicalities of a patient's eating environment are important to assess. Recommendations are more relevant and feasible when the clinician understands the patient's access to food, food budget, delineation of responsibility for

TABLE 42.1
Dietary Intake Assessment Methods

Method	Strengths	Limitations
Food Record/Food Diary *Patients are asked to prospectively record intake for a specified period of time*	• Doesn't rely on patient memory • Can be completed in advance of dietetic visit • Portion sizes can be measured at time of consumption • Data can be entered into dietary analysis program • Records of multiple days provide valid measure of usual intake for most nutrients	• Patient intake may change as a result of keeping a food record • Requires patient to be literate, numerate, and have portion size knowledge • High patient burden, time consuming • Relies on self-reported information
24-hr Recall *Patients are retrospectively asked about intake from the past 24 hours*	• Unlikely to modify behavior • Inexpensive • Low patient burden • No patient literacy requirement • Can be conducted in person or by telephone • Data can be entered into dietary analysis program	• Dependent on patient memory • Relies on self-reported information • Requires skilled interviewer • High inter-interviewer variability • Time consuming • Not representative of usual intake
Food Frequency Questionnaire *Patients complete a survey that retrospectively queries how often certain foods/beverages were consumed in a specified period of time*	• Low patient burden • Quick, inexpensive • Easily standardized • Useful screening tool	• Requires patient to be literate and numerate • Dependent on patient memory • Can be cognitively difficult for patient because food lists are not meal-based • Doesn't provide valid estimate of total intake or meal patterns
Diet History *Patients are interviewed about their usual eating habits*	• No patient literacy requirement • Low patient burden • Enables assessment of meal patterning, usual nutrient and food group intake in one interview	• Dependent on patient memory • Requires skilled interviewer • Time consuming

shopping and preparation, location of meals, cultural food practices, and with whom meals are eaten. Assessing the environment may help the clinician and the patient identify potential barriers to carrying out recommendations.

Although recommendations may focus on timing and meal frequency, there is limited evidence to support such recommendations for weight loss.[3] Consistently with the principles of energy balance, solely changing the frequency of meals, without decreasing total energy intake, does not appear to induce a change in weight. For example, increased eating frequency has been associated with increased energy intake through snacks, and individuals rarely compensate at mealtimes for previously eaten snacks.[13] Lower-calorie (<200 calories) snacks can help patients meet restricted energy intake goals. Breakfast consumption has not been found to lead to greater weight loss in randomized control trials.[3] However, research looking at the relationship between circadian rhythm and weight loss has indicated that eating a higher proportion of total energy intake earlier in the day may be helpful in weight loss.[14] Importantly, different timing strategies may be helpful for different individuals to adhere to reduced caloric intake. Assessing patients' schedules and lifestyle patterns can aid in the determination of how patients may be most successful in incorporating recommendations into their day.

Current guidelines also recommend assessment of motivation, readiness, and self-efficacy for weight management, based on behavior change theories and models (e.g., cognitive-behavioral therapy, transtheoretical model, and social cognitive theory/social learning theory). Patient motivation is a key component of success in a weight loss program and is essential for any weight loss treatment. Motivational Interviewing is a collaborative, goal-oriented method of communication between a practitioner and a client with a focus on drawing out a client's personal motives by allowing a person to find answers on his or her own. Motivational Interviewing is believed to enhance motivation and self-efficacy, which are both considered to be key for making and sustaining behavior changes.[8,11] Asking a patient to rate on a scale from 0 to 10 the importance of behavior change and their confidence in being able to make the change is a quick tool clinicians can use to gauge a patient's readiness to change.

42.5 DIETARY INTERVENTION

Before beginning intervention, it is critical for the RDN to discuss expectations and set realistic weight loss goals together with the patient's input. As little as a 3–5% weight loss has been shown to improve clinical cardiovascular markers, and 5–10% weight loss improves even more cardiovascular risk factors.[4] While clinically meaningful, this amount of weight loss may differ from a patient's expectation. Addressing this potential mismatch prior to treatment can be important to a patient's success. Utilizing body composition measurements to look at reduction in body fat and increases or maintenance of muscle mass during weight loss may be more motivating and related to changes within a patient's control, rather than total body weight loss.

Many dietary approaches exist that facilitate the reduction of energy consumption. However, there is no one ideal dietary composition for weight loss or weight maintenance.[3] Low- and very low-calorie diets focus specifically on the creation of an energy deficit. Very low-calorie diets (≤800 kcal/day) are only appropriate for use among patients with a BMI ≥30. While very low-calorie diets have been shown to produce significantly greater weight loss than low-calorie (>800 kcal/day, usually 1,200–1,600 kcal/day) diets in the short term, long-term weight loss is equivalent between the two diets.[3] Meal replacements (liquids, bars, frozen entrees) are an effective strategy to increase adherence to the energy restriction imposed by either diet and are helpful with long-term weight management.[3] Meal replacements, which are generally formulated products such as shakes or portion controlled entrees, have value because they provide a regulated amount of calories per serving, are usually fortified with essential nutrients and fiber, and are economical, safe, and convenient to use. They also provide a departure from normal eating patterns and can serve as a venue for reeducation about and/or reformulation of what foods can be substituted or reintroduced.

Other dietary approaches achieve a caloric deficit through the restriction of particular foods or macronutrients. Results of randomized control trials indicate no difference in the rate or magnitude of weight loss between diets of differing macronutrient composition when caloric intake is held constant.[3] On the individual level, however, it is likely that some approaches will be superior to others at helping a patient achieve the necessary caloric deficit and adhere to the diet long term. Additionally, cardio-metabolic outcomes may differ based on the dietary approach taken. For example, greater reductions in low-density lipoprotein cholesterol have been achieved through a low-fat diet compared with a low-carbohydrate diet; however, low-carbohydrate diets have produced a greater reduction in triglycerides and a larger increase in high-density lipoprotein cholesterol than a low-fat diet of equivalent energy restriction.[4] In addition to weight loss, the Dietary Approaches to Stop Hypertension (DASH) diet with energy restriction produces reductions in blood pressure, and the Mediterranean diet with energy restriction may also result in cardiovascular risk factor improvements greater than those seen with low-fat diets.[3] As discussed in another chapter, dietary patterns described in the Dietary Guidelines for Americans 2020–2025 coupled with energy restriction can be a good starting point for patients.

Eating foods with low energy density, the ratio of energy in a food to the weight of the food (kcal/g), may be a strategy for appetite control and subsequent achievement of energy restriction, as it allows a greater amount of food to be eaten relative to energy consumed. It is important to note that for an energy deficit to occur using this strategy, high energy density foods must be replaced by lower energy density foods.[15] Randomized controlled trials have shown

that solely increasing fruits and vegetables (foods with low energy density) does not produce weight loss.[16] Although the low energy density approach warrants further research, a lack of standardized methods and consensus on how to include beverages prohibits conclusions from being drawn on the efficacy of this strategy for weight loss at this time.[17]

Similarly, because people typically do not compensate for energy consumed from beverages by reducing their energy from foods, it is recommended that caloric beverages be reduced or eliminated from the diet. For example, reducing sugar sweetened beverage consumption has been shown in randomized controlled trials to aid in weight loss[18]. Nonnutritive sweeteners and fat substitutes have a role in the dietary management of overweight and obese individuals, primarily because they can potentially lower caloric intake overall. For this reason, nonnutritive sweeteners have been endorsed by the Academy of Nutrition and Dietetics as a strategy to reduce energy intake by replacing sugar.[19] It is important that sugar and fat substitutes are used in the context of a regular diet, used in moderation and balance with other foods, are appreciated for total energy and nutrient value, and do not replace other nutritious foods.[19,20]

Finally, while total energy intake is of central importance, reductions in intake are too often accompanied by a decline in essential nutrients and overall quality of the diet. Dietary supplements should be considered when eating patterns are compromised, erratic, limited in choices, or <1,200 kcal/day.[3] Vitamin and mineral supplements should not be used in lieu of a healthy diet, and their use should be evaluated on a case-by-case basis.

Regardless of the dietary approach taken, close collaboration with the patient will help to create a realistic diet plan that takes into consideration weight loss and adequate nutrition. The dietary intervention should begin with the patient's usual pattern in mind. The diet plan should build on the strengths of the patient's current diet and incorporate modifications necessary to manage comorbid conditions. The usual food pattern derived from food records can be used to determine recommendations for change. Realistic strategies (e.g., increasing or decreasing food groups, assessing portion sizes, changing or substituting foods, especially of high caloric and/or high fat value, altering eating patterns when feasible, etc.) to impose a practical energy deficit should be decided upon through collaboration with the patient.

Although the concept of energy balance seems straightforward, great individual variation exists in weight loss treatment response and maintenance of weight loss. Dietary intake is complicated by the complex interplay between behavioral, psychological, and environmental factors. Individual variations in microbiome have been suggested to explain some of the individual variation in how much energy is absorbed from foods.[21] Established genetic and epigenetic variability underscores the importance of individualizing dietary intervention; however, it is unknown how to do this effectively.[22] Long-term adherence to dietary interventions is affected by how well the diet composition meets the most important of these established needs. The magnitude of weight loss achieved in the first few months of treatment is the best predictor of overall outcomes.[23,24] For these reasons, realistic goals and expectations for weight loss need to be addressed prior to beginning intervention, dietary approaches taken need to be decided on iteratively with the patient, and patient progress should be regularly monitored so that adjustments can be made as needed.

42.6 INTENSITY OF INTERVENTION

After dietary intervention and appropriate weight loss goals are determined with the patient, discussion about the intensity of the intervention is important. The American Heart Association/American College of Cardiology/The Obesity Society (AHA/ACC/TOS) Guideline recommends referral for comprehensive lifestyle intervention for all patients encouraged to lose weight, including those for whom medical or surgical intervention is recommended.[4] Frequency of contact is an important characteristic in achievement of weight loss. There is strong evidence for at least 14 MNT encounters (group or individual) with an RDN over a period of at least six months.[4] High intensity, comprehensive weight loss interventions produce on average a weight loss approaching 5–10% of initial weight.[4] Energy needs change as weight is lost. Continual monitoring and evaluation of energy requirements enables adjustments to energy intake recommendations to be made as needed. This will help to prevent the weight loss plateau that occurs around six months for many patients. For weight maintenance after weight loss, there is also strong evidence for monthly visits of MNT over at least one year.[4] Alternative modes of delivery, including electronically providing visits through phone, internet, or telehealth technology, may be indicated.

If patients are unable to meet health and weight loss goals, more intensive behavioral treatment, pharmacology, or evaluation for bariatric surgery should be considered as appropriate. It is important to note that dietary intervention plays an important role in all these treatment approaches. Working with the patient's medical team, the RDN can tailor the dietary approach to be appropriate for the patient's specific treatment plan.

For those with a BMI ≥27 kg/m^2 and an obesity-related comorbid condition, or a BMI ≥30 kg/m^2, pharmacotherapy can be considered as adjunctive to comprehensive lifestyle intervention to achieve targeted weight loss and health goals.[4] Clinicians should be aware of the current Food and Drug Administration (FDA)-approved medications indicated for weight loss through appetite suppression or absorption of fat. The potential risk of the medication should be weighed against the potential benefit of weight loss for the individual. Patients taking weight loss medications may be more likely to consistently adhere to a lower-calorie diet, increase physical activity, and experience weight loss and maintenance.[4] Newer GLP-1 agonists and GIP anti-obesity medications used for diabetes and obesity have been considered "game changers" for obesity care and

should become part of all healthcare providers' arsenal of tools to help patients lose and maintain weight loss, as well as improving metabolic health.

At this point in time, the obesity care community is still using BMI to assess whether patients are candidates for the next level of care, but more targeted protocols and algorithms are expected to become available in the near future that rely on more accurate assessment of adiposity and body composition, rather than weight and BMI alone. Patients who have a BMI ≥35 kg/m^2 with obesity-related comorbid conditions or BMI ≥40 kg/m^2 and who are motivated to lose weight but for whom behavioral treatment has not resulted in sufficient weight loss should be offered a referral to an experienced bariatric surgeon with an interdisciplinary team of medical, nutritional, and psychological professionals for evaluation.[4] Several factors are involved in the decision to undergo surgery: patient motivation, treatment adherence, operative risk, optimization of comorbid conditions, and insurance coverage.[4] Although bariatric surgery is the most clinically and cost-effective treatment for severe obesity, fewer than 1–2% of patients with severe obesity undergo surgery. The decision to discuss surgical options is subjective and inconsistent among providers, likely due to bias toward people with obesity and stigma associated with having surgery.

Patients rely on recommendations from primary care providers and other healthcare practitioners for treatment recommendations for chronic diseases, including obesity.[25] Providers often incorrectly assume that people with obesity are well aware of their excess weight and report feeling ineffective at helping patients with obesity lose weight.[25] It is important for clinicians to be compassionate, recognizing the complexities of the disease of obesity and following a shared decision-making approach. It is imperative that healthcare providers tell patients when their weight is a health concern, that there are treatment options for overweight and obesity, that the provider recommends treatment, and that the provider will support the patient throughout treatment and maintenance.[4]

42.7 CONCLUSIONS

A number of dietary approaches have produced weight loss in the short term; however, long-term maintenance of weight loss remains a critical challenge. The patient's ability to adhere to a diet long term is an important factor to consider when selecting the dietary intervention. Successful selection of the dietary approach taken in MNT depends on thorough assessment, monitoring, and evaluation of a patient's eating behaviors, environment, and level of readiness for intervention. Despite the critical role of dietary intervention in the treatment of obesity, reimbursement for MNT weight management varies by state and insurance provider. Future directions include continued progress in reimbursement for MNT for weight management by RDNs, consideration of "non-diet" approaches for people with obesity (e.g., intuitive eating), counseling to modify behavior, and greater focus on preventing weight recurrence after weight loss. It is critical that patients have a relationship with their healthcare team based in trust that the provider will continue to work with them, without judgment, even if they experience weight recurrence. Like other chronic conditions, management of obesity will be lifelong and will require change in approach by provider and patient alike.

PRACTICAL APPLICATIONS

- Clinicians have a variety of tools available for nutrition assessment, most notably, referral to RDNs to provide medical nutrition therapy for weight loss and maintenance.
- While nutrition assessment includes objective assessment of anthropometric data such as weight, waist circumference, and resting energy expenditure, clinicians should spend time discussing eating behaviors, environment, preferences, motivation, access, living situation, and history of disordered eating in order to individualize treatment recommendations.
- Dietary interventions generally reduce calorie intake through mechanisms designed to manipulate total calories, specific macronutrients, caloric density or texture of foods, or timing of eating occasions. Utilizing a shared decision-making approach will help create a realistic plan together with the patient that is both grounded in evidence and considerate of the patient's preferences, which can help with longer-term adherence to the plan.
- It is important that providers appreciate their role as a trusted member of the patient's long-term care team and facilitate continual follow-up and monitoring in order to recommend changes based on response, as well as to increase intensity to include pharmacology or surgical intervention when appropriate.

43 A Clinical Approach to Pharmacological Management of the Patient with Obesity

Magdalena Pasarica, MD, PhD

43.1 INTRODUCTION

The current obesity management guidelines highlight the role of pharmacotherapy in the management of people with excess adipose tissue (with a body mass index [BMI] at or above 30 kg/m^2 or a BMI at or above 27kg/m^2 with at least one comorbidity).[1,2] The recommendations are very clear in stating that weight loss drugs should be used as approved by the U.S. Food and Drug Administration (FDA) as adjuvants to lifestyle interventions. The guidelines cite comprehensive lifestyle interventions as the most effective. These include diet, activity changes, and behavior change counseling during frequent visits, followed by weight maintenance interventions with a medical team.

However, medical providers are often reluctant to prescribe weight loss drugs for reasons of safety, probably due to the scandal caused by Fen-Phen in 1997. This drug contained Fenfluramine, which caused valvular heart defects and subsequently was taken off the market. How about present times? Are the available weight loss drugs still the same? Currently, the FDA requires all weight loss drugs to be studied long term for serious cardiac side effects in a large population before approval.[3] More than this, three of the five drugs approved for long-term management of weight loss include drugs approved and used safely for other indications for a long time without concerns for safety.[4,5]

This chapter will discuss the FDA-approved pharmacological treatment of obesity with detailed clinical considerations for medical providers who are considering pharmacological therapy in the management of patients with excess adipose tissue.

43.2 DRUGS APPROVED FOR PHARMACOLOGICAL MANAGEMENT OF OBESITY

Currently, there is one drug approved for short-term management of obesity and five drugs approved for long-term management of obesity. We will discuss the indications, mechanisms, efficacy, side effects, black box warning, contraindications, formulations, titration schedule, and practical considerations for each of them, beginning with the most recent ones approved by the FDA.

43.2.1 Semaglutide (Trade Name Wegovy)

Indications: Semaglutide is indicated for chronic weight management as an adjunct to lifestyle changes in adults with a BMI at or above 30 kg/m^2 or at or above 27 kg/m^2 in the presence of at least one weight-related comorbidity.[6]

Mechanism: Semaglutide is a GLP-1 analog that is distributed to and activates neurons from brain regions involved in the regulation of food intake. Semaglutide acts to decrease weight by decreasing calorie intake, likely mediated by increased satiety and decreased appetite.[6]

A double-blind parallel-group trial of 72 adults with obesity treated for 20 weeks showed that Semaglutide significantly decreased ad libitum energy intake by 35% more compared with placebo ($p < 0.0001$). It also produced better control of eating and weaker food craving ($p < 0.05$).[7]

Efficacy: The weight loss effect of Semaglutide 2.4 mg weekly was studied in a double-blind, placebo-controlled trial of 1,961 adult subjects with a BMI at or above 30 kg/m^2 or at or above 27 kg/m^2 in the presence of one or more weight-related coexisting conditions (hypertension, dyslipidemia, obstructive sleep apnea, or cardiovascular disease) but excluded patients with diabetes. The intervention and placebo subjects received lifestyle change intervention, which included counseling sessions every 4 weeks, daily self-recording of dietary intake and activity, and advice for a low-calorie diet (500 kcal/day less than the estimated energy expenditure levels at randomization) and increased physical activity (150 minutes/week of walking or similar activities). After 68 weeks of treatment, Semaglutide caused 12.4% body weight loss, more than the placebo control. Importantly, significantly more subjects achieved 5% or more weight loss (86.4% vs. 31.5% in intervention vs. placebo); 10% or more weight loss (69.1% vs. 12.0% in intervention vs. placebo); and 15% or more weight loss (50.5% vs. 4.9% in intervention vs. placebo).[8]

There were several other health benefits observed. Semaglutide caused a 0.45% decrease in HbA1C compared with a 0.15% decrease in the control group. In patients with prediabetes, significantly more patients with prediabetes in the intervention group (84.1%) vs. placebo (47.8%) experienced a return to normoglycemia. Systolic and diastolic blood pressure decreased with Semaglutide (5.1 mmHg and

DOI: 10.1201/9781003227793-50

2.4 mmHg more, respectively, compared with the control group). Total cholesterol decreased by 0.97 compared with baseline, and high-density lipoprotein (HDL) cholesterol increased by 1.04 more than control (ratio of week 68 to baseline). As expected, there was a significant decrease in the detrimental impact of weight on quality of life in the Semaglutide group versus placebo (14.7 vs. 5.2 points in physical function score, $p < 0.001$).[8]

Side effects: Common side effects include nausea, diarrhea, constipation, vomiting, headache, dyspepsia, gastroenteritis, gastroesophageal reflux disease, abdominal pain, flatulence, eructation, fatigue, and dizziness. Patients with diabetes mellites can develop hypoglycemia. Serious adverse reactions include thyroid C-cell tumor, acute pancreatitis, acute gallbladder disease, acute kidney injury, hypersensitivity reaction, diabetic retinopathy complications in patients with type 2 diabetes, heart rate increase, and suicidal behavior and ideation.[6]

It is important to note that gastrointestinal side effects were the most common ones, and those were mild to moderate and transient,[8] which should reassure patients interested in this treatment.

Black box warning: Semaglutide has a black box warning for use in patients with personal/family history of medullary thyroid carcinoma or in patients with multiple endocrine neoplasia syndrome type 2.[6]

Contraindications: Semaglutide is contraindicated in patients with a personal or family history of medullary thyroid carcinoma or multiple endocrine neoplasia syndrome type 2 (MEN2), or hypersensitivity to Semaglutide or any other excipients in Wegovy. Semaglutide should not be used concomitantly with another GLP-1 receptor agonist. It should not be used two months before planned pregnancy, during pregnancy, or in the pediatric population,[6]

Formulations: The trade name is Wegovy, which is a prefilled injection pen that delivers doses of 0.25 mg, 0.5 mg, 1 mg, 1.7 mg, or 2.4 mg. Semaglutide is to be administered subcutaneously (abdomen, thigh, or upper arm) once a week on the same day each week, at any time of day, regardless of meal timing.[6]

Titration schedule: Medical providers are instructed to start with 0.25 mg once weekly for four weeks, and then increase the dose every four weeks to 0.5 mg, 1 mg, 1.7 mg, and finally, 2.4 mg as the maintenance dose. If patients do not tolerate the dose escalation due to side effects, then consider keeping the same dose or decreasing the dose for another four-week interval. If after all these, the patient cannot tolerate the maintenance dose, then discontinue the treatment.[6]

Monitoring: It is recommended to monitor blood glucose in patients with diabetes mellitus, especially those also treated with insulin and/or the insulin secretagogue, to avoid hypoglycemia. Additionally, monitoring heart rate, renal function, depression, and suicidal thoughts before initiating the treatment and at regular intervals is recommended.[6]

Practical considerations: Semaglutide was approved by the FDA in 2021 for long-term weight loss. However, Semaglutide (administered either as an injectable for 1 mg weekly as Ozempic or orally 14 mg daily as Rybelsus) has been used since 2018 and 2019, respectively, for the treatment of type 2 diabetes.

43.2.2 Liraglutide (Trade Name Saxenda)

Indications: Liraglutide is indicated as an adjunct to lifestyle changes in adults with a BMI at or above 30 kg/m^2 or at or above 27 kg/m^2 in the presence of at least one weight-related comorbidity.[4]

Mechanism: Liraglutide is a human glucagon-like peptide-1 (GLP-1) analog, which delays gastric emptying, increases satiety, and decreases appetite.[4]

Efficacy: The weight loss effect of Liraglutide 3 mg/day was studied in a double-blind, placebo-controlled trial of 3,731 subjects with a BMI at or above 30 kg/m^2 or at or above 27 kg/m^2 in the presence of hyperlipidemia or hypertension (HTN) with lifestyle change counseling. After 56 weeks of treatment, Liraglutide caused 5.6 kg more body weight loss than the placebo control. In addition, Liraglutide treatment was accompanied by an improvement in the cardiometabolic profile.[9]

Liraglutide has additional benefits in patients with prediabetes or type 2 diabetes and obesity. A large double-blind, placebo-controlled trial in 2,254 subjects with prediabetes and a BMI at or above 30 kg/m^2, or at or above 27 kg/m^2 in the presence of comorbidities, was undertaken for three years. A lower proportion of conversion to type 2 diabetes was observed in the Liraglutide group (2%) compared with the control group (6%), with a hazard ratio being calculated at 0.21 (95% confidence interval [CI] 0.13–0.34). In addition, the subjects with prediabetes treated with Liraglutide lost significantly more weight compared with placebo (4.3% difference).[10] In 1,361 subjects with type 2 diabetes with overweight or obesity, Liraglutide for 56 weeks caused 6% weight loss (for the 3 mg/day dosage) and 4.7% weight loss (for the 1.8 mg/day dosage), compared with 2% weight loss in the placebo group.[11]

Liraglutide also has additional benefits for patients with obstructive sleep apnea, as shown by a study where the apnea-hypopnea index improved after a 32-week study of treatment (−12.2 vs. −6.1 events h^{-1}), and this improvement was related to the degree of weight loss. This study also demonstrated that Liraglutide produced a significantly larger percentage of weight loss compared with placebo (4.3% difference) and an improvement in HbA1C and systolic blood pressure.[12]

Side effects: Common side effects include nausea, diarrhea, constipation, vomiting, headache, dyspepsia, fatigue, dizziness, abdominal pain, flatulence, and insomnia. Serious adverse reactions include thyroid C-cell tumor, medullary thyroid carcinoma, papillary thyroid carcinoma, colorectal malignancy, first-degree atrial ventricular block, and pancreatitis.[4]

It is important to note that a large double-blind trial studied the cardiovascular side effects of Liraglutide in

9,340 subjects with type 2 diabetes and with high cardiovascular risk followed for 3.8 years. Death from a cardiovascular cause, nonfatal myocardial infarction, or nonfatal stroke occurred in significantly fewer subjects treated with Liraglutide (13.0%) compared with placebo (14.9%), with a hazard ratio of 0.87 (95% CI 0.78 to 0.97). The rate of death from cardiovascular events was lower in the Liraglutide (4.7%) compared with the placebo group (6%). There was no significant difference in the rate of nonfatal stroke, myocardial infarction, and pancreatitis in the Liraglutide compared with the placebo group.[13]

Black box warning: Liraglutide has a black box warning for use in patients with personal/family history of medullary thyroid carcinoma or in patients with MEN2.[4]

Contraindications: Liraglutide is contraindicated in patients with a personal or family history of medullary thyroid carcinoma or MEN2, hypersensitivity to Liraglutide, or pregnancy, and should not be used concomitantly with insulin or another GLP-1 receptor agonist.[4]

Formulations: The trade name is Saxenda, which is a prefilled injection pen with multiple doses of 0.6 mg increments. One pen has 3 ml solution, which contains 6 mg/ml of active drug. Liraglutide is to be administered subcutaneously (abdomen, thigh, or upper arm) daily at any time of day, regardless of meal timing. Liraglutide should be used with caution in patients with renal or hepatic impairment.[4]

Titration schedule: Medical providers are instructed to start with 0.6 mg/day for one week, then increase the dose weekly to 1.2 mg, then 1.8 mg, then 2.4 mg until the maximum dose of 3 mg/day is reached.[4]

Monitoring: It is recommended to monitor blood glucose in patients with diabetes in order to avoid hypoglycemia. If after 16 weeks of treatment the patient has not lost at least 4% of initial body weight, it is recommended to discontinue the drug and consider alternative treatment options for obesity.[4]

Practical considerations: Liraglutide was approved by the FDA in 2014 for long-term weight loss; however, a different dosage (lower) of Liraglutide has been used as Victoza since 2010 for the treatment of type 2 diabetes.

43.2.3 Naltrexone-Bupropion ER (Trade Name Contrave)

Indications: Naltrexone-Bupropion is indicated as an adjunct to lifestyle changes in adults with a BMI at or above 30 kg/m^2 or at or above 27 kg/m^2 in the presence of at least one weight-related comorbidity.[14]

Mechanism: Bupropion is a dopamine and norepinephrine reuptake inhibitor approved for depression and smoking cessation that acts on the reward pathways. Naltrexone is an opioid receptor antagonist approved for alcohol and opioid dependence, which in this combination antagonizes the feedback loop that limits the anorectic effects of Bupropion. Therefore, the combination drug works synergistically to suppress appetite and decrease food cravings.[14]

Efficacy: The efficacy of this drug was studied in a 56-week double-blind, placebo-controlled study in 1,496 subjects with obesity or overweight (BMI at or above 27 kg/m^2) with at least one weight-related comorbidity. The combination of Naltrexone 32 mg/day and Bupropion 360 mg/day caused a significant weight loss of 6.4% versus 1.2% in the placebo-controlled group. Additionally, the combination drug caused an improvement in several cardiometabolic risk factors and increased control of eating impulses.[15]

The drug was also studied in 505 subjects with overweight/obesity and type 2 diabetes in a double-blinded, placebo-controlled trial. Naltrexone 32 mg-Bupropion 360 mg once daily for 56 weeks caused 5% weight loss compared with 1.8% in placebo, and 44.5% of subjects achieved more than 5% weight loss compared with 18.9% in placebo. Interestingly, the drug achieved a significantly greater reduction in HbA1C (−0.6%) compared with placebo (−0.1%). The percentage of subjects achieving the recommended American Diabetes Association target of 7% HbA1C was doubled in the treatment group compared with placebo (44.1% vs. 26.3%). More than this, the treatment group observed an improvement in cardiovascular risk factors, triglycerides, and HDL cholesterol.[16]

Side effects: Common side effects include nausea, vomiting, constipation, headache, dizziness, and insomnia. Serious adverse reactions include neuropsychiatric disorders, homicidal ideation, suicidality, depression exacerbation, HTN, hepatotoxicity, and closed angle glaucoma.[14]

Black box warning: Naltrexone-Bupropion ER has a black box warning for use in patients with major depression disorders or other psychiatric disorders, as it may cause suicidality.[14] However, we note that three large studies showed that there was no increase in depression or suicidal events compared with placebo.[15–17]

Contraindications: Naltrexone-Bupropion is contraindicated in patients with uncontrolled HTN, seizure disorders, anorexia nervosa, bulimia, and chronic opioid use, in patients taking Bupropion containing products, or MAOI (during or within 14 days of discontinuation), and in patients undergoing abrupt discontinuation of alcohol, benzodiazepine, barbiturates, and antiepileptic drugs.[14]

Formulations: The trade name is Contrave, and it is dispensed in 8 mg Naltrexone HCl/90 mg Bupropion HCl extended release tablets.[14] The maximum dose is 32 mg Naltrexone HCl and 360 mg Bupropion HCl for the general population; however, patients with renal and hepatic impairment need dose adjustment.

Titration schedule: Naltrexone-Bupropion is to be taken as two tablets twice a day by mouth. Patients should be started with one tablet in the morning for one week, then one tablet twice a day for one week, then two tablets in the morning and one tablet in the evening for one week, followed by two tablets twice a day as the maximum dose from then on as tolerated.[14]

Monitoring: Patients with HTN should be monitored for changes in blood pressure and heart rate. If the patient has

not lost at least 5% of initial body weight in 12 weeks, then the drug should be discontinued, and alternative management of obesity should be investigated.[14]

Practical considerations: Naltrexone-Bupropion was FDA approved for long-term management of obesity in 2014. However, both component drugs have been approved by the FDA for almost 25 years, which speaks to the safety of this combination drug.

43.2.4 Phentermine-Topiramate ER (Trade Name Qsymia)

Indications: Phentermine-Topiramate was approved as an adjunct to lifestyle changes in adults with a BMI at or above 30 kg/m^2 or at or above 27 kg/m^2 in the presence of at least one weight-related comorbidity.[5]

Mechanism: Phentermine-Topiramate is a combination of the appetite suppressant Phentermine together with the anticonvulsant Topiramate, which acts on gamma-aminobutyric acid (GABA) receptors to decrease appetite and increase satiety.[5]

Efficacy: A 56-week phase 3 study of Phentermine-Topiramate was conducted in 2,487 adults who had overweight or obesity with two or more of the following comorbidities: HTN, dyslipidemia, type 2 diabetes, prediabetes, or abdominal obesity.[18] The drug doses were once-daily Phentermine 7.5 mg plus Topiramate 46.0 mg, or Phentermine 15.0 mg plus Topiramate 92.0 mg. All subjects received counseling for lifestyle management. The change in body weight was minimal in the placebo group (−1.4 kg), but was significant and dose-dependent in the drug groups (−8.1 kg and −10.2 kg, respectively).[18] Selected subjects (676) completed an additional 52 weeks of either active drug (Phentermine/Topiramate 7.5/46 mg, 15/93 mg) or placebo, in addition to lifestyle therapy. This length of treatment was not only well tolerated but caused significantly more weight loss and clinically significant improvement in systolic and diastolic blood pressure, triglycerides, HDL cholesterol, low-density lipoprotein (LDL) cholesterol, and insulin sensitivity compared with placebo. Interestingly, the incidence rate of diabetes significantly decreased in the Phentermine-Topiramate 15/93 mg group.[1]

Side effects: At the higher dose, Phentermine-Topiramate causes dry mouth and paresthesia, constipation, insomnia, dizziness and dysgeusia, anxiety-related adverse events, and depression-related adverse events.[18] Due to the Phentermine component, rare serious adverse reactions include cardiac ischemia, tachycardia, pulmonary HTN, psychosis (see the Phentermine section for more information), and potential for abuse and dependence.[5]

Black box warning: None.[5]

Contraindications: Phentermine-Topiramate should not be used in pediatric patients; pregnant and lactating patients; patients with uncontrolled HTN, arrhythmia, heart failure, hyperthyroidism, glaucoma, agitated states, history of stroke, coronary artery disease, drug abuse, or reactions to sympathomimetic amines; or within 14 days of treatment with monoamine oxidase inhibitor. Caution for use in women of childbearing age.[5]

Formulations: The trade name is Qsymia, and it is dispensed in 3.75 mg/23 mg, 7.5 mg/46 mg, 11.25 mg/69 mg, 15 mg/92 mg of Phentermine and Topiramate ER combination, respectively. The two largest dosages are contraindicated in patients with moderate or severe renal or hepatic impairment.[5]

Titration schedule: Phentermine-Topiramate is to be taken once a day in the morning. Medical providers are instructed to start with the lowest dose and increase to the next dose in 14 days. Due to the Topiramate component, medication should not be discontinued abruptly, to avoid seizures, which occur in patients with a predisposition to seizures.[5]

Monitoring: Discontinue if after 12 weeks, the weight loss is less than 3% (with 7.5 mg/46 mg dosage) or 5% (with 15 mg/92 mg). Due to the Phentermine component, patients should be monitored for changes in heart rate and blood pressure. Because Topiramate increases the risk for cleft palate in pregnant women in the first trimester, there is a required negative pregnancy test before the beginning of the treatment and every four weeks after that. Patients should avoid concomitant use of alcohol; monitor irregular bleeding in women using oral contraceptives and potassium in patients using non-potassium sparing diuretics.[5]

Practical considerations: Phentermine-Topiramate ER combination was approved in 2012; however, both drugs have been FDA approved and used individually for more than 20 years: Phentermine for short-term weight loss and Topiramate for seizures and migraines.

43.2.5 Orlistat (Trade Name Xenical™, Alli™)

Indications: Orlistat is indicated for the management of obesity in conjunction with a reduced-calorie diet.[19]

Mechanism: Orlistat acts through inactivating gastrointestinal lipase, thereby partially inhibiting the digestion of fat. This action results in a decrease in fat absorption and energy intake, and the promotion of malabsorption.[19]

Efficacy: In a two-year study, subjects treated with Orlistat (120 mg three times a day) lost nearly 10% body weight in the first year compared with 5% weight loss in the placebo group, and fasting LDL cholesterol and insulin levels improved.[20] Other studies showed improvement in glucose metabolism and a reduction in high blood pressure.[21,22]

Side effects: Common side effects include oil-spotting, flatus with discharge, fecal urgency, and fecal incontinence. Serious adverse effects of Orlistat include hypersensitivity, anaphylaxis, angioedema, leukocytoclastic vasculitis, fat-soluble vitamin deficiency, hepatotoxicity, nephrotoxicity, and oxalate nephropathy.[19]

Black box warning: None.[19]

Contraindications: Patients with chronic malabsorption syndrome and cholestasis should not take Orlistat.[19]

Formulations: The trade name Xenical contains120 mg of active substance to be taken three times a day. The trade

name Alli is available over the counter and contains 60 mg of active drug to be taken three times a day in conjunction with a reduced-calorie and low-fat diet.[19]

Titration schedule: none.[19]

Monitoring: Monitor for side effects as indicated.[19]

Practical considerations: FDA approved Orlistat for weight loss and weight maintenance in 1999 as Xenical and in 2007 approved Alli as an over-the-counter medicine. Several attempts to decrease the inconvenient gastrointestinal side effects caused by Orlistat have been made without any success.[23]

43.2.6 Phentermine (Trade Name Adipex, Ionamin, Lomaira)

Indications: Phentermine is approved for short-term (a few weeks) weight loss as an adjunct to lifestyle changes in patients with a BMI of 30 kg/m^2 or greater or patients with a BMI of 27 kg/m^2 or greater in the presence of at least one weight-related comorbidity.[24] Even though it is FDA approved for short-term use, there are reports to show that in practice, it is used for longer periods of time with acceptable side effects and efficacy.[25]

Mechanism: It is a centrally active adrenergic drug, a sympathomimetic amine that stimulates norepinephrine release in synaptic terminals. With Phentermine usage, patients can experience increased satiety and less hunger, craving, binging, and nighttime eating.[24]

Efficacy: A meta-analysis of nine randomized controlled trials showed that patients treated with Phentermine (15–30 mg/day) and lifestyle changes for 2 to 24 weeks lost an additional 3.6 kg compared with the lifestyle change group only.[26] Another study used Phentermine with lifestyle changes for the treatment of obesity for 156 weeks and showed a 6.1-kg additional weight loss compared with lifestyle changes only.[27]

Side effects: The most common side effects of Phentermine include dry mouth, headache, insomnia, irritability, nervousness, euphoria, palpitations, tachycardia, and elevated blood pressure. There have been a few case reports of primary pulmonary HTN and cardiac valvulopathy in patients taking Phentermine;[28] however, these probably represent the background in the general population, as this was not confirmed in controlled studies.[26,27] Drug abuse potential and addiction are reported as minimal;[29] however, it is still a Drug Enforcement Administration (DEA) Scheduled IV drug.

Black box warning: None.[24]

Contraindications: Phentermine is contraindicated in the pediatric population; pregnant and lactating patients; patients with uncontrolled HTN, arrhythmia, heart failure, hyperthyroidism, glaucoma, agitated states; patients with history of stroke, coronary artery disease, drug abuse, reactions to sympathomimetic amines; and within 14 days of treatment with a monoamine oxidase inhibitor (MAOI).[24]

Formulations: Phentermine is available as a 37.5 mg scored tablet, in 15 and 30 mg capsule form, and as an 8 mg tablet.[24,30,31] The lower dosage formulation can be taken up to three times a day and is used for patients who are sensitive to higher dosage. Therefore, this increases the options for a personalized treatment plan.

Titration schedule: Dosing should be individualized to obtain an adequate response with the lowest effective dose. Patients should avoid taking Phentermine before going to sleep to avoid sleep disturbance.[24]

Monitoring: Patients should be monitored for changes in heart rate and blood pressure.[24]

Practical considerations: The FDA approved Phentermine for short-term treatment of obesity in 1959, and it is now the most commonly prescribed obesity drug in the United States.[32] The popularity of Phentermine over the other drugs is most likely due to the long-term data,[33–35] the association with a rapid onset of appetite control, and improvement in patient attitude.[33–35] This is also the only drug approved for weight loss that can be found as a formulary, and consequently, at a relatively low price.

43.3 A Practical Approach to Pharmacological Management of Obesity: A Treatment Algorithm

Once it is determined that the patient meets the indications for using weight loss drugs (see earlier in the description of each drug), the management can be approached in a stepwise manner to maximize the rate of success.

43.3.1 Step 1. Pre-Treatment Discussion

Before initiating the pharmacological management of obesity, there are certain facts that need to be clearly discussed with the patient to correct popular myths about obesity and weight loss drugs.

Fact 1: Obesity is a serious condition, not a character flaw, and should be treated this way (https://media.npr.org/documents/2013/jun/ama-resolution-obesity.pdf). *Fact 2*: The FDA has approved five drugs for long-term management of obesity, and just like any other FDA approved drugs, weight loss drugs have risks that should be outweighed by the benefits when used in the management of a disease.[4–6,14,19] *Fact 3*: Weight loss drugs are approved to be used along with lifestyle changes for weight loss, and therefore, are not substitutes for but supplements to behavior change. They empower a person to adhere to the behavior changes implemented by decreasing appetite and craving and increasing satiety.[4–6,14,19] *Fact 4*: Since obesity is a chronic condition, weight loss drugs should be used long term for the management of obesity. Just like any other chronic disease, when drugs are discontinued, the disease comes back, i.e., weight loss is regained.[36] *Fact 5*: Few patients treated for obesity reach their goal weight, and almost no one reaches their ideal weight, with or without drugs.[37] However, weight loss improves comorbidities[1,10–12,15,16] and quality of life.[38] *Fact 6*: Patients must be able and willing to comply with

the medical regimen and lifestyle changes to improve their chances of success.[39] Therefore, a relevant motivation should be identified in discussion with the patient. It is important to note that improvement in health with weight loss is usually not a compelling motivator from a patient's standpoint, and if used as the only argument by a medical provider, it may be unsuccessful. A more careful discussion to identify relevant goals from the patient's point of view needs to be performed and agreed upon. For example, being able to play sports with the family, go dancing with friends without experiencing knee pain, or have improved sexual health may be more relevant for some patients compared with improved disease control, such as diabetes and hypertension.

43.3.2 Step 2. Medical Optimizations

Medical providers should obtain a comprehensive history and perform a comprehensive physical exam of the patients treated for excess adipose tissue. In particular, the history should include the lifestyle history and weight gain/loss history with identifications of concomitant events for changes in weight. The physical should include signs of obesity-related complications or causes for weight gain.

If the history and/or physical suggest a secondary cause for obesity, then patients should be screened for those conditions and treated if needed. If any new obesity complications are diagnosed, then they should be treated appropriately or referred to medical providers.

Medical providers should then carefully examine the drug reconciliation list and try as much as possible to replace any drugs promoting weight gain with drugs that are weight neutral or that may promote weight loss. If the provider treating obesity is not the prescribing provider of some of the medication for which change needs to be considered, then clear, justified recommendations should be made to the prescribing provider with appropriate follow-up. For example, in patients with type 2 diabetes, medical providers should consider switching weight-promoting medicine like TZDs or sulfonylurea with a weight-losing anti-diabetes drug like metformin, pramlintide, or GLP-1 agonists. For the treatment of hypertension (HTN), it may be worth considering either an angiotensin-converting enzyme inhibitor, an angiotensin receptor blocker, or a calcium channel blocker to avoid beta-blockers, which have a weight-gaining effect in most patients. For treatment of depression, medical providers should consider switching mirtazapine or tricarboxylic acid drugs with drugs that are associated with weight loss, like Bupropion. For women interested in contraception, medical providers should consider intrauterine devices or barrier methods rather than injectable or oral contraceptives that are associated with weight gain. For patients with rheumatoid arthritis or another chronic inflammatory disease, it is recommended to avoid (if possible) usage of corticosteroids, known to increase weight, and replace them with nonsteroidal anti-inflammatory drugs or disease-modifying antirheumatic drugs. For seizures, medical providers should consider the use of Topiramate and zonisamide instead of gabapentin or valproate to decrease the risk of weight gain and maintain the benefit.[40,41]

43.3.3 Step 3. Rule Out Pharmacotherapy Choices

Once the decision to use pharmacotherapy for weight loss has been made, and the patient has been medically optimized, medical providers need to identify what drug to start the treatment with. If the patient needs a short-term weight loss treatment, then Phentermine is the drug of choice.

If the patient needs long-term weight loss treatment, then the available drugs are Phentermine-Topiramate, Naltrexone-Bupropion, Semaglutide, Liraglutide, and Orlistat. We recommend a systematic approach that starts with an initial step to ruling out drug choices based on patient age, medical history, current pharmacological treatment, preference for medicine administration route, side effects, and medication cost.

For example, if the patient is 12 years old or younger, there are no FDA drugs approved for long-term weight loss. If the patient is between 12 and 18 years old, the only available choice is Orlistat, and therefore, the other four drugs are ruled out for use. Patients 18 years old or older have all the five drugs available for long-term weight loss treatment.[4–6,14,19]

The medical history relevant for this step is pregnancy, lactation, and medical comorbidities. Even though only Phentermine-Topiramate is labeled as a teratogen, none of the other drugs are approved for pregnant or lactating women due to lack of safety data.[4–6,14,19,24] The main contraindications based on the systems affected include the following. For head and neck, if the patient has glaucoma, then medical providers should not use Phentermine/Topiramate. For cardiovascular, if the patient has an unstable cardiac disease, then medical providers should not use Phentermine/Topiramate. For endocrine, if the patient has medullary thyroid carcinoma or MEN2, medical providers should not use Liraglutide or Semaglutide. For psychiatric, if the patient has bulimia or anorexia, medical providers should not use Naltrexone-Bupropion.[4–6,14,19,24]

The medication reconciliation list that the patient is taking at the time of the weight loss treatment is also important. Several weight loss drugs cannot be prescribed in combination with other drugs. For example, if the patient is taking a monoamine oxidase inhibitor, then medical providers should not prescribe Phentermine-Topiramate ER or Naltrexone/Bupropion. If the patient is on chronic opioid treatment, then medical providers should not prescribe Naltrexone-Bupropion. If the patient is taking warfarin, anti-epileptics, levothyroxine, or cyclosporine, medical providers should not prescribe Orlistat in order to avoid modified absorption of active substance.[4–6,14,19,24]

Patients' dislike for or inability to comply with certain administration routes and frequency is common and should be considered for improved compliance and effectiveness.

Liraglutide and Semaglutide are to be administered subcutaneously, which may not be accepted by some patients and therefore could be used to rule out drug choices. All the other drugs are administered orally. The frequency of administration may also represent an impediment for some patients and a reason to rule out some medication choices. Liraglutide is administered once a day, while Semaglutide is administered once a week. Phentermine-Topiramate is administered once daily. Naltrexone-Bupropion is administered twice daily. Orlistat is administered three times a day.[4–6,14,19,24]

Another important factor to rule out medication choices is the possible side effect profile. Patients should decide which risks they are willing to take. For example, in terms of cardiovascular risks, increased heart rate could be observed with Liraglutide, Semaglutide, Naltrexone-Bupropion, and Phentermine-Topiramate; and increased blood pressure could be caused by Naltrexone-Bupropion. For psychiatric risk, depression could be caused by Naltrexone-Bupropion. In terms of neurological risks, dizziness could be caused by Naltrexone-Bupropion and Phentermine-Topiramate; headache could be caused by Liraglutide, Semaglutide, and Naltrexone-Bupropion; insomnia could be caused by Naltrexone-Bupropion and Phentermine-Topiramate; inattention could be caused by Phentermine-Topiramate; seizures could be precipitated by Naltrexone-Bupropion, paresthesia by Phentermine-Topiramate, and metallic taste by Phentermine-Topiramate. Gastrointestinal symptoms and signs are the most common side effects: nausea may be caused by Liraglutide, Semaglutide, and Naltrexone-Bupropion; constipation may be caused by Liraglutide and Naltrexone-Bupropion; abdominal pain by Liraglutide and Semaglutide; pancreatitis by Liraglutide and Semaglutide; fecal urgency and oily stools by Orlistat. Disturbance in electrolytes may also happen, with decreased serum potassium observed in some patients taking Phentermine-Topiramate. For women of childbearing age, congenital malformation may be caused by Phentermine-Topiramate if taken in the first trimester of pregnancy.[4–6,14,19,24]

Cost is also a valid concern for patients, especially because most insurances do not yet cover weight loss drugs. The most inexpensive obesity drugs are Orlistat and Phentermine-Topiramate, so if this is a limiting factor for the patient, they may be a good choice to start with. Naltrexone-Bupropion price is mid-level, while the other drugs are reported as expensive without insurance.[40]

43.3.4 Step 4. Rule In Pharmacotherapy Choices

The next step in choosing the appropriate weight loss medication is to rule in pharmacotherapy choices so that the patient can have additional benefits, including concomitant improvement of other comorbidities, maximum effect on certain behaviors, and efficacy potential.

Patients' current comorbidities should be an important consideration when selecting a new drug. Weight loss by itself improves obesity-associated diseases, but as seen in the previous sections, weight loss drugs have benefits for other chronic diseases and therefore can be used to improve more than one condition. For example, if patients have migraines, medical providers should consider the use of Phentermine-Topiramate. If the patient has type 2 diabetes or prediabetes, medical providers should consider Liraglutide or Semaglutide. If the patient is smoking or has mild depression, medical providers should consider Naltrexone-Bupropion.

When taking the history of present illness, if the patient cites cravings as the major contributor to excess food intake, then Phentermine-Topiramate or Naltrexone-Bupropion should be considered. When the patient reports dissatisfaction with not feeling full when following a calorie-restrictive diet, medical providers should consider Liraglutide or Semaglutide. All the other long-term weight loss drugs (except Orlistat) are helping the patient to have a lower appetite and consequently, adhere to a low-calorie diet.[4–6,14,19,24]

One of the most frequently asked questions from the patients is which medicine is most effective. This is different for each patient depending on the causes of excess weight gain. Currently, we know that the average weight loss caused by Semaglutide is 10–12%, by Phentermine-Topiramate 7–9%, by Liraglutide 5–6%, by Naltrexone-Bupropion 3–5%, and by Orlistat 2–3%. This is the starting point for a discussion about effectiveness, with the note that each patient is different and that all these percentages are caused by the weight loss drug in addition to lifestyle changes.[4–6,14,19,24,42]

43.3.5 Step 5. Prescribe Medicine Using the Recommended Titration Schedule; Monitor the Efficacy and the Possible Side Effects

When using Phentermine-Topiramate, Naltrexone-Bupropion, Liraglutide, and Semaglutide for the management of obesity, medical providers should follow the recommended titration schedule as mentioned in the previous section. Side effects should be carefully monitored, and if medication is not tolerated, medication should be either discontinued or kept at lower dosages.[4–6,14,19, 24]. As with any other symptom or sign, a detailed history should confirm that the presented complaint is not due to a different disease or drug but is indeed caused by the weight loss medication prescribed.

The weight of the patient should be carefully monitored also, with a minimal target of 4–5% weight loss in 12 weeks.[4–6,14,19,24] If this target is not achieved, then medical providers should consider choosing a different drug for the management of obesity, referral to bariatric surgery, or optimizing the lifestyle change intervention. The change in behavior could be hindered by multiple facts, including certain barriers, inappropriate goals, or aberrant eating behaviors. Some patients may need to attend a comprehensive behavior weight loss program or a very low-calorie diet program to successfully reach their goals.

43.3.6 Step 6. Concomitant Management of Chronic Comorbidities

As with any other intervention that is causing weight loss drugs, medical providers should monitor the progression of the diseases improved by the weight loss. For example, patients with type 2 diabetes undergoing concomitant treatment with drugs for weight loss should be advised to monitor their blood glucose more often and report any change in glucose patterns to the medical provider. This will ensure that changes in the diabetes medication can be made appropriately and on time. Patients with HTN should also be instructed to monitor their blood pressure every morning at home and report any change in pattern. Patients with hyperlipidemia should be monitored with fasting blood lipids after three months of the program so that an adaptation in the management plan can be made as needed. Patients may need a decrease or discontinuation of type 2 diabetes, HTN, or hyperlipidemia medication as weight loss is achieved.

If the medical provider prescribing weight loss drugs is not the medical provider managing the other obesity comorbidities, then written recommendations for increased follow-up and the possible need for management optimizations should be sent to the appropriate medical provider. Coordination of care between the medical providers is essential to ensure compliance and effectiveness of weight loss management.

43.4 PRACTICE CONSIDERATIONS BEFORE PRESCRIBING DRUGS FOR WEIGHT LOSS

43.4.1 Prepare Your Medical Providers for Prescribing Drugs for Weight Loss

Medical providers looking to start using pharmacotherapy for weight loss need to be aware of the following. Some drugs are DEA Schedule IV: Phentermine, and Phentermine-Topiramate. Therefore, medical providers should follow all the local guidelines for prescribing any drug that is scheduled IV as defined by the DEA. One drug (Phentermine-Topiramate) has a risk evaluation and mitigation strategy in place, and therefore, all prescribing medical providers and dispensing pharmacies need a special certification[5, 43] obtained from the Qsymia website. This is meant to prevent congenital effects, which can occur if Topiramate is taken in the first trimester of pregnancy. It is recommended that Qsymia can be prescribed to women of childbearing age only if they have either a) an intrauterine device; b) tubal ligation/hormonal contraception and a barrier method; or c) two barrier methods. Medical providers can also seek out comprehensive education in obesity medicine by conducting training and obtaining a certification from the American Board of Obesity Medicine (www.abom.org). However, this certification is not required for managing obesity with drugs for weight loss.

43.4.2 Prepare Your Practice for Introducing Pharmacological Management of Obesity

All the drugs approved by the FDA for short-term or long-term weight loss should be used as indicated, in addition to counseling and education for lifestyle changes. And as per obesity management guidelines,[1,2] the lifestyle changes should match the characteristics of comprehensive intensive lifestyle intervention. This is an important aspect that needs to be considered by clinicians, practice managers, and owners of primary care practices. Just offering the weight loss drugs without lifestyle change interventions may not result in the desired/studied weight loss effects.

Just like with any other interventions for treating patients with obesity, special attention must be given to the environment of the clinic. The furniture and the medical equipment have to be appropriate for the management of patients with excess weight. The staff must be trained in managing problems that are associated with excess weight.

43.5 FUTURE DIRECTIONS

As most patients want either to lose weight or maintain their weight, and obesity is associated with multiple comorbidities from various specialties, most medical providers should be prepared to treat patients with obesity. In some cases, for which pharmacotherapy is indicated, they will need to prescribe, monitor, and optimize their treatment with weight loss drugs. A lot of progress has been made in this direction. First, obesity was declared a disease by the American Medical Association (https://media.npr.org/documents/2013/jun/ama-resolution-obesity.pdf), which should increase the number of insurance companies covering obesity management with reimbursement of medical providers' time and reasonable co-pays for patients. Second, an Obesity Medicine certification has been developed and is available for any provider to complete to become experts in the clinical management of obesity (http://abom.org/). Third, obesity medicine competencies have been developed in order to target objectives for educational activities,[44] and ready-to-use peer-reviewed educational activities are published.[45,46] Therefore, we predict that the management of patients with obesity using FDA approved medicine for weight loss will increase in use and popularity.

Acknowledgments: This chapter is built upon and expanded based on a previous version that included a significant contribution from Dr. Nikhil V. Dhurandhar.

CLINICAL APPLICATIONS

1. Obesity is a chronic condition that requires lifelong treatment. Add obesity diagnosis for all patients that meet the criteria, and address during clinic visit as needed.
2. Use of pharmacologic treatment of obesity is indicated as an adjunct to lifestyle changes in adults with a BMI at or above 30 kg/m^2 or at or above 27

kg/m^2 in the presence of at least one weight-related comorbidity.

3. Selection of an obesity drug should be performed in a stepwise manner, considering the patient's preferences, resources, medical and social history, current and past medications, and behaviors targeted, as well as the characteristics of the obesity drug (including administration route and schedule, side effects, other benefits).
4. If a weight loss drug in conjunction with lifestyle management does not cause at least 5% weight loss in three months or if it causes non-tolerable side effects, then the drug should be discontinued, and an alternative approach should be discussed with the patient.

44 Surgery for Severe Obesity

Robert F. Kushner, MD

KEY POINTS

- Metabolic and bariatric surgery is an effective treatment approach for patients with severe obesity (BMI ≥40 kg/m^2) or moderate obesity (BMI ≥35 kg/m^2) with a comorbidity.
- All patients who are considering weight loss surgery should undergo a comprehensive assessment by a multidisciplinary team.
- Patients should receive ongoing lifestyle counseling throughout the perioperative process and particular attention to preventing and treating nutritional deficiencies.

44.1 INTRODUCTION

Bariatric surgery has been endorsed as an acceptable weight loss option for patients with a BMI of ≥40 kg/m^2 (severe or class III obesity) or those with a BMI of ≥35 kg/m^2 who have comorbid conditions.[1,2] Currently, overall age-adjusted U.S. population prevalence rates for those with severe obesity (BMI of ≥40 kg/m^2) are 6.9% and 11.5% for men and women, respectively, and 13.8% for non-Hispanic black adults, the most vulnerable subgroup.[4] According to the American Society for Metabolic and Bariatric Surgery,[5] 256,000 bariatric surgeries were performed in the United States in 2019. Given the high prevalence rates for moderate-to-severe obesity and the increased availability of bariatric surgery, it is likely that healthcare professionals from all disciplines will encounter patients who have undergone a bariatric surgical procedure. Similarly, primary care professionals will be expected to monitor and manage their patients on a long-term basis. Many of the weight loss surgeries—most notably the combined restrictive-malabsorptive surgical procedure Roux-en-Y gastric bypass (RYGB), the malabsorptive biliopancreatic diversion (BPD), and biliopancreatic diversion with duodenal switch (BPDDS)—place patients at high risk for development of both macro- and micronutrient deficiencies unless they are properly counseled and supplemented. Since most of the deficiencies can be identified at a preclinical stage, early identification and treatment will prevent or reduce symptoms and deficiency syndromes. Although bariatric surgery does not cure obesity, it is considered a significant tool for weight loss and maintenance of weight loss. As such, patients are at risk to experience weight regain several years following surgery. This chapter will review the most commonly performed weight loss procedures, the importance of preoperative and postoperative management, identification and management of nutritional deficiencies that may occur following bariatric surgery, and factors associated with weight regain.

44.2 BARIATRIC SURGICAL PROCEDURES

Weight loss surgeries have traditionally been classified into three categories on the basis of anatomic changes: restrictive, restrictive-malabsorptive, and malabsorptive. However, the clinical benefits of bariatric surgery in achieving weight loss and alleviating metabolic comorbidities have been attributed largely to changes in the physiologic responses of gut hormones, bile acid metabolism, the microbiota, and adipose tissue metabolism.[6] Metabolic effects resulting from bypassing the foregut include altered responses of ghrelin, glucagon-like peptide 1, peptide YY3-36, and oxyntomodulin. Additional effects on food intake and body weight control may be attributed to changes in vagal signaling. The loss of fat mass, particularly visceral fat, is associated with multiple metabolic, adipokine, and inflammatory changes that include improved insulin sensitivity and glucose disposal; reduced free fatty acid flux; increased adiponectin levels; and decreased interleukin 6, tumor necrosis factor α, and high-sensitivity C-reactive protein levels. The surgical procedures commonly performed are shown in Figure 44.1.

Restrictive surgeries limit the amount of food that the stomach can hold and slow the rate of gastric emptying. The laparoscopic adjustable gastric banding (LAGB) is the prototype of this category. However, due to poor long-term weight loss response, the LAGB has fallen into disfavor and accounts for only 0.9% of all bariatric surgeries performed in 2019.[5] The most commonly performed procedure (accounting for 59.4% of all procedures) is the laparoscopic sleeve gastrectomy (LSG). In this procedure, the stomach is restricted by stapling and dividing it vertically and removing approximately 80% of the greater curvature, leaving a slim "banana-shaped" remnant stomach along the lesser curvature.

The restrictive, malabsorptive bypass procedure combines the elements of gastric restriction with limited macronutrient malabsorption, primarily of fat. In the RYGB procedure (accounting for 17.8% of all procedures), a 10- to 30-ml proximal gastric pouch is formed by surgically separating the stomach across the fundus. Outflow from the pouch is created by performing a narrow (10-mm) gastrojejunostomy. The distal end of the jejunum is then anastomosed 50 to 150 cm below the gastrojejunostomy.

"Roux-en-Y" refers to the Y-shaped section of small intestine created by the surgery; the Y is created at the point where the pancreo-biliary conduit (afferent limb) and the Roux (efferent) limb are connected. RYGB may be performed with an open incision or laparoscopically. There are two malabsorptive procedures, which account for fewer than 1% of all procedures performed in the United States: the biliopancreatic diversion (BPD) and the biliopancreatic diversion with duodenal switch (BPDDS).

44.3 IMPORTANCE OF LIFESTYLE INTERVENTION

Since obesity is fundamentally a disorder of energy balance, all treatments must include attention to caloric intake (energy in) and physical activity (energy out). By altering gastrointestinal anatomy and physiology, weight loss surgery is a powerful tool to reduce caloric intake. Nonetheless, patients need counseling on diet and nutrition that is consistent with the specific surgical procedure (restrictive vs. malabsorptive) and with optimal health. They also need guidance on implementing dietary changes within the structure of their daily life. Similarly, patients benefit from education and advice about increasing daily physical activity and implementing an exercise routine.

44.4 PREPARING THE PATIENT FOR SURGERY

Several practice guidelines have been published regarding the nonsurgical medical and lifestyle support of patients undergoing bariatric surgery.[7–9] All patients who are considering weight loss surgery should undergo a comprehensive assessment by a multidisciplinary team of healthcare providers that includes a physician or advanced practice provider, registered dietitian, and mental health professional.[7] During the preoperative process, patients are typically instructed on healthy eating and physical activity patterns, behavioral strategies to implement the lifestyle changes, and the importance of stress reduction and social support for long-term success. Specific dietary and nutritional recommendations pertinent to the surgical procedures include use of protein supplements, consumption of multiple meals and snacks, and slowing the rate of eating. Patients are seen either individually or in small groups.

Although it is reasonable to encourage weight loss prior to surgery, the literature is conflicting regarding the benefit of mandating preoperative weight loss as a criterion to undergo surgery. The primary rationale for requiring routine preoperative weight loss is to decrease the short-term operative morbidity and mortality. Furthermore, the patient's motivation for and ability to adhere to the dietary restrictions considered essential for a successful surgical outcome can be assessed. While 5–10% of preoperative weight loss has been shown in some studies to reduce postoperative complications[10] and 30-day mortality[11] as well as improve one-year weight loss,[12] other studies have not

shown a benefit in longer-term weight loss outcomes.[13,14] An additional compelling reason to endorse preoperative weight loss is to optimize the operative field by reducing liver volume and visceral adipose tissue (VAT). A systematic review showed that preoperative treatment with a very low-calorie liquid diet (VLCD) for 9 to 12 weeks led to weight loss (−2.8 to −14.8 kg) and to liver reduction by 5% to 20% of the initial volume.[15] Based on the existing literature, there is a general agreement on the beneficial effects of recommending a modest loss in the immediate presurgical period.[16]

44.5 WEIGHT LOSS OUTCOMES AND IMPROVEMENT IN OBESITY-RELATED MEDICAL CONDITIONS

Several meta-analyses and systematic reviews of bariatric surgery outcomes have been conducted.[17–20] In general, weight loss is greatest with the malabsorptive procedures (BPD, BPDDS), followed by the restrictive-malabsorptive procedure (RYGB), and least with the restrictive procedures (LAGB, LSG). As compared with standard care, differences in BMI levels from baseline at year one are –11.3 kg/m^2 for BPD, −9.0 kg/m^2 for RYGB, −10.1 kg/m^2 for LGS, and −2.4 kg/m^2 for LAGB.[21] Mean weight loss at two to three years following a surgical procedure ranges from 20% to 34% of initial body weight, depending on the procedure. The trajectory of weight loss also differs between procedure types. Whereas the rate of weight loss is slower with LAGB, with maximal weight loss achieved after 2 or 3 years, maximal weight loss with RYGB and LSG is achieved at 12–18 months.

Significant improvement has been reported in multiple obesity-related comorbid conditions, including type 2 diabetes (T2D), hypertension, dyslipidemia, and obstructive sleep apnea.[22–30] One of the most significant clinical outcomes is the role of bariatric surgery in the treatment of patients with T2D. A substantial body of evidence from randomized controlled trials (RCTs) demonstrates that bariatric/metabolic surgery achieves superior glycemic control in patients with T2D compared with various medical and lifestyle interventions. The improvement in diabetes control appears to be due to both weight loss and weight loss–independent effects.[31] Based on these data, the Second Diabetes Surgery Summit (DSS-II) Consensus Conference published guidelines in 2016 that were endorsed by more than 50 other organizations interested in the treatment of diabetes.[3] According to the guidelines, metabolic surgery should be recommended to treat T2D in patients with class II obesity (BMI of 35.0 to 39.9 kg/m^2) when hyperglycemia is inadequately controlled with lifestyle and optimal medical therapy, and it should be similarly considered for those with class I obesity (BMI of 30.0 to 34.9 kg/m^2). The 2021 Standards of Care for Diabetes from the American Diabetes Association includes bariatric surgery in the treatment algorithm for T2D.[32]

44.6 NUTRITIONAL CARE

44.6.1 Dietary Changes after Bariatric Surgery

A variety of dietary changes occurs after bariatric surgery that can result in unbalanced diets and inadequate micronutrients and protein intake.[33] Most importantly, there is a significant and sustained reduction in caloric intake. Although portion sizes tend to increase gradually over time in postoperative patients, caloric intake is typically still reduced by 25% or more for years after surgery.[34,35] An analysis of the Swedish Obese Subjects (SOS) study, a prospective, matched (non-randomized), intervention trial of bariatric surgery, demonstrated the importance of early caloric restriction.[36] Study participants with greater reductions in energy and fat intake in the first six months after bariatric surgery maintained greater weight loss after ten years.

Food intolerances may occur and can lead to alterations in dietary patterns after bariatric surgery. Lactose intolerance can develop in patients who have undergone gastric bypass; as a result, nearly one-third of patients report avoiding milk after this procedure.[37] Dumping syndrome occurs in up to 76% of patients after RYGB and may lead patients to reduce their intake of concentrated sweets and fatty foods to avoid associated postprandial symptoms, such as abdominal cramping, nausea, diarrhea, light-headedness, sweating, and tachycardia.[38] Over 60% of patients report avoiding sweets and nearly 30% avoid fatty foods after RYGB surgery.[37] Other food intolerances include difficulty consuming whole meats, fresh fruits, and raw vegetables, presumably due to the phenomenon referred to as "plugging," when a food becomes lodged in the gastric pouch.

Regardless of the types of foods consumed, regurgitation or vomiting can occur when patients eat too quickly, fail to chew food thoroughly, or eat more than what the gastric pouch will hold. However, it should be noted that vomiting is not an intended consequence of bariatric surgery, and it should not be viewed as normal, particularly in the late postoperative period. Patients who have persistent vomiting or regurgitation after surgery should be evaluated for the presence of maladaptive eating behaviors as well as anatomical or functional issues such as stomal stenosis or ulceration, reflux, and gastric dysmotility.[7,39]

Patients with symptoms of dumping syndrome can usually be managed by dietary modification, including avoidance of concentrated sweets and simple sugars, consumption of small frequent meals, and inclusion of protein at every meal. Patients with symptoms suggestive of postprandial hypoglycemia that are not ameliorated by dietary modification should undergo evaluation for the presence of endogenous (or "post-bypass") hyperinsulinemic hypoglycemia.[7,40] Patients with more severe neuroglycopenic symptoms (such as confusion or loss of consciousness) should also undergo evaluation for this condition, which can occur after gastric bypass. For most patients with post-bypass hypoglycemia, dietary modification, including carbohydrate restriction to less than 30 grams per meal, can

significantly reduce the frequency and severity of symptoms.[41] However, when symptoms persist, pharmacologic therapies may be required.[42]

44.6.2 Recommended Dietary Patterns and Eating Behaviors

As a result of the reductions in gastric capacity and caloric intake after surgery, patients must take care to ensure that nutritional needs are met. Postoperative patients should be advised to consume small portions, have four to six small meals daily, and ensure an adequate intake of lean protein (60–120 grams/day), fruits and vegetables (more than five servings/day), and whole grains.[7] Patients should also eat slowly, chew thoroughly, avoid fatty foods, sweets, and sugar-sweetened beverages, and avoid ingestion of liquids within 30 minutes of meals. Unfortunately, many postoperative patients struggle to follow the recommended guidelines, particularly regarding fruit and vegetable consumption and avoidance of sweets and caloric beverages. For this reason, clinicians should routinely assess patients' dietary intake during postoperative visits and reinforce recommended dietary goals.

44.6.3 Prevention of Micronutrient Deficiencies after Bariatric Surgery

Patients who have undergone bariatric surgery should be counseled that they are at risk for the development of micronutrient deficiencies after surgery. After RYGB, the most common micronutrient deficiencies include those of vitamin B_{12}, vitamin D, calcium, and iron.[43–46] Folic acid deficiency has also been reported but is largely preventable with regular use of a standard multivitamin preparation. Sleeve gastrectomy has been reported to produce similar deficiencies as gastric bypass but at a somewhat lower frequency. As compared with RYGB, the BPDDS is much more likely to produce deficiencies of the fat-soluble vitamins, including vitamin A. Purely restrictive procedures such as LAGB are infrequently associated with specific nutritional deficiencies.

In most cases, micronutrient deficiencies can be prevented by regular vitamin and mineral supplementation along with appropriate clinical follow-up and routine biochemical surveillance. Expert guidelines are available regarding recommended vitamin and mineral supplementation after surgery and the frequency of laboratory screening for deficiency states.[7,43-45] Tables 44.1 and 44.2 summarize these recommendations. Patients who are found to have evidence of specific micronutrient deficiencies will need additional vitamin or mineral supplementation, as indicated.

44.7 PHYSICAL ACTIVITY

Among individuals who have lost weight with nonsurgical treatment approaches, physical activity clearly plays a vital role in long-term maintenance of weight loss.[47,48] Much less is known about the role of physical activity in weight control after bariatric surgery, but it is likely an important factor.

44.7.1 Physical Activity Levels after Bariatric Surgery

Numerous studies suggest that self-reported levels of physical activity increase significantly after bariatric surgery.[49]. However, there are few objective data regarding changes in

TABLE 44.1
Recommended Micronutrient Supplementation after Bariatric Surgery

Supplement	Dose and frequency
Vitamin B_1 (thiamine)	[a]12 mg daily
Folate (folic acid)	[a]400–800 µg daily800–1,000 µg daily for women of childbearing age
Calcium	[b]1,200–1,500 mg/day from all sources (after RYGB, SG, or LAGB)[b]1,800–2,400 mg/day from all sources (after BPD/DS)
Vitamin D (in calcium supplement or separate)	3,000 IU/day
Elemental iron	[a]18 mg daily for low risk patients40–60 mg/day for menstruating females
Vitamin B_{12}	350–500 µg/day orallyOr 500 µg every week intranasallyOr 1,000 µg/month parenterally (IM or SQ)
Zinc	[a]16–22 mg/d (after BDP/SD)[a]8–22 mg/d (after RYGB)[a]8–11 mg/d (after SG/LAGB)
Copper	[a]2 mg/d (after BPD/DS or RYGB)[a]1 mg/d (after SG or LAGB)
Vitamins A, E, and K	[a]Vitamin A 5,000 IU/D and vitamin K 90–120 µg/d (after LAGB)Vitamin A 5,000–10,000 IU/D and vitamin K 90–120 µg/d (after RYGB and SG)[a]Vitamin A 10,000 IU/d and vitamin K 300 µg/d (after DS)[a]Vitamin E 15 mg/d (after LAGB, SG, RYGB, and BPD/DS)

LAGB, laparoscopic adjustable gastric banding; RYGB, Roux-en-Y gastric bypass; SG, sleeve gastrectomy; BPD/DS, BPDDS.
Patient subgroups at higher risk requiring additional supplementation are indicated.
[a]Obtained from multiple vitamin-mineral supplements.
[b]Calcium should be given in divided doses; calcium carbonate should be taken with meals; calcium citrate may be taken with or without meals.

physical activity levels in the postoperative period, and self-reported increases are likely to be overestimated.[50] The data suggest that only 6–24% of post–bariatric surgery patients meet national guidelines regarding minimal physical activity levels for general health promotion (i.e. ≥150 min/week of moderate-to-vigorous physical activity).[51,52]

Significant weight loss, such as that achieved after bariatric surgery, may enable patients with severe obesity to become more active. However, cognitive barriers to physical activity may persist after bariatric surgery and may influence patients' activity levels.[53] These barriers include reduced awareness of the health benefits of exercise, fear of injury, a lack of confidence in the ability to participate in physical activity, and self-consciousness or embarrassment. Treatment strategies that address these barriers may help patients become more physically active.

44.7.2 Benefits of Physical Activity Interventions in Postoperative Bariatric Surgery Patients

Several meta-analyses of randomized controlled studies have reviewed the effect of physical activity in bariatric surgery.[54–57] Using large databases, they concluded that exercise leads to increased improvement in functional capacity and physical fitness over surgery alone, along with improving cardiometabolic risk factors such as blood pressure. However, the amount of additional weight loss is modest compared with the 30% or more loss of initial weight after bariatric surgery itself.

44.7.3 Recommendations for Physical Activity after Bariatric Surgery

National guidelines suggest that for optimal weight control, most overweight individuals will need to accumulate at least 150–300 minutes of moderate physical activity per week, or 30–60 minutes most days of the week.[58] Data from the National Weight Control Registry indicate that walking is the preferred form of physical activity in this group of individuals.[59] Regular pedometer use may be a practical and helpful strategy for patients who have had bariatric surgery.[60] However, a RCT suggested that the provision of pedometers to bariatric surgery patients may be an ineffective strategy unless it is coupled with ongoing exercise counseling.[61]

44.8 BEHAVIORAL/PSYCHOLOGICAL CARE

Bariatric surgical patients experience a variety of psychosocial challenges in the postoperative period. Initially, patients must adjust to the postoperative diet and to their altered relationship with food. As weight loss progresses, patients must adapt to changes in their appearance and their interactions with others. Dramatic weight loss, however desirable to the patient, can lead to unexpected consequences, such as body image issues related to excess skin, unwanted sexual attention from others, and jealousy from friends and loved ones. As a result of these many challenges, mood disorders, disordered eating patterns, and substance abuse are common among postoperative patients.

44.8.1 Mood Disorders

Mood disorders are prevalent among candidates for bariatric surgery. For example, in one prospective study utilizing structured clinical interviews to assess mood pre- and postoperatively, clinical depression was present in approximately one-third, and anxiety was present in almost 20% of preoperative patients.[62] In this population, the prevalence of clinical depression decreased by over 50% in the three years following surgery, but the

prevalence of anxiety remained relatively stable. Other studies have reported significant improvements in depressive symptoms that persist for up to five years postoperatively.[63,64] Data from the large SOS study suggest that after dramatic improvements in both depression and anxiety in the first postoperative year, there may be some deterioration of mood over time.[65] Data from the Longitudinal Assessment of Bariatric Surgery (LABS) study, a prospective, observational study of patients undergoing bariatric surgery, have provided further information regarding the effect of weight loss surgery on psychiatric disorders.[66] At pre-surgery, 30% of patients met the diagnostic criteria for an Axis 1 disorder. The prevalence dropped to 17% and 18% at two and three years after surgery, respectively. The corresponding prevalence rates at baseline and at years two and three for any anxiety disorder were 17.2%, 12.3%, and 7.8%, respectively. A recent systematic review and meta-analysis concluded that bariatric surgery improved depression and anxiety symptoms following the first 24 months after surgery.[67,68]

It is important to note that some studies have yielded discrepant findings. Patients who have undergone bariatric surgery may be at an increased risk of suicide, particularly in the first three years after surgery.[69–72] In a large, retrospective cohort study, individuals who had undergone gastric bypass surgery were twice as likely to commit suicide as control subjects with obesity matched for sex, age, and baseline BMI.[70] Case studies suggest that patients who commit suicide after bariatric surgery often have a history of recurrent major depression, both before and after surgery, and that their depression persists even if they have excellent weight loss results.[71] These reports highlight the importance of continued attention to psychosocial health in the postoperative period, regardless of weight loss outcomes.

44.8.2 Disordered Eating

Data from the LABS study have provided information regarding the effect of weight loss surgery on eating pathology.[73] Following a cohort of 183 patients for up to three years postoperatively, investigators found that pathological eating behaviors and eating-related experiences are common prior to bariatric surgery and improve following surgery. For example, comparing pre-surgery and one year after, prevalence rates for bulimic episodes declined from 11.6% to 1.3%, loss of control eating declined from 18.3% to 6.2%, picking/nibbling diminished from 36.0% to 20.2%, and evening hyperphagia was reduced from 16.5% to 5.0%. Post-surgery eating-related variables associated with poor weight outcomes included loss of control eating, hunger, and the eating disorder examination global score (which combines several factors, such as restraint and shape/weight concerns). It is important to probe for eating pathology, since patients may not report these behaviors unless they are prompted by a clinician.

44.8.3 Alcohol Misuse

The concern about the potential for development of alcohol dependence or abuse in postoperative patients was previously raised as a possible "addiction transfer" or "cross addiction," whereby patients substitute alcohol for binge eating after surgery.[74,75] Although there is little support for this hypothesis, it does raise the question of whether patients who drink alcohol preoperatively are at increased risk for continued use, and what effect (if any) bariatric surgery may have on development of alcohol use disorder (AUD). In a sub-study of LABS, patients completed baseline and follow-up assessments of alcohol consumption using the Alcohol Use Disorders Identification Test (AUDIT), a ten-item test. After RYGB, there was an increase in the prevalence of AUD from baseline (pre-surgery) (6.6%) to year two (9.6%) and year seven (16.4%).[76,77] The five-year cumulative incidence of AUD treatment was 20.8%. Male sex, younger age, smoking, and any or regular alcohol consumption pre-surgery were associated with increased risk for developing AUD. In another comprehensive review of the literature,[76] a preoperative history of substance use (including alcohol) was a reliable predictor of postoperative use.

The absorption and metabolism of alcohol may be altered after bariatric surgery, and as a result, postoperative patients may be more susceptible to the intoxicating effects of alcohol.[77–82] Patients should therefore be counseled to exercise caution when consuming alcohol after surgery. In addition, clinicians who care for bariatric surgery patients should ask patients about alcohol intake after surgery and remain alert to the possible presence of AUD in this population.[83]

44.8.4 Psychological Counseling and Peer Support in the Postoperative Period

Data suggest that patients with postoperative depression experience poorer weight loss than those who are not depressed.[62] Similarly, postoperative patients who exhibit disordered eating patterns, such as grazing and loss of control over eating, have poorer weight loss and greater weight regain.[84,85] Patients who are found to have mood disorders, disordered eating behavior, or substance abuse after bariatric surgery should be offered expert psychological counseling and support. It is not known, however, whether such treatment improves weight loss or other outcomes.

44.9 COMPREHENSIVE LIFESTYLE INTERVENTIONS AFTER BARIATRIC SURGERY

There are limited data regarding the benefits of comprehensive lifestyle interventions in the postoperative period. Several systematic reviews and meta-analyses on behavioral and psychotherapeutic interventions in the bariatric surgical population have been published. In the review by Rudolf and Hilbert,[86] they identified 15 behavioral management

studies published prior to 2012. Eight provided cognitive behavioral therapy (CBT), and seven included group support attendance. Across all the behavioral studies, patients in the treatment groups showed greater weight loss than patients in the control groups; however, differences did not reach significance in any samples. For the group support studies, the majority found greater weight loss among those who attended support group meetings than in those who did not, though the difference was once again marginal.

In the systematic review and meta-analysis of RCTs involving lifestyle and nutritional interventions by Swierz et al.,[87] 22 studies were included for analysis. Due to inconsistency in data reporting, they concluded that there was insufficient evidence whether perioperative interventions improve long-term outcomes, and called for better research and reporting.

In the review by Beck et al.,[88] they identified nine studies investigating the effect of psychotherapeutic interventions and support groups on weight loss following bariatric surgery that were published prior to 2012. Psychotherapeutic treatment targets the psychological factors that have been associated with variability in post-surgical weight loss, including binge eating, depression, motivation, and coping skills. They concluded that both psychotherapeutic interventions and support groups provided a modest beneficial effect on post-surgical weight loss, with an overall effect size of 0.18. In a subsequent review by Kushner and Sorenson[89] in 2014, seven RCTs were identified investigating the efficacy of behavioral, dietary, or exercise counseling for postoperative weight loss. The authors concluded that the lifestyle interventions either had no effect or were only modestly effective in enhancing further weight loss and influencing lifestyle-related behaviors among post–bariatric surgery patients. Additional pilot studies using CBT,[90] CBT and dialectical behavioral therapy,[91] and acceptance-based therapy[92] have been published. However, enhancement of weight loss outcomes has been largely disappointing. Multiple factors appear to influence the varied outcome results, including patient selection, timing and intensity of the intervention, comprehensiveness of counseling provided, and selection of outcome measurements. Further studies will need to be conducted to identify the most suitable targets and patients for intervention.

44.10 WEIGHT REGAIN FOLLOWING BARIATRIC SURGERY

Although clinicians commonly see bariatric surgery patients regain some weight postoperatively, the prevalence and incidence of weight regain has not been well characterized. Follow-up data from the LABS study have continued to inform clinical care regarding various aspects of postoperative management, including postoperative weight loss trajectories, behavioral variables, and three-year weight change.[93,94] The underlying factors that influence weight regain following bariatric surgery are multifactorial and include endocrine/metabolic alterations, anatomic surgical failure, dietary indiscretion, mental health issues, and physical inactivity.[95,96] The extent and significance of these factors is currently uncertain and likely varies between individuals and the operative procedure performed. Using cross-sectional data, weight regain has been estimated to occur in 20–35% of patients, depending on the procedure performed and the duration of time following surgery.[39] The physiological and behavioral (diet and physical activity) causes are common to surgical and nonsurgical patients. Depending on the patient's age and gender, a through history should be performed that reviews all these reasons, followed by appropriate counseling. More recently, there has been interest in the use of pharmacotherapy to treat insufficient weight loss and weight regain following bariatric surgery.[97]

44.11 CONCLUSION

Bariatric surgery is an effective and acceptable treatment for individuals with severe obesity who are at risk for or have complications associated with obesity. Several surgical procedures are available, with variable risk and weight loss outcomes. However, regardless of the procedure performed, surgery is considered a tool that is adjunctive to choosing a healthy, calorie-controlled diet and engaging in daily physical activity. For patients who undergo restrictive-malabsorptive or malabsorptive operations, dietary supplementation is necessary to avoid nutritional deficiencies. Patients are at risk for weight regain following surgery due to several biopsychosocial factors. In order to maximize successful outcomes, all patients should be monitored and managed by a multidisciplinary team of healthcare providers knowledgeable in bariatric surgical care.

CLINICAL APPLICATIONS

- Bariatric surgery should be considered for patients with a BMI of ≥40 kg/m^2 or those with a BMI of ≥35 kg/m^2 who have comorbid conditions and have failed nonsurgical approaches.
- Preoperative assessment and postoperative management should be conducted by a multidisciplinary team of healthcare providers with attention to medical, dietary, physical activity, and mental health aspects of care.
- Since obesity is considered a chronic disease, patients who undergo bariatric surgery require long-term management, employing lifestyle behaviors and strategies conducive to maintaining a healthy body weight.

45 Chronic Exercise and Immunity

Melissa M. Markofski and Michael G. Flynn

KEY POINTS

- Regular exercise training is linked to overall better health, which extends to improved outcomes related to the immune system.
- Exercise training may induce beneficial changes to resting immune function.
- Participation in regular exercise is encouraged for prevention of many inflammation-related diseases, especially cardiometabolic diseases.

45.1 INTRODUCTION

Exercise training influences numerous aspects of host defense and indices of immune function. The field of exercise and immune function continues to be an active area of research, and there are documented potential changes in immunity that are induced by regular exercise training. The objective of this chapter is to identify practical implications of chronic exercise that are applicable to both fitness exercisers and athletes. The influence of chronic exercise on innate and adaptive immunity will be reviewed, along with the effect of excessive exercise training on selected immune parameters and resistance to infection. We will also address the influence of moderate exercise training on inflammation, wound healing, and the efficacy of vaccines.

45.2 EFFECT OF CHRONIC EXERCISE ON LEUKOCYTE NUMBER AND FUNCTION

Leukocytes are circulating cells of the immune and lymphatic systems derived from bone marrow hematopoietic stem cells, which are collectively responsible for mounting an immune response. A physically active or regularly exercising person has a lower number of circulating leukocytes at rest, but it can be difficult to partition the specific effects of exercise on immunity from the associated health benefits of regular exercise.[1–4] Furthermore, regular exercise and physical activity can alter the phenotype and influence the function of specific subsets of leukocytes.[5,6] These changes potentially mediate the systemic anti-inflammatory effects of chronic exercise, as evidenced by lower levels of circulating markers of inflammation (interleukin [IL]-6 and C-reactive protein [CRP]). In this section, we will summarize current literature to support regular exercise training eliciting changes in the number, function, and phenotype of major leukocyte subsets.

45.3 EFFECT OF CHRONIC EXERCISE ON INNATE IMMUNITY

45.3.1 Monocytes and Tissue Macrophages

Monocytes are circulating cells that have both innate and adaptive immune functions.[7] Monocytes can respond to infection or tissue damage by traveling to the lymph nodes to become dendritic cells[8] or migrating to the site of insult, where they then differentiate into tissue-specific macrophages (e.g., Kupfer cells in liver, macrophages in adipose tissue). Antigen presentation and subsequent cytokine release help to coordinate the responses of the adaptive immune system. Although beneficial in an acute immune response, chronic low-grade activation of the monocyte/macrophage lineage is thought to contribute to the pathophysiology of numerous diseases.[9,10]

Several researchers highlight the role of chronic exercise–induced alterations in monocyte phenotype/inflammatory response as a possible mechanism underlying the anti-inflammatory effects of exercise. In both cross-sectional and longitudinal training studies, participants who regularly exercised had lower mitogen-stimulated, ex-vivo whole blood production of inflammatory cytokines.[11,12] Regular exercise improves cardiovascular disease markers and inflammation—specifically, a reduction in monocyte chemoattractant protein-1 (MCP-1) and macrophage inflammatory protein (MIP-1α).[13] Taken together, this emerging evidence supports the contention that regular exercise can improve inflammation and cardiovascular disease linked to monocyte/macrophage activation.

Major populations of circulating monocytes are phenotypically classified based on cell-surface expression of CD14 and CD16. CD14++CD16− cells are classical monocytes, which make up the largest proportion of the circulating monocyte population.[14] CD14+CD16+ monocytes are non-classical "inflammatory" monocytes—a subpopulation with a proclivity for production of pro-inflammatory cytokines. CD14++CD16+ monocytes are called intermediate monocytes, but a range of methodologies employed in measuring this subpopulation makes it difficult to compare the influence of exercise on this subset of intermediate monocytes. Circulating inflammatory monocyte percentage is elevated in patients with subclinical atherosclerosis and obesity,[15] and is higher in healthy adults with an elevated risk for cardiovascular disease.[16] These findings are significant, as inflammatory monocytes adhere robustly to activated endothelial cells[17] and may be precursors to CD16+

DOI: 10.1201/9781003227793-53

macrophages found distributed throughout atherosclerotic lesions and adipose tissue.[18,19] Regular exercise training can reduce the circulating inflammatory monocyte population[6, 20,21] and induce a shift in adipose tissue monocyte expression away from the more inflammatory M1 macrophage phenotype and toward the anti-inflammatory M2 phenotype,[22] thus providing another potential mechanism by which exercise reduces inflammation.

There is strong evidence in support of the concept that regular exercise can reduce monocyte/macrophage inflammation, possibly through modulation of TLR4 expression and/or altering the phenotype of circulating monocyte subpopulations. However, more studies need to be conducted to clarify the effect of regular exercise on adipose tissue macrophage recruitment and activation. This body of work is clinically important, as activation of the monocyte/macrophage lineage is implicated in the pathophysiology of diseases such as diabetes and cardiovascular disease.

45.3.2 Natural Killer Cells

Natural killer (NK) cells are cytotoxic lymphocytes and a major constituent of the innate immune system. They protect against certain tumors and virally infected cells by releasing granules containing proteases and porins that induce apoptosis in the target cell. The results of NK cell exercise/physical activity studies are varied, with exercise reported to suppress,[23] increase,[24–27] or not change the number or cytotoxic activity of NK cells.[28–30] The differences reported between studies may be attributable to differences between recreationally trained individuals and athletes, the length of time a person has engaged in habitual exercise, and the specific NK measurement used. Given the cytotoxic role of NK cells, some groups of people may benefit from increased NK cell number and/or activity—such as cancer survivors. Numerous researchers have reported NK cell benefits related to exercise training in people with cancer, including preserving NK cell activity during (neo)adjuvant chemotherapy[31] and an increase in circulating NK cells.[32] The benefits of exercise training to improve immune function in cancer survivors need to be further investigated, especially regarding the specific exercise prescription required to elicit maximum benefits.

45.3.3 Neutrophils

Neutrophils are polymorphonuclear cells and are the most abundant leukocyte subtype. They are the first responders of the innate immune system and migrate to the site of infection or injury within minutes. In athletes, resting circulating neutrophil number is similar to that in sedentary individuals.[33, 34] A lack of difference in neutrophil count may not indicate neutrophil function, as exercise training programs in physically inactive adults increased neutrophil cell-surface CCR5[35] along with phagocytosis and oxidative burst.[36,37] Further, comparing mostly healthy people may not provide a comprehensive view of the exercise-related neutrophil benefits. For example, an exercise training program lowered neutrophil count in overweight women with multiple risk factors for cardiovascular disease,[38] and the decrease in neutrophil number was correlated with improvements in insulin sensitivity. Although regular exercise may be of benefit to neutrophil numbers and function, when the regular exercise is intense, such as many elite athletes perform, it may reduce neutrophil function.[39–41]

45.4 Effect of Chronic Exercise on Adaptive Immunity

45.4.1 T and B Lymphocytes

T and B cells are the primary circulating cells of the adaptive immune system. T cells are involved in cell-mediated immunity, and B cells are primarily responsible for producing antigen specific antibodies (humoral immunity). It is well accepted that T cells are susceptible to immunosenescence, aging-related changes in adaptive immunity, which is also believed to contribute to age-associated morbidity.[42] However, immunosenescence may be offset by moderate resistance exercise training.[43] Regular exercise may also impact the number, function, and ex-vivo proliferative response of T cell populations in older adults, and as such, may be an important modality for maintaining immune health as one grows older. For example, the ex-vivo lymphocyte proliferative response to mitogen (PHA) was significantly higher in older runners than in non-runners.[44,45] Koizumi et al. reported that exercise training increased the absolute numbers of T cells and T helper cells in older adults, and a six-month aerobic exercise training intervention increased T cell proliferation in response to mitogen.[30] However, other researchers have reported that ex-vivo lymphocyte responses are not affected by exercise interventions. As such, ex-vivo T cell proliferation did not change after 12 weeks of exercise training,[39] and a 12-month moderate resistance exercise program for elderly women did not alter circulating numbers of lymphocytes.[29] This lack of consensus on the effects of regular exercise should be interpreted with caution, as the variability in results may be due to the wide range of exercise intervention type, the T cell–related outcome studied, or possibly, the infection history of the participants. For example, participants who were seropositive for cytomegalovirus (CMV) had a higher acute aerobic exercise response to total lymphocytes, KLRG1+CD28−CD4+ and CD8+ T cells, and CD45RA+CCR7−CD8+ T cells, than CMV negative participants.[46,47]

45.4.2 Th1/Th2 Balance

CD4+ T helper cells can be divided into several distinct subpopulations, including Th1, Th2, Th17, and T regulatory (Tregs) cells. Specifically, Th1 cells are part of cell-mediated immunity and produce tumor necrosis factor (TNF) and interferon gamma (IFNγ); Th2 cells release IL-4, IL-5, and IL-10 and respond to parasites; Th17 produce IL-17 and

appear to play a prominent role in autoimmune disorders. Tregs also suppress the activity of other immune cells and maintain discrimination between self and non-self antigens during an immune response, thereby preventing autoimmune diseases. In some respects, the ratio of T cell subsets may be a better indicator of health than the absolute numbers. For example, the ratio of Thelper1/Thelper2 (Th1/Th2) cytokines is often used as an index of inflammatory signaling, and intensive exercise training induces a shift toward Th2 dominance.[48] A pronounced shift in cytokine production typical of the Th2 anti-inflammatory milieu could render the vigorous exerciser more susceptible to infection.[49,50] However, moderate training appears to induce a positive, subtle shift toward a Th2 cytokine profile, balancing the Th1/Th2 response and inducing the anti-inflammatory influences of regular exercise.[49]

Treg and Th17 cells are not well studied in an exercise training or physical activity context. In the limited research available, Yeh et al. reported an increased Treg function in both healthy middle-aged adults[51] and subjects with Type2 diabetes[52] after 12 weeks of Tai Chi training. In response to a strenuous acute aerobic exercise event, athletes had a decrease in absolute numbers of Treg and an increase in Th17 cells. Furthermore, there was a decrease in percent circulating Treg cells that remained depressed below pre-race levels ten days after the event.[53] Treg and Th17 cells both have a role in regulating inflammation and need further examination in a physical activity context.

45.5 EXERCISE TRAINING AND INFLAMMATION

Evidence for the role that inflammation plays in the development and exacerbation of chronic disease has grown substantially. Inflammation or inflammatory biomarkers are clearly linked to cardiovascular disease,[54] type 2 diabetes,[55] osteoporosis,[56] and several other chronic diseases not previously believed to have an inflammatory etiology.[57] Exercise can provide substantial benefits for the prevention and management of chronic diseases. There is growing evidence that exercise has anti-inflammatory effects, but it is not clear how much of the benefit of exercise is due to the contribution of an anti-inflammatory effect or to the other actions of exercise. Regardless of the relative contribution, inflammatory biomarkers are significantly lower in segments of the population with moderate to high levels of physical activity.[58] Not surprisingly, intervention studies provide less consistent support of an anti-inflammatory effect of exercise. Small participant numbers, different exercise modes and intensities, supervised versus unsupervised exercise, and different choice of biomarkers all likely contributed to these inconsistencies. Nevertheless, there is fairly strong intervention literature to support the observation that exercise training has anti-inflammatory effects in serum or circulating cells,[6,20,59], in muscle,[60,61] and to a lesser extent, in adipose tissue.[62,63] Regular exercise reduces inflammation-promoting nuclear factor kappaB (NFκB) and toll-like receptor (TLR) 4 expression in diabetic subjects.[64,65] Thus, it appears that the ability of exercise to ameliorate the symptoms of chronic disease may be linked, in part, to its anti-inflammatory effects.

It is unclear whether exercise training can exert an anti-inflammatory effect in the absence of changes in body fat.[63,66] The literature in this area is mixed, but there are several examples of exercise providing an independent anti-inflammatory effect. In one review by Beavers, Brinkley, and Nicklas[58] (2010), the authors identified 19 studies in which self-reported physical activity level was linked to biomarkers of inflammation and an additional 9 studies during which the fitness level was measured. These authors concluded that accounting for obesity "attenuated, but did not negate, the strength of the relationship between inflammatory biomarkers and physical activity." There are few studies in which an exercise intervention with and without body weight losses have been compared, and conflicting results of exercise studies in general underscore differences that may be attributed to type and intensity of exercise. The equivocal nature of prior research is supported by a recent weight loss intervention study in people with metabolic syndrome, where all participants were counseled for weight loss and were also randomized into one of five 12-week interventions: low-volume high-intensity interval training, single set resistance training, three sets of resistance training, whole-body electromyostimulation, or control (no additional intervention beyond the nutritional counseling). Although all five groups reduced their body weight by a similar amount, and all three exercise groups reduced their severity of metabolic syndrome, only the low-volume high-intensity group reduced inflammation, specifically CRP and IL-6.[67]

In summary, exercise has anti-inflammatory effects, but these effects may be dependent on the exercise prescription and health of the individual. It is possible that there is an intensity threshold, but evidence in support of low-intensity exercise exerting anti-inflammatory effects suggests the need for further study. Although some mechanisms remain to be determined, the anti-inflammatory effect of exercise has important health implications.

45.6 CLINICAL AND APPLIED OUTCOMES OF CHRONIC EXERCISE AND IMMUNITY

45.6.1 Excessive Training and Immunity

Excessive training, often referred to as "overtraining" or "overreaching," can result in a wide range of negative clinical signs and symptoms, including lethargy, fatigue, mood disturbances, underperformance, immune suppression, and poor healing of cuts and scratches. Resting immunity is not substantially different between athletes and healthy individuals, but it appears that intensive training could negatively affect several resting immune measures. Changes in NK cell activity and T cell function have been observed

after intensified training programs, but it is unclear whether the changes in the immune system induced by hard training are to blame for a higher incidence of infection in athletes.[30] Nevertheless, the collective toll of excessive training on the immune system would appear to render athletes more susceptible to infection.

45.5.2 Excessive Training: URS or URTI?

Several indices of immune function are suppressed by heavy exercise, and athletes who train hard are frequently reported to have an increased incidence of upper-respiratory symptoms (URS) related to upper-respiratory tract infection (URTI).[68] These and similar findings have led to the assertion that heavy exercise lowers immune defenses and increases URTI risk. Two important factors remain unclear in this regard. First, whether excessive training suppresses immune function to the extent possible to result in an increased susceptibility to infection has not been determined.[30] There is a general consensus that several immune parameters are depressed following prolonged or severe exercise, most notably and consistently mucosal immunoglobulin A (IgA), but it is not known whether the immune depression is causative of an increased incidence of URTI. Second, it is not clear whether the URTIs reported by athletes in the majority of studies are pathogen-based or a result of local airway irritation or inflammation.[69] Problematically, most of the studies in which the incidence of URTI has been assessed in conjunction with heavy training largely relied on self-report and a lack of the presence of an infectious pathogen in the sputum of athletes reporting symptoms of URTI.[69] However, most researchers also acknowledge that the ability to detect these pathogens in sputum is far from perfect.

No increase in the rate of infectious episodes was found in marathon runners when runners with a pre-race infection were removed from the cohort,[70] casting further doubt on the relationship between hard exercise and URTI. Although there is evidence that regular, modest exercise reduces the risk of URTI[39] and prolonged, intense, or excessive exercise training increases the risk of URTI,[68] there is considerable controversy in this area, which prevents us from making concrete conclusions about the links between hard exercise and illness. Logistically, excessive time and cost make it difficult to include quantitative cellular immune measures in large cohort studies of infection incidence and prevalence.

Mucosal secretion or the secretion rate of immunoglobulin A (Ig_A) is considered a first line of defense against infection. Ig_A secretion appears to be consistently lowered following repeated, hard exercise sessions. Ig_A has also been more strongly and consistently linked to infection risk in athletes than other measurable aspects of immunity.[50] There are some larger-scale studies in which salivary Ig_A has been measured and negatively correlated with URTI incidence.[71] Gleeson et al.[50] monitored 80 athletes for several months and identified a sub-group of "illness-prone" subjects who had higher training loads, higher levels of multi-antigen-stimulated anti-inflammatory cytokines—illustrating a Th2 dominant response—and lower salivary IgA secretion and flow rates. In addition, the highest quartile of IL-10 producers had higher training loads, higher production of inflammatory and anti-inflammatory cytokines, lower Ig_A, and higher URTI incidence than the lowest quartile. The authors suggested that IL-10 might be a useful predictor of infection risk in physically active individuals.[50] There is clearly an increase in URS associated with hard training, but further research is required to document what proportion of these illnesses are pathogen-based or are linked to airway inflammation/irritation.

A relatively new area of research is related to the relationship between the microbiome and health in athletes. Between-study variability in the types of supplements, doses, and subject populations in this new research area makes it difficult to define an optimal regime for intestinal microbiota health in an athlete. However, there is some evidence that altering gut microbiota may reduce infection risk or length of symptoms in athletes. Post-marathon, runners who received a probiotic for a month prior to the race had lower incidence and severity of URTI symptoms than those in a placebo group.[72] In a separate study, highly trained athletes who received a multi-species probiotic had a lower incidence of URTI, but no improvement in athletic performance, during the 12-week study period.[73] Other researchers have also found a decrease in URTI infection incidence and length of symptoms in athletes taking probiotics, but the benefit may be dependent on the type of probiotic.[74–76] Additionally, more work is needed to determine if a sex difference exists in the responses to probiotics.[77]

45.6.2.1 Wound Healing

Aging and chronic conditions are known to slow the rate at which wounds heal. The influence of exercise training or physical activity levels on wound healing have been studied in a relatively small number of investigations, but the limited available information is promising. A recent scoping review of exercise or physical activity as an adjunct treatment in people with venous leg ulcers acknowledges the small number of studies in this area, but there does appear to be potential for exercise to improve would healing. The most promising interventions were multimodal, such as combined resistance and range of motion exercises.[78] In an experimental wound healing study, Emery et al.[79] divided 28 healthy older adults into an exercise and a non-exercise group. The exercise group had a significantly improved healing rate compared with the non-exercise group. Although this research was limited by a small number of subjects, the exercise effect in Emery's study was substantial, with 55% of the subjects in the exercised group having complete healing at day four compared with 0% in the non-exercised group. More work is needed to determine if simple, cost-effective interventions such as exercise training can alter the rate at which wounds heal. However, the paucity of literature on the topic prevents us from making solid conclusions regarding practical strategies for clinicians or patients.

45.6.2.2 Exercise and Efficacy of Vaccines

Aging is associated with a decline in immune function[80] and an increase in susceptibility to infections,[81] and can also result in low-grade chronic inflammation.[82] Aging-related immunosenescence contributes to the increased incidence and severity of infectious disease among older adults, who experience a greater mortality rate from influenza infection and generally exhibit reduced vaccine efficacy compared with young adults.[83,84]

Exercise training may improve immune competence among older adults who have been administered an influenza vaccine. Several cross-sectional studies in which physically active older adults were compared with sedentary controls have shown a greater influenza vaccine respo nse.[44,85,86] A cross-sectional comparison of older physically active, moderately active, and sedentary groups showed that physical activity was associated with greater response to influenza immunization. The older physically active group developed greater flu-specific IgG and IgM titers two weeks post immunization compared with the moderate activity and sedentary groups.[86] Peripheral blood mononuclear cell proliferation in vitro was also lower in the sedentary group. These studies suggest that lifestyle factors, including regular exercise, may influence immune response to influenza immunization.

In a longitudinal study, Kohut et al. reported that a ten-month exercise intervention in older adults resulted in a greater increase in influenza specific antibody titer and IFN-γ production following flu vaccine.[87] Additionally, 144 sedentary older adults were randomized to either a ten-month aerobic training (n = 74) or a flexibility and balance program (n = 70).[30] The intervention resulted in a significant increase in seroprotection, determined by a hemagglutination Inhibition titer of >40, 24 weeks after vaccination (30–100%). These titer data are significant, as they suggest that an enhanced vaccine response following exercise training can be maintained over a period greater than the length of a typical flu season.

The mechanisms responsible for mediating the effects of exercise on vaccine efficacy are not fully understood, and more recent research seems to be focused on a single bout of exercise rather than a longitudinal exercise training program. However, given that immunosenescence in aging is associated with an elevation in the ratio of memory T cells to naive T cells, potentially reducing the ability of the adaptive immune system to respond to novel antigens, exercise training to improve immune function and overall health in older adults is critically important. Exercise training has been previously shown to reduce the memory:naive T cell ratio,[30] leading to the speculation that exercise may prolong antibody response, potentially by restoring the naive T cell level and subsequent ability to respond to novel antigen exposure.

The SARS-CoV-2 pandemic has increased general interest in immune response and also whether fitness levels or exercising prior to or after vaccination can influence vaccine effectiveness or side effects. Healthy adults who exercised regularly were randomized to either 90 minutes of walking/running or continuing their non-exercise daily routine after receiving their first dose of the Pfizer BNT162b vaccine.[88] All participants were instructed not to exercise on the day of their second vaccine. Two weeks after the first vaccine dose and one week after the second dose, serum anti-RBD IgG antibody was higher in the group that exercised. Interestingly, there was a negative relationship between age and serum anti-RBD IgG antibody. This is important to note, as some of the most impactful effects may be in groups with lower immunity. In a separate study,[89] immunocompromised adults who performed 4 sets of 8–12 exercises on the vaccinated arm prior to immunization with their third dose of Coronavirus vaccine did not have a difference in neutralizing antibody positivity compared with the control group. However, the differences in exercise type and timing—whole-body exercise after the vaccine versus one arm before the vaccine—make it difficult to draw conclusions from these findings, and more studies are needed before specific recommendations can be made about whether exercise can serve as a behavioral adjuvant to the COVID-19 vaccine.

45.7 SUMMARY

It is clear that regular exercise has the potential to alter indices of immune function. Regular exercise may offer some protection against URTI, provide anti-inflammatory actions, and enhance the response to vaccines. However, many unanswered questions remain. For example, excessive training (overtraining) has been linked to increased risk of URTI, but researchers have questioned the reliability of both self-report of URTI and the direct method to detect pathogens in sputum. There is also much research that needs to be conducted on the effects of exercise to restore immune function after a substantial health outcome, such as that observed with cancer treatments or moderate to severe SARS-CoV-2 infection.

The ability of exercise to improve the course of chronic disease via anti-inflammatory and other immune changes is an exciting avenue for researchers. These studies will help to close the gap between the myriad benefits of exercise training and the available mechanisms to explain the benefits. Despite the gaps in our knowledge, it is clear that athletes can train effectively without excessive illness and that fitness exercisers adapt in primarily positive immunological fashion to regular, moderate exercise.

CLINICAL APPLICATIONS

- Regular exercise shifts circulating T cells toward a more anti-inflammatory profile and reduces pro-inflammatory cell-surface receptors on monocytes.
- Excessive training may increase the risk of developing an URTI, possibly in part by alterations in salivary IgA secretion and flow rate.

- Participation in regular exercise may improve wound healing and response to vaccine.
- High inflammation is implicated in many diseases, and people who regularly exercise have lower pro-inflammatory immune cells. An anti-inflammatory effect of exercise training at least partially explains the lower chronic disease rate observed in people who regularly exercise.

46 HIV and Exercise

Jason R. Jaggers and Gregory A. Hand

KEY POINTS

- Investigations have continuously reported significant physiological and psychological health improvements by modest changes in activity.
- Light to moderate intensity levels are sufficient to achieve short-term health benefits as long as the individual stays consistent with their exercise plan.
- There is no evidence to indicate that exercise performed at low, moderate, or high intensity will negatively impact immune function or disease progression in HIV-infected individuals.
- Future research is necessary to determine successful motivational and behavioral changing interventions aimed at increasing physical activity for this population.
- With an increased lifespan and aging population, incorporating resistance training as part of a weekly exercise prescription for people living with HIV/AIDS (PLWHA) over the age of 50 is strongly encouraged.

46.1 INTRODUCTION

Living with HIV has become more of a management of chronic conditions in recent years than the battle of opportunistic infections from a depleted immune system that it was in the first two decades of the epidemic. Even faster have been the changes in patient symptomatology. With rapid advances in medical science, the pharmacological regimens designed to block viral replication and prevent the spread of infection have quickly gone from a multi-pill daily routine to a single combo-pill. Many people can now live decades longer and well into old age, but they also must be more health conscious to offset negative consequences from antiretroviral therapy (ART) side effects.

Although the advances in ART have increased life expectancy, this is not without consequence. Early into treatment, the chief complaints are often psychological in nature, which over time either subside or become more tolerable. However studies have shown that there are many physiological consequences, like increased lipids and risk for cardiovascular disease (CVD) and diabetes.[1–3] On top of medication related side effects, there is still an ongoing social stigmatization that comes with living with HIV. Even researchers still struggle not only to recruit eligible participants for HIV specific studies but to maintain their participation throughout the study duration. This, in turn, makes it more difficult to determine solid results due to a lack of longitudinal clinical trials and interventions with large datasets.

Due to increased life expectancy and only slight reductions in new infections, we have also begun to experience increased prevalence rates and an aging HIV population who are living well into their senior years. Healthy lifestyle choices, like diet and exercise, have now become that much more important with this population. Exercise alone has shown to have positive impacts on health across all populations, regardless of disease or health status, for both psychological and physiological outcomes. Research from our laboratory and others has also demonstrated significant improvements to the health and quality of life for people living with HIV/AIDS (PLWHA).

46.2 SYMPTOMATOLOGY OF HIV INFECTION

46.2.1 Psychological Consequences

PLWHA are burdened with multiple psychosocial stressors at all stages of illness. Immediately upon diagnosis, patients must face life-changing issues such as managing the illness, affording appropriate healthcare, and the daily struggles that accompany living with the stigmatization of HIV. In addition to these personal stressors, various environmental factors could potentially exacerbate the levels of stress already experienced, such as living in a lower socioeconomic status, facing unemployment, reduced access to healthcare, and many others. The patients' ability to cope with these burdens ultimately depends on their psychological state, their social support network, and their stage of HIV disease. Many studies of various chronic diseases have investigated consequences of distress among patients and reported positive associations with mood disturbance, poor treatment adherence, and negative health outcomes.[4,5] Similar findings have been reported among HIV-related investigations.[6] Although distress has been identified as an important measure to manage mental health, and self-reported symptoms have become a common method used to indicate health status, the literature on self-reported symptom distress within the HIV population is scarce.

Generally, a level of distress is experienced when symptoms are present, and research has shown a negative impact of psychological distress on HIV disease progression.[7] Increases in symptom distress potentially have negative consequences for both physical and psychological health that have been recently discovered, with a growing body of evidence supporting the psychoneuroimmunology (PNI) framework, as discussed by McCain et al.[8] Recent investigations have begun

DOI: 10.1201/9781003227793-54

to show consistent reports of psychological distress and disturbances impairing immune function[9] as well as cytokine-induced changes in neurotransmitter and neuroendocrine function, which have been shown to correlate with the onset of depression and/or fatigue.[10] The burden of frequent symptoms is known to negatively affect disease management and mental health.[11] Identifying factors that are associated with increased symptom distress may provide possible strategies to lessen the burden of HIV infection and related symptoms while improving treatment adherence. It is also important to note that now that life expectancy has improved for PLWHA, there has also been evidence to suggest that this population may experience other disturbances in mental functions at younger ages than the general population, such as cognitive decline or early onset dementia.

46.2.2 Physical Consequences

All clinical populations face a large variety of disease-related physical and psychological symptoms, but prevalence rates of self-reported symptoms are generally over 50% among PLWHA, ranging from a single symptom to multiple concurrent symptoms.[12–14] Common physical symptoms reported include diarrhea, loss of appetite, nausea, muscle weakness, peripheral neuropathy, fever, dry skin, and persistent cough. These are often experienced in conjunction with antiretroviral side effects for those placed on an ART regimen. As a result, the management of multiple symptoms has become a daily task for PLWHA in an effort to maintain an optimal quality of life[15,16] and ultimately leads to a chronic state of deconditioning resulting in functional aerobic impairment.

As was the case before the discovery of antiretrovirals, the association between the number of self-reported symptoms and disease status still allows the use of reported symptom frequency as an indicator of disease progression and health-related quality of life. This has been able to assist health professionals with monitoring how well a patient is responding to current ART regimens.[13,17] Symptoms lasting anywhere between a few days and a few weeks increase the burden of disease among individuals, often resulting in negative lifestyle habits. The side effects and symptoms of HIV infection often have many patients turning to self-medication either by altering their daily ART regimen or by seeking additional alternative treatments, which may include illegal narcotics. Although the discovery of ART has led to an increased lifespan and decreased reports of AIDS and AIDS related deaths, many scientists have reported a complex variety of symptoms and side effects associated with ART regimens, creating a metabolic syndrome effect.

46.3 ANTIRETROVIRAL THERAPY TREATMENT AND SIDE EFFECTS

The timing for initiating treatment varies depending on viral infection as well as the patient's primary healthcare provider, but generally, it is recommended that patients begin an antiretroviral regimen if asymptomatic but with a CD4 cell count <500 cells/μL,[18] which should be checked every three to four months, or symptomatic. For optimal results, treatment is suggested for asymptomatic patients with CD4 cell counts >500 cells/μL.[3,18] The timing for initiating treatment is widely debated, but there is strong evidence to indicate that PLWHA who are taking ART are less likely to transmit HIV onto others due to higher rates of undetectable viral loads. The reason some healthcare professionals may recommend waiting until a decline in CD4 cell count is due to the negative implications long-term use of ART can have on a person's health.

The majority of side effects associated with ART are physiological in nature and directly alter metabolic processes, resulting in increased circulating blood lipids, lipodystrophy, and insulin resistance, thus creating a metabolic syndrome. What was once a short-term muscle wasting disease for people living with HIV that ended in death over a period of several months has evolved into a chronic metabolic disorder, with primary causes of mortality no longer being AIDS related.

Symptoms and side effects from ART medications will vary depending upon specific antiretrovirals included in the patient's pharmacological regimen as well as the total number of antiretroviral medications included. For example, nucleoside reverse transcriptase inhibitors (NRTIs) are associated with lactic acidosis, hepatic steatosis, and lipodystrophy. Evidence has shown that lipodystrophy is more prevalent among individuals currently taking a combination of NRTIs and PIs (prolase inhibitors), both of which have known side effects of stripping metabolic function and disrupting adipocyte mitochondrial function. Other symptoms specific to the type of NRTI being taken include pancreatitis, nausea, diarrhea, headache, insomnia, peripheral neuropathy, fatigue, malaise, anemia, and many others. For a more extensive list of all symptoms and side effects, please refer to Bartlett et al., medical management of HIV infection.

Further caution is advised over the possibility of drug interactions; for example, the PI ritonavir has demonstrated interactions with analgesics, cardiac medications, lipid-lowering agents, antimycobacterials, calcium channel blockers, antihistamines, antidepressants, neuroleptics, psychotropics, and ergot alkaloids (vasoconstrictors). It has also become evident that when an individual begins an ART regimen, their risk of developing CVD or diabetes increases every year. A complementary treatment that may help address ART toxicities in viral related side effects is exercise training. Similar metabolic abnormalities within the general population respond positively to prescribe dosages of routine exercise designed to increase fitness. These exercise-induced changes include decreases in total cholesterol and triglycerides, decreased fat mass, increased lean tissue mass, decreased waist circumference, and increased insulin sensitivity.[19–21]

46.4 LIFESTYLE MEDICINE FOR MANAGING SIDE EFFECTS ASSOCIATED WITH HIV

In populations with a broad range of chronic diseases, there is a growing body of evidence showing that health benefits can be obtained by incorporating structured aerobic and resistance exercise into an individual's recovery and/or treatment plan. For those living with chronic conditions, aerobic combined with resistance exercises can have positive effects in alleviating symptoms associated with the diseases and side effects of the medical interventions. More recently, research has been indicating that a combination of aerobic and resistance training is most effective, but that also any form of progressive resistance training that the individual can tolerate will lead to improvements in overall quality of life and activities of daily living as PLWHA reach older age groups.[22]

Only in the last few years has an association been established between HIV and increased risk of chronic diseases such as CVD and diabetes.[1,23] As a result, there is limited evidence to make a definitive statement as to whether or not exercise is a beneficial alternative to pharmacological therapy for decreasing the risk of CVD among PLWHA. Although limited, the data that are available suggest that even modest amounts of routine exercise can yield both psychological and physiological health improvements that are known to reduce the risk of CVD within the general population. Table 46.1 provides an overview of the primary findings that have been discussed in greater detail from previous literature rev iews.[22,24,25] There follows a general overview of the main physiological benefits reported within the literature.

46.4.1 Cardiorespiratory Fitness (VO_{2peak})

Most exercise-related interventions measure cardiorespiratory fitness (CRF) as common practice prior to any low- or moderate-intensity intervention. As a result, there are substantial data consistently showing both functional aerobic impairment (FAI) and training adaptations that increase CRF in as little as six weeks.[26,27] FAI is defined as a peak VO_2 less than 25% of one's age-predicted VO_{2peak}. This aerobic impairment results in a reduced CRF level, which is known to be a significant indicator of various chronic conditions and all-cause mortality.[19–21] Even before the introduction of ART, a common consistency among exercise interventions has been significant FAI. Whether this is due to lifestyle factors or disease-related pathologies is not well understood. In a previous investigation from our laboratory, we have demonstrated significant improvements in VO_{2peak} and reductions in submaximal heart rate.[26,28] Hand et al. showed evidence of these findings, which suggests that PLWHA can reverse any indications of FAI even by meeting less than half of the Surgeon General's recommendation of 150 minutes per week. This study also demonstrated that there were additional cardiovascular adaptations, such as a reduced resting heart rate and a reduced heart rate at submaximal workloads, which is a cardiovascular adaptation known as training bradycardia. These findings have also been in agreement with others.[22,25]

TABLE 46.1
Summary of Clinical Exercise Interventions: Physiological and Psychological Changes

	Response to Exercise
Psychological	• ↓ Depressive symptoms[37] • ↓ Anxiety[37]
Physiological	• ↑ VO_{2peak}[22,24,26,27] • Significant increases between 2.40 and 3.71 mL/kg/min • ↑ Strength[22,29] • ↓ Fat mass and waist circumference[22,40] • ↓ Cortisol[29,40]
Immunological	• No change in CD4+[22]

46.4.2 Muscular Strength and Endurance

With an increased number of PLWHA getting older due to successful disease management, it is imperative that resistance training for muscular strength and endurance also be included in a routine exercise program. It is important to be mindful of preventing other chronic conditions associated with general aging in more elderly populations, such as sarcopenia and osteoporosis. If there are no underlying conditions or concerns to prevent them from doing so, PLWHA over the age of 50 should follow similar resistance training guidelines recommended for elderly populations. The general consensus within the literature findings has clearly shown that resistance training, alone and/or combined with aerobic training, will lead to improvements in muscular strength for both upper and lower body.[29]

46.4.3 Blood Lipids

Another variable of interest regarding CVD risk is the blood lipid panel. Although not as strong as CRF, evidence suggests a potential effect regarding improvements in blood lipids following routine exercise. Thoni et al. and Grinspoon both showed increases in HDL cholesterol following light- to moderate-intensity aerobic exercise.[30, 31] Thoni also reported decreases in cholesterol and triglycerides. However, there is still limited evidence to draw any formative conclusions regarding blood lipids and exercise training. One of the common side effects of ART is increased blood lipids and fat deposits. Future studies should look into the long-term protective effects exercise may have in regard to normalizing blood lipids panels for PLWHA taking ART.

46.4.4 Body Composition

As stated previously, an increase in central fat accumulation is a common side effect of various ART regimens.

Additionally, it is well known that an increased waist circumference is a strong indicator of CVD risk. Multiple investigations have reported significant improvements in body composition by decreasing fat mass, waist circumference, and/or body mass index, as well as increasing lean tissue mass (see Table 46.1). Dudgeon et al. confirmed these findings by showing significant decreases in trunk fat and total fat while also increasing lean tissue mass following a six-week combination aerobic and resistance training intervention.[28] Although still limited by the small sample sizes, this evidence appears strong enough to confirm that similar benefits in body composition (specifically, fat mass and lean tissue mass) to those commonly observed among general populations can be obtained by PLWHA.

46.4.5 Inflammation Markers

Promising evidence has been shown in research studies examining markers of inflammation following exercise training.[29] However, with only a few studies published at this time, no real evidence can suggest current exercise routines that would work to help reduce markers of inflammation. It is believed that such improvements could possibly be met with a long duration of routine moderate-intensity activity as part of one's daily lifestyle. Limited evidence would also suggest that higher-intensity exercise may lead to better improvements in inflammation, but it is still unclear whether or not PLWHA can safely tolerate a more vigorous workout regimen at the earlier stages of a new exercise prescription; this needs further investigation.

46.4.6 Immune System

No significant changes in CD4+ cell count have been reported in high- or moderate-intensity exercise groups.[22] Further, there have been no significant changes from baseline reported in CD8+ cell count, leukocytes, or lymphocytes following moderate- or high- intensity exercise.[32] Also, it was shown that patients with dyslipidemia and lipodystrophy had no significant changes in immunological variables after completing 12 weeks of moderate-intensity aerobic exercise.[33] Notably, there are no published reports of exercise-induced immunosuppression in PLWHA who participated in physical activity regimens designed to reduce the psychological or physiological symptomatology associated with HIV.

46.5 PSYCHOLOGICAL IMPROVEMENTS WITH EXERCISE

Early investigations conducted prior to widespread use of ART compared the effects of aerobic exercise on psychological components, such as depression and anxiety. Eight to 12 weeks of moderate-intensity aerobic exercise completed twice weekly for 45–60 minutes has shown significant reductions in anxiety and depression.[34] Other investigators reported significant improvements after only five weeks of aerobic exercise. Men who exercised for 45 minutes a day, 3 days a week, reduced anxiety and depression upon learning of their seropositive status.[35] As most of these investigations were performed before ART, the results are limited to symptoms specific to viral progression and not treatment.

In the era of widespread use of ART, there has only been one investigation utilizing aerobic exercise as the primary intervention for HIV-associated depressive symptoms. Like those investigations previously discussed, reductions in depressive symptoms and/or significant improvements in quality of life were shown.[36] Findings from this study suggest that 60 minutes of moderate-intensity (60–80% VO_{2peak}) aerobic exercise conducted 3 days a week can be used as a beneficial method for improving the psychological disturbances experienced by PLWHA. These findings have also been demonstrated in studies with combined aerobic and moderate-intensity exercise over the years, leading to published meta-analyses.[37,38] In a meta-analysis by Gomes-Neto and colleagues in 2021, following a review of 40 published research studies, it was shown that the majority of the literature indicated that the higher chance of beneficial outcomes in psychological well-being was similar to that of increased fitness (VO_{2max}) when combining aerobic and resistance exercise at a moderate intensity level on three or more days a week.[27]

Emerging areas of research have looked more closely at the impact of exercise on cognitive function and its role in helping to reduce the risk of developing dementia and possibly offset its progression with the general aging of the population. Now that we are beginning to see an aging HIV population, there are indications that we will also experience a higher prevalence of those with dementia and cognitive decline, similar to that in general elderly populations. It is important that similar research efforts in cognition and mental health be considered for PLWHA and further investigated.

46.6 RECOMMENDATIONS FOR EXERCISE

Current exercise training recommendations as described in *ACSM's Guidelines for Exercise Testing and Prescription* (11th edition) for PLWHA suggest a moderate-intensity aerobic and resistance training regimen.[39] This includes accumulating a total of 150 minutes of moderate-intensity physical activity a week, as well as 2 days of full body resistance training at approximately 60% of one repetition maximum. Regardless of disease status, it is strongly recommended that anyone living with HIV or AIDS receive medical clearance from their primary healthcare provider prior to beginning an exercise program. The scientific literature shows a much higher strength of evidence to support a combined moderate-intensity aerobic and resistance exercise prescription for long-term health benefits. Even though the majority of PLWHA have a reduced aerobic capacity, most of the standard physical fitness tests are applicable to this population and can be completed with little or no risk to the individual. Table 46.2 outlines potential HIV-associated

TABLE 46.2
HIV-Associated Changes to Exercise Testing

Disease Status	Response to Exercise
Asymptomatic	• Physiological parameters within normal limits (e.g. blood pressure, heart rate, VO_2) • Possible functional aerobic impairments due to sedentary lifestyle
Symptomatic	• Reduced aerobic capacity and muscular strength • Possibility of increased heart rate at rest and submaximal work rates • Increased difficulty in adhering to exercise prescription • ART related side effects
AIDS	• Drastically reduced aerobic capacity and muscular strength • Possible abnormal neuroendocrine responses at moderate- and/or high-intensity work rates

changes that may be observed during exercise testing and/or training according to disease state.

Ongoing investigations by Jaggers and colleagues have been studying community-based approaches to facilitating increases in daily physical activity. A recent nine-month home-based activity program used accelerometers to assess changes in activity from baseline. As indicated in the results, the average number of total minutes of daily moderate-intensity activity was approximately 90 minutes, suggesting that the majority of the participants were already meeting the physical activity recommendations. However, when looking at step counts, the daily average was only approximately 5,200 steps per day.[40] It is possible that with such a deconditioned population, physical activity prescribed by total minutes, as indicated by wearable activity monitors, may grossly overestimate the amount of activity that is being achieved for health benefits. Therefore, it may be a more realistic approach that recommendations for deconditioned populations such as this focus more on gradual increases in daily steps with the ultimate goal of 10,000 or more daily steps.

46.7 CONCLUSION

Evidence would suggest that PLWHA, regardless of disease status, can obtain similar short-term health benefits from routine physical activity to those reported within general populations. Research has shown significant improvements following moderate levels of routine exercise in as little as six weeks. It is also clear that across various populations, routine moderate-intensity physical activity reduces the risk of chronic disease and that many of these conditions have been established as major causes of morbidity and mortality among PLWHA. It is therefore imperative that healthcare professionals and researchers test various approaches to help PLWHA adopt healthy lifestyle choices for the rest of their lives.[41]

In regard to immunity, research among PLWHA has demonstrated that aerobic exercise performed at low, moderate, or high intensity does not negatively impact immune function or disease progression at any stage of HIV infection.[32–34] This clearly shows that aerobic exercise can be both safe and beneficial for this clinical population. However, it is recommended that if aerobic exercise is to be performed by this population, they do so at a low or moderate intensity level, as data are lacking to draw the conclusion that a high-intensity aerobic regimen will not have a negative impact on overall health or quality of life in this population. To our knowledge, only one investigation with a modest sample size examined the effects of a four-month high-intensity interval training protocol among PLWHA ≥50 years of age and found similar improvements to those previously discussed for moderate-intensity exercise interventions.[42] It was also shown to be safe, with no adverse events reported or impaired immune function.

Responses and adaptations to exercise training will vary depending on current fitness level, disease status, and whether or not that patient is currently on an ART regimen. Asymptomatic individuals generally respond in a manner similar to someone without HIV of the same body size, age, and gender. However, some may be more deconditioned due to psychological disturbances commonly associated with daily sedentary behavior, such as depression or anxiety, among others. Further, individuals with symptomatic status will generally be on a current ART regimen, which also puts them at an increased risk of CVD. Therefore, extra caution should be taken prior to beginning an exercise prescription.

Although exercise itself is not going to eliminate the burdens of healthcare costs, social stigmatization, or other daily stressors, it could potentially reduce the health consequences of chronic stress, improve quality of life, and possibly increase the reduced lifespan of PLWHA. Most of the negative side effects from both the virus itself and treatment-related toxicities, including impaired glucose tolerance, fatigue, increased blood lipid profile, chronic inflammation, anxiety, depression, circulating cortisol, and others, are known to improve with routine exercise in various populations. Additional evidence from longitudinal studies has clearly shown that modest increases in CRF can decrease the risk of all-cause mortality as well as the risk of most chronic diseases. Whether or not PLWHA would have a similar response to long-term exercise is unknown due to insufficient research. Further, there are no reported exercise-related interventions lasting longer than six months, making it impossible to determine the long-term effects on overall health and longevity. However, benefits observed in a short time frame, as reported by multiple investigations, would suggest long-term gains in the physical and psychological well-being of PLWHA who participate in routine physical activity.

CLINICAL APPLICATIONS

- Increase in daily physical activity and/or weekly exercise has been proven to have beneficial effects

for PLWHA with no indications of reductions in immunity or negative health outcomes.

- Chronic stress is a daily struggle for anyone managing a clinical condition with added stigmatization. Weekly exercise regimens have proven to reduce physiological and psychological stress, but more attention should also be given to additional methods of effective stress relieving practices in addition to exercise.
- Regardless of disease status, all individuals with HIV are at an increased risk for cardiovascular disease and therefore should seek consent from their primary care doctor prior to initiating a new exercise regimen. Individuals can safely begin with daily walks at a light intensity prior to receiving consent if no other health concerns are evident.
- For individuals in a deconditioned state of aerobic impairment, it is important to set practical goals, since all activity can take moderate or vigorous efforts. Gradual increases in daily step counts by a few hundred steps each day may be more suitable as opposed to 30 minutes of moderate-intensity activity.
- With an increased lifespan and aging population, incorporating resistance training as part of a weekly exercise prescription for PLWHA over the age of 50 is strongly encouraged to help maintain independence and a higher quality of life down the road.

47 Exercise, Aging, and Immunity

Brandt D. Pence, PhD, Jeffrey A. Woods, PhD, and Yi Sun, PhD

KEY POINTS

1. Aging is associated with impaired immune responses (immunosenescence) and increased inflammation (inflammaging), which are correlated with increased susceptibility to acute infections and chronic diseases.
2. Moderate-intensity cardiovascular exercise training improves immune responses and reduces inflammation in older adults.
3. The available evidence suggests that modulation of adipose tissue inflammation, alteration of the gut microbiome, stimulation of the parasympathetic nervous system, and other mechanisms may drive the effect of exercise on aging and immunity.

47.1 INTRODUCTION

The population of older individuals is expanding rapidly, with the U.S. population of adults over 65 years of age projected to nearly double by 2060.[1] Older individuals have altered immune status, including increased inflammation (termed "inflammaging"[2]) and impaired vaccine and anti-pathogen immune responses (termed "immunosenescence"[3]). Therapeutic strategies to reverse age-related immune impairments are being widely investigated, but few have been shown to be broadly efficacious. However, regular moderate cardiovascular exercise has been shown in a number of studies to improve immune function in older adults, both by potentiating immune responses and by reducing inflammation.

47.2 EXERCISE AND INFLAMMAGING

Aging increases localized and systemic inflammation associated with age-related diseases, a condition colloquially known as inflammaging.[2] Because of the association between age-related disease and inflammation, treatment strategies to reduce inflammation in older adults are of major interest. Large cohort studies such as NHANES III have demonstrated negative correlations between level of physical activity and circulating inflammatory markers such as C-reactive protein (CRP), interleukin-6 (IL-6), and tumor necrosis factor-α (TNFα),[4] suggesting a dose-dependent relationship between activity dose and inflammation reduction.

Further, numerous longitudinal studies have shown that an exercise training program reduces inflammation in older adults. Vieira *et al.*[5] demonstrated that ten months of aerobic exercise training reduced CRP levels in older adults, and this was closely associated with reductions in adiposity. Similarly, Kohut *et al.*[6] found that ten months of exercise reduced IL-6, CRP, and IL-18 in older adults, and Nicklas *et al.*[7] found that a combined aerobic and resistance exercise intervention for one year reduced circulating IL-6 (but not CRP) levels. A variety of additional training studies have corroborated these findings, as recently reviewed elsewhere.[8]

While many studies have shown positive effects of exercise, several have found no benefit from moderate exercise training on inflammation in older adults.[9] Published protocols in this area have varied widely in exercise training duration, exercise bout intensity, subject population, baseline inflammatory status, overall baseline health status, subject demographics, and numerous other factors that might impact results. As such, we currently have little understanding of the physiological determinants of the effect of exercise on inflammaging. Additionally, more work is needed to conclusively link exercise suppression of inflammaging to beneficial effects on age-related disease incidence or progression, as this is not yet well established.

47.3 ANTI-INFLAMMATORY MECHANISMS OF EXERCISE

Additionally, mechanisms by which exercise exerts its anti-inflammatory effect are not well understood. A variety of theories have been promulgated; here, we describe several of the most established.

Adipose Tissue: Adipose tissue is no longer considered an inert lipid storage organ but instead, is known as a metabolically active system, which produces numerous factors which regulate physiological responses. Excess adiposity is linked to age-related inflammatory burden, suggesting age-associated increases in obesity as a primary driver of inflammaging. Wu *et al.* demonstrated increased gene expression of a variety of pro-inflammatory cytokines in aged mice compared with younger mice.[10] Numerous other studies have shown links between adiposity and inflammation, as comprehensively reviewed elsewhere.[11] Given the well-known effect of exercise on reducing adiposity, it has naturally been hypothesized that exercise training may also reduce adipose tissue–associated inflammation during aging.

Vieira *et al.* have previously demonstrated that moderate exercise training reduces adipose tissue inflammation

DOI: 10.1201/9781003227793-55

in obese mice,[12] and this has been corroborated in aged mice by Yoon *et al.*[13] Likewise, a training study in older adults found similar exercise-mediated reductions in adipose tissue inflammation.[14] While the mechanism by which this occurs is unknown, exercise training promotes M2-like anti-inflammatory macrophages in adipose tissue and suppresses M1-like pro-inflammatory macrophages,[15] suggesting a plausible process by which inflammation is reduced in this system.

Cholinergic Anti-Inflammatory Pathway: The nervous system is known to be intimately involved in inflammatory regulation, and a substantial literature exists on this topic.[16,17] Importantly for exercise, stimulation of the efferent vagus nerve has been shown to reduce inflammation,[18] termed the cholinergic anti-inflammatory pathway. The vagus nerve controls heart rate responses during exercise, including heart rate variability and heart rate recovery, so it has been speculated that exercise-mediated stimulation of the vagus nerve may also suppress inflammatory responses. While there is little direct evidence to substantiate this at present, lower heart rate reserve is associated with decreased CRP during aging,[19] suggesting a possible link.

Gut Microbiota: The human gut is colonized by trillions of microbes, which exist more or less symbiotically with their host. Seminal research by Turnbaugh *et al.* showed that the composition of the microbiome is tightly linked to obesity, to the extent that transplanting microbiota from obese mice to lean mice caused weight gain and an obesity phenotype in the recipients.[20] Aging is also associated with microbiome changes,[21] as is the pathogenesis of a variety of age-related diseases.[22–24] Research into the links between exercise and the microbiome has therefore exploded in recent years. A cross-sectional study by Clarke *et al.*[25] demonstrated that higher fitness (in professional rugby players) was associated with increased diversity of gut microbes, which is generally considered a biomarker of a healthier microbiome. Later cross-sectional studies have directly shown an exercise-mediated effect on microbiome composition. Allen *et al.*[26] and Cronin *et al.*[27] both demonstrated in 2018 that short-term (six- to eight-week) exercise interventions modulated the microbiome in obese adults, and a variety of additional studies have since shown exercise to be efficacious in positively influencing the microbiome in both human participants and animal models.[28] Interestingly, the availability of fecal microbial transplants has also given rise to the possibility of transferring (some of) the beneficial effects of exercise between individuals. Support for this comes from Allen *et al.*,[29] who showed that transplant of microbiota from exercised mice reduced colitis symptoms in dextran sodium sulfate–treated gnotobiotic mice, and from Lai *et al.*,[30] who showed that transplant of microbiota from lean exercised mice improved metabolic profiles in sedentary obese mice. Gut microbiome–targeted therapeutic strategies have been proposed for the prevention and treatment of the symptoms of cognitive impairment.[31, 32] Other than physical exercise, administration of probiotics has been proposed to be a potent therapy. Buford *et al.*[33] showed that an orally delivered probiotic bacterium, *Lactobacillus paracasei*, modified to express angiotensin (1-7) benefits the gut-brain axis in older rats, including a reduction of neuro-inflammatory gene expression (COX2, IL-1β, and TNF-β) in the pre-frontal cortex.

Endocrine Mediators: Although somewhat speculative, a variety of endocrine mediators produced by skeletal muscle and other organs during exercise are known to have immunomodulatory effects and may reduce inflammaging. Contracting muscles (and other organs, including the liver) are known to produce immunoregulatory cytokines such as IL-6, IL-15, and growth differentiation factor-15 (GDF-15).[34,35] Exercise-derived IL-6 is thought to promote anti-inflammatory actions through stimulating cortisol and IL-10 release.[36] Likewise, GDF-15 is produced during exercise [35] and is a potent anti-inflammatory cytokine, which suppresses macrophage activation.[37] In addition to protein hormones, exercise-induced metabolites such as lactate and succinate have anti-inflammatory signaling properties[38] and may play a role in the anti-inflammatory effect of exercise. To date, these links remain speculative in the context of exercise, but endocrine crosstalk between metabolic organs and the immune system is a promising area for further research.

47.4 IMMUNOSENESCENCE

In addition to inflammaging, aging results in a generalized impairment in immune responses referred to as immunosenescence. This manifests in reduced vaccine efficacy and impaired anti-pathogen responses,[3] prominently illustrated by the substantially increased disease burden experienced by older adults during the coronavirus disease 2019 (COVID-19) pandemic.[39] Inflammaging, primarily but not exclusively a phenomenon of the innate immune system, is considered a facet of immunosenescence.[40] Additionally, profound dysregulation of the adaptive immune system occurs with aging.

Aging and Cell-Mediated Immunity: Cell-mediated immunity generally refers to antigen-specific activation of T lymphocytes (T cells), which both directly kill infected or transformed cells (CD8+ cytotoxic T cells [T_C]) and produce cytokines to activate other immune cells (CD4+ helper T cells [T_H]). Often included in this definition is the antigen non-specific activation of cell types such as macrophages, natural killer (NK) cells, and γδ T cells (among others), all of which mediate important immune responses during infection, cancer, sterile cellular damage, etc. Cell-mediated immunity is generally decreased during aging. Specifically, older adults have reductions in circulating naïve T cells and increased antigen-experienced memory and senescent T cells,[41,42] which is thought to serve to decrease the ability of the immune system to respond to novel pathogens. T cell proliferation, activation, and cytokine signaling are also decreased during aging.[41] To some degree, expansion of memory and senescent T cells and the parallel decrease in the naïve T cell pool are thought to occur due to the high

prevalence of latent herpesviruses such as cytomegalovirus (CMV) and Epstein–Barr virus (EBV),[43] as a high proportion of aged individuals are seropositive for these pathogens, and an increased proportion of circulating T cells are antigen-specific for CMV or EBV. Aging is also associated with reduced T_H1 (pro-cytotoxic) and increased T_H2 (anti-inflammatory) cytokine production,[44–46] which is thought to skew T cell responses to a state less suited for antiviral immunity.

Aging and Humoral Immunity: Likewise, humoral (antibody-mediated) immunity is suppressed in older compared with younger adults. This is especially notable in vaccination,[47] where antibody responses may be sub-neutralizing, leading to decreased efficacy and increased risk of breakthrough infection. Antibodies are secreted by circulating B lymphocytes (B cells) in an antigen-specific manner, and aging is associated with reduced B cell number and function.[48] Older adults also have more rapid loss of protective antibody levels compared with younger individuals after vaccination[49] and thus may lose pathogen neutralizing ability prior to the end of, for example, the influenza season.

47.5 EXERCISE AND IMMUNOSENESCENCE

Given the multifaceted association between aging and immunosenescence, exercise has been widely investigated for its potential positive impact on immunity in this population. Exercise training has been established to reduce infection risk.[50,51] However, many studies have had mixed results, depending on the population studied, specific outcome measures, and overall study design.

Cell-Mediated Immunity: A variety of cross-sectional studies have shown increased T cell proliferative responses in older adults who report exercising regularly.[52–54] However, individuals who regularly exercise may also have overall healthier lifestyles, and cross-sectional results may reflect preventative rather than therapeutic effects of exercise training on these outcomes. As such, multiple longitudinal exercise studies have been undertaken to determine whether a prescribed exercise intervention can revert cell-mediated immune status to a more "youthful" state in older adults, with somewhat mixed efficacy. Shimizu *et al.*[55] found increased expression of the co-stimulatory receptor CD28 on circulating T cells in older adults who underwent a six-month exercise training program, which could reflect increased ability of these cells to produce immunoactivating cytokines upon antigen stimulation. However, a similar study by Kapasi *et al.*[56] found no effect of eight months of endurance training on co-receptor expression on T cells. Likewise, NK cell cytotoxic responses and T cell proliferation were not altered by a one-year exercise training regimen in older women,[57] but six months of aerobic exercise training in previously sedentary older adults did result in increased T cell proliferation and NK cell cytotoxic activity.[58] Higher aerobic fitness (as measured by VO_{2max}) is also associated with reduced circulating numbers of senescent T cells in older adults.[59]

In order to remove potential confounding factors related to lifestyle changes in these studies, several similar exercise training experiments have been performed in aged mice. Woods *et al.*[60] found increased naïve-to-memory CD4+ and CD8+ T cell ratios after four months of treadmill training in aged mice, and Kohut *et al.*[61] demonstrated increased T_H1-associated cytokine production after experimental herpes simplex virus-1 (HSV-1) infection in mice. Kruger *et al.*[62] found that a single acute bout of exercise caused apoptosis of highly differentiated T cells, suggesting a mechanism whereby antigen-experienced, late memory/"exhausted" cells[63, 64] may be removed to increase space for naïve populations.

Additionally, several studies have used a delayed-type hypersensitivity (DTH) model to assess T cell–mediated immunity responses in human subjects *in vivo*. Cross-sectionally, physically active older men have improved DTH responses compared with sedentary men,[65] and a 17-week aerobic but not resistance training program sustained DTH responses in older adults compared with a declining response in sedentary controls.[66] However, DTH responses are highly variable, and effect sizes in these studies have been relatively small, so these results must be interpreted cautiously. Given that, this human and mouse *in vitro* and human *in vivo* evidence suggests a potential for exercise to improve some aspects of cell-mediated immune function during aging, thereby potentiating responses especially to viral infection in this susceptible population.

Naïve T cells migrate from the thymus into the periphery, and aging is associated with thymic atrophy (involution).[67] Duggal *et al.* compared older adults who were lifelong cyclists with sedentary counterparts and found increased naïve T cell frequency and more recent thymic emigrant T cells in the physically active group.[68] Likewise, circulating levels of the cytokine IL-7, which is thymoprotective, were increased. This suggests that physical exercise may be protective against thymic atrophy during aging, which is a potential mechanism for reduced immunosenescence in this population.

Humoral Immunity: A variety of cross-sectional studies have shown that vaccine responses in older adults are increased when subjects report higher levels of physical activity. Keylock *et al.*[69] demonstrated increased influenza vaccine responses in highly fit active older adults compared with less active controls, as well as increased production of more highly potent IgG2 antibodies when these individuals were exposed to a tetanus toxoid booster vaccination. Several additional studies have found similar increases in influenza vaccine antibody responses in individuals with higher fitness levels or reported training loads.[54,70,71]

As with cell-mediated immunity, cross-sectional studies of antibody responses may be confounded by other healthy lifestyle factors, so several prospective training studies have also been undertaken in this population. Influenza vaccine–elicited antibody production was increased in older adults after a ten-month exercise training program compared with sedentary control subjects,[72] and a similar study [73] found

that ten months of training prolonged the duration of protective antibody levels in older adults (although it did not increase peak levels).

In addition to plasma antibody levels (IgG, IgM), exercise training also causes increases in salivary levels of IgA, although this is not consistent across all studies. A 6-month cycling intervention increased salivary IgA by 40% in older men and women,[74] and a 12-month combined resistance and aerobic training intervention increased salivary IgA levels in older men and women.[75] Conversely, a 16-week aerobic exercise intervention did not increase salivary IgA (but did increase plasma IgA, IgG, and IgM) in a similar population.[76] This suggests potential roles for exercise mode, intensity, and duration in determining changes in humoral immunity during interventions in the aged population.

Exercise and Immune Cell Redistribution: While mechanisms involved in these responses are not well defined, important progress has been made in recent years in characterizing the mobilization and redistribution of immune cell subsets via β2-adrenergic receptor signaling during acute exercise. Activation of this system preferentially mobilizes memory, highly differentiated, exhausted, and latent virus-infected lymphocyte subtypes,[77] possibly promoting their apoptosis [78] Additionally, exercise mobilizes effector cell subtypes that may promote enhanced immune responses.[79,80] While the links between these acute effects and the effects of chronic exercise training outlined earlier are not conclusive, it is possible to speculate that repeated exercise bouts mediate a more permanent shift in circulating immune cell phenotype that may underlie (some of) the beneficial effects of exercise training on the aging immune system.[77]

47.6 SUMMARY

During aging, exercise has anti-inflammatory and immunopotentiating roles that serve to limit aberrant inflammation and enhance immune responses in this critical expanding population. To date, we know little about the mechanisms by which exercise mediates these effects, although some progress has been made in defining exercise-induced metabolic, endocrine, nervous system, and microbiome changes that may play a role in modulating immunity in older adults. Additionally, variability of study results indicates that exercise intensity, dose, duration, and modality may be a determinant of the efficacy of immune modulation, and this is an area of important work in the future.

CLINICAL APPLICATIONS

- Aging is associated with "inflammaging," a chronic condition that is associated with increased age-related disease.
- Aging impairs the immune system, including by reducing innate and adaptive immune responses, a phenomenon referred to as "immunosenescence."
- Hallmarks of aging-related immunosenescence include poor vaccine efficacy and impaired defense against microbial infection.
- Regular, moderate-intensity exercise training may improve both inflammaging and immunosenescence.
- Changes in body composition, the gut microbiome, and exercise-associated endocrine mediators may be responsible for the anti-inflammatory and immune boosting effects of exercise in older adults.

48 Respiratory Symptoms

Jeremy B. Richards, MD and Richard M. Schwartzstein, MD

KEY POINTS

- Dyspnea represents a spectrum of subjective symptoms as a result of the complicated multisystem pathophysiology that results in the sensation of breathlessness.
- Understanding the pathophysiologic mechanisms that result in dyspnea can guide the clinical evaluation and diagnostic testing in a patient with shortness of breath.
- The history and physical exam are critical in identifying causes of dyspnea and guide the appropriateness and necessity of further diagnostic testing.
- Dyspnea is often associated with a series of affective or emotional responses, which may alter behavior in a way that leads to greater breathing discomfort.
- Treatment of dyspnea is primarily dependent on treating the underlying disease process, although palliative interventions with both pharmacologic and non-pharmacologic interventions can provide symptomatic relief.
- Cough is clinically characterized as acute, subacute, or chronic, and treatment is predicated on the etiology of cough and symptomatic management.
- Hemoptysis is classified as massive (≥600 cc of blood over 24 hours) or non-massive.
- Wheezing is caused by turbulent flow due to narrowing of intra- and/or extrathoracic airways; intrathoracic airway narrowing results in expiratory wheezing and in severe cases of asthma, inspiratory wheezing, while extrathoracic narrowing causes inspiratory stridor.
- Snoring is of uncertain clinical significance, but a patient or bed partner complaining of snoring should prompt questions regarding signs or symptoms of obstructive sleep apnea.
- Apnea is defined as cessation of breathing for ≥10 seconds, while hypopnea is defined as a reduction of airflow for ≥10 seconds with a ≥4% decrease in oxygen saturation; an apnea hypopnea index of >5 is diagnostic of obstructive sleep apnea.
- Obstructive sleep apnea syndrome is the combination of an apnea hypopnea index of >5 and symptoms of day-time somnolence and fatigue.

48.1 RESPIRATORY SYMPTOMS

48.1.1 Introduction

Shortness of breath, cough, and wheezing are among the most common symptoms experienced by patients seeking medical care. As in most areas of medicine, the evaluation of patients with respiratory symptoms largely depends on a comprehensive and insightful history obtained by the healthcare provider. Information offered spontaneously by patients is the starting point in the evaluation of any problem, but knowledge of the pathophysiology and differential diagnoses underlying the symptoms allows the provider to probe further, to determine which areas of the physical examination require special attention, and ultimately, to narrow if not eliminate the radiographic and laboratory testing required to confirm the diagnosis. We must also remember that, as with pain, many patients do not spontaneously tell healthcare providers about breathing discomfort, and it is important to directly inquire about this symptom.

Often, there is confusion between respiratory symptoms and signs. For example, patients are described as being "short of breath" as part of the physical examination. In fact, symptoms can only be described by the patient. Healthcare providers may speculate that a patient is experiencing respiratory discomfort based on observing physical signs such as recruitment of accessory muscles of ventilation, tachypnea, or an inability to speak in full sentences, all of which are signs of underlying pathophysiology and the body's response to maintain adequate gas exchange. Nevertheless, *symptoms* characterize what patients are experiencing and can only come from their self-reported perceptions of their somatic experiences.

The timing of respiratory symptoms and conditions that precipitate or alleviate the discomfort can clarify the impact of the symptom on the patient. Understanding the "language of dyspnea," developed from descriptive research on patients with a variety of respiratory diseases, can help clinicians understand the significance of their patients' symptoms.

This chapter focuses on the physiologic and clinical significance of several common respiratory symptoms. The clinical utility of quantitative dyspnea scales, the multidimensional nature of breathing discomfort, and the consequences of dyspnea are briefly discussed. The role for and utility of pulmonary function tests (PFTs) is briefly reviewed, but a more complete description is beyond the

DOI: 10.1201/9781003227793-57

scope of this discussion. Clinical and pathophysiologic details of specific disease states such as asthma and chronic obstructive pulmonary disease (COPD) will be addressed in other chapters. This chapter does cover how specific elements of the physical examination, in concert with reported symptoms, can narrow the differential diagnosis.

48.1.2 Objective Assessment of Respiratory Symptoms

Respiratory symptoms can be due to a variety of pathophysiological processes involving disparate organ systems. A general understanding of the use of PFTs is helpful in developing a preliminary, physiologically based approach to respiratory symptoms. We will also comment briefly on some of the common pitfalls associated with the use of pulse oximetry.

48.1.2.1 Objective Dyspnea Scales

There are several quantitative scoring systems designed to assess the severity and impact of dyspnea in patients with respiratory disease. Examples of such scales include the Medical Research Council (MRC) dyspnea questionnaire, the modified MRC (mMRC), the COPD assessment test (CAT), the oxygen cost diagram (OCD), the COPD Clinical Questionnaire (CCQ), the multidimensional dyspnea profile (MDP), and other scoring systems. These scales assess different components of the sensation of breathlessness.[1,2] The scoring systems demonstrate relatively similar performance with regard to assessing symptom severity in clinical practice, such that one scale is not clearly superior to another.[3] Assessing dyspnea severity using a quantitative scale can be useful to characterize baseline symptom burden, although following dyspnea scales in response to therapeutic interventions is of less certain clinical utility.[2]

The majority of available dyspnea scales assess patient-reported perceptions of functional disability attributable to dyspnea (e.g., MRC, mMRC, CAT) or more general perceptions of healthcare associated quality of life attributed to dyspnea (e.g., CCQ, OCD). As dyspnea manifests as a constellation of symptoms not solely defined by perceived functional limitation, multidimensional assessment using the MDP instrument has been increasingly used in clinical and research settings.[4] MDP measurements, as compared with other objective dyspnea scales, have demonstrated adequate sensitivity to detect changes in symptoms of dyspnea over time.[2] In addition, the MDP gives us insight into the relationship between the sensations of breathing discomfort and the affective or emotional responses associated with this frequently debilitating symptom. Anxiety, fear, and frustration are commonly associated with certain types of dyspnea, and these emotional responses may cause individuals to curtail activity, leading to cardiovascular deconditioning, more dyspnea, and even more drastic functional limitation.[5]

Quantitative dyspnea scales can be used for any patients with respiratory disease but may be of most use for patients with COPD as a component of determining the Global Initiative for Obstructive Lung Disease (GOLD) stage of disease severity, which has prognostic and therapeutic value for this patient population.[6]

48.1.2.2 Pulmonary Function Tests

Pulmonary function testing refers to maneuvers in which spirometry, lung volumes, inspiratory and expiratory pressures, and/or diffusion limitation of carbon monoxide (DLCO) are measured. Confusion regarding PFTs arises from imprecise use of the term "pulmonary function tests" in clinical practice to refer to measurements of spirometry alone. It is more precise to consider PFTs to include spirometry, lung volume, and DLCO measurements.

PFTs can provide objective data regarding a patient's specific respiratory impairment and can provide important insight into the cause of patients' respiratory symptoms. Not all respiratory symptoms are best assessed by PFTs, but several common symptoms are due to diseases that may be diagnosed by PFTs. For example, the diagnosis of COPD, which may affect 4–10% of adults in the United States,[7] is dependent on spirometric measurements. COPD is typically suspected based on clinical symptoms, but further evaluation by measuring spirometry confirms or excludes the actual diagnosis.

When obtaining PFTs, a trained respiratory therapist or technologist can influence the quality of data obtained; the instructions, prompts, and encouragement provided to the patient prior to and during the test can significantly affect the patient's respiratory maneuvers. Normal values for PFTs are determined from predictive equations developed from large descriptive studies and incorporate an individual patient's age, gender, and height.[8]

48.1.2.2.1 Spirometry

Spirometry refers to measurements of the flow and volume generated when a patient performs a forced vital capacity (FVC) exhalation; these tests are critical for assessment of airway resistance. To perform a FVC exhalation, the patient takes in as big a breath as possible to completely fill the lungs with air (to total lung capacity, or TLC) and then forcibly exhales as rapidly as possible until no more air can be emptied from the lungs (to the residual volume, or RV.) In addition to measuring the FVC, determining the volume of air the patient is able to exhale in one second (FEV1) is important in diagnosing and characterizing the severity of obstructive airways diseases. If a patient has increased airways resistance and is unable to generate high flows from TLC, the FEV1 relative to the FVC will be reduced.

Patients may develop increased airways resistance due to airway narrowing from airway inflammation, mucus accumulation, and/or smooth muscle hypertrophy (e.g., as a consequence of chronic asthma) or from loss of tethering of the airways leading to airway collapse during active exhalation (e.g., COPD). Increased airways resistance causes obstruction of airflow during exhalation, which results in a decreased FEV1 out of proportion to the FVC. Therefore,

the ratio of the FEV1 to the FVC (FEV1/FVC) will be reduced in such patients. In patients with severe airway resistance, expiratory time is insufficient to permit exhalation of a full vital capacity, and RV may be elevated. An elevated RV above 120% of the patient's predicted value (as determined by their age, sex, and height) is referred to as "air trapping."

Obstructive airways diseases are conditions that decrease the FEV1/FVC ratio. COPD and asthma are by far the most common causes of obstructive airways disease. Bronchiectasis, tracheobronchomalacia, sarcoidosis, and other esoteric processes are much less common causes. While a reduced FEV1, FVC, and a preserved (or increased) FEV1/FVC ratio suggest a restrictive pulmonary disease, lung volumes (particularly TLC) must be measured separately to confirm restrictive disease. Spirometry results alone can only suggest restrictive pathophysiology; lung volume measurements demonstrating a TLC of less than 80% predicted are necessary to diagnose restriction.

48.1.2.2.2 Lung Volume Testing

Lung volumes may be measured by one of two methods. Plethysmography refers to measuring lung volumes based on the change of pressure and volume of a known quantity of air in a closed container (a so-called "body box") to calculate lung volumes via Boyle's Law. Helium dilution refers to the measurement of lung volumes based on the differential exhaled helium concentration and the helium concentration in a closed, external container. Since helium is an inert gas that does not cross the alveolar–capillary basement membrane, the concentration of helium after the gas has equilibrated between the patient's lungs and the external container of helium provides a measurement of a patient's lung volumes. This technique is used to measure functional residual capacity (FRC), or relaxation volume at the end of a passive exhalation. Once this volume is known, other volumes (TLC and RV) can be determined with spirometric determinants of the change in volume as the patient goes through various maneuvers. Helium dilution may underestimate lung volumes in patients with poor ventilation (e.g., patients with large bullae) or patients with global hypoventilation (e.g., patients with severe COPD and air trapping).

As noted earlier, a TLC measurement below 80% of predicted is diagnostic of restrictive disease. When TLC and FRC are greater than the predicted value, one should consider reduced elastic recoil of the lung as a potential cause, most commonly due to emphysema. Specifically, a TLC of >120% of predicted indicates hyperinflation. Gas trapping and an elevated RV will commonly also be present in such patients.

48.1.2.2.3 Diffusion Limitation of Carbon Monoxide

The DLCO measures the transfer of carbon monoxide (CO) across the alveolar–capillary basement membrane. DLCO is considered a surrogate for oxygen transfer across the basement membrane and into the circulation. A patient performs the DLCO maneuver by inhaling air with a small, known concentration of CO to TLC and holding their breath for ten seconds to allow sufficient time for diffusion of CO into alveoli and for transfer of CO across the alveolar–capillary basement membrane. The amount of CO transferred into the blood stream is determined by the difference in the quantity of CO in inhaled air (which is known) minus the quantity of CO in exhaled air (which is measured).

The severity of the reduction is expressed as the percentage predicted. A DLCO 60–79% of predicted is consistent with a mild reduction in DLCO, 40–59% a moderate reduction, and <40% a severe reduction. The DLCO is reduced primarily when there is destruction of the alveolar–capillary interface (reduced surface area for diffusion) due to disease of the lung tissue, e.g., emphysema, or pulmonary vasculature, e.g., pulmonary arterial hypertension or chronic thromboembolic disease. Table 48.1 lists diseases associated with a decreased DLCO.

48.1.2.2.4 Pulse Oximetry

Assessment of oxygen saturation with a pulse oximeter is common in both inpatient and ambulatory clinical environments. Normal oxygen saturation does not mean that a patient's lungs are functioning appropriately. Patients with many cardiopulmonary conditions leading to dyspnea (e.g., asthma, pulmonary embolism, pneumonia, congestive heart failure [CHF]) may hyperventilate, leading to normal oxygen saturation with a low $PaCO_2$. Such hyperventilation can mask the presence of severe pulmonary disease. An accurate interpretation of the oxygen saturation must include an overall assessment of the patient's clinical status and/or an accompanying arterial blood gas. There are data suggesting that pulse oximetry, which is based on the wavelengths of light emitted by capillary blood in the finger nail, may be altered by racial differences in skin color.[9]

48.1.3 Dyspnea

48.1.3.1 Definition

The word *dyspnea* derives from the Greek term for difficult breathing, but has come to represent a more global set of sensations that can be grouped as "breathing discomfort." Dyspnea, or breathlessness, may be experienced by healthy individuals when exercising to the limits of their aerobic capacity, may represent primary pulmonary or cardiac disease, or may be a manifestation of a severe metabolic acidosis. In a study of more than 1,000 randomly selected adults, investigators discovered the presence of dyspnea in approximately 35% of adult patients without known, underlying cardiopulmonary pathophysiology.[10] Dyspnea in ambulatory patients has been associated with increased morbidity and possibly mortality as compared with patients without dyspnea;[10–12] similarly, dyspnea in hospitalized patients is also predictive of higher mortality and resource use.[13]

Given the frequency with which physicians encounter patients with dyspnea and the varied conditions that may lead to this symptom, having a clear understanding of the physiology and causes of dyspnea is critical in making a

TABLE 48.1
Causes of Decreased DLCO Categorized on the Basis of Lung Volume

	Causes of decreased DLCO
High lung volumes	• Advanced COPD • Bronchiectasis • Cystic fibrosis
Normal lung volumes	• Pulmonary vascular disease (e.g., pulmonary vasculitis or primary pulmonary hypertension) • Early pulmonary fibrosis • Anemia[a]
Low lung volumes	• Pulmonary fibrosis • Sarcoidosis • Congestive heart failure • Pneumonectomy[b]

[a] Anemia causes reduced DLCO by reducing hemoglobin binding sites for carbon monoxide; this will occur even in the presence of normal lungs and normal pulmonary vasculature.
[b] DLCO corrected for alveolar volume (DLCO/VA) should be normal, assuming the remaining lung tissue functions normally.

correct diagnosis. A summary of common cardiopulmonary conditions and the associated pathophysiological mechanisms that cause dyspnea is outlined in Table 48.2.

48.1.3.2 Physiology of Dyspnea

Dyspnea associated with respiratory disorders appears to arise due to a variety of physiologic mechanisms that involve stimulation of receptors in the upper airways, lungs, and chest wall as well as peripheral and central chemoreceptors (Figure 48.1). In addition, there are believed to be neural discharges, termed *corollary discharges*, between the motor and sensory cortex that are activated when ventilation is consciously increased. The physiology of cardiac dyspnea is less well understood, but likely involves many of these mechanisms as well as others unique to low cardiac output states.

TABLE 48.2
Relationship of Possible Mechanisms of Dyspnea to Selected Conditions

Asthma	Increased sense of effort Stimulation of irritant receptors in airways
Neuromuscular disease	Increased sense of effort
COPD	Increased sense of effort Stimulation of irritant receptors in airways Hypoxia Hypercapnia Dynamic airway compression
Pulmonary embolism	Stimulation of receptors in pulmonary vasculature or right atrium (?)
Congestive heart failure	Stimulation of J-receptors in the lung Stimulation of receptors in pulmonary vasculature (?) Hypoxia Stimulation of ergoreceptors (?)
Deconditioning	Stimulation of ergoreceptors (?)

Question marks indicate that the data in support of the listed mechanism are limited.

In the presence of increased mechanical load on the respiratory system, the motor cortex must increase the neural signals it sends to ventilatory muscles to overcome the load. These outgoing messages, or efferent signals, are associated with a simultaneous corollary discharge to the sensory cortex that is hypothesized to provide the individual with a sense of how much "effort" or "work" is being expended in the act of breathing.[14] Dyspnea associated with muscle weakness (e.g., myasthenia gravis, Guillain–Barre syndrome) is similarly attributable to this mechanism. Dyspnea also results when the respiratory system does not respond as expected to an elevated level of neural drive to breathe, often leading to a sensation of "air hunger" or "urge to breathe,"[15] discussed later, and the larger the discrepancy, the more intense the dyspnea experienced. This discrepancy between respiratory center output and the mechanical response of the system has been termed *efferent-afferent* or *neuromechanical dissociation*.[16–18]

Conditions resulting in a reflexive or automatic increase in the neural output from the brainstem respiratory control centers are also associated with breathing discomfort, generally described as a sense of "air hunger" or an increased "urge to breathe." Stimulation of peripheral chemoreceptors by hypoxia and hypercapnia and stimulation of central chemoreceptors by hypercapnia and metabolic acidosis is thought to produce dyspnea by this mechanism. Interestingly, inducing either hypoxia or hypercapnia in healthy volunteers results in similar levels of "air hunger" for each condition, demonstrating the importance of the corollary discharge from the brainstem in creating the sensation of dyspnea.[19] Hypoxemia, however is a relatively weak stimulus for ventilation and for dyspnea; most patients who are short of breath and hypoxemic have other derangements (e.g., increased airways resistance, hyperinflation, and pulmonary vascular disease) that contribute to the dyspnea. This is particularly evident when you encounter a patient with acute dyspnea and hypoxemia and you note that after administration of supplemental oxygen, there is relatively little change in the dyspnea. In patients with COVID-19 pneumonia, many people were surprised by individuals with relatively low intensity of dyspnea despite hypoxemia, overestimating the contribution of hypoxemia to dyspnea, particularly when a patient is able to hyperventilate, since hypocapnia reduces the drive to breathe and discomfort.[20] Stimulation of pulmonary mechano- or irritant receptors (e.g., from asthma or pulmonary embolism) may also result in an increase in ventilation and be responsible for part of the breathlessness in these conditions.

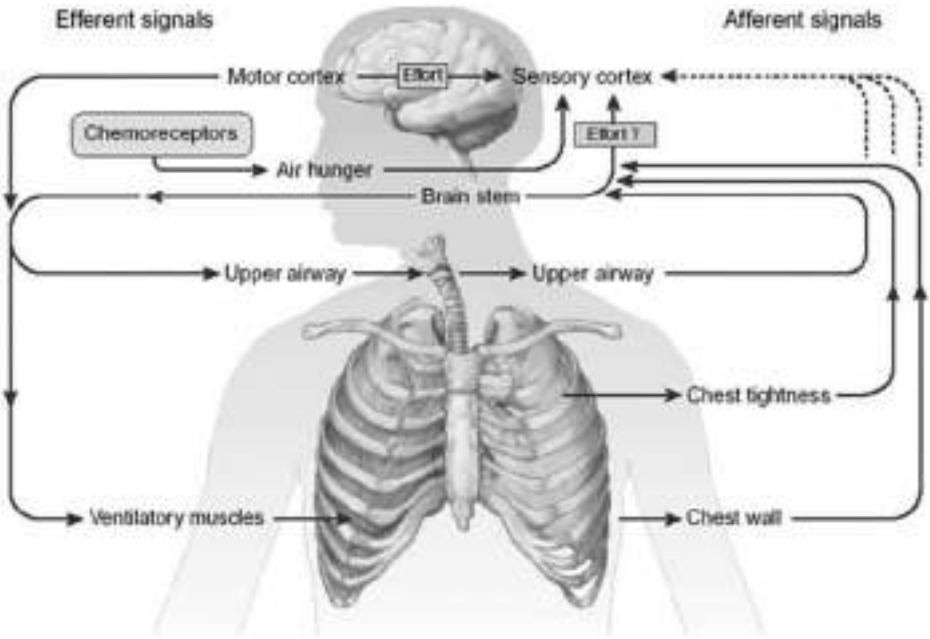

FIGURE 48.1 Physiologic mechanisms producing dyspnea. Respiratory symptoms included in the term "dyspnea" result from stimulation of a range of receptors throughout the respiratory system, as well as from corollary discharge thought to originate in the motor cortex when efferent neural discharges are sent to the ventilatory muscles. Qualitative phrases used to describe the sensations are based on research on and interviews with patients experiencing dyspnea. (From ***N. Engl. J. Med***. 333, 1547–1553, 1995. Copyright 1995 Massachusetts Medical Society. All rights reserved.)

Bronchoconstriction is associated with a sensation of chest tightness,[21–23] which is believed to arise from stimulation of pulmonary receptors by bronchoconstriction.[13] Studies of the possible palliative effects of inhaled furosemide demonstrate decreased dyspnea scores in subjects experiencing limited tidal volume excursion, acute hypercapnia, and resultant breathlessness.[24] The mechanism of action of inhaled furosemide likely involves stimulation of pulmonary stretch receptors, thereby creating a sensation that the lung is inflating more than it actually is in response to central efferent signaling, resulting in a decreased sensation of breathlessness. In addition, there is likely a psychological effect of the therapeutic intervention of delivering an inhaled aerosol that contributes to an expectation of relief of dyspnea with inhaled furosemide.[25]

Cardiac dyspnea may occur due to impaired systolic or diastolic function and resultant high left ventricular diastolic pressure. This leads to increases in pulmonary capillary wedge pressure and in some instances, transudation of fluid into the pulmonary interstitium and alveoli. As a result, the lung becomes less compliant, increasing the respiratory system mechanical load, and hypoxia may occur. Increased pulmonary vascular pressures and stimulation of pulmonary receptors by interstitial fluid may also directly lead to respiratory discomfort. Furthermore, low cardiac output states may lead to reduced blood flow to ventilatory muscles, resulting in muscle weakness and fatigue.[26] Also, congestive heart failure appears to alter respiratory control mechanisms, leading to increased levels of ventilation compared with control subjects for any given level of exercise.[27] Stimulation of the neural drive to breathe may lead to dyspnea. Finally, there appear to be receptors (ergoreceptors) in the peripheral muscles that are sensitive to increases in byproducts of anaerobic metabolism and may contribute to increased ventilation and breathing discomfort associated with low cardiac outputs.[28]

48.1.3.3 Qualities of Dyspnea

Do patients with CHF, COPD, pulmonary embolism, and asthma all experience the same sensations of respiratory discomfort? Can we differentiate distinct types of dyspnea by the questions we ask patients? Studies demonstrate that dyspnea, like pain, is actually multiple, qualitatively distinct sensations, and that attention to the "language of dyspnea" can provide insights into an individual patient's disease.

Using a questionnaire (Table 48.3) derived from interviews with patients and studies in which normal subjects were made breathless while performing a range of ventilatory tasks,[29] various cardiopulmonary conditions associated with dyspnea could be characterized by a unique set of verbal phrases.[22] These findings were confirmed in an investigation using a similar approach but with an expanded questionnaire.[23] Responses offered by patients when asked to describe their breathing discomfort have been shown to be reproducible over time.[25]

From these and related studies, a language of dyspnea has emerged (Table 48.4). Patients with bronchoconstriction commonly describe a sensation of "chest tightness." Increased mechanical loads (typical of airway obstruction), interstitial disease, and chest wall abnormalities

TABLE 48.3
Descriptors of Dyspnea

1. My breath does not go in all the way.
2. My breathing requires effort.
3. I feel that I am smothering.
4. I feel a hunger for more air.
5. My breathing is heavy.
6. I cannot take a deep breath.
7. I feel out of breath.
8. My chest feels tight.
9. My breathing requires more work.
10. I feel that I am suffocating.
11. I feel that my breath stops.
12. I am gasping for breath.
13. My chest is constricted.
14. I feel that my breathing is rapid.
15. My breathing is shallow.
16. I feel that I am breathing more.
17. I cannot get enough air.
18. My breath does not go out all the way.
19. My breathing requires more concentration.

TABLE 48.4
The Language of Dyspnea: Association of Qualitative Descriptors and Physiologic Mechanisms of Shortness of Breath

Qualitative Descriptors	Pathophysiology
Chest tightness or constriction	Bronchoconstriction, interstitial edema (asthma, myocardial ischemia)
Increased work or effort of breathing	Airway obstruction, neuromuscular disease, chest wall disease (COPD, moderate to severe asthma, myopathy, kyphoscoliosis)
Inability to get a deep breath	Hyperinflation (COPD, asthma)
Air hunger, need to breathe, urge to breathe	Increased drive to breathe (CHF, pulmonary embolism, moderate to severe airway obstruction)
Heavy breathing, rapid breathing, breathing more	Deconditioning

usually result in increased "effort of work" of breathing. Neuromuscular weakness produces a sensation of increased effort to breathe. Significant hyperinflation, as in severe COPD, may cause a sensation of an "inability to get a deep breath."[30] In experimental conditions, acute hypercapnia produces a discomfort characterized as "air hunger" or an increased urge to breathe.[31]. Air hunger occurs in diseases associated with an increased urge to breathe (e.g., severe asthma, pulmonary embolism, acute hypoxia, exercise in patients with underlying lung disease). Air hunger may include the sense of an inability to get a deep breath, seen with hyperinflation. Patients may express several of these sensations simultaneously, as many diseases are characterized by multiple pathophysiological derangements (e.g., asthma may result in chest tightness due to bronchoconstriction *and* increased effort of breathing due to hyperinflation and airway resistance).

Deconditioning, the inability to achieve maximal workloads with exertion because of reduced aerobic capacity of the heart and limb muscles, afflicts both healthy people and patients with cardiopulmonary diseases. It deserves special attention because deconditioning is a state that can be corrected with an exercise program.[32–34] Often, patients with underlying cardiopulmonary diseases are assumed to be limited by their disease when they are actually deconditioned. For example, when patients with asthma were asked why they had reduced exercise capacity, they stated that it was because of their asthma. When that same group was subjected to formal exercise testing, their primary exertional limit was cardiovascular deconditioning, not airway reactivity.[32] Patients with COPD, even those with severe airway obstruction (FEV1 <40% predicted), are often primarily limited by leg fatigue rather than by poor ventilatory reserve.[35] In the context of the "language of dyspnea," dyspnea associated with deconditioning has been characterized as "heavy breathing," "breathing more,"[23] or "huffing and puffing."

When questioning a patient with shortness of breath, it is best to inquire about the nature of the "breathing discomfort." This phrase is generic and allows one to elicit specific qualities of a patient's distress without introducing bias toward a particular sensation. At times, it may be helpful to show patients a dyspnea questionnaire and ask them to select up to three phrases that best describe their breathing discomfort. Patients may have different sensations (and different kinds of dyspnea due to different problems) under varying conditions (e.g., a patient with interstitial lung disease and superimposed airway reactivity, or a patient with asthma who also is deconditioned). It is also important to distinguish between dyspnea due to chest wall pain and breathing discomfort that is a primary sensation. For example, a patient with fractured ribs may have severe pain with inspiration and express a sensation of "inability to get a deep breath" or "air hunger" despite the absence of pulmonary or cardiovascular pathology.

48.1.3.4 Essentials of the History

48.1.3.4.1 Timing: Acute Versus Chronic Dyspnea

There are relatively few conditions that result in an abrupt onset of breathing discomfort (Table 48.5). These tend to be due to sudden changes in airway resistance, sudden hypoxemia, or sudden increases in pulmonary vascular pressures. With treatment, these conditions often improve as rapidly as they began. On occasion, dyspnea may develop acutely in a patient with a chronic pulmonary disease and limited pulmonary reserve from a sudden metabolic stress (e.g., a patient with severe COPD who develops an infection with a high fever and metabolic acidosis). The need to increase ventilation in the setting of a sudden metabolic stress to

TABLE 48.5
Acute Causes of Dyspnea

Bronchospasm

Pulmonary embolism
Sudden Increased Demand for Ventilation
Acute metabolic acidosis
Chest Wall Pathology
Trauma (e.g., rib fractures)

meet increased demands for oxygen consumption and/or carbon dioxide elimination may result in both increased work of breathing and an increased urge to breathe.

Chronic dyspnea tends to develop slowly over the course of weeks or months. Often, patients have difficulty pinpointing the exact onset of symptoms, or attribute symptoms to a respiratory infection, despite resolution of all systemic infectious symptoms except for chronic breathing discomfort. Not infrequently, the date that a patient gives up cigarette smoking is, in retrospect, consciously or unconsciously related to the onset of dyspnea. Causes of chronic dyspnea include COPD, fibrotic lung disease, pleural effusion, progressive chest wall deformities, chronic CHF, and recurrent pulmonary emboli, among others. The chronicity of these conditions may be masked by lifestyle changes. As walking upstairs becomes progressively difficult, a patient with COPD may move to a building with elevators or to the ground floor. Children are called upon to do shopping. Deconditioning becomes superimposed on the underlying cardiopulmonary disorder, making even routine tasks uncomfortable. Patients may present with seemingly new symptoms over the course of a few weeks; however, the reality is that the patient has a chronic condition and is only able to avoid recurring dyspnea because of avoidance of physical activity.

48.1.3.4.2 Timing: Night Versus Day

Nocturnal dyspnea, awakening in the middle of the night with acute respiratory distress, can be an extremely frightening experience for a patient. The majority of cases are due to one or more of three problems: bronchospasm, aspiration, and CHF.

Patients with asthma may have worsening symptoms at night because of a trough in the level of bronchodilator medications, triggering of bronchospasm by gastroesophageal reflux through a reflex mediated by the vagus nerve when acid enters the esophagus, and/or as a result of exposure to allergens localized to the bedroom. Nocturnal sensations are usually similar to day-time asthma attacks (e.g., chest tightness and increased effort to breathe), although the precipitating factors are generally different. At times, patients may cough without discernible wheezing. The association of symptoms with changes in the home environment (e.g., new carpeting or a new pet) may give clues to the precipitant.

Recurrent aspiration causing nocturnal dyspnea can be an elusive diagnosis. Reports of witnessed aspiration or gagging are rare. The presence of partially digested food on a patient's pillow is infrequently reported, but if present, is suggestive of regurgitation and aspiration. The diagnosis is usually suspected in a patient with a history of gastroesophageal reflux or hiatal hernia, infiltrates on chest imaging in dependent portions of the lung, and no history of asthma.

Nocturnal dyspnea characterized as a sense of air hunger or a suffocating feeling is most typical of CHF and is termed *paroxysmal nocturnal dyspnea* (PND). Clues to the diagnosis of PND include the presence of peripheral edema and relief of the respiratory discomfort shortly after assuming an upright position. Redistribution of peripheral edema fluid to the central circulation during the night with consequent increases in pulmonary vascular pressures in a patient with compromised left ventricular function is believed to be the pathophysiologic basis for PND. Acute myocardial ischemia at night may mimic PND but is unlikely to have a recurring pattern, may be associated with chest pain, and is less likely to be relieved by sitting upright.

One cause of dyspnea that never occurs while sleeping is hyperventilation syndrome. The primary clinical manifestations of hyperventilation syndrome are intermittent episodes of tachypnea and subjective discomfort characterized by air hunger or an urge to breathe. Despite taking large tidal volumes, patients perceive that they cannot get a deep breath. Patients with hyperventilation syndrome experience dyspnea during the day, but objective assessment reveals normal spirometry, normal DLCO, and normal chest imaging. While sleeping, these patients have normal breathing patterns and appear quite comfortable.

48.1.3.4.3 Position

Dyspnea that occurs with or is relieved by changes in position should prompt a consideration of abnormalities in the ventilatory pump (i.e., the muscles of ventilation and the configuration of the chest wall), focal lung abnormalities that lead to hypoxemia when blood flow is increased to that area, or redistribution of fluid into the central circulation in patients with a history of CHF.

Orthopnea is dyspnea that occurs in the recumbent position. The most common explanation is redistribution of blood pooled from dependent veins into the central circulation, leading to increased pulmonary vascular pressures in the setting of compromised cardiac function. However, given the very rapid onset and resolution of orthopnea with change in position, it is probably secondary to stimulation of intracardiac (possibly right atrial) or pulmonary vascular receptors rather than the development of interstitial

pulmonary edema. In very obese patients, or patients with a distended abdomen due to ascites, the large abdomen increases the work of breathing with positional changes, as it now requires more force to initiate an inspiration due to the weight of the abdomen on the chest wall.[36] Severe dyspnea when bending over (bendopnea), frequently described by the patient as shortness of breath when tying one's shoes, is common in these patients, as there is little room for the diaphragm to move downward during inspiration. Lying supine, which removes gravity as a factor in pulling the abdomen away from the diaphragm, worsens dyspnea in these individuals. Bendopnea has also been described with CHF, likely due to acute increases in intracardiac pressure.[37] Patients with cervical spinal cord injury, amyotrophic lateral sclerosis, or bilateral phrenic nerve paralysis, who lack active intercostal inspiratory muscles or diaphragm, may also suffer from orthopnea.

Arteriovenous malformations (AVMs) in the pulmonary circulation lead to shunting of blood from the right to the left side of the heart (i.e., the blood never passes through the pulmonary capillaries and is sent to the systemic circulation with a low oxygen saturation). Any position that increases the gravity-dependent flow of blood through an AVM can lead to worsening hypoxemia and dyspnea. Focal areas of atelectasis or pneumonia will lead to similar gas exchange derangements when the body position is such that blood flow to that region of lung is enhanced. Consequently, the guiding principle in these circumstances is "good lung down" when positioning a patient to maximize gas exchange and minimize dyspnea.

Platypnea describes the development of tachypnea and hyperventilation when the patient is in the upright position. It is a physical finding rather than a symptom, although the patient may also complain of associated breathing discomfort. The exact mechanism of platypnea is unclear, but it probably relates to pathology at the lung bases with stimulation of pulmonary receptors or worsening gas exchange when blood flow increases to these areas with the patient upright.

48.1.3.5 Palliative Management

Management of dyspnea primarily involves treating the underlying pathophysiologic process causing the patient's breathlessness, and a detailed review of different treatments for the variety of medical conditions that can cause dyspnea is beyond the scope of this chapter. However, despite appropriate medical management, severe and debilitating dyspnea may persist for some patients. In these cases, symptomatic management may be indicated to achieve some degree of palliation of dyspnea.

Palliative management of persistent and severe dyspnea has been assessed in different patient populations and diseases, and systemic opioids have consistently demonstrated efficacy in ameliorating dyspnea in patients with cancer, COPD, and interstitial lung disease.[38] Opioids act by agonizing central mu-receptors, decreasing cerebral responses to afferent neuronal signals, as well as inducing cerebral depression and neurosystemic analgesia. Inhaled opioids may provide targeted symptom relief for patients with dyspnea while decreasing the effects of somnolence; however, the available data do not demonstrate superiority of inhaled opioids as compared with systemic opioids.[39]

Non-pharmacologic interventions, such as developing coping strategies for managing the physical and psychological aspects of breathlessness, have demonstrated effectiveness in helping patients manage dyspnea. A significant proportion of patients with COPD, up to 40–50%, have clinical evidence of depression, and counseling and cognitive behavioral therapy can address both depression and dyspnea.[40] In addition, environmental interventions such as blowing cool air on a patient's face can significantly reduce the severity of dyspnea in normal subjects with induced breathlessness, indicating that this intervention is likely of benefit in dyspneic patients.[41]

Benzodiazepines induce drowsiness in patients with dyspnea refractory to medical treatment but do not clearly improve symptoms of breathlessness. Multiple randomized trials assessing the effects of benzodiazepines do not provide compelling evidence for or against benzodiazepines for the management of dyspnea.[42] As such, benzodiazepines should be reserved for patients with persistent dyspnea despite treatment with other palliative interventions and/or for patients with a significant component of anxiety contributing to or caused by dyspnea.

Finally, while supplemental oxygen is frequently prescribed to patients with severe dyspnea, the available evidence does not support this intervention for patients who are not hypoxemic.[43] Administration of humidified air and providing high-flow air may provide some palliative benefit, possibly by stimulating nasal receptors that reduce the drive to breathe, but supplemental oxygen, per se, does not improve dyspnea for patients who are not hypoxemic.[44]

48.1.4 Cough

48.1.4.1 Definition and Physiology

A cough is a sudden expiratory maneuver, associated with high intrathoracic pressures, intended to clear secretions and foreign material from the airways. An effective cough starts with a deep breath, which expands the lungs and chest wall to a point of elevated elastic recoil. This elastic recoils works in synchrony with optimally contracting expiratory muscles to produce high intrathoracic pressures against a closed glottis. The sound of the cough is associated with the sudden opening of the glottis and the subsequent explosive release of pressurized intrathoracic gas with vibration of the vocal cords. Vibration may help to loosen secretions from the larynx.

Impaired inspiratory or expiratory muscle function leads to weakened cough. Patients with vocal cord paralysis or tracheostomy are unable to seal the glottis and cannot generate sufficiently high intrathoracic pressures needed to effectively clear secretions. Such patients are at increased risk for lower respiratory infections and may complain of

TABLE 48.6
Selected Causes of Cough Stimulation

Anatomic location	*Mechanism of cough stimulation*
Larynx	Activation of epithelial irritant receptors
Trachea and large airways	Activation of epithelial irritant receptors
Lung parenchyma	Activation of stretch receptors Activation of C fibers
Pleural space	Activation of irritant receptors
Esophagus	Reflex mechanism in response to reflux of gastric acid
Tympanic membrane	Stimulation of irritant receptors in the external auditory canal

increased chest congestion. The triggers for cough are complex; selected examples are reviewed in Table 48.6.

48.1.4.2 Clinical Causes of Cough

The most common etiologies of cough are outlined in Table 48.7. The differential diagnosis for cough varies based on whether a patient has an acute, subacute, or chronic cough. The differential diagnosis for chronic cough is further subdivided based on whether the patient has a normal versus abnormal chest x-ray.

48.1.4.3 Acute Cough

Acute cough is a cough that has been present for less than three weeks.[39] The most common cause of acute cough is a respiratory infection; it is characterized by sputum production and may be accompanied by a "raw" substernal sensation. Chest congestion may also be present. Fever, malaise, and other systemic symptoms of a viral or, less likely, bacterial infection are likely to coexist.

Subclinical bronchospasm is another cause of acute (as well as chronic) cough. In patients with mild asthma, wheezing may not be present. Sudden exposures to allergens, cold air, or exercise may result in transient cough. A high index of suspicion, along with appropriate PFTs, including spirometry and possibly bronchoprovocation maneuvers, is needed to make this diagnosis.

Inhalation of toxic fumes (e.g., cleaning agents, smoke) can damage the airway epithelium and precipitate cough. Airway hyperreactivity may also result from such exposures. As with acute infections, a raw substernal sensation is often present. Dyspnea commonly accompanies inhalational exposures. Foreign body aspiration (e.g., a food particle or in children, a small toy) may not be recalled by the patient. Cough may occur immediately after aspiration, but in some cases can be delayed for hours or days, at which point airway inflammation is probably contributing to the cough. A focal wheeze is appreciated on examination of the chest in some cases, and post-obstructive pneumonia can develop if the foreign material occludes a sufficient diameter of the airway lumen.

TABLE 48.7
Common Clinical Causes of Cough

Acute Cough
- Respiratory infection, airway inflammation
- Bronchospasm

Inhalational injury
- Aspiration

Subacute Cough
- Infectious or post-infectious cough (*Bordella pertussis*)
- Sinus infection/inflammation resulting in post-nasal drip

Chronic Cough with Normal Chest X-ray
- Upper airway cough syndrome (post-nasal drip)
- Bronchospasm
- Gastroesophageal reflux
- Chronic bronchitis
- Bronchiectasis
- Endobronchial neoplasms

Chronic Cough with Abnormal Chest X-ray
- Interstitial lung disease
- Recurrent aspiration
- Endobronchial neoplasm
- Indolent infections (e.g., *Pneumocystis jerovici*, pneumonia, tuberculosis)

48.1.4.4 Subacute and Chronic Cough with Normal Chest X-Ray

Chronic cough is defined as a cough lasting for more than eight weeks, while subacute cough lasts three to eight weeks.[45] There is considerable overlap in causes of subacute and chronic cough, and they are generally considered together in this section. However, post-infectious etiologies are an important cause of subacute, but not chronic, cough. A history of recent airways or sinus infection should be sought in patients with subacute cough. Subacute cough and a normal pulmonary exam may be due to sinus infection and inflammation resulting in post-nasal drip. In the appropriate clinical scenario, sinus imaging and/or treatment with nasal decongestants and antibiotics for bacterial sinusitis may be warranted.[46]

Paroxysms of cough resulting in post-tussive emesis or, less frequently, cough that produces a "whooping" sound are clues to a potential diagnosis of *Bordella pertussis* infection. For patients with cough and these symptoms, *B. pertussis* infection should be considered the diagnosis barring clinical evidence of another cause being more likely.[46] Although infants are typically vaccinated against pertussis, immunity wanes over five to ten years. As such, adolescents and adults are at risk for developing infections from *B. pertussis*.[47] While early antibiotic treatment (macrolides are particularly effective) can reduce the severity and duration of cough due to *B. pertussis*, the efficacy of antibiotics after two weeks of symptoms is unclear. General consensus based on the available studies is that after four weeks of symptoms, it is not appropriate to provide antibiotics; rather, care should focus on symptom management.[45,48]

Chronic cough without significant dyspnea and with a normal chest x-ray is commonly seen by both primary care physicians and pulmonary specialists. This entity has been well studied,[46,49] and the vast majority of patients will have one or a combination of three findings: upper airway cough syndrome (UACS), asthma, and gastroesophageal reflux disease (GERD).

UACS includes the spectrum of rhinosinusal causes of post-nasal drip. From perennial rhinitis to the sequela of upper respiratory infections, UACS encompasses the breadth of diseases that result in posterior nasopharyngeal secretions descending to the larynx, causing an irritating feeling or "tickle" in the throat. Cough due to UACS may be nonproductive or result in small amounts of white sputum; however, UACS due to chronic sinus infections may result in purulent sputum. Typically, the cough worsens when patients assume a supine position to go to sleep because of both positional worsening of nasal drainage and a greater awareness of the "irritation" in the absence of typical distractions one encounters during the day. Not uncommonly, patients will not be aware of a "drip" per se, but when questioned about the source of the cough (i.e., where the cough seems to be originating), they will localize it to the throat rather than the chest. Frequent "throat clearing" may be a clue suggestive of UACS. Friends or family members may be more aware of frequent throat clearing than the patient, and frequent throat clearing may be observed during the interview. A history of allergies may be suggestive of UACS due to rhinitis, particularly if there is seasonal variation of cough frequency or severity. However, in most cases, patients are unaware of specific allergens, and skin testing may be necessary if symptoms persist despite treatment.

Hyperactive airways without wheezing can present as chronic cough; this has been termed *cough variant asthma.*[50] In a patient without a prior history of asthma, symptoms often follow a respiratory infection. Systemic infectious symptoms will clear over several weeks, but cough persists. In many cases, the cough will resolve spontaneously in 8 to 12 weeks, but it can continue indefinitely. Typically, the cough will be nonproductive or result in small amounts of clear to white sputum. In contrast to cough due to UACS, patients with cough variant asthma localize the origin of the cough to the chest. Exposure to cold air, exercise, smoke, and toxic fumes characteristically worsens cough arising from airway reactivity. Spirometry is often normal during routine evaluation, and the diagnosis may be made based on response to a therapeutic trial of bronchodilators or by bronchoprovocation tests. Patients with cough variant asthma are typically quite responsive to treatment and generally achieve symptom control more easily than patients with classic asthma symptoms.[50,51]

GERD completes the triad of common causes of chronic cough and a normal chest x-ray. GERD may produce cough on its own or exacerbate cough in a patient with airway reactivity. Cough due to GERD is typically nonproductive and localizes to the chest. A history of heartburn or reflux symptoms is helpful if present, but is frequently absent. "Waterbrash," the sudden sensation of a sour taste in the mouth, is typically associated with reflux of gastric contents. Treatment of cough due to GERD should focus on lifestyle modifications (e.g., raising the head of the bed at night, avoiding foods that dilate the lower esophageal sphincter, and avoiding eating shortly before lying down). In one study, proton pump inhibitors were no better than placebo in treating cough due to GERD,[52] but in a more recent investigation, up to 28% patients with chronic cough *and* symptoms of heartburn responded to treatment for reflux compared with 14% in individuals without heartburn.[53]

Other, less common causes of chronic cough with a normal chest x-ray include non-asthmatic eosinophilic bronchitis (NAEB), bronchiectasis, chronic bronchitis, and bronchial carcinoid. NAEB causes cough by allergic airway inflammation in response to an environmental stimulus. NAEB is associated with normal chest imaging and normal spirometry. NAEB is not associated with airway hyperresponsiveness in response to bronchoprovocation maneuvers such as a methacholine challenge, in contrast to chronic cough due to asthma. The definitive diagnosis of NAEB requires identification of eosinophils in sputum or bronchial washings, or bronchial mucosal biopsy demonstrating increased eosinophil concentrations.[54] Given that these diagnostic modalities are not clinically practical for most patients with cough, empiric treatment may be appropriate when NAEB is suspected. The best treatment for NAEB is identification and avoidance of a causative environmental stimulus. When that is not possible or not effective, empiric treatment with glucocorticoids can be attempted. Typically, patients with NAEB return to their premorbid baseline after treatment with glucocorticoids or avoidance of causative environmental stimuli.

Patients with bronchiectasis typically have a cough productive of purulent sputum, although upper lobe disease, which tends to drain well throughout the day, may be associated with a dry cough or scant secretions. Sputum may be occasionally streaked with blood. A history of prior pneumonia(s) is suggestive but not diagnostic of bronchiectasis. Bronchiectasis increases the risk of recurring respiratory infections associated with low-grade fever, worsening cough, and sputum production. Growth of *Pseudomonas aeruginosa* on repeated sputum cultures is very suggestive of bronchiectasis. Although chest x-ray is often normal, focal areas of fibrosis or fibrocystic disease may be present, and chest computerized tomography (CT) scan is quite sensitive in defining the extent of disease.

Chronic bronchitis is defined as a productive cough present for at least three months of the year for at least two years. Chronic bronchitis is due to chronic airway inflammation induced by cigarette smoking or other environmental irritants. The cough associated with chronic bronchitis is typically most pronounced early in the morning and tends to diminish as the day progresses. Patients localize the cough to the chest. Sputum is occasionally mixed with blood. Due to associated obstructive lung disease, these patients can have dyspnea on exertion.

Endobronchial neoplasms in central airways can produce cough and in the absence of significant airway obstruction leading to focal atelectasis, will usually have a normal chest x-ray. Although bronchogenic carcinoma can present in this manner, bronchial adenomas or carcinoid tumors are more likely. These tumors, which usually behave as low-grade malignancies with a small potential for distant metastases, may have a polypoid appearance that in some cases leads to a postural cough due to intermittent positional airway obstruction from the adenoma.

48.1.4.5 Chronic Cough with an Abnormal Chest X-Ray

Interstitial lung disease typically presents with the gradual onset of dyspnea on exertion, but nonproductive cough, particularly with a deep breath, may be the prominent (or only) symptom early in the disease. Patients localize the cough to the chest. In severe cases, cough can be quite debilitating and refractory to cough suppressants. Chest x-ray findings may be subtle in early disease; later in the clinical course, chest x-ray frequently demonstrates low lung volumes and reticular interstitial changes.[55] For patients with normal chest x-rays but suspected interstitial disease, high-resolution CT scans are a very sensitive tool for confirming the diagnosis.[56] The interview should include questions about the occupational history (e.g., exposure to inorganic or organic dusts), tobacco use, joint symptoms or peripheral skin nodules suggesting collagen-vascular disease (e.g., rheumatoid arthritis, systemic lupus erythematosus), and eye symptoms or lower extremity joint pain suggesting sarcoidosis. Patients with symptomatic interstitial fibrosis typically have a restrictive defect on spirometry and lung volume testing.

Bronchogenic carcinomas in the central airways may cause partial or complete obstruction of a segmental or lobar bronchus, leading to focal atelectasis on chest x-ray and chronic cough. The cough is typically nonproductive but may be associated with intermittent hemoptysis.

Although cough due to lower respiratory infections usually presents acutely, there are indolent infections that can present with a chronic cough and minimal systemic symptoms. PCP pneumonia (i.e., pneumonia caused by *Pneumocystis jerovici*) in patients with acquired immunodeficiency syndrome due to human immunodeficiency virus or other immunosuppressed states is characterized by a nonproductive cough and dyspnea on exertion over weeks to months. Similarly, early reactivation of *Mycobacterium tuberculosis* can present with cough, fatigue, and mild weight loss. Chest x-ray usually provides evidence of the underlying infection in these cases.

48.1.5 Hemoptysis

48.1.5.1 Definition and Physiology

Hemoptysis refers to coughing or expectoration of blood or blood-tinged sputum. As a general principle, the term is reserved for blood that originates in the lower respiratory tract (i.e., below the larynx). However, it may be difficult to determine whether blood is coming from the lungs versus the posterior nasopharynx or the gastrointestinal tract, especially if vomiting is associated with a paroxysm of cough. It is worth noting that the normal tracheobronchial tree should not bleed even in the presence of coagulopathy. Thus, hemoptysis in the setting of anticoagulation is considered a pathologic finding.

The four major sources of blood in the lower respiratory tract are airways, pulmonary parenchyma, pulmonary circulation, and bronchial circulation. Inflammation or irritation of airway epithelium (e.g., with acute pulmonary infections, chronic bronchitis, or foreign body aspiration) usually results in small volume hemoptysis, often mixed with sputum. Bleeding from the pulmonary parenchyma occurs with pulmonary infarction or contusion. In the presence of pulmonary AVMs or greatly elevated pulmonary venous and/or capillary vascular pressures (e.g., from mitral stenosis), bleeding may occur as well. Finally, the bronchial circulation may result in hemoptysis in patients with bronchiectasis or large intrapulmonary cavities.

Massive hemoptysis is generally defined as production of ≥600 mL of blood in 24 hours, although the precise volume qualifying as "massive" hemoptysis varies between authors and guidelines. Patients commonly overestimate the amount of blood they have expectorated because of concomitant anxiety associated with coughing up blood. Therefore, it is important to encourage the patient to be as explicit as possible when quantifying the amount of blood. One should show the patient, and witnesses to the episode(s), various-sized containers to assist them in estimating the quantity expectorated. While massive hemoptysis can occur from an endobronchial carcinoma, it is more commonly associated with erosions of bronchial vessels in large intrapulmonary cavities or with bronchiectasis.[57]

48.1.5.2 Etiology

There are six etiologic categories to be considered when evaluating a patient with hemoptysis (Table 48.8). Determining the reason for a patient's hemoptysis depends on the presence or absence of additional symptoms beyond hemoptysis itself.

Lower respiratory tract infections cause airway inflammation, which can result in epithelial injury and bleeding. This is most common with bacterial tracheobronchitis but can also occur with bacterial pneumonias. Typically,

TABLE 48.8
Etiologic Categories for Hemoptysis

Pulmonary infections
Neoplasms
Collagen-vascular and immunologic lung diseases
Cardiovascular diseases (including pulmonary vascular and valvular diseases)
Aspiration of foreign bodies
Chest trauma with pulmonary contusion

hemoptysis in the setting of an acute infection is small in volume (<50 mL) and resolves with improvement in the other symptoms (e.g., cough, fever, malaise). Bronchiectasis and chronic bronchitis predispose patients to acute infections and are associated with occasional episodes of blood-streaked sputum, typically in the presence of an acute infection. Bronchiectasis infrequently leads to massive hemoptysis.

Lung cancers, most commonly bronchogenic carcinoma, are a common cause of hemoptysis. Lung cancer should be especially considered in patients over age 40 with a significant smoking history and more than ten days of hemoptysis.[58] Patients with an extrathoracic malignancy that can metastasize to the lungs (e.g., renal cell carcinoma, breast carcinoma, or sarcoma) are at increased risk of hemoptysis due to cancer. Bleeding due to cancer usually occurs in the absence of other symptoms and presents as frank blood without sputum.

Hemoptysis in association with joint symptoms, rashes, dyspnea, and/or renal dysfunction suggests collagen-vascular disease as an etiology. Pulmonary-renal syndromes (e.g., systemic lupus erythematosus, granulomatosis with polyangiitis [previously referred to as Wegener's granulomatosis], and anti-glomerular basement membrane disease [previously referred to as Goodpasture syndrome]) may present with hemoptysis as part of the symptom complex. In most cases, hemoptysis is not an isolated finding.

AVMs, pulmonary emboli, pulmonary edema, and mitral stenosis are cardiovascular causes of hemoptysis. Pulmonary edema classically produces pink sputum, and lung biopsy reveals hemosiderin-laden macrophages consistent with pulmonary hemorrhage. Gross blood is uncommon in CHF without concomitant coagulopathy. Bleeding may occur as the first symptom of an AVM, and massive hemoptysis has been reported.[59] Hemoptysis from pulmonary emboli or mitral stenosis usually occurs with other symptoms such as dyspnea and chest discomfort.

Foreign body aspiration can lead to hemoptysis by causing either direct airway trauma or local inflammation. Pulmonary contusions result most commonly from blunt chest trauma and are associated with other injuries such as rib fractures, pneumothorax, and cardiac contusion. Hemoptysis in these settings is usually small in quantity.

48.1.6 Wheezing

48.1.6.1 Definition and Physiology

Wheezing is a sound that emanates from lower airways (i.e., below the larynx), resulting from turbulent flow. It is a "continuous" sound as compared with the intermittent or staccato sounds that accompany chest congestion with mucus in the airways (commonly called rhonchi). Wheezing may occur during expiration or inspiration, or throughout the respiratory cycle. It is both a symptom, a sound that patients report hearing with breathing, as well as a physical finding appreciated when one examines a patient.

TABLE 48.9
Common Causes of Wheezing

Primary airway reactivity (e.g., asthma)
Interstitial edema
Airway inflammation and mucous hypersecretion
Endobronchial obstruction (e.g., neoplasm or foreign body)
Vocal cord dysfunction

The sound is produced by turbulent flow through narrowed airways and in some cases, may reflect rapid oscillation of the airway walls.[60] There are multiple causes of airway narrowing (Table 48.9). Wheezing, a sound originating in the airways, should be distinguished from stridor, a primarily inspiratory sound. Stridor is qualitatively similar to wheezing, but it arises from the larynx and upper airways. During inspiration, transmural pressure across the *intrathoracic* airways favors expansion (due to negative pleural pressures). As such, inspiratory wheezing is relatively uncommon. In contrast, atmospheric pressure surrounding *extrathoracic* airways is greater than the negative pressure inside them; consequently, the extrathoracic airways tend to collapse during inspiration. Collapse of extrathoracic airways during inspiration accentuates any pre-existing airway narrowing. Thus, wheezing that worsens during inspiration is likely due to an obstruction in the extrathoracic airways, whereas wheezing that is more pronounced on expiration likely originates in the intrathoracic airways. When the intensity of wheezing is constant throughout both inspiration and expiration, a fixed obstruction is likely.

48.1.6.2 Etiology

The most common cause of wheezing is asthma, although asthma may occur in the absence of wheeze. Historical data suggestive of asthma include wheezing associated with exposure to inhaled allergens or irritants, cold air, and/or exercise. Decreased wheezing in response to inhaled bronchodilators also suggests asthma. Physical examination reveals diffuse expiratory wheezing when a patient is suffering acute asthmatic symptoms and is usually normal in the absence of symptoms. With acute symptoms, spirometry demonstrates an obstructive ventilatory defect with decreased FEV1 and reduced FEV1/FVC. In the absence of symptoms between asthma exacerbations, PFTs are typically normal. Airway hyperresponsiveness can be elicited by performing bronchoprovocation maneuvers such as a methacholine challenge, which is sensitive but not specific for diagnosing asthma.

Mucus hypersecretion due to infections and/or airway inflammation may also cause wheezing. Since lower respiratory tract infections can also produce transient airway hyperreactivity, it may be difficult to distinguish wheezing from infection and/or inflammation from asthma. Rapid improvement of wheezing after cough or with bronchopulmonary clearance, however, is more suggestive of mucus hypersecretion than asthma.

"Cardiac asthma," wheezing in association with increased pulmonary capillary pressures and interstitial edema, which compresses small airways, is another common cause of wheezing. Generally, there are other symptoms or signs of CHF in the history (orthopnea, PND) and physical examination (distended jugular veins, S_3 gallop, and peripheral edema). However, acute CHF secondary to myocardial ischemia may be difficult to distinguish from asthma in a patient with a history of airway reactivity.

Partial endobronchial obstruction can lead to focal or localized wheezing. The patient may not recognize the focal origin of the sound or be able to localize any internal sensations associated with the wheeze. Bronchogenic neoplasms, either carcinomas or adenomas, and aspirated foreign bodies can cause focal wheezing.

Expiratory wheezing may originate from the upper airways when laryngospasm is present. Termed paradoxical vocal cord dysfunction (PVD), this condition is due to adduction of the vocal cords during expiration; expiratory wheezing originating from the upper airways can be extremely difficult to distinguish from asthma by history alone. Frequently, PVD occurs in young women, often with a history of emotional and/or psychiatric difficulties. When paradoxical vocal cord movement occurs only in the setting of exertion, particularly strenuous exertion, it is referred to as exercise-induced laryngeal obstruction (EILO).[61] PVD and EILO are commonly treated as asthma for months or years before the diagnosis is recognized.[61,62] Clues to the diagnosis of PVD are a very rapid symptom onset, an association of psychological stress with wheezing, and inconsistent bronchodilator response. EILO is characterized by exertional expiratory wheezing and excessive breathlessness, symptom resolution with exercise cessation, and normal resting spirometry results. Fiberoptic laryngoscopy during an attack of either PVD or EILO can confirm the diagnosis by directly visualizing adduction of the vocal cords during expiration. Treatment is primarily speech therapy and psychological counseling to assist patients in understanding the cause and nature of their symptoms and to teach techniques to develop better vocal cord control.

Vocal cord swelling from infection, allergic reaction, or chemical or smoke inhalation narrows the upper airway, increases turbulent flow, and may lead to stridor. As inhalational injuries can damage both upper and lower airways, laryngeal edema and inspiratory wheezing may be associated with intrathoracic airway hyperresponsiveness and expiratory wheezing. Allergic reactions causing laryngeal edema can be differentiated from inhalational injuries both from the history and from an association with urticaria and angioedema.

48.1.7 Nocturnal Respiratory Symptoms: Snoring and Apnea

48.1.7.1 Definition and Physiology

The prevalence, clinical importance, and societal impact of nocturnal respiratory symptoms have increased markedly in the 21st century. The primary cause of the increased frequency and severity of nocturnal respiratory symptoms is likely the marked increase in obesity in the general population. In 2022, 2.5 billion adults were overweight (43% of the world population), of whom 890 million were obese.[63] In the United States, the National Health and Nutrition Examination Surveys have demonstrated progressive increases in obesity (defined as a body-mass index of ≥30 kg/m^2) since the 1960s. The importance of high quality sleep for general health is increasingly recognized, with calls for more patient education about this problem.[64]

Snoring is defined as noisy breathing during sleep and is very common in the general population. The prevalence of snoring varies between studies, ranging from 10% to 60%.[65] Loud snoring more commonly afflicts men than women.[66] The prevalence of snoring increases with age up to 50–60 years of age, after which prevalence decreases.[67]

Snoring occurs due to vibration of the soft palate and faucial pillars. The likelihood that snoring will occur is dependent upon the size of the airway, the tone of the soft tissue structures in the airway, and body position.

The clinical significance of snoring is uncertain. Generally, in the absence of observed or measured apneic episodes, snoring is considered to be benign. However, the decrease in the prevalence of snoring that occurs with advancing age (>50–60 years of age) may indicate a survivorship phenomenon.[65] It is unknown whether snoring indicates pathologically narrowed airways causing comorbid conditions and death, or whether snoring is simply a marker of comorbid conditions that ultimately cause morbidity and death. Regardless, when a patient (or a patient's bed partner) complains of snoring, a history of signs or symptoms of obstructive sleep apnea (OSA) syndrome should be performed.

Nocturnal apneas are defined as a cessation of airflow during sleep. The term "apnea" specifically describes a cessation of airflow for at least ten seconds; hypopnea is a transient reduction in airflow (a reduction in the respiratory rate and/or tidal volume) that lasts for at least ten seconds and is associated with a ≥4% decrease in oxygen saturation. Frequent nocturnal apneas and hypopneas may result in hypoventilation. The diagnostic criteria for clinically significant OSA is an average of >5 apneas and/or hypopneas per hour of sleep (the "apnea hypopnea index" [AHI]). Polysomnography (i.e., a "sleep study") must be performed to accurately measure the AHI.

The clinical syndrome of OSA is the combination of an AHI of ≥5 with day-time symptoms due to chronic nocturnal hypoventilation. Day-time symptoms associated with the OSA syndrome include fatigue, somnolence, and morning headache. These symptoms are common even in patients without nocturnal hypoventilation, but clinical suspicion of OSA syndrome is increased in patients with concomitant obesity, snoring, and/or comorbid conditions such as hypertension, coronary artery disease, and cerebrovascular disease. Cognitive issues (specifically difficulty concentrating), erectile dysfunction, enuresis, and depression

TABLE 48.10
Epworth Sleepiness Scale

How likely are you to doze off or fall asleep in the following situations, in contrast to just feeling tired? This refers to your usual way of life in recent times. Even if you have not done some of these things recently try to work out how they would have affected you. Use the following scale to choose the *most appropriate number* for each situation:

0 = would *never* doze
1 = *slight* chance of dozing
2 = *moderate* chance of dozing
3 = *high* chance of dozing

Situation	Chance of dozing
Sitting and reading	
Watching TV	
Sitting, inactive in a public place (e.g., a theater or a meeting)	
As a passenger in a car for an hour without a break	
Lying down to rest in the afternoon when circumstances permit	
Sitting and talking to someone	
Sitting quietly after a lunch without alcohol	
In a car, while stopped for a few minutes in the traffic	

TABLE 48.11
Mechanisms of End-Organ Damage in the OSA Syndrome

Pathophysiologic mechanism	Systemic effects	End-organ consequences
Increased sympathetic tone due to apneas/hypopneas	Increased systemic vascular resistance	Hypertension Cardiovascular disease Cerebrovascular disease
Increased systemic inflammation due to intermittent hypoxemia	Accelerated atherosclerosis	Coronary artery disease Cerebrovascular disease Peripheral vascular disease
Systemic oxidative stress due to cyclical hypoxemia and re-oxygenation	Atherosclerotic changes Tissue ischemia	Cardiovascular disease Cerebrovascular disease
Endothelial dysfunction (uncertain mechanism)	Increased thrombogenesis	Coronary artery disease Cerebrovascular disease

Chronic nocturnal hypoventilation results in increased sympathetic tone during airway obstruction, which leads to increased systemic vascular resistance and hypertension. Intermittent hypoxemia results in increased systemic inflammation, which accelerates vascular atherosclerotic changes and increases the risk cerebrovascular and/or coronary artery disease.[38] Systemic oxidative stress is increased due to the nightly cycle of hypoxemia and re-oxygenation.[43] Endothelial dysfunction occurs, resulting in increased thrombosis, although the mechanism is speculative.

may also be associated with the OSA syndrome due to end-organ damage from the systemic consequences of chronic nocturnal hypoventilation and cyclical hypoxemia.

The severity of day-time somnolence can be assessed and quantified by the Epworth Sleepiness Scale (ESS).[68] The ESS asks patients to rank their sleepiness in eight scenarios, such as "sitting quietly after a lunch without alcohol" or "in a car, while stopped for a few minutes in traffic" (see Table 48.10)[68]. Patients with a high score (≥9) have increased day-time sleepiness, but the ESS has not been validated as an independent predictor of the OSA syndrome.

There are multiple pathophysiologic mechanisms in the OSA syndrome that account for the epidemiologic association between OSA and cardio- and cerebrovascular disease (see Table 48.11). Essential hypertension occurs in at least 50% of patients with the OSA syndrome.[69] Congestive heart failure, arrhythmias, coronary artery disease, myocardial infarction, and cerebrovascular disease, including stroke, are all associated with and likely due to systemic physiologic derangements caused by OSA.[70]

The "obesity-hypoventilation syndrome" (OHS) is the combination of chronic hypoventilation with chronic hypercapnia and obesity. Right ventricular dysfunction, due to elevated pulmonary arterial pressures and left heart dysfunction, is commonly present in patients with OHS.

Of note, certain cerebral pathologies, particularly abnormalities involving areas of non-voluntary respiratory control, may result in a rare condition called central sleep apnea syndrome. Central sleep apnea is not associated with obesity, while OSA and obesity are clearly directly correlated.

48.1.7.2 Etiology

While snoring can be a normal finding, it may be associated with the OSA syndrome. As noted previously, extrathoracic airways, including the hypopharynx, are prone to collapse during inspiration due to the combination of positive atmospheric pressure outside the airway and negative intraluminal pressure during inspiration. Snoring is more likely to occur in obese patients, as the hypopharynx is already narrowed from increased soft tissue fat. Conditions that reduce the muscle tone of the surrounding tissue (e.g., alcohol, sedative agents) further increase the risk of hypopharyngeal obstruction and snoring. Rapid eye movement (REM) sleep is associated with decreased muscle tone, and snoring occurs most commonly during this phase of sleep.

The tongue is a major component of the anterior wall of the hypopharynx, and movement of the tongue can contribute to upper airway obstruction. When the tongue falls posteriorly, obstruction is worsened. Given the lack of bony support to maintain hypopharyngeal patency, intact glossal and pharyngeal muscle tone is necessary to keep the airway from collapsing. Patients who sleep in the supine position are more likely to snore or develop more severe obstruction because of the propensity of the tongue to be pulled posteriorly by gravity.

Children with large tonsils or adenoids may present with snoring, although significant airway obstruction is unusual.

48.1.7.3 Essentials of the History

Snoring, unlike many symptoms, is much less likely to be reported by patients than by bed partners. It may be valuable to distinguish between nasal and mouth snoring, as nasal snoring is generally not considered indicative of a pathologic process. If possible, the healthcare provider should ascertain whether the patient has been observed to experience apneas, either central (when there is no evidence of airflow or chest wall movement) or obstructive (no airflow but preserved chest wall motion). Loud snoring or loud snorts (which may occur at the end of the obstructive episode) indicate intermittent airway obstructions. Additional questions are focused on day-time symptoms of the OSA syndrome as outlined previously.

The chronicity of snoring, changes in weight, and/or drug and alcohol use are also important components of the history. For example, a middle-aged, non-obese woman whose snoring dates back to adolescence and who has otherwise been clinically well is likely to have a benign condition. Alternatively, a middle-aged man with a 20-pound weight gain over the last year and six months of snoring should be questioned about symptoms of the OSA syndrome.

Definitive diagnosis of OSA requires the presence of associated day-time symptoms and an AHI of ≥5. AHI can only be measured by formal polysomnography, which requires a patient to spend a night in a sleep laboratory, although the accuracy of home sleep studies is being assessed. There is no role for PFTs or chest imaging in diagnosing OSA, although these studies may be helpful in searching for associated conditions.

48.1.8 Summary

Respiratory symptoms are extremely common in clinical practice. As the lungs and upper airways have fairly limited ways to respond to pathologic changes, the challenge for clinicians is to understand the nuances of descriptions of the sensations and the sounds that patients report, and to ask probing questions that elicit these subtle distinctions. Understanding the physiology underlying respiratory symptoms can help a healthcare provider perform a focused yet thorough history and physical exam, determine what further testing is needed, and recommend targeted and effective interventions. Additionally, and importantly, having a better understanding of the physiology of respiratory symptoms aids in diagnosis, often guides treatment decisions, and augments one's intellectual enjoyment when caring for patients with these symptoms.

CLINICAL APPLICATIONS

Respiratory symptom	History and physical exam determinations	Diagnostic studies

Dyspnea	• Employ a dyspnea questionnaire to characterize the nature and origin of the patient's dyspnea
	  • "Chest tightness"—bronchoconstriction
	  • "Effort/work of breathing"—mechanical load
	  • "Air hunger"—increased drive to breathe
	  • "Smothering," "suffocating,", "short of breath bending over"—congestive heart failure
	  • "Huffing and puffing," "heavy breathing"—cardiovascular deconditioning
	• Determine whether the dyspnea is acute or chronic in nature
	• Identify if a patient's dyspnea occurs primarily during the day or at night
	• Assess for a positional component to the patient's dyspnea
	• Observe for use of accessory muscles of ventilation
	• Note if patient has difficulty completing a full sentence before stopping to get a breath
	• Assess for psychogenic component to the patient's dyspnea (e.g., are they "not getting enough air" despite normal lung function?)
		• Pulse oximetry at rest and on exertion
		• Pulmonary function testing (for suspected airway-related causes of dyspnea)
		• Complete blood count (to assess for anemia)
		• Chest x-ray
		• Chest CT (if the chest x-ray is abnormal and/or if clinical suspicion is sufficiently high)
		• Transthoracic echocardiography (for suspected cardiac causes of dyspnea)
		• Cardiopulmonary exercise testing (for patients with unexplained dyspnea despite an otherwise thorough evaluation)

Cough	• Determine if cough is acute, subacute, or chronic • For acute or subacute cough, determine if there has been a recent airways or sinus infection • For chronic cough, differentiate between upper airway cough syndrome, GERD, and asthma • Determine if the patient can localize the source of irritation provoking the cough to the throat or deeper in the chest	• Chest x-ray • Spirometry (when bronchospasm is suspected) • Methacholine challenge (when bronchospasm is suspected) • Sinus imaging (when sinusitis is suspected) • Chest CT for patients with an abnormal chest x-ray
Hemoptysis	• Quantify the amount of blood expectorated to determine massive versus non-massive hemoptysis • Determine the origin of hemoptysis (upper respiratory tract, lower respiratory tract, or non-respiratory source)	• Chest x-ray • Chest CT angiogram • Flexible bronchoscopy

Respiratory symptom	History and physical exam determinations	Diagnostic studies
Wheezing	• Differentiate between pulmonary, cardiac, and laryngeal causes of wheezing • Differentiate between inspiratory and expiratory wheezing • Differentiate between intra- and extrathoracic wheezing	• Spirometry (for pulmonary causes of wheezing) • Methacholine challenge (for pulmonary causes of wheezing) • Transthoracic echocardiography (for cardiac causes of wheezing) • Flexible laryngoscopy (for laryngeal causes of wheezing)
Nocturnal snoring and apnea	• Direct observations of snoring and/or apneic episodes by bed partner • Epworth Sleepiness Scale	• Polysomnography ("sleep study")

49 Asthma

Evan W. Jones and Stephen J. Krinzman

KEY POINTS

- Asthma is a heterogeneous, inflammatory disease of the airways characterized by intermittent symptoms including dyspnea, cough, chest tightness, and wheezing.
- Both nonpharmacologic and pharmacologic interventions are often necessary to achieve disease control.
- Inhaled corticosteroids are the mainstay of pharmacologic chronic controller therapy for asthma.
- It is essential to evaluate medication compliance prior to escalating pharmacologic therapy in a seemingly uncontrolled asthmatic.
- Asthma symptoms are impacted by multiple lifestyle factors, including exercise, occupation, obesity, stress, and pregnancy.

49.1 INTRODUCTION

Asthma is an inflammatory disease of the airways that affects all age groups. It is characterized by intermittent symptoms that commonly include dyspnea, cough, and wheezing. While nonspecific, these symptoms are suggestive of asthma when associated with airway hyperresponsiveness and variable airflow obstruction.

In 2019, an estimated 20 million adults in the United States, representing 8% of the population, had asthma.[1] The disease remains a large burden to the healthcare system, accounting for over 1.6 million emergency department visits in the United States in 2018.[1] It is a frequent cause of absenteeism from both school and work. In 2019, over 3,500 deaths in the United States were attributed to asthma.[1]

The prevention and treatment of asthma are dependent upon a variety of interventions, both pharmacologic and nonpharmacologic. The daily habits and activities of asthmatics play an important role in disease management. Alterations in lifestyle practices can make a substantial difference to the long-term health of the asthmatic patient.

49.2 CLINICAL FEATURES

Typical symptoms of asthma are dyspnea, cough, chest congestion and tightness, and wheezing. Asthma is a heterogeneous disease, and clinical presentation will vary between individuals. Additionally, each individual is likely to have symptoms that vary in frequency and severity over time. An asthmatic is often able to identify certain triggers that destabilize his or her asthma. Common triggers include exercise, viral infection, exposure to furry or feathered animals, and environmental allergens including pollen, dust, mold, and smoke. Changes of weather, emotions such as laughing or crying, and menses may destabilize the asthmatic. Ingestion of aspirin or other medications can result in symptoms.

The asthmatic will often have a normal physical examination when asymptomatic. However, when patients are having symptoms, the physical examination often reveals an increase in respiratory rate, a prolonged expiratory time, and wheezing. On forced expiration, wheezing is accentuated, and coughing generally occurs. During more severe attacks, the patient will often be diaphoretic, using the accessory muscles of ventilation, and unable to speak in full sentences.

Multiple schemes have been proposed to classify asthma severity.[2–5] The classifications of mild, moderate, and severe are often used, although the defining characteristics for each group are not universally agreed upon. Some organizations advise against the use of the term "mild" asthma, as this may incorrectly suggest that these patients do not require careful and active management of their disease.[5]

49.3 PATHOPHYSIOLOGY

The hallmarks of asthma pathophysiology are: 1) airflow obstruction that may change over time, 2) airway inflammation, and 3) hyperresponsiveness of the airways to stimuli.

49.3.1 Variable Airflow Obstruction

Increased airway resistance and airflow obstruction in asthma occur through three major mechanisms:

- Increased airway lumen debris
- Airway wall thickening from inflammation, edema, and over time, fibrosis
- Airway smooth muscle contraction[2]

Damaged epithelial cells detach from the mucosal surface of the asthmatic airways. Airway wall thickening occurs from an unimpeded inflammatory process. The effects of inflammation accumulate over time, leading to smooth muscle hypertrophy, epithelial basement membrane thickening, connective tissue deposition, and proliferation and hypertrophy of mucus-producing glands. All these factors contribute to progressive airflow obstruction, which

DOI: 10.1201/9781003227793-58

is further decreased by the presence of thick mucus, ineffective mucociliary clearance, and edema in the bronchial walls. Episodic smooth muscle contraction further leads to the variability of symptoms.

49.3.2 Airway Inflammation

Multiple mechanisms produce airway inflammation, and they involve a variety of interactions between pro-inflammatory and inflammatory mediators. The asthmatic inflammatory cell matrix is made of eosinophils, activated T-helper type 2 lymphocytes, mast cells, neutrophils, and macrophages. Both immune and non-immune factors can activate the disease process. Exposure to a specific activating allergen causes the release of a variety of mediators via high-affinity immunoglobulin E (IgE) receptors found on bronchial mast cells, and low-affinity IgE receptors on macrophages and eosinophils. Lymphocytes control these processes. Both antibody-mediated and cell-mediated immune systems are involved. There are increased levels of pro-inflammatory cytokines such as interleukin (IL)-4, IL-5, and IL-13. Chemical mediators from the activated cells can directly contract airway smooth muscle, stimulate mucus secretion, enhance vascular permeability, and promote airway edema. Furthermore, some mediators actually attract other inflammatory cells and activate them, further damaging the airway. Part of the inflammatory reaction causes a disruption of airway epithelial cell wall integrity, which allows increased permeability to inhaled allergens and other triggering substances, decreased mucociliary clearance of airway debris, and enhanced cholinergic-mediated airway hyperreactivity, and predisposes patients to bacterial and viral infections. The loss of epithelial integrity exposes nerve endings, which partially explains the enhanced cholinergic-mediated airway hyperreactivity found in asthma.

Inflammation can be acute or chronic. The acute inflammatory response involves early recruitment of cells to the airway. This is followed by an evolving inflammatory reaction as recruited and resident cells are activated and produce a complex pattern of inflammation. Chronic inflammation can lead to permanent airway damage.

49.3.3 Airway Hyperresponsiveness

Airway hyperresponsiveness is a hallmark of asthma. Airway inflammation induces airway hyperresponsiveness. This hyperresponsiveness, along with the inflammatory changes of the airways, contributes further to airflow obstruction. Certain triggers may not only activate, but also propagate, inflammation and drive airway responsiveness to a more severe state. The magnitude of airway hyperresponsiveness seems to correlate with the activity of airway inflammation. Furthermore, airway hyperresponsiveness seems to correlate with the clinical symptoms and signs of asthma.

Hyperresponsiveness is assessed by measuring airflow before and after the inhalation of increasing doses of methacholine or histamine (Figure 49.1).[6] Hyperresponsive airways will develop obstruction at lower cumulative doses than normal airways. This increased response is thought to be a protective mechanism against the detrimental effects of irritating inhalants. Airway hyperresponsiveness is not unique to asthma and can be found in other conditions affecting the airways, including some patients with chronic obstructive pulmonary disease. The treatment of asthma

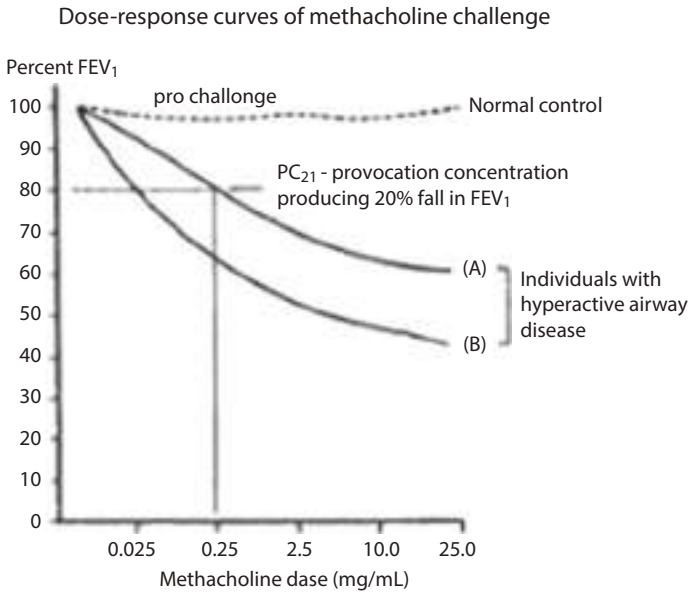

FIGURE 49.1 Asthmatics have hyperresponsive airways that are overly sensitive to immunologic or non-immunologic stimuli. Bronchial provocation testing can serve as a useful tool to measure the severity of bronchial hyperresponsiveness and is helpful to confirm the diagnosis of asthma.

by improving airway inflammation may diminish, but not eradicate, airway responsiveness, suggesting that additional factors are involved.

49.4 NON-PHARMACOLOGICAL MANAGEMENT

The management of asthma requires a comprehensive strategy that includes both pharmacologic and nonpharmacologic measures.[5] Effective management requires clear communication between the patient and medical provider. As an asthmatic's symptoms will vary over the course of time, so will the interventions necessary to achieve disease control.

The goals of asthma therapy are: (1) to prevent symptoms that interfere with quality of life; (2) to prevent exacerbations; (3) to avoid emergency department visits or hospitalizations; (4) to meet patient and family expectations for asthma care; and (5) to provide optimal pharmacotherapy with minimal adverse effects.[2] This section will focus on the nonpharmacologic management of asthma and strategies for longitudinal asthma care. The pharmacologic management of asthma will be reviewed in the following section.

49.4.1 Environmental Control

Environmental control measures, such as allergen avoidance, should always be included in asthma management strategies.[2] A comprehensive approach to control of allergen or irritant exposure is needed, since single measures for avoidance of allergens are generally not effective. Identifying the specific allergens and irritants causing symptoms for each individual is paramount. Common inhalant allergens include animal hair and dander, house dust mites, cockroaches, indoor and outdoor fungi, and tree, grass, and weed pollens. The NAEPP guidelines recommend environmental control at each step and have a questionnaire to help determine environmental and other factors that worsen asthma symptoms.[2,7] A history of likely sensitivity to seasonal allergens and positive skin testing or allergen immunoassay IgE blood testing can be helpful in identifying these allergens.[7]

When evaluating a patient with asthma, it is important to take a thorough history to identify triggering factors. Exposure to tobacco smoke should be avoided.[8,9] Most asthmatic patients should avoid beta-blocker therapies if possible. If these medications are essential for management of cardiovascular disease, there should be careful attention to any worsening of asthma symptoms.[10,11] Sulfite sensitive asthmatics should avoid foods and drinks that contain sulfite preservatives, such as shrimp, dried fruit, processed potatoes, sauerkraut, beer, and wine, all of which can cause exacerbations in a small percentage of asthmatics.[12] Asthmatics with a history of sensitivity to non-steroidal anti-inflammatory agents (NSAIDs) should strictly avoid these agents.[13,14]

49.4.2 Indoor Allergens

Major indoor allergens that are of particular importance include animal dander, dust mites, mold, and cockroaches. All warm-blooded pets can cause allergic reactions, with cats being a particularly strong trigger in sensitized individuals. While there is a popular notion that certain breeds of dogs and cats are "hypoallergenic" and less likely to cause allergic symptoms, no specific breed has ever been proven to have this quality. If there are pets in the home, and the person is sensitive to that animal, then removal of the pet should be encouraged, although it can take months for allergen levels to decrease.[2] Pets should be kept out of the bedroom, and all air ducts leading to the bedroom should be covered with a filter.[15]

House dust mite allergen is a major environmental factor in asthma.[2] House dust mites are universal in areas of high humidity, which include most of the United States. In addition to high humidity, mites depend upon human dander for survival. Dust mites thrive in mattresses, pillows, carpets, upholstered furniture, and soft toys. There are a variety of desirable control measures that should be considered in asthmatics with demonstrated dust mite sensitization.[2] Mattresses and pillows should be encased in allergen-impermeable covers. Bed sheets and blankets should be washed weekly in hot water, which must be >130 °F to kill mites. Indoor humidity should be maintained at less than 50%. Carpets, upholstered furniture, and stuffed animals should be removed as far as possible. Although there are a variety of chemical agents available for killing mites and denaturing the antigens, they are not as effective as the environmental control measures described here.

Molds are fungi that proliferate in humid environments, especially damp indoor environments. Creating a drier environment by fixing old water leaks and eliminating water sources reduces mold growth. Reducing indoor humidity to less than 50% substantially limits mold growth.

Asthma severity seems to increase with increasing levels of cockroach antigen. If cockroach infestation is present in the home, chemical control measures should be instituted to reduce the antigen load.[2] When chemical agents are used, the home should be well ventilated, and the patient should not return to the home until the odor has dissipated. Nonchemical strategies include keeping food out of bedrooms and storing food and garbage in closed containers.

A variety of measures can be taken to improve indoor air quality and reduce allergens, although the measures should not substitute for the strategies previously described. Vacuuming carpets twice a week using a vacuum equipped with a high-efficiency particulate air filter can reduce house dust accumulation. Ideally, the asthmatic should not be in the room when the vacuuming is occurring. Air conditioning and the use of a dehumidifier are helpful. Humidifiers and evaporative coolers are not recommended for use around dust mite–sensitive patients with asthma. High-efficiency particulate air filters and electrostatic precipitating filters

have been shown to reduce certain animal dander, mold spores, and the particulates from tobacco smoke.

49.4.3 Outdoor Allergens

A variety of tree, grass, and weed pollens, and seasonal spores, contribute to the outdoor allergens that affect many asthmatics. Avoidance, however, is challenging. Pollen sensitive asthmatics should use air conditioning when possible and keep windows closed. Pollen and spore counts are highest during the midday and afternoon at periods of brightest sunlight. Conducting outdoor activity shortly after sunrise or before sunset can result in reduced pollen exposure. Identifying the specific allergens that cause symptoms in an individual patient can help guide decisions about certain times of year when outdoor activity should be limited.

49.4.4 Allergy Testing and Immunotherapy

The two most common modalities used to identify the specific allergens affecting an individual are skin testing and in vitro immunoassay blood tests. Skin testing involves exposing the patient to a panel of allergen extract solutions and monitoring for a local cutaneous reaction to individual allergens. The discovery of IgE as the antibody responsible for allergic reactions has led to the development of immunoassay blood tests that can measure the level of allergen-specific IgE from a blood sample.[7] The total IgE level does not identify individuals with sensitization to specific aeroallergens and should not be used as a screening test for atopy.

Allergy skin testing is less expensive and more sensitive than in vitro immunoassay tests. It is also rapid, usually providing results within minutes. Skin testing is generally easy to perform and causes minimal patient discomfort. The results are dependent in part on the use of standardized extracts and the expertise of the tester. On the other hand, in vitro immunoassay tests do not require a specialized testing center and can be obtained anywhere phlebotomy is available. No allergen extracts are necessary, and they can be performed on patients who are taking medications that often suppress the skin test reaction (e.g., antihistamines and tricyclic antidepressants).

A positive allergy test from either methodology does not indicate to what extent the identified allergen is causing asthma symptoms. When a positive result is found with skin testing or an in vitro immunoassay, the clinician must look for clinical significance of the positive result in the context of the patient's medical history. When used in isolation, a positive allergy test alone only confirms exposure to an allergen, not that this exposure is clinically meaningful.

If the relationship between allergen exposure and asthma symptoms is clear, the allergen cannot be avoided by environmental control measures, and symptoms persist despite optimal pharmacologic therapy, then allergen immunotherapy can be considered.[2] Although available in both subcutaneous and sublingual preparations, current guidelines recommend that only subcutaneous immunotherapy be used in the treatment of asthma.[16] Immunotherapy should be administered in facilities with the ability to treat the possible serious adverse reactions that can occur.[17] It is unknown whether immunotherapy targeting multiple allergens simultaneously, versus a single allergen, impacts efficacy. Although multiple-allergen mixes are used for immunotherapy, only a few studies clearly support this practice.[18] Allergy immunotherapy is typically administered for three to five years.

There are controlled studies and a meta-analysis that support the use of immunotherapy in the treatment of asthma. Benefits include improved symptoms, decreased bronchial reactivity, and reduced medication use.[2,19–21] Immunotherapy is felt to reduce both the frequency and the severity of symptoms. Immunotherapy is most effective for some types of seasonal pollens (tree, grass, weed) and house dust mites, and also has some utility in pet allergy.[19–21] The success of immunotherapy is dependent upon identifying the correct target allergen(s).

There are risks associated with immunotherapy.[17] The most common is a local reaction at the site of injection, which can include swelling, erythema, and pruritus. This type of reaction is usually short-lived and can be minimized by using topical anti-inflammatory therapy or an oral antihistamine. The most serious adverse reaction is anaphylaxis. Therefore, immunotherapy should be performed in the presence of a physician experienced in treating anaphylaxis. Sufficient time should be allowed for anaphylaxis to occur, so an observation period of 15 to 30 minutes after each injection is required. Less serious reactions include nasal congestion and sneezing, worsened asthma symptoms, difficulty swallowing and talking because of a tongue or larynx edema, and lightheadedness. Because of the increased risk in severe asthmatics of adverse reactions to immunotherapy, including anaphylaxis and severe asthma exacerbations, and with the advent of effective biological agents that are safe and highly effective in severe asthma, biological therapies, when available, may be preferred over subcutaneous immunotherapy in most severe asthmatics. Immunotherapy could be considered when there is strong evidence of a specific allergic trigger, as in a cat allergic asthmatic who cannot avoid household cat exposures.

49.4.5 Asthma Action Plans

The NAEPP guidelines recommend a written asthma action plan for all asthmatics, based on signs and symptoms, changes in peak expiratory flow rate (PEFR), or both.[2] Written asthma action plans may be particularly helpful for those with poorly controlled asthma, moderate-to-severe persistent asthma, or a history of severe exacerbations. Action plans are useful in clarifying the roles of the medications and the medication plan, especially in less knowledgeable patients, and for adjusting treatment according to changes in symptoms and PEFR as needed. The more chronic and severe the asthma, the greater is the importance of a written asthma action plan.

49.4.6 Management According to Asthma Severity and Control

Multiple schemes have been developed to guide both the initial medication regimen at the time of asthma diagnosis as well as adjustments to pharmacologic therapy over time depending on the degree of asthma control. The two most commonly cited are from the NAEPP and the Global Initiative for Asthma (GINA).[2,5,16] Both schemes suggest an initial regimen according to disease severity at the time of diagnosis as well as stepwise adjustments over time depending on the ongoing degree of asthma control. Despite much overlap, there is variability between the two guidelines. Each guideline also provides multiple acceptable regimens at each step in the process. This highlights the need for an individualized management strategy for each patient depending on their specific modifiable risk factors, comorbidities, and overall preferences and goals. Clear and thoughtful communication between the provider and patient, and attention to medication compliance, are paramount throughout this process.

49.4.7 Monitoring Disease Activity

Periodic assessment and ongoing monitoring are necessary to achieve and maintain asthma control. Variables that require monitoring include daytime and nocturnal symptoms, amount of interference in daily activities due to asthma symptoms, quick-relief medication use for acute symptom relief, and measurement of airflow obstruction by spirometry and PEFR.[2] Both physician assessment and patient self-monitoring are part of the process.

Measurements of airflow are not necessarily related to asthma symptoms but do provide an objective measure to evaluate asthma control. Spirometry is recommended at least every one to two years, and especially at initial assessment, after treatment has stabilized symptoms and PEFR, and during periods of progressive or prolonged worsening of symptoms.[2,22] Spirometry is performed by taking a full breath and forcefully exhaling air from the lungs through a spirometer until all airflow has ceased.[23,24] As shown in Figure 49.2, airflow obstruction is shown by a decrease in the forced expiratory volumes, including the forced vital capacity (FVC) and the forced expiratory volume in one second (FEV1), and a decreased FEV1/FVC ratio. The normal, or predicted, ranges for these values are based on databases matched to the patient by parameters including age, height, and gender.

Measurements of the FVC and FEV1 are generally taken before and after inhalation of a quick-acting bronchodilator. The asthmatic typically shows significant improvement in these airflows following quick-acting bronchodilator treatment, indicating reversible obstructive airway disease. Significant improvement is defined as a post-bronchodilator increase in either FVC or FEV1 by at least 12%, and having a minimum absolute increase of 200 mL in the same parameter, compared with pre-bronchodilator measurements. The asthmatic can also independently measure airflow from the large airways using PEFR. The patient should determine a personal baseline PEFR. PEFR monitoring can be considered in asthmatics who have a history of frequent or severe exacerbations, who are poor perceivers of airflow obstruction or worsening asthma, or who have moderate-to-severe persistent asthma.[2]

The airflow obstruction of asthma waxes and wanes with variations in the degree of inflammation and smooth muscle constriction. There are alterations in FEV1 and PEFR with these changes (Figure 49.2). Over time, there will be variable needs for the use of medication to relieve symptoms. As asthma becomes better controlled with therapeutic interventions, overall airflow improves, and variability in airflow decreases. This results in a decreased need for quick-relief medication use to relieve acute symptoms and hopefully to an overall improvement in quality of life.

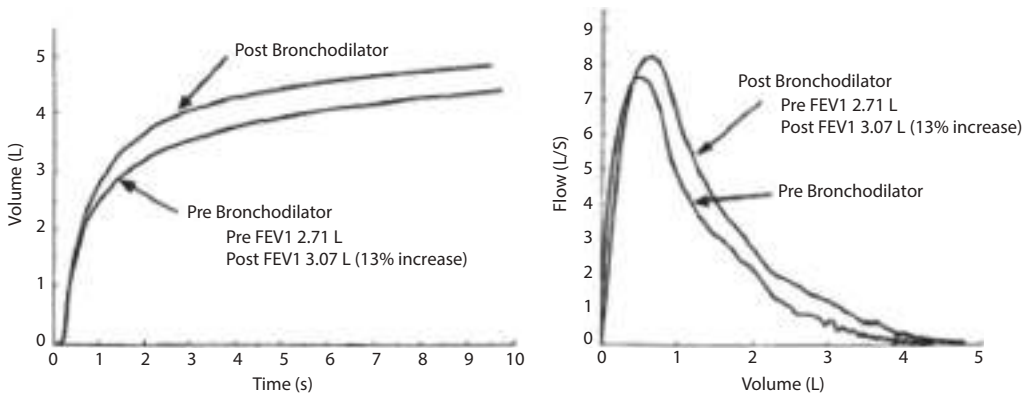

FIGURE 49.2 Spirometry pre-/post-bronchodilator in the asthmatic. Administration of an inhaled bronchodilator improves airflow significantly. The left panel depicts the volume-time curve and shows improvement in FEV1. The right panel shows the flow-volume curve and improvement in peak expiratory flow over exhaled lung volume. The dependent portion of the curve is also curvilinear (not straight), consistently with airflow obstruction.

Improved quality of life measures include better sleep at night, and improved resistance to asthma exacerbation during exposure to environmental challenges such as exercise or cigarette smoke. It is important to teach patients to recognize symptom patterns that indicate inadequate asthma control.

While spirometry and PEFR both help gauge asthma control based on the degree of airflow obstruction, it would be advantageous to have more directly measured biomarkers of airway inflammation. At the present time, however, although biomarkers can be helpful in establishing an asthmatic individual's inflammatory and immunologic phenotypes, and guide selection of biological agents, none have been found to be helpful in choosing or titrating conventional asthma therapies. The two most commonly employed biomarkers are fraction of exhaled nitric oxide (FENO) and peripheral eosinophil counts.[25]

Nitric oxide is produced by inflammatory cells and other cells in the airway. The FENO, which is easily measured with handheld devices, correlates with airway eosinophilia and is elevated in non-smokers with eosinophilic asthma, but it is also elevated in other illnesses such as allergic rhinitis, non-asthmatic eosinophilic bronchitis, and hypersensitivity pneumonitis.[5] In adult asthmatics, FENO-guided treatment did not show a reduction in exacerbations as compared with guideline-based treatment.[5,26] Accordingly, guidelines for severe asthma do not recommend using FENO for guiding therapy in adults, given the increased cost of care with an uncertain benefit.[4]

49.4.8 Bronchial Thermoplasty

Bronchial thermoplasty has been investigated as an additional therapeutic modality in poorly controlled asthma. The airways of chronic asthmatics are narrowed by increased wall thickness due to several mechanisms, including airway smooth muscle hypertrophy. Bronchial thermoplasty is a technique that delivers radiofrequency wave generated heat to the walls of airways to reduce airway smooth muscle hypertrophy and contractility.[27] The airways distal to the main stem bronchi are treated in a systematic manner during three separate bronchoscopies spaced about three weeks apart.

The benefits of thermoplasty remain uncertain. A systematic review and meta-analysis of 3 trials with a total of 429 patients found that overall, bronchial thermoplasty did not produce a clinically significant improvement in asthma symptoms or quality of life, and did not improve pulmonary function.[28] Exacerbation rates were lower in two of the three trials, but with an increase in hospitalizations and exacerbations during the treatment period. The most recent NAEPP recommendations conditionally recommend against the routine use of bronchial thermoplasty, given the proven benefits are small, the risks are moderate, and the long-term outcomes

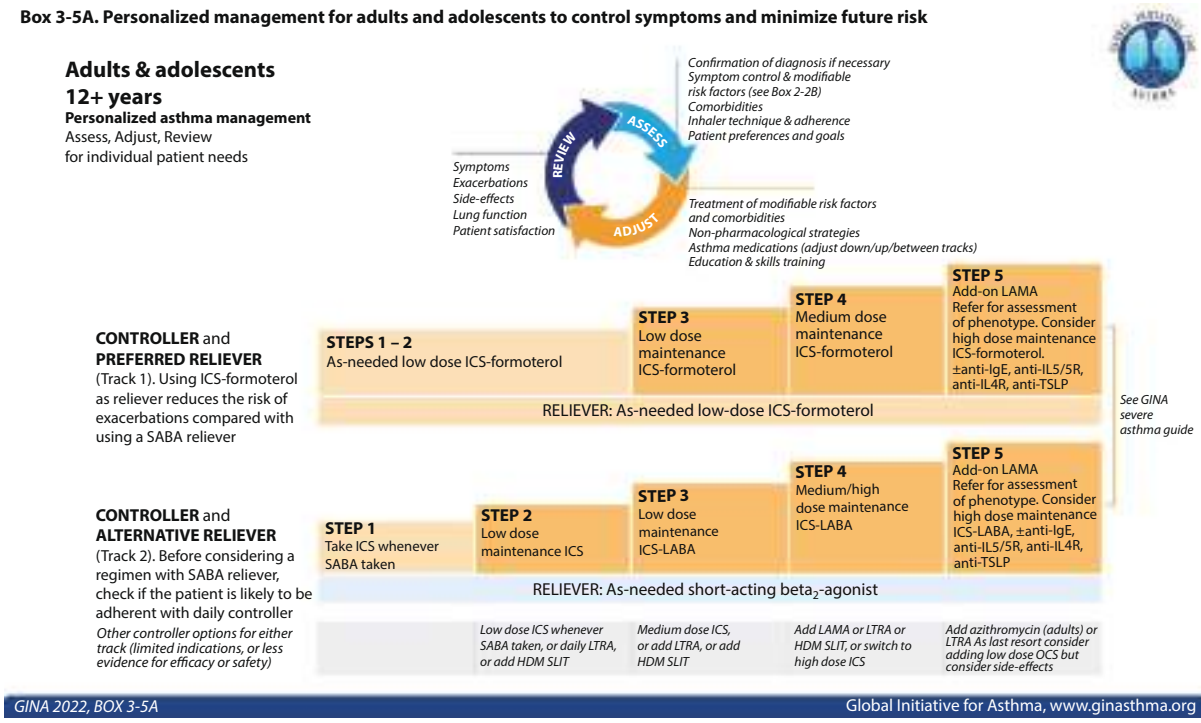

FIGURE 49.3 Personalized management strategies for asthma. HDM: house dust mite; ICS: inhaled corticosteroid; LABA: long-acting beta agonist; LAMA: long-acting muscarinic antagonist; LTRA: leukotriene receptor antagonist; OCS: oral corticosteroids; SABA: short-acting beta agonist; SLIT: sublingual immunotherapy. ***Source***: Adapted from 2022 GINA Main Report, Global Initiative for Asthma.

are uncertain. Furthermore, the efficacy and risks of thermoplasty need to be considered in comparison to an increasing number of effective alternative therapies for severe asthma, most notably biological agents. If pursued, bronchial thermoplasty should be performed in a clinical trial or registry study to enable the collection of long-term data.[16]

49.4.9 Other Issues in Long-Term Asthma Management

To enhance compliance with pharmacologic therapy, it is often helpful for patients to integrate medication administration into their lifestyle. For patients who are uncontrolled, or even controlled on their current regimen, it is important to determine if they are taking their medication as prescribed, especially inhaled corticosteroids. It is not uncommon to find that patients on a twice-daily regimen will remember the morning dose but forget the evening dose. To improve medication adherence, it may be prudent to change to a formulation that requires only once-daily administration. While mild asthma can often be effectively managed by general practitioners, there are multiple instances where referral to an asthma specialist for evaluation or co-management may be warranted.

49.5 PHARMACOLOGIC THERAPY

As noted earlier, multiple organizations have published guidelines for pharmacologic therapy in asthma. The two most commonly cited are the NAEPP and GINA. A detailed discussion of the specifics of the NAEPP and GINA management strategies is outside the scope of this publication. Also, each organization periodically updates its recommendations as new data becomes available. A provider should reference the recommendations directly from each organization to ensure that he or she remains up to date with the most current practices. That being said, there are some general strategies that are reasonable to review.

Pharmacologic therapy at the time of initial asthma diagnosis will vary depending on the severity of the patient's symptoms. Those with mild symptoms, such as less than twice per month, can often initially be managed with an as-needed rapid relief medication alone.[2,5,16] Patients with more frequent and severe symptoms at the time of diagnosis may benefit from an initial regimen including a chronic controller medication in addition to an as-needed quick-relief medication.[2,5,16]

After the initial diagnosis of asthma, evaluation of symptoms, exacerbation risk, quality of life considerations, and the need for medication adjustments should be assessed at regular intervals. How often this occurs will be different for each individual patient. When assessing the success of a medication adjustment, it is prudent to wait at least two weeks for a response to manifest, but reassessment should not be delayed more than three months.[5,16]

When asthma control is poor on optimal maintenance therapy, it is essential to review compliance. This cannot be accurately assessed from self report and requires a direct review of medication fill records from the pharmacy. This can now be performed directly with some electronic medical record systems. One of the most common pitfalls in asthma management is to escalate or add on therapies when the actual problem is non-compliance with the existing controller medication.

If asthma control is not optimal despite high dose inhaled steroids and a long-acting bronchodilator, with or without a long-acting muscarinic agent, it is important to review and identify extrinsic triggers, and re-check compliance with pharmacy record review. Addition of a leukotriene receptor antagonist can be considered, although the efficacy of these agents in severe asthma is uncertain and needs to be re-evaluated after instituting therapy. In asthmatics with poor control despite documented compliance with high dose inhaled steroids and long-acting bronchodilators, biological agents should be considered.[5,16] If not already pursued, at this point, the patient should be referred to an asthma specialist prior to initiating any additional therapies.

The pharmacologic treatment of asthma includes two broad categories of medications: bronchodilators that relax airway smooth muscle, and anti-inflammatory drugs that reduce the influx of inflammatory cells and the subsequent release of chemical mediators. Bronchodilators include short- and long-acting beta-2 receptor agonists (beta agonists), short- and long-acting muscarinic antagonists (anticholinergics), and methylxanthines. Anti-inflammatory agents include corticosteroids, leukotriene inhibitors, cromolyn, and monoclonal antibodies. The monoclonal antibodies available for the treatment of asthma are often collectively referred to as "biologics."

Pharmacologic therapy for asthma is administered through multiple routes. Inhalational therapy is the main route for bronchodilator administration, although the methylxanthines are administered orally or intravenously. Inhalational therapy can be administered via either an inhaler or a nebulizer. Inhalers can be further subdivided into metered-dose inhalers, dry powder inhalers, and soft-mist inhalers, all requiring a different technique to use properly. Anti-inflammatory administration route depends on the medication. Inhalation is the main route for corticosteroids used for chronic control, although systemic oral corticosteroids can be used in the chronic control of severe asthma, while oral or intravenous corticosteroids are used during acute exacerbations. Leukotriene inhibitors are administered orally. The currently available biologics are administered either via subcutaneous injection or intravenously, depending on the agent.

Medications are often characterized according to the manner in which they are used: rapid relief medications, or relievers, which are used to treat acute symptoms, and long-term chronic control medications, which are used to achieve and maintain control of chronic asthma.

49.5.1 Rapid Relief Medications

In order to achieve immediate relief of bronchoconstriction and the discomforting symptoms associated with asthma,

quick-relief medications, such as fast-acting/short-acting beta-2 agonists and anticholinergics, are employed. Short-acting beta-2 agonists relax airway smooth muscle within minutes and improve airflow. These agents are the drugs of choice for treating acute asthma symptoms and exacerbations.[2] They are also used for preventing exercise-induced bronchospasm.[2] The most commonly used fast-acting/short-acting beta-2 agonist is albuterol. Inhaled short-acting anticholinergic therapy, such as ipratropium bromide, can also be used as a bronchodilator in this setting, generally in combination with a beta agonist. Ipratropium bromide may provide some additional benefit during a moderate-to-severe asthma exacerbation, and it may also be considered as an alternative for those who absolutely cannot tolerate beta agonists.[2] These agents can be administered via an inhaler or nebulizer. Formoterol, a long-acting beta-2 agonist with a fast onset of action, alone or as part of a combination inhaler including an inhaled corticosteroid, can also be used in a quick-relief fashion in patients with mild to moderate asthma. Compared with using a short-acting bronchodilator alone, the combination of budesonide with formoterol used as a rescue inhaler significantly decreases exacerbations.[5,16] For patients with severe asthma, who are already likely to be on a maximal dose of an inhaled steroid and long-acting bronchodilator, using a combination of albuterol with an inhaled steroid as rescue inhaler also decreased exacerbations compared with albuterol alone.[29] Systemic corticosteroid therapy can speed the resolution of airflow obstruction and reduce the rate of relapse of treated severe asthma.[2]

The frequency at which quick-relief therapy is required for acute symptom control can serve as a marker of asthma stability. The more frequently these medications are necessary, the stronger the need for optimization of chronic controller therapy. Using a short-acting beta-2 agonist inhaler at the rate of one or more canisters per month has been associated with an increase in asthma morbidity and mortality.[30] It should be possible for 70–80% of chronic asthma patients in the United States to be controlled to a level of mild asthma with only intermittent symptoms, generally two or fewer mild episodes of symptoms per week. Therefore, if more than four puffs of a short-acting beta agonist are used weekly, then enhanced asthma control is necessary. A well-controlled asthmatic should only need one or two canisters of a short-acting bronchodilator per year, not counting the therapy that would be used to prevent exercise-induced bronchospasm.

49.5.2 Chronic Controller Medications

Corticosteroids are the most potent and effective anti-inflammatory medications available for the management of asthma. The inhaled form of these medications from an inhaler, or alternatively from a nebulizer in selected patients, is the first-line therapy for the long-term control of asthma. Corticosteroids reduce airway inflammation and airway hyperresponsiveness.[31–34] They also prevent bronchial wall remodeling, known to occur with chronic inflammation and to be responsible for the development of fixed airflow obstruction later in life. There are many different products and delivery devices for the administration of inhaled corticosteroids, and their inhalation doses vary.[2] The lowest daily dose of an inhaled corticosteroid should be used in order to control the disease. Systemic corticosteroids, administered orally or intravenously, are used during periods of acute destabilization and worsening of asthma. Long-term and chronic use of systemic corticosteroids should be avoided due to the numerous associated complications; however, some patients with severe chronic disease may require this therapy.

Antileukotrienes are another group of anti-inflammatory agents. These oral therapies block or inhibit the production of leukotrienes, which are by-products of the arachidonic acid–metabolic pathways and are potent bronchoconstrictors and inflammatory stimulants.[35] Leukotrienes are released from a variety of inflammatory cells, including lymphocytes, eosinophils, and mast cells, and not only induce bronchoconstriction but also increase vascular permeability, mucous secretion, and the abundance of other inflammatory cells. When these additional cells enter the airway, they are activated and release other powerful chemicals that propagate the inflammatory state.[35]

There are three antileukotriene agents currently available in the United States: montelukast and zafirlukast, which are leukotriene receptor blockers, and zileuton, a 5-lipoxygenase inhibitor. Leukotriene-pathway agents improve lung function, diminish asthma symptoms, and reduce the need for quick-relief medications.[36–39] Their efficacy has been shown in patients with mild-to-moderate asthma, and the improvements seen are modest in nature when compared with inhaled corticosteroid therapy.[40,41] These agents have been shown to reduce bronchoconstriction caused by exercise, aspirin, and inhaled allergen exposure.[37,42–45] Of note, very little is known as to whether these agents are helpful in severe asthma not controlled with high dose inhaled steroids and bronchodilators.

Theophylline, a methylxanthine compound, acts as a bronchodilator and may also improve asthma through certain anti-inflammatory effects and reductions in bronchial reactivity.[46,47] When theophylline is administered in a sustained-release oral therapy form, it has a long duration of action and can further control asthma when used in combination with inhaled corticosteroid therapy.[48,49] However, theophylline is now rarely used, because it has a narrow therapeutic margin of safety, multiple medication interactions, and overall weak bronchodilator effect.

The dosing of theophylline is titrated to a therapeutic level and also, importantly, to minimize the potential for drug toxicity. The target serum concentration has been recommended to be approximately 5–15 mg per liter.[2,50,51] Theophylline levels may be affected by several factors, including smoking, which decreases the level, and medical conditions that increase the level, such as heart failure, cor pulmonale, cirrhosis, hypoxia, hypothyroidism,

febrile illness, and pregnancy. Levels can also be affected by drugs that inhibit theophylline metabolism and hence increase levels (clarithromycin, ciprofloxacin) or drugs that enhance theophylline metabolism and decrease levels (rifampin, phenobarbital, phenytoin, carbamazepine). After the patient is on a stable dose of theophylline, drug levels should be checked at least once a year provided the patient has no changes in health or other medications.

49.5.3 Long-Acting Beta-2 Agonists

Inhaled long-acting beta agonist (LABA) medications are often used as add-on controller therapy to inhaled corticosteroids. Patients with moderate-to-severe asthma generally require at least two or three controller medications to optimize their pharmacologic therapy, and LABAs are generally next added following inhaled corticosteroids.[2,5,16] LABAs are generally not fast-acting but have a duration of action of at least 12 hours, far longer than that of the fast- and short-acting beta agonists used for the acute control of symptoms.[52] Formoterol is a unique LABA, as it is both fast- and long-acting, allowing use as both a quick-relief and a chronic controller medication. For ease of use, LABAs are commonly paired with inhaled corticosteroids into combination inhalers, where both medications are administered in a single puff. LABAs should not be prescribed separately from inhaled corticosteroids due to concerns of increased mortality in the absence of appropriate anti-inflammatory therapy.[5]

49.5.4 Long-Acting Muscarinic Antagonists

Initially studied in the treatment of chronic obstructive pulmonary disease, inhaled long-acting muscarinic antagonist (LAMA) medications also have a role as chronic controllers in asthma.[5,16] LAMAs moderately improve lung function and moderately increase time to severe exacerbation requiring corticosteroids.[53,54] In a meta-analysis from 2018, the addition of a LAMA to inhaled steroids resulted in lower asthma exacerbations but was no different from a LABA.[55] LABAs remain the preferred initial add-on agent to inhaled corticosteroids, but LAMAs can be substituted if LABAs cannot be used.[16] A LAMA can also be added to an existing inhaled corticosteroid and LABA regimen if the patient continues with suboptimal asthma control.[5,16]

49.5.5 Biologic Therapy

A patient with persistent suboptimal asthma control despite the combination of an inhaled corticosteroid and at least one other controller medication may be a candidate for monoclonal antibody therapy.[16] When used in asthma, these monoclonal antibodies are collectively termed "biologics." The first biologic approved for use in asthma was omalizumab in 2003. Since then, multiple new agents, with multiple different molecular targets, have been Food and Drug Administration (FDA) approved. Importantly, many asthmatics will meet criteria for more than one biologic. Currently there are no head-to-head trials comparing biologics, and it is unknown whether a patient may respond better to one medication or another. Despite this, algorithms to choose the best biologic for an individual have been proposed based on the best available information and expert opinion.[56–58]

Omalizumab is a recombinant humanized monoclonal IgG antibody that binds to circulating IgE antibodies. Subsequently, it prevents IgE binding to high-affinity receptors on mast cells, basophils, and other cells, leading to decreased mediator release from these cells.[2] It is used in patients with moderate-to-severe persistent allergic asthma and sensitivity to perennial allergens such as dust mites, animal dander, cockroaches, or molds.[59–62] Patients using omalizumab are able to reduce the dose of their inhaled corticosteroids and experience reduced frequency of exacerbations, including those requiring hospitalization.[59,63–70] However, in patients already on therapy for asthma, omalizumab does not improve spirometry.[62,70] There is also little to no effect on bronchial hyperresponsiveness, but it does decrease some airway inflammatory markers.[64,65,71,72] In rare circumstances, it has been used in occupational asthma with beneficial effects.[73,74]

Omalizumab is administered via subcutaneous injection every two to four weeks, with dosage and frequency determined by both body weight and IgE level. Treatment will affect the accuracy of most allergen-specific assays. Adverse effects include anaphylaxis and local injection site reactions.[75] Anaphylaxis is rare and has been reported as any combination of bronchospasm, angioedema of throat or tongue, hypotension, syncope, and/or urticaria. Of the patients who develop anaphylaxis, approximately 40% do so after the first dose and 20% after the second dose.[63] A Joint Task Force Report on omalizumab-associated anaphylaxis has made safety and management recommendations.[76]

There are currently two anti-IL-5 monoclonal antibodies available, mepolizumab and reslizumab. IL-5 is the major cytokine involved in the production and survival of eosinophils. While the mechanism of action of these agents is not fully understood, they do reduce the production and survival of eosinophils. This results in lower blood and sputum eosinophil counts, which is thought to reduce airway inflammation.[77]

Mepolizumab is administered as a subcutaneous injection at a fixed dose of 100 mg every four weeks. It has been shown to provide a corticosteroid-sparing effect and reduces asthma exacerbations by greater than 50% and exacerbations requiring emergency department care or inpatient hospitalization by greater than 60%.[77–79] Mepolizumab may increase the risk for herpes zoster infection; it is therefore important to determine if the patient has had the chicken pox or the varicella vaccine. The safety of mepolizumab during pregnancy is unknown. Mepolizumab may cause allergic hypersensitivity reactions, including anaphylaxis. The most common side effects of mepolizumab include headache, injection site reactions (pain, redness, swelling, itching, or burning), back pain, and weakness/fatigue.

Reslizumab is administered as an intravenous infusion over 20–50 minutes at a dose of 3 mg/kg every 4 weeks. It has been shown to reduce asthma exacerbations by approximately 50% and improves airway function.[80, 81] The most important side effect is anaphylaxis.

Benralizumab is a monoclonal antibody that binds to the IL-5 receptor alpha present on eosinophils and basophils. It also leads to a reduction of eosinophils and basophils in blood and sputum through an antibody-dependent cell-mediated cytotoxicity.[78] It is administered as a subcutaneous injection of 30 mg every four weeks for the first three doses, followed by 30 mg every eight weeks. It has been shown to reduce exacerbations, improve FEV1, and improve asthma symptom scores.[82] As with multiple other biologics, the most important side effect is anaphylaxis.

Dupilumab is a monoclonal antibody that binds the IL-4 receptor alpha subunit. Blockade of this receptor inhibits the activity of not only IL-4 but also IL-13. It is administered by subcutaneous injection every two weeks, with multiple dosage schemes depending on disease severity. It has been shown to provide a corticosteroid-sparing effect, reduce exacerbations, and improve lung function.[83–87] The most common adverse effects are dermatologic injection site reactions as well as ocular surface disorders including conjunctivitis and pruritus.

The most recently FDA-approved biologic for the treatment of asthma is tezepelumab, a monoclonal antibody that binds thymic stromal lymphopoietin. Thymic stromal lymphopoietin is a cytokine derived from epithelial cells, and serum levels in asthmatics correlate with airway obstruction, asthma severity, and glucocorticoid resistance.[88] Tezepelumab is administered via subcutaneous injection at a fixed dose of 210 mg every four weeks. Studies have shown improved lung function, lower rates of asthma exacerbations, and improved health-related quality of life compared with placebo.[88,89] The most commonly reported adverse effects are arthralgias and hypersensitivity reactions, including rash and conjunctivitis.

There are no direct comparative trials of biological agents to inform precise recommendations on which of these drugs is most effective for a given patient. Several recent publications recommend using an assessment of relevant comorbidities, including specific allergic triggers, chronic sinusitis with nasal polyposis and eczema, along with biomarkers such as peripheral eosinophilia and FENO, to predict the optimal first choice agent.[56–58]

49.6 ASTHMA COMPLICATIONS

There are both acute and chronic complications of asthma. Acute asthma attacks are associated with a variety of complications, including pneumothorax, pneumomediastinum, cardiac arrhythmias, lung atelectasis, and respiratory failure. Rarely, death can occur. The young and elderly are at particular risk for death because the severity of their disease is often not appreciated or is ignored. Death from asthma can be sudden, possibly associated with laryngospasm.

TABLE 49.1
Factors Associated with Increased Risk of Asthma Exacerbations or Mortality

Severe airflow obstruction, as detected by spirometry
Two or more ED visits or hospitalizations for asthma in the past year
Past intubation or ICU admission, especially in past five years
Patients feeling in danger or frightened by their asthma
Patient characteristics: female, nonwhite, nonuse of ICS therapy, and current smoking
Psychosocial factors: depression, increased stress, socioeconomic factors
Attitudes and beliefs about taking medications

ED: emergency department; ICU: intensive care unit.

However, most asthmatic deaths are slow in evolution to the point of respiratory failure as a multitude of metabolic problems develop.[90] Table 49.1 shows the factors that have been implicated in asthma exacerbation and mortality.

Irreversible airflow obstruction can develop with long-term poorly controlled asthma.[91,92] Recurrent airway infections are subsequently associated with fixed airflow obstruction.[93] Allergic bronchopulmonary aspergillosis (ABPA), often with mucoid airway impaction and secondary bacterial infection, can occur in some long-term poorly controlled asthmatics. ABPA associated with asthma is characterized by recurrent episodes of severe asthma exacerbations.[94] Fever, chest pain, and hemoptysis can be associated with this condition, and mucus impaction causes transient infiltrates to develop on chest imaging. There are no universally accepted diagnostic criteria for ABPA, although usual findings include a positive skin prick test or elevated *Aspergillus fumigatus* specific IgE, elevated total IgE, blood eosinophilia, and serum precipitating *Aspergillus fumigatus* antibodies. This condition generally requires daily high dose inhaled corticosteroids and sometimes, oral corticosteroid therapy. The addition of anti-fungal medications is controversial, although the most recent guidelines from the Infectious Diseases Society of America recommend their use.[95]

49.7 LIFESTYLE CONSIDERATIONS

49.7.1 Exercise and Asthma

Exercise-induced asthma (EIA) or bronchoconstriction (EIB) is a transient airway narrowing and airflow obstruction that occurs during or after exercise.[6,96] Nearly 90% of persistent asthmatics have EIB, and patients with allergic rhinitis, or even relatives of asthmatics, can demonstrate this phenomenon. As with asthma, the common symptoms are cough, wheezing, chest tightness, shortness of breath, and what the patient describes as an inability to take in a full breath of air during or following exercise. Symptoms and airflow decline can start within minutes of initiating

exercise and usually improve within one hour of exercise cessation, even without medication use. EIB can seriously and adversely affect athletic performance if not recognized and controlled.

EIB is thought to be caused by the exchange of heat and water in the airways that occurs due to increased minute ventilation during exercise. The main factors affecting the severity of EIB are the amount of minute ventilation attained and sustained as well as the inspired air-water content and temperature. The high minute ventilation causes a cooling and drying effect on the airway.[6,96,97] It is thought that the drying of the airway causes an increase in surface osmolarity, which triggers the release of inflammatory mediators. This cooling and drying effect also sets the stage for the rapid rewarming of the airway that occurs with rest.

EIB can be diagnosed clinically in most patients and does not require special testing. In those where the diagnosis is uncertain, and particularly if other diagnostic tests or interventions for these symptoms have not been helpful, provoking protocols can be employed. After an exercise challenge, airflow is measured sequentially at 5, 15, and 30 minutes. The patient with EIB often has a reduction in airflow within this time period. When airflow falls, especially when associated with symptoms consistent with asthma, the diagnosis can be made. This evaluation can be done by a physician or by individuals such as trainers or coaches under the guidance of a physician. EIB is likely underdiagnosed among urban varsity athletes. In one study, it was reported that during screening for asthma and EIB, approximately 10% of 238 students had a history of treated asthma and that another 9% had unrecognized EIB during screening. This suggests the need for vigilance for the presence of EIB, especially when it affects activity tolerance or quality of life.[98]

It is important to distinguish exercise-induced asthma from poorly controlled asthma with reduced pulmonary function and from deconditioning. Patients with poorly controlled asthma or deconditioning will develop exercise intolerance with low levels of activity, such as climbing one flight of stairs, and usually have abnormal baseline spirometry to explain these symptoms. Patients with true EIB only develop asthma symptoms with high levels of sustained activity, such as running for several minutes. Symptoms include wheezing, coughing, and chest tightness, which may help distinguish EIB from the general fatigue that characterizes deconditioning.

Management and prevention of EIB can be accomplished by both nonpharmacologic and pharmacologic approaches. It is helpful to avoid exercising in extremes of temperature. When exercising in cold air, a mask or scarf covering the mouth may help reduce EIB.[99] A warm and moist environment can often be helpful in minimizing EIB. The use of an extended warm-up session and special breathing techniques that help minimize hyperventilation and promote relaxation can also help. There are reports that a warm-up period before exercise results in a refractory period or reduction in EIB in more than 50% of individuals for up to two hours.[97,100,101] The athlete should warm up slowly to loosen muscles and elevate heart rate. With the beginning of a light sweat, the athlete can exercise at, or close to, maximum exertion for up to five minutes and then take a rest. More accomplished athletes can continue this warm-up process recurrently for 30 to 40 minutes. Another strategy is to do brief bouts of exercise for two to three minutes followed by three to five minutes of rest. These repetitive exertional challenges should occur over a 30- or 40-minute period. It is important for the individual athlete to determine which warm-up protocol works best for him or her.

The post-exercise period is also important. The cool-down phase after a workout or competition should consist of taking deep, slow breaths. Cooling down in a warmer environment can be helpful.

Medications are often necessary to prevent EIB. Using inhaled beta agonists shortly before, during, or even after exercise can prevent or relieve asthma symptoms.[2] Inhaled beta agonists will prevent EIB in more than 80% of patients. Administering a short-acting inhaled beta agonist approximately 15 to 30 minutes before exercise provides protection for two to three hours. When symptoms break through, these medications can be safely administered by an inhaler. The inhaled long-acting beta-2 agonists (formoterol, salmeterol) can be helpful for controlling the frequent need for short-acting beta-2 agonists. Salmeterol has been shown to prevent EIB for 10 to 20 hours and is valuable for prolonged prevention when the athlete will be re-exposed to the exercise challenge over an extended time period.[102] Long-acting beta-2 agonists should not be used alone as daily prophylaxis of EIB, as the duration of effect is reduced and may be masking suboptimally controlled asthma.[2] Other therapies can be used in addition to beta agonists. If available, inhaled cromolyn can be taken approximately 30 minutes to 1 hour prior to exercise, often in addition to the pre-exercise use of short-acting beta agonists, for further control in those patients who fail single preventative therapy.[103] Administered in a single dose at least 2 hours before exercise, the leukotriene receptor antagonists can decrease EIB in more than half of patients for a period of 12 hours or more.[2,104]

Most EIB occurs in the chronic asthmatic, making control of chronic asthma that much more crucial. Inhaled corticosteroids can decrease airway responsiveness over the long term and decrease EIB. When chronic asthma is controlled, the frequency and severity of EIB are reduced.[105]

49.7.2 Occupational Asthma

It has been estimated that occupational factors account for approximately 9–15% of cases of asthma in adults of working age, including new-onset or recurrent disease.[106] A variety of substances in the workplace have been implicated in the development of asthma, including a large variety of animal proteins, flour and grain dust, wood dust, cotton dust, chemical compounds such as isocyanates and hydrides, metal salts, and even pharmaceuticals.[106] The workers

TABLE 49.2
Selected Causes of Allergic and Non-Allergic Occupational Asthma

High-Molecular-Weight Substance	Occupations
Animal protein	Laboratory workers
Papain	Brewers, lens workers
Wheat flour	Bakers, millers
Trypsin	Plastic/pharmaceutical workers
Soybean dust	Farmers, food workers
Vegetable gums	Printers, food workers
Low-Molecular-Weight Substance	**Occupations**
Platinum	Jewelers, refiners
Trimellitic anhydride	Plastic and epoxy resin workers
Phthalic anhydride	Plastic and epoxy resin workers
Isocyanates	Spray painters, foundry workers
Polyvinylchloride	Meat wrappers
Western red cedar	Carpenters

most commonly reported for occupational asthma include paint sprayers, bakers and pastry makers, animal handlers, nurses, chemical workers, welders, food processing workers, and timber workers.[106]

The causative agents of occupational asthma can be grouped into immunologic and non-immunologic (e.g., smoke, aerosols, fumes). Up to 90% of cases have been of the immunologic type. Some causative agents, such as toluene diisocyanate, can produce occupational asthma through both immunologic and non-immunologic mechanisms resulting from airway damage and sensitization. The immunologic agents can be divided into high- and low-molecular-weight substances (Table 49.2). The high-molecular-weight agents are complete sensitizing agents, while the low-molecular-weight agents need to combine with a protein to form a sensitizing agent. The high-molecular-weight agents are usually mediated through IgE.

It is important to recognize occupational asthma as soon as possible because the likelihood of complete resolution of symptoms decreases over time.[2] Occupational asthma is suspected when either the patient or clinician realizes a relationship between asthma symptoms and work exposure. There is often a time delay between exposure to the offending agent and the development of symptoms of occupational asthma. Many times, the patient will improve on days away from the workplace, particularly during vacations. Sometimes, coworkers have similar symptoms. Serial PEFR measurements at work and away from work can help diagnose occupational asthma.[106] There are some (not well standardized) allergens available for skin prick testing, and some immunoassays for agent specific IgE exist. Occupational asthma can usually be diagnosed without using specific bronchial provocation testing, although occasionally, a bronchial provocation challenge performed with a suspected allergen or irritant from the workplace can be helpful.[106]

The management of occupational asthma can be difficult, and the patient may require referral to an occupational asthma specialist. Diagnosing patients early and avoiding further exposure to the causative agent will give the best opportunity for a complete recovery. Often, the patient must avoid the triggering substance. If impossible, the patient should be moved to an area of low or occasional exposure with increased health monitoring. The use of respiratory protection by wearing a respirator mask can be helpful. Many times, the patient must completely avoid exposure to the irritating agent; therefore, a new job position may be necessary.

The outcome of any intervention for patients with confirmed occupational asthma depends on factors such as age and the type of agent.[106] Unfortunately, some patients will have persistent asthma despite the removal of the inciting substance.

Irritant-induced asthma is a subset of occupational asthma where exposure to an occupational irritant induces new-onset asthma in a patient without preexisting disease. A variety of chemicals, dust, and other particulates can sensitize the airways and induce chronic asthma.[107] This is different from work-exacerbated asthma, in which preexisting asthma exists and is worsened by workplace exposure, but the workplace agents do not actually initiate the disease process. The syndrome known as reactive airways dysfunction syndrome (RADS), an acute form of irritant-induced asthma, occurs when a single high-intensity exposure to a non-immunologic irritant causes asthma-like symptoms within minutes. In RADS, symptoms may last for years.

49.7.3 Medication-Induced Asthma

Aspirin-exacerbated respiratory disease, also known as Samter's Triad, is characterized by the presence of asthma, rhinosinusitis with nasal polyps, and aspirin sensitivity. The ingestion of aspirin in sensitive individuals may result in nasal congestion, eye irritation, facial flushing, and an asthma exacerbation, which usually occurs rapidly after ingestion and often within 30 minutes.[108] Approximately 4–20% of asthmatics are sensitive to aspirin and related compounds, especially NSAIDs.[109,110] Severe and even fatal asthma exacerbations have been associated with aspirin ingestion. In adult patients with severe persistent asthma who have nasal polyps, it is important to take a careful history to determine whether there is any evidence suggesting exacerbations of upper or lower airway symptoms after NSAID use. Even if no such history can be elicited, high risk patients, such as those with chronic sinusitis and nasal polyposis, should be counseled to maintain vigilance for NSAID induced exacerbations. If such a history does exist, the patient should be instructed to avoid all NSAID exposures. Acetaminophen, particularly in lower doses, is tolerated in the large majority of NSAID sensitive asthmatics. The COX-2 inhibitor celecoxib is also tolerated in most NSAID sensitive asthmatics, but because there is still some risk of this agent precipitating exacerbations, the first dose should be given in an observed setting.[2,13,111,112]

Nasal polyposis and chronic rhinosinusitis occur in nearly 90% of patients with aspirin sensitivity.[113] The prevalence of aspirin sensitivity increases with age and the severity of the asthma. There is no known familial predilection to aspirin sensitivity. It is not known to be associated with atopy. The mechanism seems to be related to altered arachidonic acid metabolism and to inhibition of the enzyme cyclo-oxygenase (COX-1), in which arachidonic acid metabolites are passed through the leukotriene pathway, resulting in increased production of the leukotrienes C4, D4, and E4 (the slow reacting substance of anaphylaxis).[114] Therefore, medications that interfere with leukotriene synthesis or leukotriene receptor antagonists are helpful in the management of aspirin-induced asthma. Patients are treated according to asthma guidelines, but usually, a leukotriene modifying agent is added, which may also diminish nasal symptoms.[42,43,115] The treatment of aspirin-induced asthma also includes either avoiding all NSAIDs that inhibit the COX-1 enzyme or performing aspirin desensitization and maintaining daily aspirin therapy.[2] The biological agent dupilumab can be highly effective in treating both sinus disease and asthma in patients with chronic sinusitis and nasal polyposis, and is an attractive therapeutic alternative to aspirin desensitization in these patients.

Tartrazine, or yellow food dye No. 5, can induce asthma symptoms in some individuals. This food coloring is found in a number of foods and in some medications.

Beta blockers, including a variety of eye drop preparations, can induce asthma symptoms.[2,10,11] The NAEPP guidelines suggest avoiding non-selective beta blockers, and ideally, beta-blocker therapy should be avoided altogether unless the medication is necessary for a cardiac or ophthalmologic condition.[116] However, many patients who have mild-to-moderate airflow obstruction are able to tolerate more cardioselective beta blockers, and the NAEPP recommends using them in patients with cardiac disorders after careful consideration.[2] Fortunately, there are satisfactory alternatives to beta blockers for most of these patients.

49.7.4 Obesity

Asthma is more common and more difficult to control in obese patients.[5, 117] Some obese patients with asthma have prominent respiratory symptoms and little eosinophilic inflammation. These symptoms need to be distinguished from those of obese patients who have respiratory symptoms due to deconditioning, chest restriction, and obstructive sleep apnea.[5,117] Because of the potential contributors to dyspnea and wheeze in obese patients, it is important to confirm the diagnosis of asthma with objective measurement of variable airflow obstruction. There are various strategies for weight reduction. However, as part of a lifestyle change, the addition of exercise twice a week or a weight loss program in obese asthmatics can improve asthma control, pulmonary function, and inflammatory markers.[118]

49.7.5 Stress

Asthma is not a psychosomatic illness. However, there is evidence that stress plays an important role in precipitating asthma exacerbations and may act as a risk factor for the increased prevalence of the disease.[119] Stress exacerbation of asthma may involve enhanced generation of pro-inflammatory cytokines, but more importantly, psychosocial factors associated with stress influence the asthmatic's personal sphere and often lead to a poor outcome.[120] Since emotional upset does contribute to the asthma symptom picture, a variety of psychological interventions may be necessary to enhance overall asthma care. In some cases, a patient may need help to distinguish between asthma flares and panic attacks.

Conflict that develops between the patient, the family, and the medical staff often interferes with appropriate asthma care. The poorly controlled chronic asthmatic can often despair, and his or her disease can have a significant negative effect on personal relationships, family life, and self-image. Enhanced asthma control, and careful discussion of these issues with the patient and family, can help the overall asthma care process. The asthmatic who needs psychosocial assistance should take advantage of appropriate professional counseling with a psychologist, psychiatrist, social worker, or other licensed practitioner.[2] There are a variety of psychologically oriented approaches to asthma care that can be helpful, including family counseling, educational seminars, and psychotherapy. Ignoring asthma symptoms and neglecting to use medication can seriously adversely affect overall asthma control. Asthma education is associated with enhanced personal confidence in the management of chronic asthma.[2]

49.7.6 Food Hypersensitivity

Food allergens may rarely precipitate asthma symptoms alone but more commonly are associated with extra-pulmonary involvement, such as skin and gastrointestinal signs and symptoms.[2,121]

49.7.7 Gastroesophageal Reflux

Gastroesophageal (GE) reflux results when the acidic, liquid contents of the stomach are regurgitated into the esophagus, causing irritation. The reflux material does not have to be aspirated into the lungs to induce asthma. Reflux of the acidic fluid into the esophagus likely destabilizes asthma by enhancing the cholinergic autonomic nervous system influence or microaspiration, or both. GE reflux should be suspected in patients with poorly controlled asthma, particularly those who have nocturnal symptom breakthroughs.[2] The strongest evidence supports a link between symptomatic reflux and asthma symptoms. Empiric treatment with a proton pump inhibitor in asthmatics without GE reflux symptoms did not improve asthma symptoms.[122] A patient who has a hiatal hernia is at particular risk for GE reflux.

Treatment of patients with symptomatic GE reflux has been associated with improvement in some aspects of their asthma.[123,124] If GE reflux symptoms are present, medical management includes (1) avoidance of eating food and drinking liquids within three hours prior to bedtime; (2) sleeping with the head of the bed elevated by using six- to eight-inch blocks; (3) eating smaller, and if necessary, more frequent meals; (4) using appropriate pharmacologic therapy such as H2 receptor blockers or proton pump inhibitors; (5) cessation of alcohol, cigarettes, and caffeinated foods.[2]

49.7.8 Pregnancy and Asthma

Asthma is the most common medical condition during pregnancy, occurring in 4–8% of pregnant women.[125] The risk of asthma exacerbation during pregnancy is higher, especially in the second trimester.[5,126] As a general rule, one-third of all pregnant asthma patients improve, one-third remain the same, and one-third have worsening disease during pregnancy.[2,5,127] However a patient's asthma changes during the first pregnancy, it is likely that similar symptoms will occur with subsequent pregnancies. Patients with more severe and difficult-to-control asthma generally have worse symptoms during pregnancy.

Asthma also has an effect on pregnancy complications.[128] Uncontrolled asthma is risky for the fetus. One large study showed that asthmatic patients had an increased risk of infant mortality, preterm birth, and low birth weight.[128] Those with more severe asthma have a higher risk of complications.[128] However, this study did not find an increased risk of congenital defects.[128] A mother whose asthma is well controlled and free of complications imposes no additional risk to the fetus.

The goals of asthma treatment during pregnancy are to prevent acute exacerbations and to optimize lung function, providing maximum benefit to the health of the mother and the fetus.[2,129] If asthma medications are necessary during pregnancy, one must keep in mind the benefit of keeping asthma under control against the small potential risk for adverse effects from medication. The majority of asthma medications that are used in practice present little to no risk during pregnancy, although prospective well-designed and well-controlled clinical trials do not exist for most medications.[130] In one study, inhaled corticosteroids, beta-2 agonists, theophylline, and montelukast were not associated with an increased frequency of fetal abnormalities.[5,130]

The medications used for the treatment of acute asthma exacerbations during pregnancy are the same as in nonpregnant adults. Allergy immunotherapy can be continued through pregnancy but should not be initiated or altered. The safety of biologics during pregnancy is unknown.[131] The initiation of biologic therapy during pregnancy is generally not recommended. The decision on whether to continue existing biologic therapy once pregnancy is established involves a detailed discussion between the patient and the medical provider. The risks of the medication to the fetus must be balanced with the risk of discontinuation resulting in suboptimal asthma control. Patients electing to continue existing biologic therapy during pregnancy are encouraged to participate in a pregnancy exposure registry.[131]

The FDA currently requires all medication labels to include narrative sections regarding use during pregnancy. The information required includes details regarding pregnancy exposure registries, risk summaries, clinical considerations, and data. They also have similar sections regarding medication use by people of reproductive potential and medication use while lactating. The obstetrician, asthma specialist, and primary care physician should work together to create the safest treatment regimen for the pregnant asthmatic patient.

CLINICAL APPLICATIONS

- A positive allergy test from either skin testing or immunoassay blood testing does not necessarily indicate that the identified allergen is causing symptoms. The clinician must look for clinical significance of the positive result in the context of the patient's medical history.
- The mainstay of chronic controller medications for asthma is inhaled corticosteroids. Chronic controller inhaler regimens should never consist of a LABA or LAMA without an accompanying inhaled corticosteroid.
- It is essential to assess medication compliance prior to escalating pharmacologic therapy for uncontrolled asthma.
- For uncontrolled asthma, the addition of a monoclonal antibody is often more appropriate than pursuing immunotherapy. Monoclonal antibodies are highly efficacious, easy to administer, and have favorable side effect profiles for most individuals.

50 Occupational and Environmental Lung Diseases

Shaun Toomey, Sunkaru Touray, Emil Tigas, and Nicholas A. Smyrnios

50.1 WORK-RELATED ASTHMA

50.1.1 Epidemiology

Asthma affects about 8% of the adult U.S. population, and it is estimated that about 15–20% of patients with asthma have work-related asthma (WRA).[1] Work-related asthma is a chronic inflammatory lung disease characterized by the presence of reversible airway narrowing following exposure to airborne dust, gases, or fumes in the work environment. Work-exacerbated asthma (WEA) is a subset of WRA, which describes asthma that worsens in individuals with a pre-existing diagnosis of asthma occurring in the context of exposure to triggers in the work environment.[2] Work-related asthma is grouped into sensitizer-induced asthma (SIA) and irritant-induced asthma (IIA) based on the mechanism of disease.

SIA is an immune-mediated inflammatory reaction to compounds known to be sensitizers, of which there are over 200. Diisocyanates are the most common cause of SIA in many industrialized areas.[1] Other sensitizers include proteins, polysaccharides, animal dander, castor beans, latex, cobalt, and vegetable gum. SIA is caused by the activation of T-lymphocytes resulting in cytokine-mediated airway inflammation. IIA, on the other hand, is thought to be caused by a direct irritant effect of inhaled chemical compounds on the bronchial wall that results in the activation of inflammatory pathways that cause reversible airway obstruction. It is less common than SIA.

50.1.2 Clinical Presentation and Diagnosis

Sensitizer-induced symptoms are variable and can occur at any time during the workday or toward its end. Symptom remission or improvement typically occurs during weekends and holidays when the patient is away from the work environment. Making a confident diagnosis of WRA first requires establishing a diagnosis of asthma on the basis of a consistent history, associated with reversible airway obstruction on spirometry.[3] In patients without airway obstruction, bronchial hyperresponsiveness demonstrated on bronchial provocation testing with either methacholine or histamine supports the diagnosis. Chest imaging in the form of a chest x-ray is recommended to exclude parenchymal lung disease that may be causing symptoms.

Once a diagnosis of asthma is established, the next step involves demonstrating an objective association between work-environment exposures and worsening lung function as determined by an objective demonstration of airflow obstruction measured by peak expiratory flow rate (PEFR) or FEV1 (forced expiratory volume in one second) on spirometry. The recommended minimum monitoring period should be two weeks at and away from work during which asthma treatment should be kept constant. Worsening of symptoms during work that improves when the patient is away from work is consistent with a diagnosis of work-related asthma. In patients who are unable to continue employment due to symptom limitation, referral to specialized centers for bronchoprovocation testing using occupational inhalational agents is recommended.[4, 5]

50.1.3 Prevention and Treatment

Primary prevention of work-related asthma involves employee education, avoidance of exposure to sensitizing agents; and, where this is not possible, substitution of known sensitizing agents with non-sensitizers. Periodic medical surveillance using respiratory questionnaires with or without spirometry and immunologic tests are recommended secondary preventative measures.[4]

Pharmacotherapy is an adjunct to sensitizer and irritant avoidance in the treatment of work-related asthma and follows recommended guidelines, including the use of short-acting beta agonists (SABA) on an "as-needed basis" for symptom relief, with the addition of an inhaled corticosteroid (ICS) inhaler in moderate cases. An inhaled long-acting $beta_2$–adrenergic (LABA) bronchodilator can be added to the regimen as a "step-up" therapy in refractory moderate-severe cases. Oral steroids are used for severe acute exacerbations, while immunotherapy has been tried in a few small studies with variable efficacy.[6,7] Additional emerging therapies in the severe and difficult to treat allergic asthma population include the use of biologic agents. Omalizumab, an anti-IgE antibody, was shown in one small study of work-related asthma to improve asthma control and corticosteroid use.[8]

50.1.4 Chronic Obstructive Pulmonary Disease

Chronic obstructive pulmonary disease (COPD) is an inflammatory lung disease characterized by irreversible airway obstruction.[9–11] Smoking is the most important risk factor, with more than two-thirds of COPD cases linked

DOI: 10.1201/9781003227793-59

to the long-term effects of cigarette smoking.[12] Another important risk factor is biomass smoke exposure, which has been shown to be a risk factor for the development of COPD independent of smoking status.[13] This is an important consideration in the assessment of obstructive lung disease in non-smokers.

50.1.5 Epidemiology

COPD affects about 10% of the general population, with a prevalence that increases with age and smoking.[10,11] Globally, 65 million people are affected, and COPD kills over 3 million people annually.[14,15] In the United States, it is the third most common cause of death, affecting about 16 million people and causing over 120,000 annual deaths.[16,17] Healthcare costs from COPD are estimated to be over $50 billion annually.[17]

50.1.6 Clinical Presentation and Diagnosis

A diagnosis of COPD should be considered in any patient presenting with a chronic cough, shortness of breath, and sputum production in the context of a smoking history and suspected or established biomass fuel exposure. The latter should be considered in patients originating from low- and middle-income countries in sub-Saharan Africa, parts of South America, and Asia.[18]

COPD is a heterogeneous disease with different phenotypes that include chronic bronchitis and emphysema. Chronic bronchitis manifests as a cough and sputum production on most days for three months in two consecutive years. Patients with an emphysema phenotype have an abnormal and permanent dilatation of airspaces distal to the terminal bronchioles. Emphysema is associated with the destruction of the alveolar walls. Symptoms common to these two major phenotypes include wheezing, fatigue, and loss of appetite.

Spirometry is required to make the diagnosis of COPD. A post-bronchodilator FEV1/FVC less than 0.70 confirms the presence of persistent airflow limitation and identifies the presence of COPD in patients with appropriate symptoms and predisposing risks.[11] Physical examination findings are nonspecific and rarely aid in the diagnosis except in advanced cases where chest wall deformities such a barrel-shaped chest may be present.[19] The disease course is variable, with extended periods of chronic daily symptoms punctuated by periods of acute exacerbations during which there is a sustained worsening of the patient's condition, from the stable state and beyond normal day-to-day variations that necessitate a change in regular medication.[20]

Once a diagnosis of COPD is made, a combined assessment is performed to determine symptom burden, degree of airflow limitation, and the risk of acute exacerbation. To assess symptoms, the modified Medical Research Council (MMRC) or COPD assessment test (CAT) score should be used. Next, the FEV1 is used to classify the degree of airflow obstruction based on the Global Initiative for Chronic Obstructive Lung Disease (GOLD) criteria. Finally, the number of acute exacerbations and hospitalizations in the preceding year is determined. Using these variables, presented in Figure 50.1, patients are categorized into one of four groups (A, B, C, and D). The GOLD criteria present a framework on which treatment is instituted.[11]

50.1.7 Prevention and Treatment

The therapeutic objectives in COPD management include symptom control, prevention of acute exacerbations, and improvement of exercise tolerance. This is usually achieved with a combination of non-pharmacologic and pharmacologic interventions.

50.1.8 Non-Pharmacologic Therapy

Smoking cessation is the most effective non-pharmacologic intervention in preventing COPD and slowing its

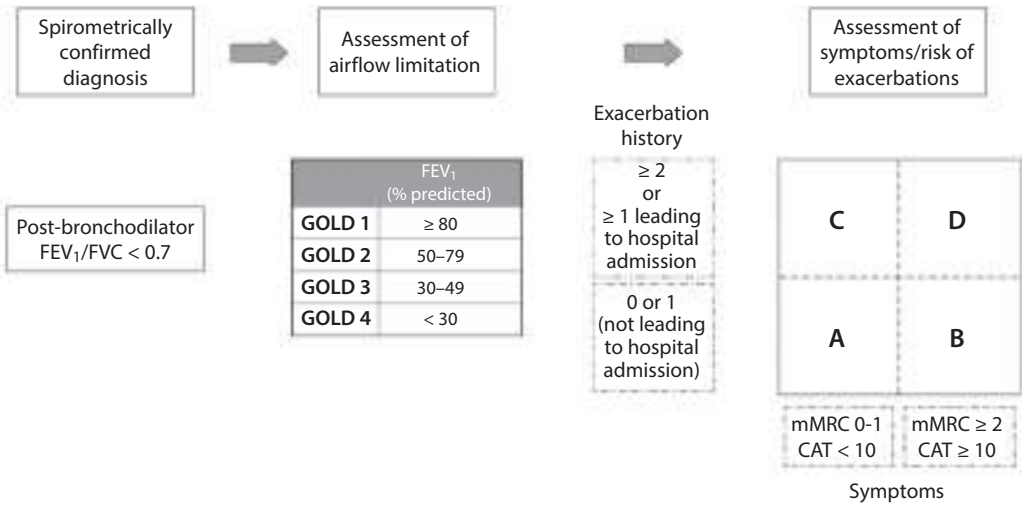

FIGURE 50.1 GOLD COPD assessment tool. (From Global Initiative for Chronic Obstructive Lung Disease, © 2021)

progression. All patients should be offered tobacco cessation counselling.

Assessing medication adherence and training in good inhaler technique are integral parts of patient education.[21,22] Pulmonary rehabilitation is a multidisciplinary program that aims to improve exercise capacity, reduce symptoms, and improve overall quality of life in patients across the spectrum of disease severity and has been shown to improve dyspnea, health status, and exercise tolerance.[21] It is therefore recommended that all patients with COPD be considered for pulmonary rehabilitation as part of a multimodality treatment regime.

Age-appropriate pneumococcal vaccination should be offered to all patients in accordance with established guidelines.[23]

50.1.9 Pharmacologic Therapy

Bronchodilators are the first-line pharmacologic drug class for symptom control and have been shown to improve lung aeration and exercise tolerance. In patients with low risk of acute exacerbation and fewer symptoms (Category A), the use of a short-acting beta agonist (SABA) alone or in combination with a short-acting muscarinic antagonist (SAMA) is appropriate for use as a reliever medication on an as-needed basis. For low-risk patients with high symptom scores (Category B) and high-risk patients (Categories C and D), maintenance therapy is indicated for symptom control. This involves the use of long-acting bronchodilators such as beta agonists (LABA) or a long-acting muscarinic antagonists (LAMA) singly or in combination. Patients in category D may also benefit from the addition of an inhaled corticosteroid (ICS). ICS use as monotherapy is discouraged, and evidence suggests a better outcome in patients on LAMA/LABA compared to an ICS/LABA, with a lower incidence of pneumonia in patients with moderate-to-severe COPD and higher dyspnea scores.[11, 24]

50.1.10 Asbestos-Related Lung Disease

Asbestos-related lung disease is a group of lung diseases caused by exposure to naturally occurring asbestos fibers. These fibers have desirable physical properties for industrial use, such as high tensile strength, flexibility, and resistance to chemical and thermal degradation, hence their prior extensive use in the construction, automotive, and textile industries.[25] Chrysotile (also known as white asbestos) is the most common and only type of asbestos currently used in manufacturing in the United States, while the more toxic amphibole fibers, including crocidolite, amosite, and tremolite are still used in parts of sub-Saharan Africa, South America, and Asia.[26] Asbestos fibers are highly carcinogenic and are known to cause lung cancer and malignant mesothelioma. Asbestos is considered one of the most important occupational carcinogens.[26]

50.1.10.1 Epidemiology

The use of asbestos has been banned in many developed countries. While there is no widespread ban in the United States, its use has been severely reduced. Therefore, exposure is limited to certain occupations such as asbestos removal, construction workers, car mechanics, and plumbers working on old homes and buildings where asbestos was used.[27] Global asbestos exposure is unknown, although it is estimated that worldwide over 40,000 people die of malignant mesothelioma each year.[26]

50.1.11 Clinical Presentation and Diagnosis

Individuals exposed to asbestos are mostly asymptomatic, and the latency period can be as long as 20–30 years between initial exposure and the development of the clinically apparent disease. In patients who develop clinical disease, benign asbestos pleural plaques are a common finding, the development of which suggests prior exposure and is reported to be prevalent in about 60–70% of individuals with an average cumulative exposure of about 32 years.[28, 29] The diagnosis is usually incidental and made during chest imaging for other reasons. Chest x-ray may show a diffuse pleural thickening in the lower portions of the chest, sparing the apices and costophrenic angles, which may be calcified in about 5–15% of cases.[30, 31] Chest CT has a higher sensitivity and specificity and can detect noncalcified pleural plaques.

Malignant pleural mesothelioma (MPM) is a dreaded consequence of asbestos exposure that typically occurs in older (median age 60) men. Patients with MPM present with nonspecific symptoms of dyspnea, cough, chest pain, and constitutional symptoms including fever, chills, night sweats, malaise, and weight loss. Pleural effusions may be present and are usually an exudate with an eosinophilic cellular profile. Unfortunately, thoracentesis has a low sensitivity for diagnosing MPM, hence a surgical pleural biopsy using a video-assisted thoracoscopic approach is the gold standard for diagnosis.[32] Treatment of MPM involves multimodality treatment, including surgery in patients who are good candidates for resection and chemoradiation therapy. In non-operable cases, chemotherapy, palliative radiation, and tunnelled pleural catheters have been employed for symptomatic relief.

Asbestos-associated pulmonary fibrosis (asbestosis) is a less common form of asbestos-related lung disease which may be difficult to distinguish from other causes of pulmonary fibrosis. Chest CT may show honeycombing and upper lobe involvement in advanced stages of the disease. The presence of pleural plaques suggests prior asbestos exposure and raises suspicion for asbestos-associated pulmonary fibrosis but is not confirmatory. Such patients should be referred to specialists familiar with asbestos-related lung disease for periodic monitoring of disease progression and the development of asbestos-associated malignancies.[33, 34]

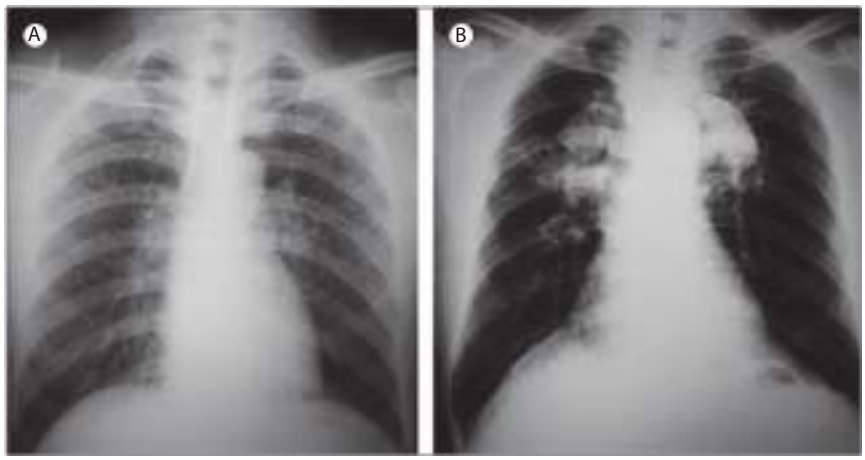
While the carcinogenic properties of asbestos remain an important factor in the longitudinal monitoring of the exposed patients, routine screening for lung cancer in exposed individuals is not recommended in patients without smoking risk factors. Low dose chest CT (LDCT) monitoring has been recommended for lung cancer screening for patients considered at increased risk for based on age and smoking.[35] Low detection rates of malignancy in patients with asbestos exposure in the absence of smoking risk factors does not make screening LDCT a viable or beneficial option in this population.[36]

50.1.12 Silicosis

Silicosis is a fibrotic lung disease caused by inhalation of free crystalline silicon dioxide or silica and is recognized as one of the most important occupational diseases worldwide. Silicon dioxide or silica is the most abundant mineral and occurs in crystalline and amorphous forms.[37] The most common free crystalline forms of silica in workplaces are quartz, tridymite, and cristobalite.[37]

50.1.13 Epidemiology

Silica exposure is highest among individuals employed in construction work involving masonry, heavy construction, painting, and in iron and steel foundries. Metalworking occupations that involve sandblasting, grinding, or buffing of metal parts are also considered high-risk jobs.[37] Global disease burden is difficult to estimate due to lack of disease surveillance in lower-and middle-income countries; however, countries like China and South Africa have reported significant silica exposure, suggesting that the disease burden in these parts of the world may be high. In the United States, about 127,000 miners are reportedly exposed, with a higher rate of disease in African Americans compared to white workers with the same dust exposure.[38, 39]



50.1.14 Clinical Presentation and Diagnosis

Acute silicosis is characterized by rapid onset of symptoms including dyspnea, cough, weight loss, fatigue, and sometimes pleuritic pain and fever following acute exposure to silica.[40] Lung examination may reveal crackles. Chest x-ray may be normal in the acute phase or may demonstrate bilateral consolidation and ground-glass infiltrates. Diagnosis of acute silicosis requires a high clinical index of suspicion and is contingent on establishing an occupational exposure to silica and the absence of other differentials.

Chronic silicosis is characterized by two clinical syndromes on two ends of a disease spectrum, namely, simple silicosis (SS) and progressive massive fibrosis (PMF). In simple silicosis, a chest x-ray may show upper lobe predominant ground-glass opacities; while in progressive massive fibrosis, there are mass-like areas of dense consolidation. Pulmonary function tests may reveal a mixed obstructive and restrictive ventilatory defect and a decreased diffusion capacity. Bronchoscopy may demonstrate a milky lipoproteinaceous bronchoalveolar lavage effluent, requiring the exclusion of other potential causes, including malignancy, pulmonary alveolar lipoproteinosis, and atypical infections such as *Pneumocystis jirovecii* and Norcardiosis. A diagnosis of silicosis can be established on the basis of a documented history of significant silica exposure, consistent chest imaging findings of diffuse nodular and patchy consolidative opacities, and supportive BAL findings in the absence of other causes (Figure 50.2).

50.1.15 Prevention and Treatment

The Occupational Safety and Health Administration (OSHA) recommends limiting exposure to silica using a combination of respiratory protection, medical surveillance, and good record-keeping. Half-face particulate respirators with N95 or better filters are considered appropriate

Chest radiographs of a patient with silicosis
Simple nodular silicosis (A) and progressive massive fibrosis (B).

FIGURE 50.2 Occupational environmental lung disease silicosis.

for silica at concentrations of 50 microgram/m3 or fewer; powered respirators are recommended for exposures above this limit.[41]

50.1.16 Berylliosis

Beryllium is a naturally occurring element that is extracted from ores and processed into metal, oxides, alloys, and composite materials used in the aerospace, automotive, and mining industries.[42] Berylliosis manifests as two clinical syndromes at opposite ends of a disease spectrum. Beryllium sensitization occurs in acutely exposed individuals, while chronic beryllium disease is an inflammatory lung disease affecting individuals who are chronically exposed to beryllium.

50.1.17 Epidemiology

It is estimated that about 134,000 current workers in government and private industry are potentially exposed to beryllium in the United States.[42]

50.2 CLINICAL PRESENTATION AND DIAGNOSIS

Acute exposure to beryllium presents with nonspecific respiratory symptoms, including cough, rhinorrhea, and dyspnea. This is associated with a delayed hypersensitivity reaction resulting in chronic granulomatous inflammation affecting the lungs, a condition known as beryllium sensitization (BeS). About 8% of individuals with BeS, may progress to chronic beryllium disease, characterized by progressive dyspnea, non-productive cough, fatigue, and exercise intolerance as lung tissues are destroyed by chronic granulomatous inflammation.[42] Patients may have constitutional symptoms, including fever, night sweats, and weight loss. Physical examination findings are nonspecific, although bibasilar crackles and digital clubbing may be present. Extrapulmonary manifestations are rare and include uveitis and cardiac conduction abnormalities.

Chest x-ray has a low sensitivity for diagnosing berylliosis in the acute setting, as it may be normal in BeS and early phases of chronic beryllium disease (CBD). Chest computed tomography has a higher sensitivity and may demonstrate hilar adenopathy, upper lobe predominant reticulonodular infiltration in a peribronchovascular pattern that is indistinguishable from sarcoidosis. It has been reported that about 6% of patients undergoing diagnostic evaluation for a clinical suspicion of sarcoidosis were ultimately diagnosed with berylliosis, highlighting the importance of a detailed occupational history to assess for exposure.[43–45] Pleural effusion is an uncommon manifestation of BeS and CBD. Pulmonary function tests may be normal in the early stages of the disease, while in advanced cases airflow obstruction, restriction, or a mixed pattern on spirometry may be present. A reduced diffusion capacity may also be present in advanced cases.

The diagnosis of beryllium sensitization is made on the basis of a positive blood beryllium lymphocyte proliferation test (BeLPT) in a patient with a history of beryllium exposure.

CBD is diagnosed when either blood or bronchoalveolar lavage fluid BeLPT is positive in a patient with a documented history of beryllium exposure. Other features supportive of the disease include consistent radiographic abnormalities and lung pathology demonstrating non-caseating granulomas with lymphocytic infiltration.

50.3 TREATMENT AND PREVENTION

Disease prevention involves the avoidance of inhalation and dermal exposures to beryllium by employing the use of personal protective equipment, administrative changes such as the exclusion of workers from specific areas to prevent nonessential contact, and regular screening of employees involved in activities with exposure to beryllium. Patients with respiratory symptoms suspicious for berylliosis should be referred to a pulmonologist for diagnostic evaluation and treatment, which generally consists of systemic corticosteroids. Inhaled corticosteroids have been shown to decrease respiratory symptoms and cough, but did not affect exercise capacity or spirometry in patients with mild disease.[46]

50.3.1 Coal Mine Dust Lung Disease

Coal mine dust lung disease (CMDLD) refers to a broad spectrum of lung diseases caused by exposure to coal mine dust. It includes disease entities such as coal workers' pneumoconiosis (CWP), progressive massive fibrosis (PMF), Caplan Syndrome, and Chronic obstructive pulmonary disease (COPD).[47, 48]

50.3.2 Epidemiology

Coal is the second largest energy source worldwide, accounting for over 25% of global energy supply and more than one-third of the fuel used to generate electricity. Consequently, the number of individuals exposed to coal particles is considerable, with China, the United States, and India being the top consumers accounting for over 70% of total global consumption. Coal production in the United States is largely concentrated in a few states, including Wyoming, West Virginia, Kentucky, Pennsylvania, and Texas, accounting for over 70% of production.[49] Most coal workers are men; therefore, CMDLD disproportionately affects men, with about 38% of coal miners showing radiographic features of interstitial lung disease. Diagnosis of CMDLD is made clinically on the basis of a combination of an appropriate exposure history, radiological or pathological findings consistent with the diagnosis, and a lack of alternative explanations for the patient's lung disease.[48]

50.4 CLINICAL PRESENTATION AND DIAGNOSIS

Coal workers' pneumoconiosis (CWP) is caused by the accumulation of coal dust in the lungs and classically presents as the occurrence of upper lobe predominant, small, rounded opacities.[48] Most cases are asymptomatic and are detected incidentally as part of surveillance programs or in the context of a diagnostic workup for other conditions.

Progressive massive fibrosis (PMF) is a progressive form of CMDLD found in miners with greater dust exposure. A study found PMF in about 63% of coal miners with a mean coal mining tenure of 27 years in Kentucky and Virginia.[50] It may present with dyspnea, cough, and the production of sputum that has been variably described as mucoid, mucopurulent, and rarely discolored as if mixed with black ink (melanoptysis). Clinical exam findings are nonspecific, and the average interval from a normal chest radiograph to massive fibrosis can be as long as 12 years.[51] Spirometry findings include a restrictive, obstructive, or mixed pattern of impairment, and a reduced DLCO depending on the severity of lung fibrosis.

An association between CWP and rheumatoid arthritis called Caplan syndrome, originally described by Anthony Caplan, describes the occurrence of multiple well-defined opacities on chest radiographs of rheumatoid arthritis patients.[52] CMDLD has also been associated with chronic obstructive pulmonary disease and other pulmonary infections which account for significant morbidity in patients with CWP.

50.5 PREVENTION AND TREATMENT

In the United States, environmental controls are mandated by federal law. Coal dust exposure can be minimized using ventilation systems, water sprays, and other dust capture devices as part of a continuous monitoring program. There is no specific medical therapy that has proven effective in reversing CMDLD. Management involves supportive care, periodic medical monitoring with periodic chest radiographs and spirometry.[47]

50.5.1 High-Altitude Illnesses

It is estimated that more than 30 million people each year travel to and from recreational areas with altitudes greater than 2,500 meters. This presents unique challenges for travellers to these areas, and therefore a good understanding of common problems that arise from exposure to high altitude is important to prevent the development of high-altitude illnesses.[53]

High-altitude illnesses (HAI) are a group of pulmonary and cerebral conditions that occur in the context of a rapid initial ascent to altitudes at a rate that exceeds the body's ability to acclimatize to changes in oxygen tension. The fraction of oxygen in inspired air is constant at 0.21 regardless of altitude, but for each unit change in altitude, there is a non-linear change in the barometric pressure of oxygen that affects the alveolar partial pressure and consequently, oxygen availability to tissues. The physiologic response to this change in oxygen tension is called acclimatization and is characterized by changes in the heart rate, respiratory rate, chemoreceptor sensitivity to hypoxia, and pulmonary vasoconstriction. These act in concert to restore normal oxygen levels in tissues, but when the rate of altitude change exceeds the body's homeostatic capacity, acute hypoxemia ensues, resulting in distinct clinical syndromes primarily affecting the lung and brain.

Risk factors for the development of HAI include pre-existing cardiopulmonary disease, heavy exertion at altitude, low-altitude residence before ascent, and obesity.[54]

50.5.2 Acute Mountain Sickness and High-Altitude Cerebral Edema

Acute mountain sickness (AMS) is the most common presentation of HAI that typically occurs about 6–12 hours after ascent to altitudes above 2,500 meters (8,000 feet). It is diagnosed when an unacclimatized traveller develops a headache, with one of the following symptoms: nausea, anorexia, vomiting, insomnia, dizziness, or fatigue. It occurs in about 10–40% of climbers at 3,000 meters, while more than 50% of climbers experienced symptoms at altitudes greater than 4,000 meters.[55]

High-altitude cerebral edema (HACE) is considered an end-stage form of acute mountain sickness and is characterized by the presence of ataxia and altered mental status in an unacclimatized climber and can occur in the absence of acute mountain sickness or pulmonary edema.

50.5.3 High-Altitude Pulmonary Edema

High-altitude pulmonary edema (HAPE) is a rare life-threatening form of noncardiogenic pulmonary edema that develops two to four days following rapid ascent above 2,500 meters (8,000 feet).

50.5.4 Prevention and Treatment

50.5.4.1 Controlled Ascent

Controlled exposure to hypobaric hypoxia remains the most effective non-pharmacologic means of preventing HAI. Gradual ascent that allows for acclimatization is the most effective preventive strategy. The ideal rate of ascent is variable, but it is generally recommended that at altitudes above 3,000 meters, daily ascent should not exceed 300–500 meters above the previous night with a rest day after every 1,000 meters (or every 2–3 days).[53–56]

50.5.4.2 Pharmacologic Therapies

The use of acetazolamide, a carbonic anhydrase inhibitor, has been shown to be effective in preventing HAI by inhibiting bicarbonate excretion in the kidneys. This results in an

increase in serum bicarbonate and a concomitant increase in minute ventilation. The benefit of acetazolamide for the prevention of AMS/HACE has been demonstrated in multiple trials, and it remains the primary pharmacologic agent of choice.[57, 58]

Dexamethasone, a systemic corticosteroid, has also been shown to have a benefit in HAI prevention and can be used as an alternative to acetazolamide in patients at moderate to high risk for development of HAI. Although dexamethasone does not facilitate acclimatation like acetazolamide, there are prospective trials that show benefit in HAI prevention[59, 60]. The exact mechanism of the benefits remain unclear, but reduced vascular permeability, anti-inflammatory/anti-oxidant effects, sympatholytic effects are thought to play a role[60]. Recommended dosing is 2mg every 6 hours or 4mg every 12 hours. Taper should be used if duration of therapy is greater than 10 days due to the risk of adrenal suppression.

Nifedipine, a calcium channel blocker, has been show to prevent HAPE in a small study and can be considered for HAPE prevention in travellers with a previous history of HAPE. Sildenafil and tadalafil, phosphodiesterase inhibitors, have also been described in prevention of HAPE but evidence remains limited[59, 60].

In patients who develop AMS, rest and descent to a lower altitude are recommended. The Lake Louise Scoring system is a screening tool that can detect AMS/HACE in high-altitude climbers. A score of 3–5 is consistent with AMS, while a score greater than 6 indicates severe AMS/HACE, and such patients should be treated with acetazolamide. The recommended dose is 125–250 mg twice a day. Common side effects include paresthesia, loss of appetite, and nausea. Because acetazolamide is sulfonamide, patients with sulfa allergies should not take this medication (Table 50.1).

50.5.5 Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis (formerly extrinsic allergic alveolitis) is an immune-mediated inflammatory disease of the lung that occurs due to exposure to an inducing agent. Exposure typically occurs in an occupational or recreational setting, which has given rise to an extensive list of diseases, including farmer's lung, bird fancier's lung, and hot-tub lung. It is characterized by a lymphocytic inflammation of the lung due to the accumulation of activated T-lymphocytes in the lung tissues.

50.5.6 Epidemiology

The incidence of HP is about one per 100,000 in the United Kingdom, with a mean age of 57 and an almost equal sex distribution. Incidence in the United States is unknown.[61] In the United States, identified risk factors are quite extensive and include bird and hot-tub exposure, contaminated humidifiers, and exposure to mold or fungi in plants and water systems.[62, 63] Lung fibrosis on chest CT has been associated with poorer outcomes with about 25% of patients with fibrotic HP dying or requiring lung transplantation during a five-year follow-up period.[64]

50.6 CLINICAL PRESENTATION AND DIAGNOSIS

HP presents with intermittent dyspnea, wheezing, cough, and constitutional symptoms, including fevers, chills, and malaise with a temporal relationship to an antigen exposure.[65, 66]

Chest CT is crucial in the diagnostic evaluation of patients in whom a diagnosis of HP is being entertained.

TABLE 50.1
High-Altitude Illnesses and Definitions

Acute mountain sickness	**Headache and *at least one* of the following symptoms:** • gastrointestinal (anorexia, nausea, or vomiting) • fatigue or weakness • dizziness or lightheadedness • difficulty sleeping
High-altitude cerebral edema	The presence of a change in mental status and/or ataxia in a person with acute mountain sickness OR the presence of both mental status changes and ataxia in a person without acute mountain sickness
High-altitude pulmonary edema	The presence of *at least two* of the following symptoms: dyspnea at rest • cough • weakness or decreased exercise performance • chest tightness or congestion • AND *At least two* of the following signs: crackles or wheezing in at least one lung field • central cyanosis • tachypnea • tachycardia

Classical features include an upper lobe predominant centrilobular diffuse micronodular ground-glass opacification and mosaicism.[67, 68]

HP is classified into acute (inflammatory) HP, with a symptom duration less than six months and chronic (fibrotic) HP, with symptom duration greater than six months.[63] Chronic HP is characterized by fibrotic changes in high-resolution computed tomography images or lung biopsy and is associated with a poorer outcome.[63]

Diagnosis of HP requires a high index of suspicion in a patient presenting with typical symptoms and diagnostic imaging. Once the diagnosis is considered, a detailed history looking for potential exposure to an HP-inducing antigen is crucial, although these are identified in only about 50% of cases.[63, 66] A detailed occupational and social history should be obtained to identify any potential exposures in the work environment or during recreational activities.[69]

Pulmonary function tests and referral to a pulmonologist are recommended for further diagnostic evaluation, including bronchoscopy with bronchioalveolar lavage and/or lung biopsy. Specific IgGs have been employed as a screening tool, but these tests are performed only in a few specialized centers.

50.6.1 Treatment and Prevention

The cornerstone of HP treatment involves identification of the offending antigen and avoidance. However, given that an inducing agent remains unidentified in half of patients with HP, consideration of treatment with inflammatory suppression agents in symptomatic patients may be indicated. Prednisone has been used in this scenario while mycophenolate, rituximab, leflunomide and azathioprine have been used as second-line agents or in addition to prednisone to minimize systemic steroid dosing. Evidence for these regimens is limited to small studies and high-quality evidence is lacking.[70–72] Another option in patients with chronic and fibrosing HP would be anti-fibrotic agents such as pirfenidone and nintedanib. Use of these agents were initially described in patients with idiopathic pulmonary fibrosis (IPF) but their use is being expanded to non-IPF progressive fibrosing interstitial lung diseases. Nintedanib has been shown to slow the decline in lung function in this population.[73] Nintedanib may be favored over pirfenidone as one study showed that there is no benefit with pirfenidone therapy in patients with interstitial lung disease other than IPF [74]

50.7 LUNG TRANSPLANTATION IN OCCUPATIONAL LUNG DISEASE

Despite increased awareness of occupational lung disease and preventive measures through exposure control and monitoring programs, there is a subset of patients that progress to end stage lung disease where lung transplantation is the remaining therapeutic option. Lung transplantation has been performed in the USA for occupational lung diseases, most commonly for coal workers pneumoconiosis or silicosis. Metal pneumoconiosis, berylliosis and asbestosis are less common indications.[75]

CLINICAL APPLICATIONS

- A diagnosis of work-related asthma should be suspected in any patient with asthma that is difficult to control.
- COPD should be considered as a diagnosis in any patient with dyspnea from parts of the world where there is significant exposure to biomass fuel or coal mining (even among non-smokers).
- Employees involved in industries with exposure to silica, coal, asbestos, and beryllium should undergo periodic surveillance for pneumoconiosis using history, lung function testing, and chest imaging.
- Travelers to high altitudes should receive information on high-altitude illnesses and be counselled on how to prevent, recognize, and treat symptoms of these syndromes.

51 Venous Thromboembolic Disease

Joseph Gallant, MD and Khabib Dgayli, MD

KEY POINTS

- Venous thromboembolism (VTE) is a common, morbid, and costly disease process with a multitude of risk factors.
- Risk factors for the development of venous thromboembolic disease are commonly present in combination rather than isolation.
- The role of modifiable risk factors for VTE, such as immobility, obesity, and smoking, is an area of growing interest.
- More study is needed to define the impact of modification of these risk factors with respect to VTE or VTE recurrence in individual patients,

51.1 VTE INTRODUCTION/OVERVIEW

Venous thromboembolic disease (VTE) in the form of deep venous thrombosis (DVT) and pulmonary embolism (PE) is a common, costly, and morbid problem encountered by both generalists and specialists in a variety of medical and surgical fields. As our understanding of the many risk factors for the development of VTE has grown, and as our approach to diagnosis and treatment has become more complex, it has become necessary to adopt an increasingly broad and multidisciplinary approach to the management of these patients; there is growing evidence that the principles of lifestyle medicine should become a central component of any comprehensive VTE management strategy.

Risk factor interaction is critical to the understanding of both VTE development and management. While it is true that many risk factors for the development of VTE have a non-modifiable genetic basis, or may exist because of an otherwise healthy or necessary exposure (e.g. oral contraceptive pills [OCP] use or surgical immobilization), others are a direct consequence of health or lifestyle choices. Application of the principles of lifestyle medicine can therefore reduce the overall risk of developing VTE due to their influence over several important risk factors that are synergistic, common, and *modifiable*. This concept of risk factor synergy acknowledges that the presence of *specific combinations* of individual factors engenders an overall risk that is potentially much greater than the sum of their individual contributions.[1] While the precise pathophysiological mechanisms underlying the interactions of these modifiable risk factors are not fully understood, we do know that adequate levels of physical activity, smart nutritional choices for maintenance of a healthy weight, and avoidance of cigarette smoking can play a prominent role in the overall management of patients at risk for, or who have developed, DVT and subsequent PE.

51.2 EPIDEMIOLOGY

Accurately assessing the true incidence of VTE disease is challenging due to the unknown number of asymptomatic DVTs or PEs that are suspected to occur each year. Asymptomatic PE alone is believed to complicate up to 50% of all confirmed cases of DVT.[2] In a retrospective study looking at 7,238 patients with 11,747 computed tomography (CT) examinations over a 5.5 year period, incidental (and unreported) PEs accounted for 54% of all PE events.[3] Estimates suggest a combined incidence rate of 1 in 1,000 people per year, with the rate of diagnosis of PE being approximately half of that of DVT (60 vs. 124/100,000).[1,4] Centers for Disease Control (CDC) data are in agreement, with up to 900,000 people affected each year in the United States.[5] As many as 80% of new cases of VTE will occur in the context of at least one, and often more than one, known risk factor.[6]

Based on updated analyses, VTE continues to disproportionately affect patients with malignancy despite broad application of best practices in prevention. In a 2021 systemic review and meta-analysis of 23 studies comprising a total of 12,977 patients, 4,200 (32.4%) incidental instances of VTE were observed.[7] In the last several years, COVID-19 infection has emerged as an important risk factor for the development of DVT and PE, and this remains an area of intense study. In a recent meta-analysis[8] of 66 studies involving 28,173 patients (19.4% of whom were intensive care unit patients), VTE prevalence was estimated at 14.1%. When asymptomatic ultrasound screening was utilized (14 of the 66 included studies), the prevalence of VTE was as high as 40%. More high-quality data are necessary to clarify the interactions between COVID-19 and more established risk factors for VTE.

The morbidity and mortality of VTE are difficult to quantify precisely and likely vary significantly with underlying patient comorbidities, characteristics of the VTE itself, as well as access to treatment.[9] PE is associated with most of the directly attributable mortality. Population data collected over the last several decades demonstrate an overall mortality rate of untreated PE as high as 30%, improving to 8% with prompt recognition and treatment. The highest mortality rates are observed in patients presenting in cardiogenic shock due to massive PE (up to 65%) or mobile

DOI: 10.1201/9781003227793-60

thrombus within the atria (up to 27%). It is estimated that up to 100,000 deaths annually in the United States are due to complications of VTE.[10]

Both PE and DVT contribute to the morbidity and the societal costs associated with VTE. Much of that comes from the impact of chronic thromboembolic pulmonary hypertension, VTE recurrence, and peripheral vascular dysfunction due to damage to the valves in the deep leg veins. Using data obtained from nearly 27,000 U.S. cases of DVT and PE from 1997 to 2004, it has been estimated that average annual individual healthcare costs increase from approximately $7,000 pre-event to $17,500 and $25,000 after events of DVT and PE, respectively.[11] In this data set, the presence of post-thrombotic syndrome was also a strong driver of additional medical costs that extended far beyond the time of diagnosis and treatment. The relatively high pre-VTE annual medical expenditure in this cohort, compared with less than $1,000 in annual healthcare costs in age-matched, "healthy," controls, was thought to be due, in part, to pre-existing comorbid diseases in this population. The aggregate annual economic burden of VTE in the United States, including longitudinal cost of therapy and management of side effects, has been estimated to be between $7 billion and $10 billion per year.[10]

The costly, morbid, and frequently mortal nature of VTE is reason enough to explore all reasonable avenues of risk reduction and therapy optimization. As we will see later in this chapter, application of the principles of lifestyle medicine may represent an accessible, cost-effective, and efficacious adjunct to the growing technological arsenal of diagnosis and therapy.

51.3 PATHOPHYSIOLOGY

The development of VTE is dependent on the local interaction of venous stasis, vascular endothelial injury, and intrinsic hypercoagulability in the paradigm attributed to Virchow in 1856.[12] Though a detailed exploration of the hematological mechanisms of clot formation is beyond the scope of this text, there are several key ideas to understand as they pertain to the development of DVT and subsequent PE.

The risk of thrombosis can be thought of as proportional to the cumulative impact of multiple risk factors.[13] It has also been observed that while venous stasis is likely the most important contributor to DVT (and by extension PE), stasis in the complete absence of endothelial disruption or hypercoagulable state is likely insufficient for clot formation. While global stasis in the context of absent muscular contraction (such as during general anesthesia) has been linked to thrombosis, autopsy and physiological studies have also demonstrated that the local effect of eddy currents in venous sinuses adjacent to the valves of the large veins creates a microenvironment of relative hypoxia and increased viscosity, which further enhances the propensity to clot.[12,14] It has been theorized that this low–oxygen tension environment further contributes to clot formation, as it promotes the downregulation of antithrombotic proteins that are otherwise expressed in greater concentrations on the endothelial surface of such valves.[15] A similar imbalance in pro- and anticoagulants is also seen in locations of decreased endothelial cell surface to blood volume, such as the large femoral and iliac veins, and may explain the higher rates of clot formation in those areas.[16] The prothrombotic effect associated with inherited or acquired defects in expression of the constituents of the fibrinolytic and clotting pathways is magnified at such sites.[17]

51.4 EMBOLIZATION TO THE PULMONARY VASCULATURE

A perfect understanding of the frequency of embolization of these lower extremity clots is impossible, given the suspected frequency of asymptomatic DVT. Data derived predominantly from the surgical literature have provided some insight into features impacting the likelihood of progression, however.[18] While it is true that the development of de-novo thrombosis of the large veins in the periphery is dependent upon the factors noted earlier, the likelihood of subsequent embolization of these clots to the pulmonary vasculature has been linked only to the proximity of the clot to the central circulation.[19] These data also suggest that nearly all venous thrombotic events are asymptomatic until they reach the proximal veins (cephalad to the popliteal circulation).[20,21] In a consecutive series of 189 patients with clinically suspected lower extremity DVT, only 11% had distal calf DVT only, and more than 90% had continuous clot extension from the calf to the proximal veins.[18] It has been estimated that nearly half of the patients with symptomatic proximal DVT will have imaging evidence of pulmonary emboli at the time of diagnosis, and one-third will be diagnosed with concurrent PE, even in the absence of chest or respiratory symptoms.[22,23]

It should also be noted that the majority of these observations were made decades ago. With the now widespread use of multidetector CT scan, our ability to detect small PEs has significantly improved. Therefore, these older data may underestimate the frequency of embolization from proximal clots. It seems reasonable to conclude that the natural history of untreated DVT is one of eventual progression and ultimately, distal migration. The risk of such an event is believed to be highest immediately following the development of thrombosis, and this risk declines over a period of several months as the stabilization effects of partial resorption and endothelization of distal clot progress.[24]

51.5 RISK FACTORS

It is likely that truly idiopathic VTE or PE is rare, and the majority of VTE occurs in the context of at least one, and often multiple, risk factors.[25] The risk factors that predispose the patient to clot can be divided generally into two groups: inherited (e.g. genetic clotting disorders) or acquired (e.g. undergoing surgery).[26] Though these risk factors might

appear varied and unrelated, the final common pathway of clotting is the perturbation of the local vascular microenvironment such that some or all of Virchow's triad is satisfied.[27] There are several published data sets that enhance our understanding of both the relative *individual* strength of risk factors and the interplay of acquired and innate risks when present *concurrently*.[28]

Describing the effect of a single risk factor is straightforward: surgery with general anesthesia and the presence of malignancy are implicated in as many as one-third of all cases and are likely the most important single risk factors for the development of VTE.[25,29–31] Delineating the synergistic effects of multiple concurrent risk factors is more complex but more reflective of real patients and real risk. Using the example of surgery: in one of the largest (4,311 cases) case-control studies of VTE, it was observed that the combination of surgical immobility and non-malignant medical illness (including renal or liver disease, heart failure, and cerebrovascular accident [CVA]) increased the odds ratio (OR) for the development of VTE by 10.9 (95% confidence interval [CI] 4.2–28).[32] The addition of any of the inherited thrombophilias to that combination increased the OR to as high as 88. For the purposes of this text, we will focus primarily on the complex synergistic interaction between several pertinent lifestyle-related health choices: risk of immobility or a sedentary lifestyle, obesity, and smoking.

51.6 IMMOBILITY

Interest in the development of VTE due to prolonged non-surgical immobility has existed since it was first observed that there was a sixfold increase in the risk of fatal PE in patients who sat for prolonged periods of time in air raid shelters during the London Blitz of World War II.[33] More recently, it was reported that rates of incidence of distal DVT in patients requiring cast immobilization without surgery may be as high as 19% (35/188).[34] The risk associated with airline travel is likely the most intensely scrutinized, though it remains controversial. Estimates from prospectively obtained data sets indicate that the risk of DVT may be twice that of non-flyers.[35] On the other hand, the overall incidence of PE may be as low as 4.8 per million patients travelling more than 6,000 miles. However, these data may underestimate the true incidence of minimally symptomatic and non-embolizing distal clot for the reasons described earlier.[36] Of note, it has been suggested that it is not only the lack of movement while flying, but concurrent mild hypoxemia (cabin PaO_2 of 72 mmHg) that promotes coagulation.[37,38] As such, and given the frequency of multiple risk factors present in the same patients, it is challenging to quantitate the risk of immobility itself during activities such as airline travel.

Immobility not related to airline travel is less well-described but of increasing importance. As the modern office becomes more de-centralized, and Americans spend more and more time with their computers for both work and recreation, there has been an increase in individual case reports and case series describing the development of significant DVT related to elective, non-flight-related immobility.[39] In one of the largest series of its kind, 61 consecutive patients with VTE were surveyed and tested for underlying thrombophilia. Multiple risk factors were present in the majority of patients. Prolonged seated immobility was the second most common risk factor after a family medical history of thrombosis. This study defined "prolonged" as sitting a cumulative 8 hours in a 24-hour period (with at least 3 hours unbroken), 10 hours in a 24-hour period (with at least 2 hours unbroken) or 12 hours in a 24 hour period (with at least 1 hour of continuous sitting). Thirty-four percent of patients with a new diagnosis of DVT demonstrated this finding.[40] A follow-up case-control study attempted to describe the OR specifically associated with work-related immobility. Ninety-seven consecutive patients with radiographically confirmed VTE (both DVT and PE) were administered a questionnaire almost identical to that used in the Aldington case series. These patients were then matched to controls from the same center admitted over the same time period. Following univariate analysis, authors found that immobility due to work or recreation carried an OR of 2.2 (CI 1.0–5.0) for the development of VTE. While this is an important observation, the effect was modest, especially when compared with the effect of recent surgery or family history of VTE in this same data set (OR 70.6 and 5.7, respectively).[41] Interestingly, the total duration of hours spent sitting, irrespective of frequency or duration of breaks, had a direct relationship with an increasing risk of VTE.

51.7 OBESITY

In parallel with the rapid rise of the obesity epidemic in Americans, there has been increasing interest in understanding the role that obesity plays in the development of DVT and PE. Although obesity has been theorized for decades to exert a pro-coagulant effect, it is only in the last few decades that we have seen significant data in support of this association.[42–46] Several meta-analyses and large population cohort studies have supported the link between increasing body mass index (BMI) and the risk of VTE. The largest of these meta-analyses includes data from 21 case-control and cohort studies and represents 63,552 patients diagnosed with PE or DVT over the last 5 decades. Obesity, defined as BMI >30 kg/m^2, carried an OR of 1.84 (95% CI, 1.55 to 2.18; $I^2 = 69.2\%$; $P = 0.01$) for the development of VTE. The average BMI in the cohort of patients who developed VTE was 1.7 kg/m^2 higher than their matched controls.[47]

Though focused on a homogeneous population, data published in 2010 from the Copenhagen City Heart Study also found obesity to be an independent risk factor for the development of VTE.[48] Based on their evaluation of more than 360,000 patient-years and nearly 1,000 individual

cases of VTE, they observed that a BMI of 30 to 35 carried a hazard ratio (HR) of 1.65 (1.17–2.34, $P = 0.005$) for the development of DVT or PE. Their data set also suggested the possibility of graded risk with rising BMI, as the subset of patients with BMI over 35 kg/m^2 had a HR of 2.1 (1.39–3.16, $P < 0.001$). A similar trend was observed by Tsai et al. in the Longitudinal Investigation of Thromboembolism Etiology (LITE) study when they combined data from Atherosclerosis Risk in Communities (ARIC) (a prospective epidemiological study focused on four American communities) and the Cardiovascular Health Study (CHS).[49,50] These authors observed increasing HR for VTE proportional to rising quintile of BMI from <25 to >40.[42] Further understanding of this proportional risk requires additional study.

In addition to its independent impact on coagulation, obesity has also been associated with a magnified risk of DVT and PE, not only in certain populations (most notably women) but also in the context of other acquired and inherited risk factors. Data from both the all-female Nurses' Health Study and the Multiple Environmental and Genetic Assessment (MEGA) study show increased risk of VTE in obese female patients on OCPs.[51] Using subjects with a BMI <25 and no OCP use as a baseline, it was observed that patients on OCPs and a BMI between 25 and 30 had an OR of 11.63 (95% CI, 7.46–18.14) for the development of VTE. As BMI rose above 30, that OR similarly rose to 23.78 (95% CI 13.35–42.34).

The risk of VTE associated with obesity and the Factor V Leiden gene mutation was also demonstrated to be significant. Though the presence of this genetic abnormality was itself associated with an OR of 4.18 in normal weight patients (BMI <25), that OR rose to 5.77 and 7.86 at BMI levels of 25–30 and >30, respectively. The combined effect of obesity and prothrombin gene mutation was of a similar scale. Although it is unclear why obesity increases the risk of DVT and PE, investigators have recently shown that increasing levels of obesity correlate with increased levels of clotting factor VIII and activated protein C resistance, possibly due to the establishment of a chronic inflammatory state.[52]

In addition to its impact on the development of the first episode of VTE, obesity has also been observed to increase the risk of recurrence after treatment of an initial event. In a recent prospective study, investigators followed more than 1,000 patients for an average of 46 months following their first episode of unprovoked DVT and completion of anticoagulation therapy. They observed a recurrence rate of 9.3% in patients with normal BMI (<25 kg/m^2) and 16.7% (95% CI 11.0–22.3%) and 17.5% (95% CI 13.0–22.0%) among overweight and obese patients, respectively. The average BMI in those who suffered a recurrence at all in the 4 years of the study was 28.5 compared with 26.9 in those who were clot-free at the end of 46 months ($P = 0.01$).[53] These data suggest that efforts to reduce BMI through healthier lifestyle choices may have an impact on management of VTE.

51.8 SMOKING

Though smoking, and specifically cigarette smoking, has long been understood to be an independent risk factor for the development of arterial atherosclerotic disease, its role in the development of venous thromboembolic disease is less well understood. This controversy stems from conflicting data, to which a 2008 meta-analysis not supporting smoking as an independent risk factor for DVT or PE was central.[54]

In 2008, Ageno et al. collated more than 20 years of observational data regarding the overlap between VTE and traditional cardiovascular disease risk factors, finding that smoking carried a (non-significant) increased risk of 1.18 (95% CI 0.95 to 1.46).[54] Other small and more narrowly focused population-based studies also argued *against* smoking as an independent risk for VTE.[42,55,56] The largely retrospective data set generated by Ageno could not be evaluated in a way that controlled for the coexistence of other VTE risk factors such as age, increasing BMI, recent surgery, presence of concurrent malignancy, or diagnosed thrombophilia.[54] Six of the included studies were focused on the interplay of VTE and OCPs and thus, had a narrow population focus. The presence of VTE was not necessarily confirmed by accepted diagnostic practices such as CT or ultrasound, and no distinction was made between current and former smokers.

In contrast, Cheng et al. published a meta-analysis of 32 studies comprising 35,151 VTE events in 2013.[57] Studies lacking additional risk factor data or specific details regarding cigarette use were excluded from their analysis. They reported that after controlling for known VTE risk factors in a generalizable population, current smokers compared with never smokers had a statistically significant risk ratio (RR) of 1.23 (95% CI 1.14–1.33) for the development of VTE. They also reported that this risk increased by 10.2% (95% CI 8.6–11.8%) for every ten additional cigarettes per day or by 6.1% (95% CI 3.8–8.5%) for every additional ten pack years of smoking. Similar modest increases in the observed RR of VTE in smokers have been reported by several smaller studies.[51,58]

Mahmoodi et al. evaluated the role of cardiovascular disease (CVD) risk factors (such as smoking) in the development of VTE using only prospectively identified and definitively diagnosed cases of VTE.[59] The study demonstrated that while current smoking did carry a modestly increased HR of 1.19 (95% CI 1.08–1.32) for the development of VTE, this *overall* effect was attributed entirely to the effect observed in the subgroup of patients ultimately diagnosed with a provoked clot over the 4.7 to 19.7 years of follow-up (again highlighting the synergistic effect of multiple risk factors, qualitatively). Most recently, Gregson et al. analyzed data from the ERFC (731,728 participants) and UK biobank (421,537 participants) data sets with a median follow-up of 15.4 years. They showed current smoking to be associated with VTE in both data sets. The HRs were 1.38 (1.2–1.58) and 1.23 (1.08–1.40) in ERFC and UK biobank, respectively.[60]

The importance of smoking as a cofactor in the development of VTE is further supported by a body of evidence that demonstrates the synergistic effect of smoking in the context of known, non-lifestyle-related risk factors such as presence of a thrombophilic gene mutation or recent surgery.

Of the many genetic risk factors for VTE that have bene identified, the most well established are Factor V Leiden (FVL) and prothrombin gene mutations.[61] It has been estimated that up to 8% of patients with DVT will carry one of these mutations.[62] Though estimates vary , heterozygosity for these mutations has been associated with a statistically significant HR for VTE of approximately 2.6 for each locus individually and as high as 5.66 when found together.[63] It has also been observed that there is some degree of variability in the incidence of VTE in patients with known mutations, with many patients never developing VTE despite exposure to known, potent cofactors.[64] Hypothesizing that lifestyle choices (specifically smoking and obesity) may therefore exert an influence over the variable development of VTE in these patients, Severinsen et al. examined the dose–response impact of smoking on the development of VTE in patients with known FVL and prothrombin gene mutations.[65] Though the relatively small number of VTEs in the study group may have overestimated the effect of smoking, they reported a HR for VTE of 4.46 (95% CI 1.83–10.88) and 76.8 (95% CI 29.2–201.7) in patients with FVL and prothrombin gene mutation, respectively, who smoked more than 25 g of tobacco (slightly more than one pack of cigarettes) per day. Also of note, matched wild-type controls in this study who smoked less than 25 g/day of tobacco were not observed to have an increased risk for development of VTE.

It is well-established that the use of estrogen and combined OCPs is itself associated with an increased risk of VTE, which has historically ranged between two and four times that of matched controls.[66] Variability in the rates of VTE has in many large reviews and meta-analyses been attributed predominantly to differences in the progestin component of these medications.[67] Pomp, et al reported an OR of 8.79 (95% CI 5.73–13.49) in the subset of patient on OCPs who identified themselves as current smokers.[51] Further subgroup analysis of these data also demonstrated a direct, proportional increase in the risk of VTE with daily smoking, similar in magnitude to that effect observed by Cheng et al. Similarly, Traven et al. looked at the risk of VTE in females undergoing arthroscopy and anterior cruciate ligament (ACL) reconstruction. Obesity and smoking increased the risk of VTE in patients taking combined oral contraceptives, with an OR of 3.1 (1.99–4.65) and 4.3 (2.41–7.50), respectively.[68] Finally, data from the surgical literature suggest an association between marijuana use and VTE in trauma patients.[69,70] Causality, however, cannot be established, and more studies are required to further elucidate the link between these two entities.

We can conclude from these studies that while some CVD risk factors increase the risk of VTE, it is likely the synergistic effects of multiple risk factors (both acquired and inherited) that lead to the development of VTE.

51.9 DIAGNOSIS

The diagnosis of PE is dependent on the maintenance of a high degree of clinical suspicion, which is itself enhanced by an awareness of the common risk factors described earlier. While the clinical presentation can be variable, and that variability can be independent of the size or location of the clot, several large study populations have demonstrated a number of more commonly observed features.[23,44,71] These include dyspnea (present in nearly three-quarters of patients) and pleuritic chest pain (in two-thirds of patients). Tachypnea has been observed in half of patients presenting with PE. Cough and evidence of lower extremity DVT are present in nearly a quarter of patients at the time of diagnosis of PE. Rapidity of the onset of symptoms is seconds to minutes in more than 75% of cases.[24,44] High risk presentations characterized by refractory hypoxemia, obstructive shock, or cardiac arrest are comparatively rare but require a specific approach to initial management: while it has been observed that the duration of symptoms prior to diagnosis has a direct relationship with increasing size of clot burden, this relationship was not significantly associated with these high morbidity presentations.[72]

A large meta-analysis, which included more than 25,000 cases of PE, suggested that the clinical impression of physicians, based predominantly on consideration of these symptoms, may carry a sensitivity of 85% though understandably, a low specificity (51%) for the detection of PE.[71] Driven partly by these data, and in part by the need of enhanced focus on healthcare expenditure and resource utilization in the last several years, there has been increasing interest in a simple, standardized schema to identify very low-risk individuals.[73] The PERC rule (pulmonary embolism rule-out criteria, a set of eight clinical and patient features used to predict risk of PE on initial presentation) was developed as a tool to accomplish just that aim, demonstrating excellent performance.[74]

Laboratory tests can play an important role in risk stratification and in ruling out pulmonary embolism in patients who have a low pre-test probability based on clinical assessment or standardized scores (e.g. Wells) but are not strictly necessary for the diagnosis of PE. d-Dimer specifically has been studied extensively, and a negative test effectively rules out embolism and obviates the need for further testing in these low-risk groups.[75] An area of active research is the use of elevated and age-adjusted d-dimer thresholds. A recent randomized controlled trial (RCT) found that using different d-dimer thresholds combined with a validated algorithm (YEARDS) was non-inferior to conventional strategy while leading to a significant reduction in chest imaging.[76,77] Nonetheless, the performance, and therefore utility, of this test is degraded significantly in populations with a high prevalence of PE or with a medical history associated with elevated levels (hospitalized patients, the elderly, or those

with end-stage renal disease [ESRD]).[78] This is especially confounding given what has already been described regarding the increased risk of thrombosis in individuals with these features; many patients with these features but low to intermediate risk will undergo definitive testing, with understandably higher rates of negative studies.

The standard of care in diagnosing those with a high pre-test probability of PE is well established: modern studies support the use of CT scan protocoled for opacification of the pulmonary arteries. The performance characteristics of this test can vary with the pre-test probability of PE: PIOPED II data demonstrated a sensitivity and specificity of 90% and 96%, respectively, in patients with high suspicion for PE.[23] False negatives do occur across all groups, though as infrequently as 0.07% in high suspicion groups.[79] Technical challenges such as obesity, movement artifact, or incorrect contrast bolus timing can disproportionately reduce the accuracy of the test at the subsegmental level; interobserver variability among radiologists has been as high as 50% in such cases.[80] Finally, V/Q scans have a role in the diagnosis of PE in patients who otherwise cannot tolerate a contrasted CT scan of the chest. A systemic review and meta-analysis of 19 studies (6,393 examinations in 5,923 patients by Phillips et al.) found single photon emission computed tomography (SPECT) V/Q to be as effective as CT in diagnosing pulmonary embolism, and found both to be superior to planar V/Q.[81]

51.10 TREATMENT

The approach to treatment of VTE is dependent upon a variety of disease and patient factors that influence the choice of therapeutic agents and duration of anticoagulation therapy. These include the location of the clot (distal lower extremity vs. proximal lower extremity/pulmonary embolism), presence of hemodynamic instability, features of the underlying provocative risk factors, and vulnerability to serious adverse effects of treatment (i.e. bleeding risk).

Many of the recent investigations center around the use of direct oral anticoagulants (DOACs) (rivaroxaban, dabigatran, etc.) in the treatment of DVT and PE. Historically, vitamin K antagonists (such as warfarin), heparin infusions, or subcutaneous low molecular weight heparin injections were the standard of care. Though in some cases they remain as such, there is growing evidence to suggest that DOACs are safe and effective.[82–85]

The American College of Clinical Pharmacy (ACCP)'s *Antithrombotic Therapy for VTE Disease*, Second Update in 2021, is the most widely accepted standard for VTE management, and a highly condensed summary is included in the following. In patients with VTE but no malignancy:[86,87]

- Dabigatran, Rivaroxaban, Apixaban, Edoxaban are all recommended over warfarin.
- Dabigatran (150 mg twice daily) and Edoxaban (30 or 60 mg once daily) are preceded by a period of parenteral anticoagulant, usually a low molecular weight heparin, for *5–10 days*.
- Rivaroxaban (15 mg BID × 21 days, then 20 mg daily, all with food) and apixaban (10 mg BID × 10 days, then 5 mg BID) do not require initial Rx with low molecular weight heparin (LMWH).
- These recommendations are based on these factors:
  - Risk reduction for recurrent VTE appears to be similar to warfarin.
  - Risk reduction among these drugs appears to be similar.
  - Risk of intracranial bleeding appears to be less than warfarin.
  - Fatal bleeding is no higher than warfarin.
  - These medications are more convenient for patients and may lead to better compliance.
- If a choice is made to use warfarin, initial LMWH is used for a minimum of five days.
- If a heparin product is used, low molecular weight heparins are considered superior to unfractionated heparins in most cases.[88]

Duration of therapy is another extensively studied and debated issue in the treatment of VTE. The nature of underlying risk is of central importance to this decision. The key consideration in addressing duration of therapy is recurrence prevention, and data have shown that irrespective of the agent used in anticoagulation, there is an elevated risk of recurrence following discontinuation of treatment after 3, 6, or even 12 months.[89] The risk of recurrent VTE instead likely varies with the persistence of provocative risk factors: the largest data set available identifies presence of malignancy, age, BMI, and persistent neurological deficits as independent predictors of recurrence.[89] Conversely, the surgical literature demonstrates that isolated DVT following surgery is adequately treated with three months of anticoagulation, and treatment duration beyond this point confers no benefit in recurrence prevention.[90] Cohorts of patients with "unprovoked" thrombosis likely have a higher rate of recurrence than the general population, and as a reflection of that observation, consideration should be given to indefinite anticoagulation.[90]

It has not been demonstrated whether clots arising in the context only of the previously identified lifestyle related risk factors are more or less likely to recur following modification of the risk. While it is tempting to assume that weight loss, avoidance of prolonged periods of sitting, and smoking cessation would return baseline thrombosis risk to "normal" levels, this is unknown.

The following special situations may require tailored management strategies.

51.10.1 Massive PE

Hemodynamic instability acts as a critical branch point in all recommended treatment algorithms. Patients at high

risk of death presenting with obstructive shock should be considered for administration of thrombolytic therapies.[86,87] The potential benefit derived from thrombolysis is believed to be a continuum, varying directly with the patient's risk of imminent death from their VTE episode and inversely with their risk of major bleeding (most notably intracranial hemorrhage). The tipping point for potential benefit is hard to identify, however, due to the dearth of data precisely describing patient characteristics and outcomes after receiving thrombolysis. That being said, guidelines published by ACCP (2021)[87] and European Society of Cardiology/European Respiratory Society (ESC/ERS) (2019)[91] recommend full dose thrombolysis alongside anticoagulation for patients with hemodynamic instability.

Furthermore, studies have attempted to describe outcomes in patients with intermediate risk/sub-massive PE. The ESC/ERS guidelines propose a classification of patients with pulmonary embolism by early mortality risk. This model uses a combination of hemodynamic instability, clinical parameters of PE severity, right ventricular (RV) dysfunction, and cardiac enzymes to risk stratify patients. A recent study attempted to describe outcomes in "intermediate risk" patients (as defined by aggregate evidence of RV dysfunction but in the absence of true shock). Although more than 1,200 patients with acute PE and evidence of RV strain were randomized to receive tenecteplase and heparin (vs. heparin alone), no clear net benefit was identified due to the counterbalancing effect of increased bleeding (including intracranial bleeding).[92] Pending further data to suggest benefit and delineate the optimal target patient population, it is recommended that patients with intermediate risk PE receive anticoagulation as a first line therapy. Both ESC/ERS (2019) and ACCP (2021 update) guidelines recommend escalation to reperfusion therapy with thrombolysis in patients who fail to respond. Notably, ACCP guidelines recommend thrombolytic therapy in those who deteriorate but are not yet hypotensive, while ESC/ESR recommends it in those who develop hemodynamic instability.

The technical method of thrombolytic delivery has also been an area of research interest, and it has been hypothesized that PA catheter-directed thrombolysis (CDT) (versus peripheral vein infusion) would carry a lower risk of serious bleeding. Data are currently limited to mostly small trials with limited generalizability of results. Based on the current body of evidence, CDT leads to resolution of clot faster than heparin alone and is potentially associated with a lower risk of major bleeding compared with systemic infusions.[93,94] Catheter-directed therapy and systemic thrombolysis, however, have not been compared head to head in any trial to date. While recommendations may change as more evidence accumulates, current guidelines reflect this paucity of data and favor systemic therapy over CDT except in cases with simultaneously increased risk of mortality and bleeding.[87]

51.10.2 Distal DVT

Distal thrombosis of the extremities that has occurred with or without a potentially modifiable risk factor does not uniformly require anticoagulation. The decision to treat these patients with anticoagulation should be based on an evaluation of the patient's symptoms, risk of adverse bleeding events, and risk of recurrence or progression of clot conferred by their medical history. An approach to patients with distal DVT includes performing serial duplex ultrasounds of the lower extremities for a period of two weeks off anticoagulation.[87] An absence of symptoms or clot progression over this surveillance interval suggests that the patient is at low risk for embolization or clot propagation. Candidates most likely to benefit from such a treatment plan will have good cardiopulmonary reserve, small distal clot, and no concurrent PE.[95] Current guidelines recognize that shared decision-making may result in a higher value being placed on definitive therapy rather than a period of uncertainty, and this cohort of patients is likely at low risk of serious bleeding events with anticoagulation.[96]

51.10.3 Isolated Subsegmental PE

Isolated, asymptomatic, subsegmental pulmonary emboli detected by highly sensitive modalities (multidetector CT) do not always require anticoagulation. Patients with low risk of recurrent VTE can be managed with continued observation following a negative ultrasound evaluation of the proximal legs. This approach is based mostly on the expectation that a number of very small defects in the periphery on low or intermediate risk scans will be false positives, with the likelihood of a true positive rising sharply in the context of a persistent underlying risk factor (see earlier).[97,98] The presence of symptoms attributable to clot or the presence of residual lower extremity thrombosis should push patients and clinicians toward therapy. Furthermore, ACCP (2021) guidelines suggest anticoagulation in patients with imaging and clinical features highly suggestive of a true positive.[87]

51.10.4 Malignancy-Associated Thromboembolism

- Multiple studies and guidelines have come out since the publication of the previous version of this textbook that recommend either initiation of DOACs or LMWH in the treatment of malignancy-associated VTE. The 2021 update to the ACCP guidelines recommends an oral Xa inhibitor over LMWH for patients with malignancy-associated VTE. It places emphasis on apixaban or LMWH for patients with luminal gastrointestinal (GI) malignancies, given the higher risk of bleeding with other DOACs (edoxaban or rivaroxaban).[87] These recommendations are based on the following evidence. The Hokusai VTE Cancer investigators compared Edoxaban with LMWH Dalteparin, finding it to have a similar rate of recurrent VTE.

Major bleeding was studied as a secondary outcome and was higher in the edoxaban group with a HR of 1.77 (1.03–3.04).[99]

- The SELECT-D investigators compared Rivaroxaban with Dalteparin and demonstrated a lower rate of VTE recurrence in the Rivaroxaban group at six months (HR 0.43 [0.19–0.99]). More patients in the Rivaroxaban group experienced bleeding events in this study.[100]
- Apixaban was compared with Dalteparin in the ADAM VTE trial, with results showing a lower rate of VTE recurrence in the Apixaban group (0.7% vs. 6.3%) with a similar rate of bleeding events.[101]
- The Caravaggio investigators also compared Apixaban with Dalteparin and found similar rates of both recurrent VTE and major bleeding, suggesting non-inferiority.[102]
- The CASTA DIVA investigators compared Rivaroxaban with Dalteparin, showing it to be efficacious and safe but not reaching the statistical significance required for a non-inferiority assessment.[103]

CLINICAL APPLICATION

- Maintenance of a high clinical suspicion for DVT or PE must include an awareness of applicable risk factors, and a sedentary lifestyle, obesity, and smoking should be considered in the clinical assessment.
- The keys to diagnosing PE are maintenance of high clinical suspicion, application of serological testing in selected low-probability patients, and CT with contrast in patients with high pre-test probability.
- Direct oral anticoagulants have become the standard of care for most cases of DVT and hemodynamically stable PE.
- A number of special circumstances exist in the treatment of PE, which require a tailored approach to therapy.

52 Influenza

Lindsey E. Bazzone, MD, PhD

KEY POINTS

- Influenza is a highly contagious respiratory virus that infects the epithelial cells of the respiratory tract and is spread through contact with an infected person.
- Influenza viruses are constantly mutating to evade the immune response, which is the reason why people can be infected with influenza more than once and why it is necessary to update vaccine formulations annually.
- Laboratory testing for influenza virus is not required to make a clinical diagnosis of influenza, but testing may be useful in certain cases to help guide clinical management.
- Annual influenza vaccination can provide both individual and population protection from infection and is strongly recommended.
- Antiviral medications are available for chemoprophylaxis and treatment of influenza in select groups, but efficacy is variable, and antiviral resistance has been reported.

52.1 DEFINITION

Influenza is an infectious respiratory illness caused by the influenza virus, a highly contagious virus in the *Orthomyxoviridae* family. Influenza is a major source of economic burden worldwide and causes annual outbreaks with high rates of morbidity and mortality, particularly in certain populations who are at increased risk for complicated disease.

52.2 HISTORY OF INFLUENZA

The name "influenza" originated in 15th-century Italy, expressing the belief in the *influenza di stelle*, or "influence of the stars," on the appearance of an epidemic.[1] Influenza is now commonly referred to worldwide as "the flu" or simply "flu," a potentially misleading designation, as the word "flu" is frequently used by the general public to describe any febrile, viral illness, i.e. "stomach flu," despite having no association with the influenza virus. Influenza virus was first isolated in ferrets in 1933 and was later found to replicate in embryonic hen eggs, a discovery that enabled further characterization and study of the virus and ultimately led to the development of the first influenza vaccines in the late 1930s and 1940s. Prior to the 1930s, influenza epidemics can be identified throughout history by the characteristic signs and symptoms of the disease, seasonal variability, and severity of outbreaks. Influenza epidemics are believed to have occurred since at least the Middle Ages and possibly even earlier. One of the earliest reports of influenza-like illness came from the Greek physician Hippocrates, who described a highly contagious disease from northern Greece in 410 B.C. Most historians agree that the first recorded worldwide epidemic, or pandemic, caused by influenza occurred in 1580, originating in Russia and spreading across several major continents including Africa, Asia, and Europe over a period of six months until finally reaching the American continent. Historically, influenza pandemics occur at 10- to 50-year intervals. Over the past three centuries, there have been at least eight influenza pandemics, four in the 19th century, three in the 20th century, and one, so far, in the 21st century. The 1918–1919 influenza pandemic known as "Spanish Flu" was the deadliest outbreak of influenza in modern history, resulting in an estimated >50 million deaths worldwide, far surpassing the roughly 17 million people killed in combat during World War I.[1,2]

52.3 VIROLOGY OF INFLUENZA VIRUS

Influenza viruses are enveloped, negative-sense, single stranded RNA viruses belonging to the *Orthomyxoviridae* family. There are four types of influenza virus: Influenza A, B, C, and D. Influenza types A, B, and C are all known to cause symptomatic disease in humans; however, Influenza A virus (IAV) and influenza B virus (IBV) are responsible for annual epidemics. IAVs are the most virulent and associated with the highest rates of morbidity and mortality. IAVs have a broad host range, infecting humans as well as a variety of other mammals, including swine and horses, and numerous species of domestic and wild birds, with wild aquatic birds serving as the natural host/reservoir of IAVs. IAVs are major contributors to annual influenza epidemics and are the agents responsible for all known influenza pandemics. IBVs almost exclusively infect humans and cause milder disease compared with IAVs. While IBVs can cause annual epidemics, due to host limitations, they have never been associated with any pandemics. Influenza C viruses cause only mild illness, mostly in pediatric patients, and are not associated with annual epidemics. Influenza D viruses primarily infect cattle and are not known to infect humans.

Influenza virus particles are encased by a host-derived lipid envelope and can vary in appearance from spherical

DOI: 10.1201/9781003227793-61

particles ranging in size from 80 to 120 nm in diameter to long filamentous-appearing particles. The genome is comprised of eight viral RNA gene segments encoding the eight essential viral proteins: RNA polymerase, the surface glycoproteins hemagglutinin (HA) and neuraminidase (NA), viral nucleoprotein (NP), matrix protein (M1) and membrane protein (M2), nonstructural protein (NS1), and nuclear export protein (NEP). The glycoproteins HA and NA project like spikes from the surface of the virion and facilitate viral entry and release, respectively. HA and NA also exhibit the most antigenic variability, making these proteins the primary targets of antibodies generated in response to natural infection and vaccination as well as the targets for certain antivirals. A total of 18 different HA subtypes and 11 NA subtypes have been identified. Of these, eight HA subtypes (H1, H2, H3, H5, H6, H7, H9, H10) and six NA subtypes (N1, N2, N6, N7, N8, N9) have been detected in humans.

All influenza virus isolates are uniquely named based on virus type (A, B, C, or D), host (if not of human origin) and geographic origin, isolate number, and year isolated. IAVs are also subtyped based on the major surface antigens HA and NA. For example, influenza A/Perth/16/2019 (H3N2) is a human IAV isolated in Perth in 2019, isolate number 16 containing HA subtype 3 and NA subtype 2. For simplicity, the name is often truncated to reflect only the HA and NA type (i.e. H3N2). Unlike IAVs, which can infect across different species, influenza B viruses are largely restricted to humans and are divided into two antigenically distinct lineages: B/Victoria/2/1987 and B/Yamagata/16/1988.

Influenza virus replicates in epithelial cells of the respiratory tract. Virus HA binds sialic acid residues on the host cell membrane, and the virus particle is internalized within an endosome. Acidification of the endosome induces a conformational change in viral HA enabling fusion of the viral and endosomal membranes and release of the viral genome into the cytoplasm. Before replicating, the negative-sense viral genome must be imported into the nucleus and transcribed into a complementary, positive-sense messenger RNA intermediate, which is then exported from the nucleus into the cytoplasm and translated into viral proteins. Viral transmembrane proteins HA, NA, and M2 are trafficked to and inserted into the host cell membrane. After additional rounds of replication, newly formed viral proteins are then packaged within endosomes in the cytoplasm and shuttled to the cell membrane, where budding of new virions occurs, incorporating the host plasma membrane containing viral transmembrane proteins. Viral replication destroys the host cell and activates the host inflammatory immune response, releasing immunomodulators such as pro-inflammatory cytokines and chemokines and recruiting additional immune cells. Although essential to virus elimination, an exaggerated or aberrant host inflammatory response can paradoxically result in severe disease.

52.4 GENETIC VARIATION

Infection with influenza virus does not confer complete, lifelong immunity against repeat infection. Influenza viruses continuously evolve and change their antigenicity to evade immune detection, thus enabling the virus to cause repeated infections throughout a person's lifetime. Much of influenza's virulency comes from its genetic variability and the ability of the virus to infect across multiple species. Genetic variability, particularly involving the surface glycoproteins HA and NA, which are the major antigenic determinants, results from two primary mechanisms known as antigenic drift and antigenic shift.

Antigenic drift is caused by point mutations within the RNA gene segments of HA and NA, which occur continuously as the virus replicates due to error-prone viral RNA polymerases. Over time, these small changes eventually result in antigenically distinct strains of the virus that are not fully recognized by the human immune system and cause symptomatic infection due to lack of pre-existing, cross-reactive antibodies. Antigenic drift is the evolutionary response of the virus to selective immunological pressure in a population over time, and along with waning humoral immunity, is responsible for annual influenza epidemics. Continuous surveillance of antigenic drift is essential for predicting flu outbreaks and is the basis for influenza vaccine generation. All human influenza virus types (A, B, and C) undergo antigenic drift.

Antigenic shift involves drastic changes in the viral genome from genetic reassortment, a process whereby genomic viral RNA is exchanged among viruses of the same type (i.e. two IAVs) that coinfect the same host cell. When a host is infected with at least two different strains of virus (typically a human strain and an animal strain), genetic reassortment between the two strains can lead to the emergence of a novel virus strain capable of infecting a species with little to no pre-existing immunity, causing widespread infection, and if the virus is easily transmissible from person to person, can result in a global pandemic. Antigenic shift occurs sporadically and is restricted to IAVs due to their unique ability to cross the species barrier. All influenza pandemics result from antigenic shift of IAVs. Additionally, antigenic shift can also occur via the direct infection of humans with an animal (usually avian) influenza strain. One example is the H5N1 "bird flu," which is known to cause sporadic infection in humans, usually in the setting of prolonged, close contact with infected birds. However, cases of person-to-person transmission are exceedingly rare and non-sustained, thus limiting the potential for H5N1 to become a pandemic threat.[3]

52.5 EPIDEMIOLOGY OF INFLUENZA

Influenza infections occur worldwide and are a major public health concern. In the United States, the annual attack rate is estimated at 5–20% but is often much higher in certain susceptible populations.[4] The major disease burden in

humans is due to seasonal epidemics of IAV and to a lesser extent, IBV strains. An epidemic is defined by a seasonal increase in influenza activity above a predicted baseline. Epidemics result from spread of a variant virus that has undergone antigenic changes differentiating it from previous strains to which some degree of pre-existing immunity in the form of cross-reactive antibodies exists within the population. The World Health Organization (WHO) and the Centers for Disease Control and Prevention (CDC) perform year-round surveillance monitoring of influenza virus outbreaks and antigenic drift, which is crucial for predicting epidemics and formulating vaccines. Influenza outbreaks usually occur in the winter months, when conditions favor viral transmission. In temperate climates, the incidence of seasonal influenza typically increases in mid- to late fall and starts to decline by mid-spring. In tropical climates, influenza infections can occur intermittently throughout the year. Typically, influenza epidemics begins abruptly, peak within two to three weeks of onset, and last five to ten weeks. Approximately 10–20% of the population will become infected during an influenza outbreak.[5] The extent and severity of infection largely depend on the presence of pre-existing immunity within the population, which is determined by the presence of neutralizing antibodies from previous influenza infections and the degree of antibody cross-reactivity against the infecting virus strain. Children have the highest overall incidence of infection due to relative lack of pre-existing immunity. Host factors such as extremes of age, particularly adults over the age of 65 and children under 2 years old, and those with underlying medical conditions, especially cardiopulmonary disease, diabetes, and immunosuppression, cause higher risk for severe or complicated disease, hospitalization, or even death from influenza infection. In the United States, the CDC estimates that between 140,000 and 710,000 influenza-related hospitalizations and up to 52,000 deaths occur annually.[5]

Pandemic influenza occurs outside the usual influenza season, historically every 10–50 years. Criteria for pandemic influenza include the emergence of a novel IAV formed via genetic reassortment to which most of the population has little to no pre-existing immunity, which is capable of sustained person-to-person transmission, and which causes serious illness associated with high morbidity and mortality.[3] Since the start of the 20th century, there have been four major influenza pandemics: the H1N1 "Spanish Flu" in 1918, the H2N2 "Asian Flu" in 1957, the H3N2 "Hong Kong Flu" in 1968, and most recently, the H1N1pdm09 "Swine Flu" in 2009. Despite its name, the 1918 "Spanish Flu" was first detected in U.S. military camps during World War I and is estimated to have infected over 500 million people, or one-third of the global population, resulting in over 50 million deaths worldwide, making it the deadliest influenza outbreak in recorded history. During seasonal epidemics, death rates are highest in infants and elderly adults. An exception to this was the 2019–2020 influenza season, which resulted in the highest number of pediatric influenza deaths on record. However, during an influenza pandemic, the age distribution shifts, with higher mortality rates seen in healthy, young to middle-aged adults. The 1918 pandemic saw the highest mortality in young adults aged 20 to 40 years old. Similarly, high mortality was also seen in healthy young adults during the most recent H1N1 "Swine Flu" pandemic, which began in Mexico in February 2009 and rapidly spread across the globe at an unprecedented rate compared with prior pandemics. The CDC estimates that between April 2009 and February 2010, the H1N1 Swine Flu infected over 60 million people in the United States, with a predilection for infecting younger adults under the age of 25, resulting in approximately 265,000 hospitalizations and 12,000 deaths, with patients under age 65 accounting for an astonishing 90% of H1N1-related deaths.[6] The shift in age-related infection and mortality during the 2009 pandemic is believed to be the result of residual cross-protective immunity acquired from prior antigenically similar influenza infections earlier in life in older individuals. While pandemic influenza is rare, the limited number of prior pandemic events makes predicting future pandemics extremely challenging.

52.6 ECONOMIC IMPACT

The annual impact of influenza on the economy is substantial, though exceedingly difficult to accurately quantify. The CDC and the U.S. Department of Health and Human Services developed a model using epidemiological data to predict influenza-related health outcomes, which were then used to estimate the annual flu burden based on the 2003 U.S. population to evaluate the potential economic impact of annual influenza. Based on these data, the total annual economic burden of influenza on the U.S. economy was estimated at a staggering $87 billion, with direct medical costs amounting to $10.4 billion annually and estimated lost earnings due to illness and death from influenza totaling $16.3 billion annually.[7] More recently, an updated evaluation based on the 2015 U.S. population estimated the average total annual economic burden of influenza to be $11.2 billion, with direct medical costs estimated at $3.2 billion and indirect costs, including lost productivity, estimated at an average of $8 billion.[8] The cost discrepancies between these studies reflect just how challenging it is to measure the true economic burden of influenza. However, both studies clearly demonstrate the enormous financial impact of influenza.

52.7 PATHOPHYSIOLOGY OF INFLUENZA

Influenza is primarily spread from person to person via inhalation of large virus-laden respiratory droplets (≥5 μm in diameter) released into the air when an infected person coughs or sneezes within 6 feet or less of an uninfected person. Influenza can also be spread, albeit to a lesser extent, by smaller aerosolized droplets (<5 μm in diameter), which can remain airborne for minutes to hours and travel long distances, enabling virus transmission directly via inhalation

or indirectly by contact transmission, i.e. touching a surface contaminated with influenza virus and then touching the nose, mouth, or eyes. Transmission via fomites or hands contaminated with respiratory secretions can also occur; however, the virus only remains infectious on the hands for a short time (approximately 5 minutes), whereas virus deposited on non-porous surfaces can remain infectious for up to 48 hours.[9,10] Practical methods of limiting virus spread, such as frequent hand washing with soap and water and covering the nose and mouth when coughing or sneezing, remain crucial to preventing influenza transmission.

The main point of entry for influenza in humans is the mucosal surface of the respiratory tract. Once virus is deposited on the respiratory epithelium, the viral HA glycoprotein binds sialic acid residues on the host cell plasma membrane, triggering viral uptake into the cell via receptor-mediated endocytosis. Virus replication occurs within four hours of viral entry, resulting in either cell lysis or death by apoptosis, releasing newly formed infectious virions that subsequently infect and destroy adjacent cells. Following adult infection, virus is shed in respiratory secretions for about 24–48 hours prior to symptom onset and can be shed for up to 5–10 days with a peak of 1–3 days following the onset of symptoms.[11,12] The duration of virus shedding is prolonged in children and immunocompromised patients compared with healthy adults. Children may shed virus for several days prior to the onset of symptoms, likely due to a comparative lack of pre-existing immunity, whereas immunocompromised patients may continue to shed virus for months following initial infection.

52.8 CLINICAL ILLNESS

The incubation period for influenza is typically between one and four days, with an average of two days, and between three and four days among household contacts. Illness is usually heralded by the abrupt onset of fever and severe myalgias. While influenza infection may present with similar symptoms as other respiratory illnesses, systemic symptoms of influenza tend to be more severe, with prostration that is often out of proportion to the severity of other symptoms, which can help distinguish influenza infections. Fever is the most important physical finding and when present, can often be high, reaching up to 41 °C in the first 24 hours. Other systemic symptoms include generalized weakness, malaise, chills, headache, arthralgias, and nausea. Respiratory symptoms are typical and include non-productive cough, pharyngitis, nasal congestion, and rhinorrhea. Gastrointestinal (GI) symptoms such as vomiting and diarrhea may also be present but are generally more common in children. Infants and young children may present with febrile seizures. Adults over the age of 65 and immunosuppressed patients may present with milder, nonspecific symptoms such as weakness, confusion, anorexia, and malaise, with or without fever, and often in the absence of typical respiratory symptoms. Despite a milder initial presentation in the elderly population, infection can progress to severe and potentially life-threatening viral pneumonia. Findings on physical exam may include toxic appearance with facial flushing, conjunctival injection or watery eyes, clear nasal discharge, and hyperemic mucosa, including the posterior oropharynx; however, tonsillar purulence is uncommon. Occasionally, mild cervical lymphadenopathy may be appreciated. Lungs are generally clear, but approximately 25% of cases have diffuse rhonchi or rales on auscultation.[13]

In adults with uncomplicated infection, systemic symptoms usually last up to 7 days, with defervescence and improvement in respiratory symptoms after about 3 days; however, complete recovery may take up to 10 to 14 days, with longer recovery times associated with advanced age. On some occasions, patients may experience continued cough or malaise that persists for several weeks after acute infection. Since recovery from uncomplicated infection usually occurs within days, prolonged or ongoing symptoms may signal complications.

52.8.1 Pulmonary Complications

The most common and critical complication associated with influenza infection is pneumonia, which can manifest as primary viral pneumonia, secondary bacterial pneumonia, or combined viral and bacterial pneumonia. Complicated influenza infection classically presents with typical influenza symptoms followed by rapid respiratory decompensation.

Primary influenza virus–associated pneumonia was first officially described during the 1957 pandemic. Infection with certain influenza strains may be more likely to cause viral pneumonia than others. While primary viral pneumonia is a relatively rare complication of seasonal influenza infection, it can be rapidly fatal, especially in elderly patients. Primary influenza pneumonia results from direct viral infection of the lower respiratory tract. Symptoms include high fever and rapid onset of severe respiratory symptoms, including dry cough and dyspnea, often leading to respiratory distress with associated hypoxemia. Cyanosis may be evident on physical exam. Diffuse bilateral infiltrates are typically seen on chest imaging, and high virus titers can be readily detected in the sputum, notably in the absence of pathogenic bacteria on sputum culture. Mortality is high, with pathologic findings on autopsy revealing pulmonary edema, interstitial inflammation, necrotizing bronchitis, hyaline membrane formation, and alveolar hemorrhage.[14]

Pneumonia caused by secondary bacterial superinfection was first described during the 1918 pandemic as a biphasic illness and remains a significant cause of mortality associated with influenza infection. The development of secondary bacterial pneumonia is classically heralded by improvement and/or resolution of typical influenza symptoms, usually followed days later by rapid decompensation with recurrence of fever, new onset productive cough, worsening dyspnea, and consolidation on chest imaging. Blood counts may reveal a leukocytosis. and sputum cultures may

be positive for pathogenic bacteria. Influenza infection complicated by severe necrotizing staphylococcal pneumonia has been described in children and young adults and may appear as multiple cavitary lesions on chest imaging.[15] Bacterial species most commonly associated with influenza superinfection are *Staphylococcus aureus* (methicillin-sensitive and community-acquired methicillin-resistant strains), *Streptococcus pneumoniae*, *Streptococcus pyogenes*, and *Haemophilus influenzae*.[16, 17]

Viral and bacterial coinfections are the most common influenza-associated pulmonary complications. Primary influenza pneumonia and secondary bacterial pneumonia occur most frequently in elderly patients >65 years old with underlying cardiopulmonary disease. Primary viral pneumonia is also more common in pregnant women and in young adults during pandemics and likely accounts for the increased mortality among young adults associated with pandemic influenza. Immunosuppressed patients, particularly with hematologic malignancy, recent solid organ transplantation, and HIV with low CD4+ count, are also at higher risk for influenza-related pulmonary complications.[18] Other pulmonary complications of influenza in children include laryngotracheobronchitis (croup), bronchiolitis, and bronchitis. In both adults and children with underlying chronic lung diseases such as asthma or chronic obstructive pulmonary disease (COPD), influenza infection can cause severe exacerbations associated with a decline in lung function, and increased risk of hospitalization and death.

52.8.2 Non-Pulmonary Complications

Although influenza primarily attacks the respiratory tract, other organ systems can also be affected with clinical manifestations that can vary based on the infecting virus type. Otitis media and sinusitis are relatively common complications of influenza infection, especially in children. During the 2014–2015 influenza season, several hundred cases of influenza-associated acute parotitis were reported in young males infected with influenza A (H3N2).[19] Myositis with elevated creatinine phosphokinase is also more common in children with influenza and can vary in severity from mild calf tenderness to problems ambulating. Myoglobinuria and rhabdomyolysis occur rarely but can result in prolonged renal failure.[20] Cardiac complications include myocarditis and pericarditis, and more commonly, exacerbation of underlying chronic disease in patients with pre-existing cardiac conditions.[21,22] Neurologic complications of influenza infection include encephalomyelitis, transverse myelitis, Guillain–Barre syndrome (GBS), aseptic meningitis, and encephalitis.[23,24] Reye's syndrome, an uncommon disease characterized by an acute and potentially life-threatening hepatic encephalopathy seen almost exclusively in children taking aspirin long term, has also been associated with influenza infection.[25] Reye's syndrome presents with nausea and vomiting followed by encephalopathy, seizures, coma, respiratory arrest, and even death. Laboratory results typically reveal transaminitis in the absence of elevated bilirubin and an elevated ammonia level. Cerebrospinal fluid studies are bland with no evidence of inflammation.[26] While the exact etiology of Reye's syndrome and the association with influenza infection remain unclear, the incidence of disease has decreased due to widespread warnings to avoid aspirin in children with acute respiratory symptoms.

52.9 Laboratory Diagnosis of Influenza

Diagnosis of influenza infection is often made clinically; however, the overlap in symptoms between influenza and other respiratory viruses can make accurate clinical diagnosis difficult. The sensitivity of clinical diagnosis ranges from 29% to 80% in healthy adults, with the likelihood of making an accurate clinical diagnosis largely dependent on the prevalence of influenza in the community as well as the clinical presentation/symptoms.[27–30] Fever and cough are the two most accurate symptomatic predictors of influenza infection, and rapid onset of these symptoms further supports the diagnosis. During seasonal epidemics when community influenza activity is high, the presence of fever plus either cough or sore throat in young to middle-aged adults can establish a clinical diagnosis of influenza with 77–90% accuracy.[27]

Laboratory tests for detecting influenza virus may be used to confirm the diagnosis, guide clinical management, or assist in surveillance efforts. Testing should be performed early in the disease course, ideally within the first 48–72 hours of symptoms when virus shedding is at its peak. Influenza can be detected in various respiratory specimens. Nasopharyngeal swabs are the most reliable and thus preferred specimen source, although nasopharyngeal washes or aspirates may also be used.[31] In patients with lower respiratory tract disease, endotracheal aspirates or bronchoalveolar lavage (BAL) specimens may be more sensitive in detecting influenza, especially in patients with influenza-associated pneumonia.[32] However, it is important to note that the respiratory specimen source(s) approved for different diagnostic tests may vary and should be considered when performing a specific test to prevent inaccurate results.

Influenza diagnostic tests include molecular assays such as reverse transcription polymerase chain reaction (RT-PCR) and other nucleic acid amplification tests, and antigen detection assays such viral culture, rapid influenza diagnostic tests (RIDTs), and immunofluorescence tests. Serologic testing for antibodies against influenza is virtually only used for research purposes and should not be used to influence clinical management. Viral culture and RT-PCR are considered the gold standard laboratory tests for diagnosing influenza. While influenza virus culture is highly specific (>95%) for influenza detection, it requires specific laboratory expertise and can take between three and seven days for results, precluding its use as an effective

diagnostic test, although it is useful for monitoring antigenic drift, detecting novel variants, and assessing response to antivirals.[33,34] Alternatively, RT-PCR is fast (results available within hours), can be performed in high volume, and is highly sensitive (>99%) and specific (>99%), making it the laboratory test of choice for diagnosing influenza. RT-PCR can determine the type and subtype of influenza virus and can also be multiplexed to detect and differentiate between influenza and other respiratory viruses. However, RT-PCR can be expensive and is subject to both higher false positive and false negative rates compared with viral culture due to specimen contamination and degradation, respectively.[35]

Rapid molecular assays are an alternative to traditional RT-PCR designed for rapid (within 15–30 mins), point-of-care detection of influenza A or B viral RNA, but unlike traditional RT-PCR, cannot distinguish between different IAV subtypes.[36] Antigen detection assays such as immunofluorescence and RIDTs are qualitative immunoassays that detect the presence of IAV or IBV antigens such as nucleoprotein (NP) in respiratory samples. Antigen detection tests provide rapid (<15 minutes to a few hours), inexpensive, point-of-care testing with high specificity but only moderate to low sensitivity (40–70%) making them good screening tests but limiting their diagnostic utility given their propensity for false negative results, often requiring follow-up confirmatory testing with a molecular assay. Rapid molecular assays have higher sensitivity (66–100%) and are thus recommended over rapid antigen tests.[37] It is important to note that treatment decisions should not be made exclusively based on laboratory tests, and the decision to treat should not be delayed for diagnostic testing, especially when the community prevalence of influenza is high.

52.10 PREVENTION

Vaccination is the most effective method for preventing influenza infection. Importantly, vaccination affords both individual and population protection from infection. Because children are very effective transmitters of influenza infection, and older adults may have a suboptimal response to vaccination, studies have proposed that vaccinating children may be more efficacious for preventing flu in the elderly than vaccinating the elderly population themselves.[38] Since influenza virus is primarily transmitted by inhaling virus-laden respiratory droplets, the cornerstone of infection prevention, aside from vaccination, is limiting exposure to infected persons, including avoiding close contact and maintaining a distance of at least 6 feet from people who are coughing or sneezing. Those who are sick with influenza or experiencing respiratory symptoms should avoid unnecessary close contact with other individuals or groups of individuals while symptomatic and attempt to limit the release of virus particles into the air by coughing or sneezing into a tissue or the crook of the arm. Other practical methods of prevention include washing hands with soap and water or alcohol-based hand sanitizers and avoiding contact with the face or eyes before washing hands, particularly during flu season and after contact with high-touch public areas such as door handles, and of course, after coughing or sneezing into the hands.

52.10.1 Vaccination

The immune response to both natural influenza virus infection and influenza vaccination is mediated by the humoral or B cell response. B cells generate antibodies primarily to the viral surface proteins HA and NA that can neutralize and eliminate the virus and protect against future infections. However, influenza virus is constantly undergoing antigenic drift to evade immune detection, and antigenic changes in HA or NA may result in incomplete immunity, whereby cross-reactive antibodies from a prior infection or immunization provide variable degrees of protection against the variant virus until new specific antibodies can be produced to clear the infection. Influenza vaccine formation relies on continuous surveillance of antigenic drift, particularly in HA, which is the main component of inactivated influenza vaccines. Vaccine composition is reviewed and updated annually based on surveillance and clinical and laboratory observations that enable prediction of the circulating strains most likely to cause human disease during a particular year. The Advisory Committee on Immunization Practices (ACIP) issues annually updated recommendations for influenza vaccination through the CDC.[39] The degree of protection afforded by influenza vaccination largely depends on community vaccination rates and how closely the predicted influenza virus strains represented in the vaccine match the actual influenza virus strains circulating during a particular year. Additionally, host factors such as age, immune function, and prior vaccination history can also impact the effectiveness of the influenza vaccine. Vaccine benefit is greatest among high-risk populations, specifically young children, adults over age 65, particularly with underlying comorbidities, and immunocompromised individuals. Vaccine-induced immunity develops within about two weeks in healthy adults, with peak antibody titers occurring after two to four months. Immunity typically lasts less than a year due to waning antibody levels and antigenic drift. Immunity may take longer to develop in children, particularly those who have not previously had an influenza vaccination. As a result, two doses of influenza vaccine are recommended for children aged six months to eight years who are influenza vaccine naïve. Studies have demonstrated the influenza vaccine to be up to 60% effective at preventing infection with influenza A and B.[40]

The ACIP recommends that all individuals aged six months or older who do not have any contraindications should receive an annual influenza vaccine.[39] Available types of influenza vaccines include inactivated influenza vaccine (IIV), recombinant influenza vaccine (RIV), and live, attenuated influenza vaccine (LAIV). Influenza vaccines are formulated as either trivalent preparations, containing antigens from two strains of influenza A (H1N1 and H3N2) and one influenza B strain, or quadrivalent

preparations, containing an additional influenza B strain. IIVs are manufactured by growing virus either in embryonic chicken eggs or more recently, in cell culture, then inactivating the virus using ether or detergents. IIVs are administered by intramuscular injection. In recent influenza seasons, all available IIVs have been quadrivalent formulations, with both egg-based and cell culture–based vaccines available for individuals aged six months and older. Pregnant women should receive IIV during each pregnancy both to prevent severe infection of the mother while pregnant and to protect the baby during the first six months of life. Since inactivated vaccines are weakly immunogenic in elderly patients, a high-dose cell culture–based vaccine and an adjuvant-containing egg-based vaccine are specifically recommended for patients ≥65 years old.[39]

In 2013, a quadrivalent RIV was generated exclusively using recombinant DNA technology. Genetic recombination circumvents the use of the influenza virus and thus, the need for embryonic eggs, thereby shortening vaccine manufacturing time and enabling the use of RIVs in individuals with egg allergy. Currently, a quadrivalent RIV is approved for patients ≥18 years old.[39]

The first LAIV was introduced in the United States in 2003 as a trivalent formulation (LAIV3), which was later replaced by a quadrivalent LAIV (LAIV4) during the 2013–2014 flu season. In LAIVs, vaccine viruses are grown in embryonic chicken eggs and passaged at low temperature (25 °C), creating a cold-adapted, "attenuated" vaccine. LAIVs are administered intranasally and compared with inactivated vaccines, have been shown to induce a more broadly protective immune response in infants and children, with the distinct advantage of inducing mucosal immunity due to the ability of the vaccine virus to replicate in the nasopharyngeal mucosa. The ACIP adjusted its recommendation to include the use of LAIV4 during the 2018–2019 flu season.[41] Currently, a quadrivalent LAIV4 is approved for use in healthy individuals aged 2–49 years who have no contraindications; it has been shown to be effective in 90% of children.[39] Antiviral drugs may reduce the effectiveness of LAIVs and should be discontinued prior to LAIV administration (at least 2 days for oseltamivir and zanamivir, 5 days for peramivir, and 17 days for baloxavir) and avoided for at least 2 weeks following LAIV administration.[42]

Side effects of influenza vaccination are generally mild. Soreness at the injection site is common after intramuscular administration of IIVs or RIVs, particularly those that contain adjuvant, and can last for one or two days. Low-grade temperature elevations can also occur after vaccination; however, the occurrence is only slightly greater than with placebo. Nasal congestion and sore throat have been reported following LAIV administration. Absolute contraindications to influenza vaccination are rare, and the variety of vaccine formulations available has enabled more people to safely receive the vaccine who may have previously been contraindicated. A history of anaphylaxis to a vaccine component or following a prior dose of influenza vaccine is an absolute contraindication to receiving any influenza vaccine. Hypersensitivity to hen eggs is a contraindication to receiving influenza vaccines propagated in egg-based culture systems. Live, attenuated vaccines are contraindicated in pregnancy and relatively contraindicated in patients with immunodeficiency, as there are limited data on the safety of LAIV in this population. Although live attenuated vaccine virus can be transmitted to close contacts, this occurs infrequently and has not resulted in clinically severe illness. Regardless, LAIV administration is not recommended for those who have close contact with severely immunocompromised patients. A history of GBS within six weeks of influenza vaccination and moderate to severe acute illness, with or without fever, at time of vaccination are considered precautions, rather than contraindications, to influenza vaccination. Regarding GBS, it is worth noting that while GBS is known to occur, albeit rarely, after influenza infection, a clear link between inactivated influenza vaccination and GBS has never been identified even after years of vaccine safety monitoring.

52.10.2 Chemoprophylaxis

The antiviral medications oseltamivir, zanamivir, and baloxavir are approved for post-exposure chemoprophylaxis and are 70–90% effective at preventing influenza when initiated within 48 hours of exposure. Oseltamivir and zanamivir should be taken at the same time each day for a duration of seven days following most exposures or for ten days following exposure to a household contact. The new anti-influenza drug baloxavir is approved for post-exposure prophylaxis in persons 12 years of age and older and is given as a single oral dose based on body weight. In a multicenter, double-blind, randomized, placebo-controlled clinical trial, baloxavir demonstrated efficacy comparable to oseltamivir in preventing influenza infection after contact with an infected household member.[43] Antivirals are helpful adjuncts to vaccination to prevent influenza, although routine administration of antivirals for prophylaxis is not recommended, as this may promote antiviral resistance. Post-exposure prophylaxis is indicated for exposed, unvaccinated individuals at high risk for complications from influenza or for residents of long-term care facilities during an outbreak.

52.11 TREATMENT

The mainstay of treatment for uncomplicated influenza infection in low-risk individuals is supportive care. Adequate hydration should be maintained to replace insensible fluid losses from fever and increased respirations. Nonsteroidal anti-inflammatory drugs such as ibuprofen or aspirin (except in children or teenagers with influenza due to the risk of Reye's syndrome) can be used as antipyretics and for symptomatic relief of headaches, myalgias, etc. Most people with influenza infection generally do not require medical treatment or antiviral therapy. However, individuals at risk for severe or complicated disease, such

as the elderly, those with chronic cardiopulmonary disease or immunodeficiency, and pregnant women, who develop symptoms consistent with influenza should be evaluated for antiviral therapy by a medical professional as early as possible.

52.11.1 Antiviral Therapy

Three classes of antiviral drugs are approved for use against influenza in the United States: Adamantanes, neuraminidase inhibitors (NAIs), and the new class of anti-influenza drug, cap-dependent endonuclease inhibitor (CENI). Adamantanes, including amantadine and rimantadine, are an older class of antiviral drugs targeting the M2 ion channel of IAVs only and are no longer recommended for clinical use due to widespread resistance among circulating IAVs. The NAIs, oseltamivir (Tamiflu), zanamivir (Relenza), peramivir (Rapivab), and the CENI baloxavir marboxil (Xofluza) are active against both IAVs and IBVs and are currently approved by the Food and Drug Administration (FDA) for treatment of influenza.[42]

NAIs target the enzymatic activity of NA by mimicking the binding of sialic acid in the active site of NA on influenza A and B viruses, preventing virus detachment from infected cells. NAIs are most effective against IAVs but demonstrate adequate effectiveness and efficacy against IBV strains as well. Oseltamivir is considered the drug of choice for treatment of influenza in most individuals. Early initiation of oseltamivir is associated with decreased duration and severity of influenza symptoms and has also been shown to significantly reduce the frequency of influenza-related secondary infections and exacerbation of underlying conditions.[44] Oseltamivir can be used to treat uncomplicated influenza infection up to 48 hours after the onset of symptoms in adults and children >2 weeks old and for chemoprophylaxis in adults and children >1 year old. It is administered orally as a prodrug absorbed by the gut, converted to the active metabolite in the liver, and excreted by the kidney. Standard dosing of oseltamivir for treatment of mild to moderate influenza infection in adults with normal renal function is 75 mg twice a day for five days. In individuals with renal impairment (creatinine clearance <60 mL/min), a reduction in the dose and/or dosing frequency of oseltamivir is recommended based on creatinine clearance. For individuals on hemodialysis, an initial 30 mg dose is recommended, followed by 30 mg after each dialysis session. The duration of therapy has also been extended in severely ill patients.[45] Oseltamivir is generally well tolerated with few side effects, the most common being GI upset, which can be abated when taken with food. It is also safe to use during pregnancy. Oseltamivir-resistant influenza A (H1N1) virus has been seen in individuals with no history of NAI use. However, most current circulating H1N1 strains remain sensitive to NAIs, although sporadic cases of oseltamivir resistance continue to be detected.

Zanamivir is administered via oral inhalation, with a standard dose of two inhalations twice a day, and is approved for treatment of uncomplicated influenza in individuals >7 years old within 48 hours of symptom onset and for chemoprophylaxis in individuals >5 years old. Zanamivir use can trigger bronchospasm in patients with underlying lung disease, such as asthma or COPD, and thus, is not recommended for use in these individuals. Zanamivir is also contraindicated in patients with milk protein allergy.

Peramivir is administered intravenously as a single 600 mg dose and is approved for influenza treatment in adults and children >2 years old within 48 hours of symptom onset. Dose reductions are recommended for individuals with renal failure with a creatinine clearance <50 mL/min, and additional doses have been used in patients with severe disease. Diarrhea has been reported with peramivir use. Peramivir is currently not approved for post-exposure prophylaxis.[46]

Studies of NAIs, usually oseltamivir, in healthy adults have consistently shown benefits, including reduced duration of illness, decreased risk of pneumonia and hospitalization, and reduced risk of mortality in hospitalized patients, with better outcomes strongly dependent on earlier antiviral administration (within the first 36 hours of illness).[44,46–51] Less is known about the benefits of early NAI use in high-risk or severely ill patients. One meta-analysis comparing oseltamivir use versus placebo in high-risk patients with underlying cardiopulmonary diseases found that oseltamivir use decreased the rate of pulmonary infections and hospitalizations by 28% and 52%, respectively, and reduced median duration of symptoms and disease severity compared with placebo.[52]

Baloxavir marboxil (Xofluza) is a new influenza antiviral medication approved for use by the FDA in 2018. Baloxavir is a CENI that prevents influenza replication by interfering with viral RNA transcription.[53] Baloxavir is given as a single-dose, weight-based oral regimen indicated for treatment of influenza or as post-exposure chemoprophylaxis in patients ≥12 years old.[43] As with NAIs, earlier administration (within 48 hours of symptoms) is associated with improved outcomes. While no significant adverse events have been associated with baloxavir use, taking this medication with dairy products, laxatives, or other products or supplements containing polyvalent cations (i.e. calcium, magnesium, iron, selenium, zinc) is not recommended, as it may decrease the efficacy of baloxavir by reducing the plasma concentration of the drug. Baloxavir is not currently recommended for patients who are pregnant or breastfeeding, for those with severe, progressive influenza infections, or in hospitalized influenza patients due to a paucity of data in these groups. Baloxavir and NAIs demonstrate similar activity against IAVs, although baloxavir has been shown to have improved activity against IBVs, significantly reducing the median duration of symptoms by over 24 hours in patients with IBV infection compared with oseltamivir.[54] The potential for combination therapy with NAIs and baloxavir is currently being investigated, although a recent randomized, double-blinded, placebo-controlled trial found no difference in time to clinical improvement in hospitalized

influenza patients who received combination therapy with an NAI and baloxavir compared with those who received NAI plus placebo.[55]

Early initiation of antiviral therapy (within 48 hours or less of illness onset) is recommended for patients with influenza or influenza-like symptoms with severe, progressive, or complicated illness, those at high risk for influenza-related complications, and those who require hospitalization.[56] Individuals at higher risk for severe or complicated influenza who should receive antivirals include children <2 years old and adults ≥65 years old, women who are pregnant or up to 2 weeks postpartum, patients with chronic pulmonary, cardiac, renal, or hepatic disease, hematologic disease including sickle cell, metabolic disorders (diabetes, obesity, body mass index [BMI] ≥40), neurologic, neurovascular, or neurodevelopmental conditions, immunocompromised patients (HIV/AIDS, chronic corticosteroids, chemotherapy), Alaska natives and American Indians, and residents of long-term care facilities.[57] Antiviral initiation in high-risk or hospitalized patients should not be delayed pending confirmatory testing results. While numerous studies have shown that antiviral initiation within 48 hours of illness onset is associated with the greatest clinical benefit, studies of high-risk and hospitalized patients with severe disease suggest potential benefits to antiviral therapy even when initiated after 48 hours of illness onset and when started up to 4 to 5 days after the onset of illness in patients hospitalized with influenza.[58,59] Antivirals can also be considered for treatment of influenza infection in previously healthy yet symptomatic patients who are not at high risk for complications, but only if initiation of treatment is less than 48 hours after symptom onset, as antiviral initiation later than 48 hours after symptom onset is unlikely to provide any clinical benefit in this population and may potentiate antiviral resistance. Factors to consider when selecting an antiviral include the indication for use (chemoprophylaxis or treatment), and the patient's age, weight, renal function, presence of chronic medical conditions, and current medications (to determine possible interactions).

52.12 INFLUENZA DURING THE SARS-COV-2 PANDEMIC

In 2019, the world was introduced to the novel severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2), to which a lack of pre-existing immunity resulted in a global pandemic on a scale that had not been seen since the influenza pandemic of 1918. Since the start of the SARS-CoV-2 pandemic, influenza activity worldwide has been at an all-time low even with increased influenza testing. In the United States, the 2020–2021 flu season saw such historically low influenza activity that the CDC was unable to provide information regarding the overall flu burden because stable estimates were impossible to ascertain. During the period from September 2020 to May 2021, only 0.2% of respiratory specimens tested by U.S. laboratories were positive for influenza compared with 26.2–30.3% of influenza-positive specimens during the previous three influenza seasons. This phenomenon is predominantly attributed to increased awareness and practice of infection prevention measures, such as physical distancing, including virtual learning, decreased global travel, self-quarantine practices, increased hand hygiene, and face mask use, among the public reducing influenza virus transmission.[60]

Influenza infection and SARS-CoV-2 infection cannot be distinguished by symptoms alone. Additionally, influenza and SARS-CoV-2 viruses can infect simultaneously, causing potentially deadly coinfections. While influenza and SARS-CoV-2 viruses are co-circulating, the CDC recommends that individuals with acute respiratory symptoms be tested for *both* influenza and SARS-CoV-2 infections, self-isolate while awaiting test results, and continue self-isolating if symptoms persist even with a negative test until symptoms abate due to the potential for false negative testing results, which depends on the type of test used and the community prevalence of both diseases. Various multiplex assays for simultaneous detection of influenza and SARS-CoV-2 viruses were approved for use by FDA Emergency Use Authorization (EUA) in December 2020.[37] Influenza vaccination remains as important as ever to prevent influenza infection as well as to prevent influenza and SARS-CoV-2 coinfections. The influenza vaccine does not protect against SARS-CoV-2 infection. However, several recent large cohort and retrospective studies have suggested potential protective effects of influenza vaccination on SARS-CoV-2 infection, including improved health outcomes and reduced risk of both severe SARS-CoV-2 infection and SARS-CoV-2 infection–related complications.[61–64] The influenza vaccine can be given simultaneously along with SARS-CoV-2 vaccines or boosters if administered at different anatomical sites. Antiviral therapies approved for influenza also have no activity against SARS-CoV-2 viruses and do not interact with any medications currently approved to treat SARS-CoV-2 infection. Given concern for coinfections, the CDC recommends early initiation of empiric antiviral treatment for influenza regardless of symptom duration for patients diagnosed with SARS-CoV-2 infection with respiratory illness who are hospitalized, have severe or progressive illness, or are at high risk for influenza complications.

52.13 SUMMARY

Influenza is a highly contagious respiratory disease caused by the influenza virus of the *Orthomyxoviridae* family. Influenza A and B virus types can cause repeated infection and seasonal epidemics in humans due to waning immunity and antigenic drift. Influenza A viruses can also undergo antigenic shift, creating a new virus subtype with the potential for causing widespread infection due to a lack of pre-existing immunity, which can ultimately lead to a global pandemic. IAVs are associated with the most severe infections and are responsible for all known influenza

pandemics. The symptoms and severity of influenza infection are determined by a combination of both virus and host factors and can range from mild upper respiratory symptoms to severe viral pneumonia. Pneumonia caused by bacterial superinfection is the most common complication of influenza infection; however, influenza can also cause a wide range of non-respiratory complications and lead to severe exacerbations of existing chronic diseases. Antiviral therapies are available for chemoprophylaxis and treatment of influenza and may be most beneficial in high-risk individuals, particularly when initiated early. While drug-resistant viruses have been detected, the clinical implications of these resistant strains are uncertain. Vaccination remains the cornerstone of influenza prevention. Despite a decline in seasonal influenza infections since the start of the SARS-CoV-2 pandemic, annual influenza vaccination remains as important as ever to prevent seasonal influenza and influenza coinfection with SARS-CoV-2.

CLINICAL APPLICATIONS

- Influenza infection is preventable through vaccination and interventions that reduce virus transmission, such as hand hygiene and avoiding close contact with those who may be sick with influenza.
- During seasonal outbreaks, when community influenza activity is high, an accurate clinical diagnosis of influenza can be made in the presence of typical symptoms (fever, cough, myalgias), and confirmatory laboratory testing is generally not indicated unless the diagnosis is in question (atypical presentation in elderly or immunocompromised individuals) or the results will impact clinical decision making (antiviral or antibacterial therapy).
- Supportive care (resting at home, adequate hydration, antipyretics) is the mainstay of treatment for uncomplicated influenza infection.
- Early initiation of influenza antiviral therapies is recommended for certain high-risk populations, and the decision to start antivirals in these populations should not be delayed pending results of diagnostic testing.

53 Indoor Air Quality

Kyle T. Halligan and Anthony C. Campagna

KEY POINTS

- Indoor smoking, elevated radon levels, and elevated carbon monoxide levels present significant health hazards.
- Humidity levels greater than 50% in your home can promote dust mite and mold growth.
- Mitigation of common allergens can improve quality of life for those with allergic asthma.
- Hookah and e-cigarette use remain prevalent and pose considerable risk.
- Home appliances including continuous/bilevel positive airway pressure (CPAP/BiPAP) devices need periodic cleaning and replacement of disposable components.

53.1 INTRODUCTION

Since humans take over 20,000 breaths daily, clean environmental air is essential. The relationship between health and air quality was recognized early in the fourth century BC by Hippocrates, the Father of Medicine. Indoor air quality is particularly important to humans, since we spend up to 90% of our time indoors.[1] Air quality in the United States is regulated by the federal government through the Environmental Protection Agency (EPA). In this chapter, we highlight some sources of potential morbidity of indoor air quality as it pertains to lung health.

One of the most important tasks of the clinician meeting a patient is taking a comprehensive history of environmental exposures both at work and in the home. The healthcare worker should ask about contemporary exposures as well as exposures in their childhood home or homes.[2] Household factors that may affect respiratory health include primary and secondhand smoke, radon levels, home water damage, heating, and ventilation, especially related to wood or coal, renovation history, the presence of a pool or hot tub, presence of pets, and specific hobbies including arts and crafts, do-it-yourself repair work, or gardening.

53.2 SECONDHAND SMOKE

The awareness of smoking and its adverse effects is widespread. Yet globally, smoking remains a prevalent lifestyle choice; in 2020, the WHO estimates that 22.3% of the global population use tobacco.[3] This number is only slightly lower in the United States, where 19% of adults are estimated to use any tobacco product.[4] As a result of such widespread individual use, secondhand smoke, or environmental tobacco smoke (ETS), is a common exposure and is itself a major public health problem. Approximately one nonsmoker dies from secondhand smoke exposure for every eight smokers who die from smoking.[5] Three publications serve as landmark summaries of the effects of ETS on human health. The U.S. Surgeon General's Report in 1986 and a report of the National Research Council described the health risks associated with passive smoking.[6] Lastly, the EPA released a report in 1992 that causally linked secondhand smoke exposure to lung cancer, effectively classifying ETS as a group A carcinogen.[7] While secondhand smoke has been referred to as ETS in the past, the term "secondhand smoke" better captures the involuntary nature of the exposure.

Secondhand smoke is composed of a mixture of both the smoke released from the burning end of a cigarette, labelled sidestream smoke, as well as smoke exhaled by the smoker themselves, labelled exhaled mainstream smoke. During cigarette burning, over 4,000 chemical compounds are created, which may be toxic and carcinogenic.[8] While sidestream and mainstream smoke contain similar compounds (Table 53.1), the concentration and the properties of these can vary significantly. Secondhand smoke can linger in the local indoor environment for about 1.5–2 hours, which may increase both the exposure period and entry into lung tissue and body cells.[9] Sidestream smoke composition does not vary significantly by tobacco product brand, but it remains as much as ten or more times more toxic than mainstream smoke.[10]

The term "thirdhand smoke" has been referred to as cigarette by-products that cling to a smoker's hair and clothing as well as to household fabrics, carpets, and surfaces even after secondhand smoke has cleared.[11] These invisible tobacco toxins pose danger to small children, who are especially susceptible when they come into contact with contaminated surfaces.[12]

Smoke exposure can be measured by testing either environments or body fluids for nicotine, cotinine (a breakdown by-product of nicotine), carbon monoxide, and other smoke-related chemicals.[11] Modern devices can perform active sampling of the environment, measuring nicotine, carbon monoxide, nitrogen oxides, polycyclic aromatic hydrocarbons, and general particulate matter on the scale of micrometers.[13,14] As expected, the measured exposure is directly related to exposure level, room size, and ventilation rate within that room.[14,15]

In June 2002, the International Agency for Research on Cancer (IARC) concluded that "involuntary smoking,

	NNN, NNK, and NAT
	Phenol
	Propionaldehyde
	Pyridine
	Quinoline
	Resorcinol
	Styrene
	Toluene

exposure to secondhand smoke or 'environmental' tobacco smoke, is carcinogenic to humans." The IARC concluded further that there is a "statistically significant and consistent association between lung cancer risk in spouses of smokers and exposure to secondhand tobacco smoke from their spouse who smokes. The excess risk is on the order of 20% for women and 30% for men."[16]

In January 2005, the U.S. Public Health Service's National Toxicology Program issued its 11th report on carcinogens. This report unambiguously states: "environmental tobacco smoke is known to be a human carcinogen based on sufficient evidence of carcinogenicity from studies in humans that indicate a causal relationship between passive exposure to tobacco smoke and human lung cancer."[17] Some studies also support an association of ETS with cancers of the nasal sinus cavity, breast cancer, leukemia, lymphoma, and brain tumors in children.[18] Evidence of an increased cancer risk from ETS stems from studies examining nonsmoking spouses living with individuals who smoke cigarettes,[15,19,20] exposures of nonsmokers to ETS in occupational settings, and exposure to parents' smoking during childhood.[11] Many epidemiological studies, including large population-based case-control studies, demonstrate an increased risk of developing lung cancer following prolonged exposure to ETS. Lifelong nonsmokers living with smokers had, on average, a 24% higher chance of developing lung cancer than those living with nonsmokers. Those exposed to the heaviest smokers for the longest time had the highest risks.[20] Similarly, there is a growing body of evidence suggesting a higher risk of death from the association of secondhand smoke exposure and ischemic heart disease. Most of the data involves spousal smoke exposure and risk ratios that range between 20% and 30% and a twofold excess risk of cardiac death in this population.[21–23] There may be a confounding effect in these studies, as there may be an innate risk in the U.S. population to develop cardiovascular disease. In addition, there are pathophysiologic changes due to secondhand smoke that have not been fully elucidated. It is known that the elevation in serum carboxyhemoglobin levels decreases exercise tolerance in both healthy persons and individuals with ischemic heart disease.[24] Also, "time until angina" decreases with increasing concentrations of serum carboxyhemoglobin, as does the frequency of arrhythmias during exercise, vascular endothelium damage, lower high-density lipoprotein cholesterol levels, and increase in fibrinogen with associated fibrinogenesis.[24–26]

53.3 SECONDHAND SMOKE EXPOSURE IN CHILDREN

The Pro-Children Act of 1994 prohibits smoking in facilities that routinely provide federally funded services to children. Many state and local governments have passed laws prohibiting smoking in public facilities such as schools, hospitals, airports, bus terminals, parks and beaches, and private workplaces, including restaurants and bars. There is no doubt that the impact caused by secondhand smoke exposure raises the frequency and severity of respiratory illnesses and respiratory symptoms in children. In a 1993 report, the EPA estimated that between 150,000 and 300,000 annual cases of bronchitis and pneumonia in children could be attributed to secondhand smoke in the United States. Of these, between 7,000 and 15,000 will result in hospitalization. Secondhand smoke was also estimated to increase the rate of asthma exacerbations, with between 200,000 and 1,000,000 affected children.[5] In addition, secondhand smoke exposure increases the risk of sudden infant death syndrome (SIDS), and one survey found the risk of SIDS to be up to threefold in children exposed to active maternal smoking in utero and secondhand smoke exposure after birth.[27] Aside from the obvious medical implications, the economic burden associated with this increase in morbidity is responsible for a rise in healthcare costs likely to be in the millions, if not billions, of dollars. A recent study in Israel educated parents of 29 families to the dangers of tobacco smoke exposure to their children and showed a reduction in hair nicotine levels of the children, the number of cigarettes smoked by parents, and parent-reported child smoke exposure.[28] More education and research are needed to identify

opportunities for parents to reduce tobacco smoke exposure in their own children.

53.4 RADON

Radon-222 is a noble gas that is produced from the decay of uranium-238 and radium-226, which are naturally present in the earth's rock and soil. It decays with a half-life of 3.8 days. It can diffuse into the soil and air before decaying. The breakdown of radon-222 occurs by emission of an alpha particle, which produces radioactive progeny that include polonium-218 and polonium-214.[29,30] These are known as the "short-lived" progeny, and they, in turn, break down into "long-lived" progeny that include lead-210, which yields bismuth-210, which yields the stable isotopes polonium-210 and lead-206. This whole decay process takes hundreds of years. When inhaled into the lung, the alpha particles can damage cellular DNA and lead to mutagenesis in never-smoking lung cancer cases.[31]

Radon gas can seep into buildings through porous soil. The rate of diffusion is related to the pressure gradient created by the building structure across the soil, which in turn, is influenced by atmospheric pressure, wind flow over the structure, and the buoyancy of the air taking advantage of cracks or gaps in building foundations, floors, and walls, along with gaps along pipes, pumps, and drains. It can easily dissolve into and evaporate out of water. Therefore, water drawn from private wells in areas enriched with uranium can increase the exposure to radon. Inhaled radon poses a much higher risk for lung cancer than the ingested form from drinking water.[32,33]

Inhaled radon progeny have been linked to an increase in the risk of lung cancer in underground miners.[29] These progeny are the number one cause of lung cancer in never-smokers and the second-leading cause of lung cancer overall. The EPA estimates that radon exposure may account for over 21,000 lung cancer deaths each year, including 2,900 never-smokers, and the remaining deaths in smokers with radon exposure at concentrations as low as 2 pCi/L of air.[34] It is difficult to ascertain the exact amount, length, and degree of exposure needed to cause lung cancer. Most studies causally link the exposure of underground miners to uranium and lung cancer. A meta-analysis of 13 European case-control studies of uranium exposure showed an increased risk of lung cancer to smokers and recent former smokers, accounting for 2% of all cancer deaths in Europe, although it is difficult to accurately estimate the lifetime exposure to radon in these settings.[30]

The EPA recommends testing radon in homes and schools below the third floor, since toxic effects have not been reported in high-rise dwellings. A "do-it-yourself" kit may be easily acquired and left in place for 48 to 72 hours in the lowest floor and first-floor rooms without active ventilation or open doors. Long-term or 90-day trackers can better estimate year-round radon exposure and may be used when short-term devices yield a value higher than 4 pCi/L. If abnormal levels higher than 4 pCi/L are detected, interventions can include sealing gaps in the foundation or installing a ventilation or radon mitigation system that expels air to the outside environment and may require professional contractors.[34]

53.5 CARBON MONOXIDE

Carbon monoxide (CO) is an odorless gas, the by-product of the combustion of carbonaceous fuels. Sources of CO include unvented kerosene heaters, gas water or space heaters, leaking chimneys or furnaces, wood stoves, generators and any gas-powered equipment, automobile exhaust, and tobacco smoke.[35,36] Approximately 400 accidental deaths in the United States are attributed to accidental exposure to CO inhalation.[37,38] Interestingly, large storms and disasters have been associated with spikes in cases, as seen in Hurricane Rita in 2007 and again in New York city in 2012.[39,40] CO binds to hemoglobin with a high affinity, 200 times greater than oxygen, forming carboxyhemoglobin (COHb), which disrupts oxygen transport. Additionally, CO binds to heme proteins in myoglobin and cytochrome oxidase.[41] Tissues with the highest oxygen demands, including myocardium, brain, and exercising muscle, are first affected. The effects of CO are directly related to the level and duration of exposure. Initial symptoms include headache, fatigue, shortness of breath, nausea, dizziness, and tachycardia. At higher concentrations, cognitive impairment, loss of muscle coordination, coma, and death are possible. Symptom progression is illustrated in Table 53.2. Reductions in maximal oxygen consumption occur in normal young men with COHb levels near 5%.[42] Cardiovascular disease brings an even higher risk of morbidity with CO exposure.[50] A clear distinction should be made between angina and onset of cardiovascular disease as related to CO exposure, as moderate to severe CO exposures resulting in myocardial injury have shown morbidity and mortality implications.[43]

The average level of CO in homes without gas stoves is generally low, at 0.5 to 5 ppm. Levels near properly adjusted gas stoves vary between 5 and 15 ppm, but in poorly adjusted stoves, these levels can rise to 30 ppm or higher. At CO levels of 70 ppm, symptoms become more

TABLE 53.2
Carboxyhemoglobin Levels and Associated Symptoms

CO-Hb	Symptoms
10%	Dyspnea on exertion, forehead tightness, dilatation of cutaneous vessels
20%	Dyspnea on exertion, headache/throbbing temples
30%	Headache, irritability, altered judgment, fatigue, dizziness, vision changes
40–50%	Headache, confusion, syncope
60–70%	Coma, seizures, respiratory failure; death if prolonged exposure
80%	Rapidly fatal

noticeable, and at levels greater than 150–200 ppm, disorientation, unconsciousness, and death may occur.

CO levels can be monitored at home with a commercially available detector. The Consumer Product Safety Commission (CPSC) and the EPA recommend that a detector be located near the home sleeping area and on each level of the home.[44] They should not be directly above or beside burning appliances, as appliances may emit a small amount of CO upon start-up. A detector should not be placed within 15 ft of heating or cooking appliances or near very humid areas such as bathrooms.[45]

53.6 INDOOR MOLD

Mold is ubiquitous in the outside environment and plays an important role in breaking down organic matter such as trees and leaves. The abundance of mold enables easy transportation into the indoor environment, including homes, schools, and businesses, where it can raise concerns for long-term adverse health effects and worsening pre-existing lung disease. Approximately 100 molds have been identified as potentially harmful to human health, although only a few are commonly found in indoor environments. The molds most commonly found in the indoor environment include *Cladosporium*, *Alternaria*, *Epicoccum*, *Fusarium*, *Penicillium*, *Geotrichum*, *Rhodotorula*, *Chaetomium*, and *Aspergillus*.[46]

Molds are organisms with rigid cell walls that lack chlorophyll and vascular tissue. Molds are a subset of fungi and live on organic matter such as decaying plants and living animal tissue. By digesting materials deemed unusable by other organisms, molds can grow on home materials such as carpeting, drywall, ceiling tiles, and building materials made from organic matter. Molds thrive in a moisture rich environment and reproduce by germination of small particles called spores. Spores can grow, aerosolize, and be inhaled by or come in contact with humans in the environment. This was seen in the aftermath of hurricanes Katrina and Rita, when many homes had to be demolished due to excessive mold growth.[47]

A small subset of molds induce an immunoglobulin mediated antibody response in humans.[48] Illness brought on by molds can be classified into two types, infectious and noninfectious. Noninfectious types include allergic bronchopulmonary aspergillosis (ABPA), hypersensitivity pneumonitis, and worsening of pre-existing asthma. The most common symptoms of excessive indoor mold exposure include non-asthmatic cough, wheezing, headache, and sneezing. This can be exacerbated by energy-efficient homes, so-called tight homes, having closed ventilation systems with high indoor temperatures and humidity.[46] Exposure to mold or dampness during infancy increased the risk of asthma and rhinitis in a variety of cohorts, a risk that persisted into adolescence.[49,50]Infectious complications are less common. For example *Aspergillus* mold can be isolated in asymptomatic individuals, found in walled off cavitary lesions called aspergillomas, or in severe cases of infection, cause invasion of lung and blood vessels. However, this spectrum rarely causes disease in immunocompetent individuals and only becomes more common and more serious in the severely ill or immunocompromised.[51]

Preventing mold exposure involves identification and removal of both the mold and the moisture rich environment. Mold growth is readily identified in areas of prior water damage or high humidity by both visual identification and odors from the breakdown of organic matter. Mold can be successfully removed from hard non-porous surfaces with detergent and water, followed by complete drying. Porous areas, including ceiling tiles and carpets, should be disposed of, as the mold cannot be eliminated with cleaning alone.[52] Dead mold may cause health effects and must also be removed. Importantly, mold removal will not be complete until the moisture source is also eliminated.

53.7 ANIMAL DANDER

Animal dander is commonly associated with allergens from the skin cells of animals such as cats, dogs, and other furred pets. Cats and dogs seem to have the greatest risk of causing sensitization and the potential for causing health issues. Epidemiologic studies have shown that sensitization to dog and cat allergens is strongly associated with asthma.[53] Cats are well known to induce sensitization by a protein, Fel d1, which is found in the saliva and salivary glands. This protein is approximately 2.5 μm in diameter and is easily inhaled deep into the lower respiratory tract.[54,55] Because of its small size, up to 1 microgram of the Fel d1 protein may be inhaled per day, which is similar to the amount used in sublingual immunotherapy.[56] Even homes without cats can have high concentrations of up to 80 micrograms of Fel d1 per gram of dust/[54,57] Current evidence suggests that early exposure to animal dander in childhood reduces the likelihood of sensitization and subsequent development of asthma from both cats and dogs. It is important to tell patients that completely non-allergenic animals do not exist, but there are some breeds that are thought to be less allergenic.[58] Studies of Can r1 and r2, antigens released by dogs, found that these proteins were significantly higher in breeds promoted as hypoallergenic.[59,60] Reducing exposure to animal dander may be accomplished by using high-efficiency particulate air (HEPA) filters, frequent bathing of the animal, or removing the animal from the environment altogether.

53.8 DUST MITES

Dust mites, *Dermatophagoides pteronyssinus* and *Dermatophagoides farinae*, are arthropods from the class Arachnida that colonize bedding, sofas, carpets, and any other woven material within the home. Dust mites are the most common allergen worldwide but are infrequently found at high altitude, in arid conditions, and in areas exposed to long, cold winters due to low humidity. Aside from causing allergic disease, dust mites

TABLE 53.3
Environmental Dust Mite Control Measures

- Use of impermeable mattress and pillow covers.
- Minimize reservoirs by frequent vacuuming and removal of stuffed animals from bedrooms.
- Remove carpeting from the bedroom.
- Decreasing the indoor humidity to less than 50%.
- Frequent washing of bedding, approximately every two weeks, in hot water.
- Removal of upholstered furniture.
- Avoidance of feathered and non-hypoallergenic pillows.
- Routine use of insecticides or allergen-denaturing agents is not recommended.

do not pose any other risk to human health. Mites, and the debris they produce, are microscopic, absorb moisture from the environment, and feed on dead animal and human skin cells. It is not the mite itself, but its fecal particles, that result in a strong allergic response in up to 26% of Americans.[61] Dust mite particles are large and heavy and when dispersed from their source only remain aerosolized for up to 15 minutes, settling very quickly.[62] This makes air purifiers such as HEPA filters ineffective with dust mite antigen removal. Although dust mites are found frequently in carpets and upholstered furniture, the most common sources are bed mattresses. Dust mite allergens can worsen pre-existing asthma but are not known to directly cause it. Table 53.3 shows control measures that can reduce dust mite allergen burden.

53.9 COCKROACHES

Cockroaches are common in the environment and play an important role in indoor air quality and the development of asthma, particularly in urban environments. While there are over 3,500 different species, the most common are the German species *Blatella germanica* and the American species *Periplaneta americana*. Antigenic particles Bla g1 and Bla g2, similar to those produced by dust mites, are found in fecal particles as well as secretions.[63] High levels of cockroach infestations are seen in densely populated areas, urban or inner-city communities, and areas of low socioeconomic status.[64] Children sensitized to cockroach antigen at high levels (>8 U/g) were more likely to develop asthma, have higher asthma morbidity, and require more office visits and hospitalizations due to asthma.[65] Matsui and colleagues outline a comprehensive review of disproportionate asthma mortality among inner-city residents where approximately half of the homes have cockroach allergen levels more than >8 U/g.[66]

Several techniques have been recommended to reduce cockroach exposure, including covering food, controlling humidity, improving indoor sanitation, and implementing both chemical and nonchemical extermination.[67] Although a difficult task, improving sanitation and reducing overcrowding may significantly minimize the development and severity of asthma in inner-city children.

53.10 MICE

Mice and the allergens they release pose a significant health risk for both urban and rural indoor air quality. Mus m 1 and Mus m 2 are the major allergens found in mice dander, hair, and urine.[68] These allergens are commonly found in inner-city urban environments and are highest in rooms where food products are stored, including the cafeteria or kitchen. Mouse allergens were found in 95% of homes in a large study of inner-city children with asthma.[69] The greatest predictor of high levels of mouse allergen exposure was the presence of visible droppings.[70] The impact of these allergens was noted by Sheehan et al., where children with pre-existing asthma in homes with high levels of mouse allergen had more missed school days due to asthma-related events.[71] Exposure to mouse allergen is associated with high rates of sensitization. Children sensitized to mouse allergen were found to have increased risk of developing asthma and higher rates of asthma-related morbidity.[72] Urban children with asthma in homes with a high bed mouse allergen concentration were shown to have an 87% higher probability of asthma-related healthcare use.[73]

Overall, mice have a significant impact on the lung health of the people exposed and sensitized to their allergen. The most effective way to limit their impact is to prevent or reduce the chance of exposure. The use of rodent-proof construction, improved sanitation, and population control using traps and chemicals may also reduce exposure.

53.11 WATER PIPE SMOKING (ALSO KNOWN AS HOOKAH)

Known by other names, including Shisha and Narghile, combustible water pipe smoking has occasionally been falsely touted as a "safe" alternative to smoking. It is not a new idea, with reports of use dating back to the fifteenth century in both the Middle East and Europe, and predates the use of cigarettes.[74] Hookah bars, some opened in response to laws limiting indoor tobacco use, are small cafés and clubs that rent hookahs and their respective materials.[74] These bars are often geographically located to market themselves to young adults aged 18–24. One study found that one in five boys and one in six girls aged 18 had used water pipe tobacco in the past year.[75]

Smoking is done through direct heating of tobacco, sometimes flavored with burning embers or charcoal. The smoke is drawn through a pipe to a mouthpiece to be inhaled. Not surprisingly, the limited existing evidence indicates that water pipe smoking carries the same or similar health risks as cigarette smoking. Links have been made to many of the same adverse health effects, including lung, oral, and bladder cancer, as well as coronary artery and heart disease.[76,77] Despite knowing the risks, almost 90% of beginning Hookah smokers thought that cigarette smoking was

more addictive.[78] Analysis of mainstream smoke from water pipes found that it contains significant amounts of nicotine, tar, and heavy metals.[78,79] Nicotine levels increased up to 250% and cotinine levels, a chemical marker of nicotine exposure, to 120% with just one water pipe session lasting 40 minutes.[79] Because water pipe smoking has a more prolonged inhalation time and exposure than a conventional cigarette, it has been estimated that one session can be equivalent to smoking 100 cigarettes within that time.[79]

Other risks are also seen with use of the heat sources that are used to light the tobacco, such as wood or charcoal. These substances alone, when ignited, put one at risk for exposure to smoke that contains heavy metals and carbon monoxide. These compounds are known to cause cancer and obstructive lung disease more commonly in developing countries that use fire to cook.

Continued research may determine the absolute long-term health risks of water pipe smoking. The current evidence supports that both direct exposure and secondhand smoke exposure are at least similar to that of cigarette smoking and does not support it as a "safe" alternative.[75]

53.12 ELECTRONIC CIGARETTES (ALSO KNOWN AS VAPING)

Similarly, somewhat based on the perception of their safety compared with combustibles, there has been an exponential growth in electronic cigarettes.[80] A variety of electronic products are available, such as e-cigars, e-pipes, e-hookah, vapes, pens, mods, and electronic nicotine delivery systems (ENDS).[81]

e-Cigarettes are now the most used tobacco product for youths. In 2021, 2.8% of middle school students and 11.3% of high school students had used e-cigarettes in the past 30 days.[82] Based on Centers for Disease Control (CDC) data in 2020, 3.7% of U.S. adults were current e-cigarette users, increasing by 0.5% in the last four years.[4]

e-Cigarettes consist of a mouthpiece, a cartridge, an atomizer, a battery, and an indicator light. Once activated, the battery-powered heating element aerosolizes and delivers to the lung a mixture of compounds, which includes propylene glycol, vegetable glycerins, flavorants, vitamin E, lecithin, solvents, sometimes adulterants, and the intended ingredient of nicotine or frequently, cannabinoids.[80,83] Each cartridge can contain 6 to 24 mg of addictive nicotine, with a real and sometimes even greater risk for e-cigarettes to become addictive.[80,84] With innumerable brands, flavors, and options from both shops and other less regulated sources, the actual ingredients and nicotine content have remained murky and unclear.

On a cellular level, ENDS may promote vascular endothelial dysfunction, increased inflammation, and oxidative stress. Impaired pulmonary immunity has been reported in animal studies.[85] Likewise, e-hookah, when compared with combustible hookah, increased larger arterial stiffening and showed an increase in inflammatory biomarkers of C-reactive protein, fibrinogen, and tumor necrosis factor.[86]

Clinically, e-cigarette use may cause bronchitic symptoms, especially in adolescents.[87] Propylene glycol and glycerol vapor are known upper airway irritants and the most common components of many e-cigarettes.[80,84] Clinically, numerous cases and even deaths from severe respiratory illness have been associated with vaping product use, leading to the novel term "e-cigarette vaping product associated lung injury" (EVALI).[88] Proposed definitions and largely supportive care management thereafter have been debated, but there is agreement that vaping proposes significant risk in these unfortunate cases.[83,88] Furthermore, the diverse nicotine derivatives, polycyclic aromatic hydrocarbons, heavy metals, and aldehydes have shown cytotoxic activity, the long-term implications of which are concerning but ultimately unknown.[89] Increased urinary excretion of known carcinogenic volatile organic compounds from adolescent e-cigarette users would support the worry of carcinogenic risk.[90] The California Department of Public Health, in fact, was among the first to issue an advisory for the potential of e-cigarettes to cause cancer and birth defects as well as other reproductive harm.[91]

Yet again, secondhand exposure to e-cigarette emissions and toxins, especially indoors, is not without risk, and as such, the German Cancer Research Center has even issued an advisory.[80] Thirdhand toxin exposure continues to be a risk, as possible transmission from residual airborne nicotine, indoor carbon dioxide, aldehydes, and other particulate matter may remain on indoor surfaces in a variety of vape shops and was strongly correlated with the number of active vapers per hour.[92]

53.13 CONTAMINATION OF HOME SHOWERHEADS, DISHWASHERS, AND CPAP DEVICES

Although showering is thought to cleanse us from bacteria and other organisms we encounter throughout our day, bacterial contamination of household showerheads with potential pathogens has been reported. Organisms that can cause pneumonia in humans, such as *Mycobacterium abscessus*, *Mycobacterium avium* complex (MAC), and *Legionella*, have been isolated from showerheads, raising concern for potential infection of immunocompromised patients even in their own homes. Unhooking and allowing the showerhead to dry did not reduce the risk of Legionella or MAC colonization.[93,94]

Home dishwashers may also be contaminated with organisms such as *Pseudomonas*, *Escherichia*, and *Acinetobacter*, which can also cause pneumonia in humans.[95] In addition to bacteria, in one study, 83% of dishwashers tested were positive for the presence of fungi. The most common sites of contamination were the side nozzles, doors, and drains. Hot aerosols from dishwashers released into kitchens were also found to contain human opportunistic yeast. The plumbing system supplying water to the home was the suspected site of dishwasher contamination.[96] While theoretically a risk to those who are immunocompromised, there have been no

scientifically tested regimens of clear benefit to rid dishwashers or showerheads of contamination.[96]

It is estimated that more than 18 million Americans carry the diagnosis of obstructive sleep apnea (OSA) and that untreated sleep apnea has cost implications with resultant workplace accidents, motor vehicle accidents, lost productivity, and comorbid diseases. It is therefore essential that patients with OSA be treated. Continuous/bilevel positive airway pressure (CPAP/BiPAP) is the therapy of first choice for patients with OSA and used as well for many other respiratory conditions. However, contamination of devices may lead to additional problems due to growth of bacteria in the humidifier chamber, contaminated tap water use, and inconsistent cleaning of the device, hoses, and filters. To prevent this contamination, distilled water, which is free from bacteria, is the safest type of water to use in the CPAP humidifier. It is recommended that nondisposable CPAP filters be cleaned and reused weekly and changed every six months, and that CPAP tubing should be cleaned with warm soapy water every week and changed every three months. It is also recommended that the cushions on a CPAP mask be replaced twice monthly and that a new mask should be obtained at least every six months.[97] Devices claiming to disinfect and sanitize CPAP machines via ozone gas or ultraviolet light have fallen out of favor following a warning that these cleaning devices are not in fact Food and Drug Administration (FDA) authorized.

53.14 SMART DEVICES THAT ANALYZE INDOOR AIR QUALITY

Smartphone technology, integration, and the internet of things allow the exciting development of smart devices for our homes, workplaces, and all public buildings. Individual tools such as smart thermostats can personalize temperature control on schedule or even autonomously. Sensors are available to monitor levels of common indoor air pollutants such as carbon dioxide, volatile organic compounds (VOC), and particulate matter, which is solid particles and liquid droplets found in the air.[98] Monitoring and integrated control of temperature and humidity could directly improve air quality while combining other comfort metrics such as lighting or acoustics, proposing complete control of the indoor environmental quality.[99] Smartphone applications for the management, display, and analysis of this data can then be personalized by users to specific targets or analysis from a public health perspective. Air quality monitoring or "e-nose" devices have been proposed to protect vulnerable groups from indoor hazards. Research will be necessary to see if smart devices will be helpful tools to improve immediate safety and long-term lung health.[100]

53.15 SUMMARY

This chapter has identified key elements of indoor air quality that significantly impact the health of individuals in the United States. We have emphasized the relationship between indoor air quality and health as it pertains to exposure to the many different agents in the home. Many individuals remain unaware of the potential detrimental effects associated with these exposures. These range from secondhand combustible or vape smoke to radon or even the family pet. Lung health is important to all ages, and it is crucial to target environmental exposures that may increase health risks, including asthma, allergic reactions, and lung cancer. The U.S. government, through various agencies, continues to monitor and provide guidelines, reports, and recommended testing for many of these agents. However, simple interventions that can promote lung health include not allowing smoking of any kind indoors; checking home radon levels; reducing conditions that promote mold growth, dust mites, and animal dander; monitoring carbon monoxide levels; and keeping home appliances clean and replacing worn parts. More research is needed to identify potentially new home contaminants and pollutants, and how best to monitor them and their potential respiratory health effects. Lifelong awareness among family members and housemates, elimination of potential indoor environmental hazards, and increased awareness by healthcare providers are essential to promote long-term lung health and wellness.

CLINICAL APPLICATIONS

- Keep pollution out of your home by not allowing smoking indoors, by checking for radon, and by protecting against carbon monoxide.
- Control humidity in your home to decrease dust mites and mold growth.
- Avoid e-cigarette and hookah use and educate adolescents to their potential dangers.
- Avoid adverse effects of pet exposure by using HEPA filters and bathing furred pets.
- Keep CPAP apparatus clean by changing masks, cleaning hoses and filters at prescribed intervals, and replacing disposable components.

54 COVID-19

Monica Hinestroza Jordan, MD and Sandeep Singh Jubbal, MD

KEY POINTS

- SARS-CoV-2 is a novel virus belonging to the *Coronavirus* family, which also includes severe acute respiratory syndrome coronavirus (SARS-CoV) and Middle East respiratory syndrome coronavirus (MERS-CoV), responsible for major outbreaks in history.
- Human to human transmission of aerosolized viral particles is the route for community spread.
- Infection can be asymptomatic, or with mild flu-like symptoms, or present as severe pneumonia and multi-organ failure.
- Old age and certain comorbidities, such as obesity, cardiovascular disease, diabetes, chronic kidney disease, chronic liver disease, chronic lung disease, malignancy, and underlying immunosuppression, have all been associated with progression to severe disease and increased mortality from COVID-19.
- Vaccination as well as early treatment with antiviral agents or monoclonal antibodies have been shown to significantly decrease the length of illness, severity, and mortality from COVID-19.

54.1 DEFINITION

Coronavirus disease 2019 (COVID-19) is an acute atypical respiratory infection caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). It was first identified as an outbreak in Wuhan, China and later declared a pandemic by the World Health Organization on March 11, 2020.[1]

54.2 BACKGROUND OF CORONAVIRUS OUTBREAK

Coronaviruses (CoV) of zoonotic origins have been known to cause infections in humans, ranging from common colds to severe respiratory infections. Out of these, three have led to more severe disease and outbreaks. Severe acute respiratory syndrome coronavirus (SARS-CoV), originating from bats in Guangdong, China, was responsible for the respiratory disease outbreak in 2002–2004 with about a 10% case fatality rate.[2] Middle East respiratory syndrome coronavirus (MERS-CoV) from dromedary camels was first reported in Saudi Arabia in June 2012 and spread to 27 countries with a case fatality rate of 34.4%.[3] In December 2019, several cases of acute atypical respiratory infections were identified in Wuhan, China. The pathogen was rapidly identified as a novel coronavirus from the family *Coronaviridae* and was later named severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2), given its resemblance to SARS-CoV. The origin of COVID-19 outbreak is unclear currently. Human to human transmission is the route for community spread. As of September 2022, COVID-19 has been reported in 228 countries and is responsible for the death of more than 6 million people worldwide with an observed fatality rate up to 5.9% in some countries.[4,5]

54.3 STRUCTURE OF SARS-COV-2

The CoVs are enveloped, single-stranded RNA viruses with a multi-domain nucleocapsid. SARS-CoV-2 possesses four structural proteins, the N (nucleocapsid) that holds the RNA genome, the S (spike) protein that is involved in cellular attachment and viral host cell entry, the E (envelope), and the M (membrane) protein, which plays a key role in viral assembly.[6] The S protein is composed of two subunits: S1 assists with binding to the host cell receptor, and S2 is responsible for fusion of the host and viral cellular membranes.[1] The S1 unit is further divided into a receptor-binding domain (RBD), which binds to the human angiotensin-converting enzyme 2 (ACE2) receptor, and an amino terminal domain (NTD).[7] The two subunits of the spike protein require cleavage by cellular proteases to allow the activation of the S protein and subsequent attachment and fusion to the host membrane.[8]

54.4 GENETIC VARIATION

Constant mutations are part of natural viral evolution. Compared with DNA viruses, RNA viruses usually have higher mutation rates. Interestingly, CoVs have a lower rate of genomic mutations due to the presence of an exonuclease enzyme that decreases replication errors.[8] Most of the documented mutation in the SAR-CoV-2 virus has been identified in the spike protein, leading to a decreased immunologic vulnerability to neutralizing antibodies, whether vaccine-induced or therapeutic monoclonal antibodies, causing increased transmissibility rates and risk of reinfection.[8] Some of the most common mutations on the SARS-CoV-2 variant include D614G mutation, associated with increase in viral replication in the respiratory epithelium as well as greater infectivity, N501Y mutation, associated with higher affinity for the ACE2 receptor,[9] and the

DOI: 10.1201/9781003227793-63

TABLE 54.1
Variants of Concern

Variant name	Initial identification	Mutations	Characteristics
B.1.1.7 (Alpha)	United Kingdom - 09/20	Spike mutations: RBD mutation N501Y, P681H; NTD deletions at 69-70 and 144 positionsNon-Spike mutations: D3L, R203K, and G204R	Able to antagonize innate immunity, which increase its transmissibilityHigh viral load in the upper airway50% increase in mortality compared with previous variants
P.1 (Gamma)	Brazil - 10/20	Spike mutations: RBD mutation N501Y, E484K, and K417TNTD mutations that interfere with the binding to neutralizing Ab	High infection rateAble to infect and cause disease in people with history of infection by prior variants
B.1.1.529 (Omicron)	South Africa and Botswana - 09/21	Highly mutated strain with amino acid changes in all four structural and in non-structural proteins	Increased transmissibilityReduction in neutralization by few monoclonal antibodiesLess severe disease
B.1.351 (Beta)	South Africa - 09/20	Spike mutations: RBD mutation N501Y, E484K, and K417NNTD deletions at 242-244 positions	50% more transmissible than other variants. Re-infections commonly seen
B.1.617.2 (Delta)	India - 3/21	Spike mutations: RBD mutations L452R, P681R, and T478KNTD deletions at 69-70 and 144 positions	Increased transmissibilityBNT162b[a] vaccine showed effectiveness of up to 85%, and AZD1222[b] vaccine was effective in 60% of cases

[a] Pfizer/BioNTech vaccine.
[b] AstraZeneca vaccine.
Table highlights common SARS-CoV-2 variant of concerns, critical mutations and other characteristics.[8–11]

E484K escape mutation, which is associated with reduced monoclonal antibody neutralization[8] (Table 54.1).

54.5 EPIDEMIOLOGY

SARS-CoV-2 has been a cause of major concern worldwide ever since it was first reported in December 2019 in China. As of September 2022, SARS-CoV-2 has been identified in 228 countries with 554 million cases and more than 6 million deaths.[5] COVID-19 was the third leading cause of death in 2020 in the United States, accounting for approximately 375.000 deaths.[12] As per the World Health Organization (WHO), the estimated case fatality globally is close to 2.2%, but this rate varies significantly between countries due to differences in socio-economic status, access to healthcare, resource limitation, capacity strain, varying comorbidities, age of the population, and severity of illness.

Patients with certain comorbidities are at a higher risk of developing severe disease and complications. Conditions associated with increased risk include age older than 60 years, obesity, cardiovascular disease, diabetes, chronic kidney disease, chronic liver disease, chronic lung disease, smoking, neoplasia, and underlying immunosuppression. Both hospitalization and mortality rates were significantly higher in this select group compared with patients with no to low risk (45.4% vs. 7.6% and 19.5% vs. 1.6%, respectively). Male patients also were found to have an increased risk of severe disease and mortality compared with female patients.[13–16]

Although the racial disparities in COVID-19 outcomes have not been clearly identified, there is clear evidence that Black-American, Hispanic, and certain ethnic minority groups experienced a higher risk of infection and severe disease. Among these minorities, Hispanics had the highest mortality rate.[12,15,16,17]

54.6 ECONOMIC IMPACT

The total economic impact of the SARS-CoV-2 pandemic is unknown at this time, but history has shown that an event of this magnitude has long lasting effects on society. Several disease control strategies to limit the spread of infection, like "lockdowns," travel restrictions, and social distancing, have significant socio-economic impact resulting in economic fallout and unemployment rates. These strategies caused significant hardships within diverse sectors including education, the manufacturing and service industry, healthcare, and supply chains.[18] COVID-19 has also exposed the fragility of healthcare systems and the lack of disaster preparation strategies globally.[18]

54.7 PATHOPHYSIOLOGY OF SARS-COV-2

SARS-CoV-2 attaches to and penetrates host cells via the spike protein, which is formed by two subunits (S1 and S2) and a cleavage site. The S1 subunit is further divided into a receptor binding domain (RBD) and an amino terminal domain (NTD). RBD acts as a binding site for the human ACE2 receptor. The latter is found in abundance on respiratory epithelial cells, upper esophageal lining, myocardial cells, renal proximal tubular cells, bladder urothelial cells, endothelial cells, and ileal enterocytes.[19] The RBD domain

is also the target for neutralization by the host antibodies.[20] Attachment of virus to the ACE2 receptor leads to exposure of a cleavage site on the S2 subunit. This is cleaved by either the host transmembrane serine protease 2 or the cathepsins, leading to host–virus membrane fusion and viral RNA release into the host cell.[16,20,21]

Although SARS-CoV-2 can affect multiple organs, COVID-19 is mainly considered as a respiratory illness. The virus induced lung damage occurs in two phases, early and late. The early phase is characterized by rapid viral replication leading to direct tissue damage, whereas the late phase is dominated by an overwhelming response of the host immune system with deployment of neutrophils, monocytes, and T lymphocytes. This so-called cellular activation precedes the release of various cytokines—interleukin (IL) 1, IL 6, IL 8, and IL 12, interferon-γ (IFN-γ), tumor necrosis factor-α (TNF-α), and granulocyte-macrophage colony-stimulating factor (GM-CSF).[16] In severe cases, the resultant overwhelming and uncontrolled systemic inflammatory response—the "Cytokine Storm"—leads to direct endothelial damage and subsequent microvascular and microthrombi deposition.[22,23]

Various other mechanisms leading to vascular permeability, such as dysregulation of the renin angiotensin system (RAS) and activation of the kallikrein-bradykinin pathway, have also been described. In the lungs, these manifest as COVID-19 pneumonia progressing to pulmonary edema and acute respiratory distress syndrome (ARDS). Besides the lungs, the overactivation of the immune system also leads to multi-organ dysfunction.

54.8 CLINICAL FEATURES

The clinical manifestations of COVID-19 range from asymptomatic to severe disease resulting in ARDS and multi-organ failure, as described earlier. The commonly reported symptoms of COVID-19 include:

- Fever
- Cough
- Shortness of breath
- Severe fatigue
- Anosmia
- Dysgeusia
- Nauseas
- Myalgias
- Diarrhea
- Anorexia

The clinical presentation of COVID-19 has been divided into five categories per the National Institute of Health:

- Asymptomatic or pre-symptomatic: Individuals with positive SARS-CoV-2 test without symptoms
- Mild disease: Patients with common COVID-19 symptoms without the shortness of breath and with normal chest radiographic findings
- Moderate disease: Patients with lower respiratory symptoms or with abnormal lung imaging but with oxygen saturation greater than 94% on room air
- Severe disease: Patients with oxygen saturation less than 94% on room air, a respiratory rate greater than 30 breaths per minute, ARDS, or lung infiltrates or pulmonary infiltrates of more than 50%
- Critical illness: Patients with respiratory failure, septic shock and/or multi-organ dysfunction

Other extrapulmonary manifestations of COVID-19 include:

- Cardiovascular: myocardial ischemia, myocarditis, arrhythmias, cardiomyopathy, cardiogenic shock
- Hematologic: lymphopenia, thrombocytopenia, leukopenia, leukocytosis, elevated inflammatory markers such as C-reactive protein (CRP)
- Renal: acute kidney injury, proteinuria, hematuria, electrolyte abnormalities, metabolic acidosis
- Central nervous system: stroke
- Gastrointestinal: transaminitis

54.9 DIAGNOSTIC TOOLS

Rapid and accurate screening is a vital step in the containment of SARS-CoV-2 virus, especially given its high contagiousness and virulence. A significant number of resources have been dedicated to the development of rapid and reliable diagnostic tests to detect SARS-CoV-2 in both symptomatic as well asymptomatic patients.[24]

The current available diagnostic tests can be divided into the following three main categories:

1. **Nucleic acid-base diagnosis**: Detection of genomic regions of the pathogen either via polymerase chain reaction (PCR) or by using hybridization probe.
   Reverse-Transcription–Polymerase Chain Reaction (RT-PCR) is currently considered the gold-standard for the diagnosis of COVID-19. Besides providing high diagnostic specificity, it also serves as a valuable tool for determining the prognosis of the disease and infectiousness using the cycle threshold (CT) value. A CT value is the actual number of cycles (or amplifications) needed for the PCR test to detect the virus.[25]

   The sensitivity of PCR is highly variable and is mainly affected by the sample type, reported technique, and initial viral burden of the sample. For example, the sensitivity is as low as 40% and 50% from a nasopharyngeal and sputum sample, respectively, but as high as 80–100% from bronchoalveolar fluid. Lately, there have been reports of higher sensitivity, up to 97%, from a self-collected salivary sample.[26,27]

Reverse Transcription Loop-Mediated Isothermal Amplification (RT-LAMP) utilizes four to six primers for amplification at a constant temperature, leading to rapid analysis. It also provides high sensitivity and specificity in a timely manner, making it a useful point of care test.[24,28]

Transcription-mediated amplification utilizes a retroviral reverse transcriptase and RNA polymerase enzyme to amplify a specific region of the viral RNA. This technique has been successfully employed for multiple-pathogen detection.

Clustered Regularly Interspaced Short Palindromic Repeats (CRISPR) based tests can detect viral RNA in fewer steps compared with PCR tests.[29]

2. **Serological and immunological** tests identify viral proteins (or antigens) or antibodies against these antigens in a patient sample. These tests are cost-effective and provide rapid results but carry a lower sensitivity and specificity when compared with molecular tests. Ideal targets for serological assays are the viral structural proteins: the nucleocapsid (N) protein and the RBD domain of spike (S) protein. Both N and S proteins are highly expressed during an infection. Given high false positive and false negative rates, test results must be carefully interpreted in the context of patient symptoms.
3. **Imaging**: Lung imaging can be used as an additional test strategy to support COVID-19 diagnosis. It can also help in categorizing the severity of illness.

   Computerized Tomography (CT) Scan: The common radiological signs of COVID-19 pneumonia include multiple and bilateral peripheral pulmonary infiltrate with ground glass, lobular, and/or segmental areas of consolidation.

   Lung Ultrasound: The point of care ultrasound (POCUS) of the lung has become an important bedside tool for a rapid, safer, and cost-effective diagnosis. Recently, there have been several studies attesting to the use of POCUS with 85–97% sensitivity, 91% specificity, and 97% positive predictive value in detecting COVID-19 pneumonia.[24–30] (Table 54.2).

54.10 ANTIVIRAL THERAPY

The spectrum of medical therapies to treat COVID-19 continues to grow and evolve. Almost all available therapeutic options are investigational and used under the United States Food and Drug Administration (FDA) Emergency Use Authorization (EUA) policy. As of September 2022, Remdesivir is the only antiviral agent that has received FDA approval for use in adult and pediatric patients weighing at least 3 kilograms.[31]

COVID-19 therapeutics are broadly classified into:

1. Antiviral agents: target viral attachment and replication
2. Anti-inflammatory agents: suppress dysregulated inflammatory response to SARS-CoV-2

After an initial exposure to SARS-CoV-2, patients typically develop symptoms within five to six days. The virus then generates a diverse range of clinical manifestations, ranging from mild infection to severe disease accompanied by high mortality in certain individuals with risk factors for

TABLE 54.2
Characteristics of the Diagnostic Tests Most Used

Detection technique	Test type	Testing site	Processing time	Accuracy	Quantitative or qualitative	Detection time after infection
RT-PCR	Nucleic acid-based	Laboratory	4 h	High	Both	1–8 days
Isothermal nucleic acid amplification	Nucleic acid-based	Laboratory	>3 h	High	Both	1–8 days
CRISPR-based assays	Nucleic acid-based	Laboratory	1 h	High	Both	5–10 days
Nucleic acid sequencing	Nucleic acid-based	Laboratory	2 h	High	Both	5–10 days
ELISA	Antibody detection	Laboratory	2 h	High	Both	5–10 days
LFA	Rapid antigen detection	Point of care	10–30 min	High	Only qualitative	10 days
Luminescent immunoassay	IgM and IgG antibody detection in patient's serum	Laboratory	2–3 h	High	Both	5–10 days
Protein microarray	IgM and IgG antibody detection	Laboratory	20–30 min	Moderate	Both	5–10 days
Agglutination assay	Antibody detection	Point of care	10–30 min	Moderate	Only qualitative	5–10 days

RT-PCR: reverse transcription–polymerase chain reaction.; ELISA: Enzyme-linked immunosorbent assay; LFA: Lateral flow assay.[24]

disease progression. In patients with mild infection, the initial host immune response is capable of controlling the infection. But in severe disease, excessive immune response leads to organ damage, respiratory failure, or death. The viral load usually peaks in the first week of infection and declines thereafter, while the antibody response gradually increases and is often detectable by day 14.

There are two main processes that drive the pathogenesis of COVID-19. Early in the clinical course, the disease is primarily driven by the replication of the SARS-CoV-2 virus. Later in the clinical course, the disease appears to be driven by a dysregulated immune and inflammatory response to SARS-CoV-2 virus leading to pneumonia, subsequent respiratory failure, and multi-organ damage. Thus, the antiviral therapies would have the greatest effect early in the course of the disease, whereas the immunosuppressive/anti-inflammatory therapies (like dexamethasone, tocilizumab, baricitinib) are likely to be more beneficial in the later stages of COVID-19.

54.10.1 Remdesivir

Remdesivir is a broad-spectrum antiviral agent with activity against members of the filoviruses like the Ebola virus, Marburg virus, and Coronaviruses. It is a prodrug that inhibits viral RNA polymerases. It is currently available only in an intravenous (IV) formulation, although an oral prodrug of the Remdesivir parental nucleoside is under investigation at the time of this writing.[32]

High-risk patients with COVID-19 having mild symptoms and a normal oxygen saturation presenting within seven days from symptom onset would be eligible for a three-day Remdesivir course.

COVID-19 patients with hypoxia (oxygen saturation less than 94% on room air), or those requiring supplemental oxygen by means of non-invasive or mechanical ventilation, would be eligible for a five-day course instead.[33] The duration can be extended to ten days if there is no clinical improvement, especially for patients on mechanical ventilation or extracorporeal membrane oxygenation (ECMO), although the evidence is limited.

Patients on Remdesivir need monitoring of their liver function. Alanine aminotransferase (ALT) value more than ten times the upper normal limit is an absolute contraindication to Remdesivir use.[33] Remdesivir should be used with caution in patients with underlying renal insufficiency due to the cyclodextrin vehicle used in the intravenous formulation, which can accumulate in patients with renal failure and may be toxic.

The rationale for a five-day treatment course came from the ACTT-1 trial, which was a multinational, randomized, placebo-controlled trial of Remdesivir that included 1,062 patients with confirmed COVID-19 having evidence of lung involvement. Eighty-five percent had severe disease, and 27% were receiving invasive mechanical ventilation or ECMO at baseline. Remdesivir resulted in faster recovery, defined as discharge from the hospital or continued hospitalization without the need for supplemental oxygen. In a subgroup analysis, the reduced time to recovery as well as the mortality benefit was statistically significant only among patients who were on low-flow oxygen at baseline. Among the subset of patients on mechanical ventilation or ECMO, the time to recovery and mortality was comparable to those in the placebo arm. Overall, there was a trend toward a lower 29-day mortality that was not statistically significant.[33]

The PINETREE study[31] was a randomized placebo-controlled trial in non-hospitalized patients with COVID-19 who were at high risk of clinical progression and were within seven days of symptom onset. Non-hospitalized participants were randomized to receive three days of IV Remdesivir or placebo. The results showed 87% relative reduction in the risk of hospitalization or death compared with placebo in patients who received three consecutive days of IV Remdesivir.

In summary, the maximum benefit of Remdesivir is seen in patients receiving no, or only low, supplemental oxygen. Patients requiring high-flow oxygen, non-invasive or invasive ventilation, or ECMO have not been proven to benefit at this time.

54.10.2 Nirmatrelvir-Ritonavir (Paxlovid™)

Nirmatrelvir-Ritonavir belongs to the class of protease inhibitors. Nirmatrelvir is active against a specific SARS-CoV-2 protease that plays an essential role in viral replication. Ritonavir, on the other hand, is used in the combination as a pharmacokinetic boosting agent. It augments Nirmatrelvir to achieve target therapeutic ranges via cytochrome P450 3A4 inhibition. Both Nirmatrelvir and Ritonavir are co-packaged and commercially available as Paxlovid™.

In the Evaluation of Protease Inhibition for COVID-19 in High-Risk Patients (EPIC-HR) trial,[34] co-administration of Nirmatrelvir and Ritonavir by mouth for five days, initiated as soon as possible and within five days of symptom onset, showed 88% reduction in the risk of hospitalization and death from COVID-19.

It is not recommended for use in patients with an estimated glomerular filtration rate (eGFR) of less than 30 mL/min and requires dose modification for patients with an eGFR between 30 and 60 mL/min. It is also not recommended in patients with severe hepatic impairment (i.e., Child-Pugh Class C). Paxlovid™ has significant drug–drug interactions, primarily due to the ritonavir component in the combination. Thus, an accurate medication reconciliation and review of drug–drug interactions must be performed.[35]

54.10.3 Molnupiravir

Molnupiravir is another oral antiviral agent used under FDA EUA in patients with mild to moderate COVID-19.[36] It is a ribonucleoside that has broad antiviral activity against RNA viruses, resulting in viral mutation. However, given

TABLE 54.3
Antiviral Agents Used in Patients with Mild to Moderate COVID-19

Drug	Route	Days from symptom onset	Dosing
Remdesivir	Intravenous	7	200 mg on day 1 and 100 mg on days 2 and 3
Monoclonal antibody	Intravenous	7	See Table 54.4
Nirmatrelvir-Ritonavir	Oral	5	eGFR ≥60 mL/min: 300–100 mg twice daily for 5 days eGFR ≥30 to <60 mL/min: 150–100 mg twice daily for 5 days eGFR <30 mL/min: contraindicated
Molnupiravir	Oral	5	800 mg twice daily for 5 days

the concerns of its mutagenic potential in human host cells, it is reserved as a second line therapy. It is also contraindicated for use in pregnant patients due to reports of fetal toxicity observed in animal studies. Likewise, sexually active men should refrain from sex or use barrier contraception while receiving molnupiravir and continue to do so for at least three months after the last dose (Table 54.3).

54.10.4 Monoclonal Antibody

A monoclonal antibody (mAb), as the name suggests, is produced by a single clone or cell line, and consists of identical antibody molecules targeting a particular protein. The monoclonal antibodies against SARS-CoV-2 are derived from immunization of humanized mice with the viral spike protein and tested for potency against the virus. The most potent antibodies are then selected and are put into a cell line for large-scale production.[35,37]

Anti-SARS-CoV-2 monoclonal antibodies binds to the RBD of the main spike protein of the virus and prevent viral attachment to the host cells. Multiple randomized trials of commercially available monoclonal antibodies have shown strong evidence of preventing hospitalization and severe outcomes, when administered early in the course of the infection, in patients with mild to moderate COVID-19.

Various formulations have been used for management of patients, primarily based on their effectiveness (or neutralization potential) against the predominant variants driving the pandemic at various points in time. Evolving mutations in the viral spike protein and eventual emergence of SARS-CoV-2 variants have rendered multiple commercially available products ineffective. For instance, the Regeneron® combination of casirivimab and imdevimab, which had demonstrated susceptibility against the Delta, Gamma, and Beta variants, lost its neutralization potential and effectiveness against the Omicron variant due to a critical mutation in its binding site on the RBD. As of September 2022, bebtelovimab is the only available monoclonal antibody that is approved under FDA EUA for use in COVID-19 patients due to its effectiveness against the predominant BA.4 and the BA.5 Omicron subvariants[38] (Table 54.4).

54.11 ANTI-INFLAMMATORY AGENTS

Anti-inflammatory agents are used in patients with severe and critical COVID-19 in whom the pathogenesis is predominantly guided by the dysregulated immune response to SARS-CoV-2 virus.

54.11.1 Dexamethasone

Dexamethasone is indicated in all patients with COVID-19 who have oxygen saturations less than or equal to 94% on room air or who are requiring supplemental oxygen,

TABLE 54.4
Anti-Spike Protein Monoclonal Antibodies

Monoclonal antibody	Dose	Variants neutralized	Variants escaping neutralization
Bamlanivimab-etesevimab	Intravenous 700–1,400 mg as a single dose	Alpha/B.1.1.7Delta/B.1.617.2	Beta/B.1.351Gamma/P.1Omicron/B.1.1.529 and all subvariants
Casirivimab-imdevimab	Intravenous 600–600 mg as a single dose	Alpha/B.1.1.7Beta/B.1.351Gamma/P.1Delta/B.1.617.2	Omicron/B.1.1.529 and all subvariants
Sotrovimab	Intravenous 500 mg as a single dose	Alpha/B.1.1.7Beta/B.1.351Gamma/P.1Delta/B.1.617.2Omicron/B.1.1.529	Omicron subvariants (BA.1, BA.1.1, BA.2, BA.2.12.1, BA.4, BA.5)
Bebtelovimab[a]	Intravenous 175 mg as a single dose	Alpha/B.1.1.7Beta/B.1.351Gamma/P.1Delta/B.1.617.2Omicron/B.1.1.529 and all subvariants (BA.1, BA.1.1, BA.2, BA.2.12.1, BA.4, BA.5)	None as of September 2022[38]

[a]As of September 2022, bebtelovimab is the only approved mAb for use in COVID-19.[38]

non-invasive ventilation, or mechanical ventilation. Results of the RECOVERY trial[39] showed survival benefit of dexamethasone among participants who required supplemental oxygen. In a subgroup analysis of patients with normal or baseline oxygen saturation, there was no evidence for benefit. In fact, there was a trend toward harm in participants who were not on supplemental oxygen.

54.11.2 Tocilizumab

Tocilizumab is a recombinant humanized anti-IL-6 receptor antibody. In an open-label trial of patients with suspected or confirmed COVID-19 with hypoxemia and CRP level ≥75 mg/L, adding one to two doses of tocilizumab to usual care reduced the 28-day mortality rate compared with usual care alone. Eighty-two percent of the trial participants were also using glucocorticoids, mainly dexamethasone, and the subgroup analysis suggested that they were more likely to benefit from tocilizumab than individuals who did not receive glucocorticoids.[40] Thus, Tocilizumab is recommended in patients with severe or critical COVID-19 requiring mechanical ventilation, ECMO, or high-flow oxygen. All eligible patients must be receiving adjunctive dexamethasone and should be within 24 hours of clinical deterioration. Tocilizumab is not recommended without concomitant dexamethasone use. Its use is not recommended in the case of elevated transaminases, thrombocytopenia (platelet counts less than 50,000), severe neutropenia (absolute neutrophil count less than 500), severe immunosuppression, or an active infection other than COVID-19, or in patients who are at a higher risk of bowel perforation.

54.11.3 Baricitinib

Baricitinib is a Janus Kinase (or JAK) inhibitor used for treatment of rheumatoid arthritis. In addition to immunomodulatory effects, it is thought to have potential antiviral effects by interfering with the viral entry. It is given at a dose of 1 to 4 mg orally once daily for up to 14 days, based on the eGFR. It is contraindicated for use in patients with eGFR lower than 15 mL/min and must be used with caution in patients with history of deep venous thrombosis and/or pulmonary embolism.[41] Like Tocilizumab, Baricitinib is indicated for use in patients requiring high-flow oxygen or non-invasive ventilation and for selected patients who are on low-flow oxygen but are progressing toward needing higher levels of respiratory support despite initiation of dexamethasone (Table 54.5).

TABLE 54.5
Drugs Used in the Management of Severe COVID-19

Drug	Route	Dose
Dexamethasone	Oral and intravenous	6 mg daily for 10 days
Remdesivir	Intravenous	Day 1: 200 mg once Days 2–5: 100 mg daily
Tocilizumab	Intravenous	Body weight <30 kg: 12 mg/kg once Body weight >30 kg: 8 mg/kg once (Maximum dose: 800 mg) If clinical improvement does not occur, a second dose may be considered ≥8 hours after the first dose
Baricitinib	Oral	1–4 mg once daily for 14 days based on age and renal functions

54.12 PREVENTION

51.12.1 Vaccination

The magnitude of the COVID-19 pandemic presented an unprecedented need for highly effective and safe vaccines against the SARS-CoV-2 virus. Traditionally, vaccine development is a long and complex process requiring years of research and testing. But, a global collaborative effort guided by expedited sequencing of SARS-CoV-2 and massive funding allowed the utilization of state-of-the-art technology to complete preclinical, phase 1 trials in less than a year's time and led to the approval and distribution of anti-SARS-CoV-2 vaccines in record time in human history.[42]

As of September 2022, there are five broad categories of available vaccines against SARS-CoV-2[43] (Table 54.6):

1. *Whole virus (live attenuated and inactivated) vaccine*: It utilizes either the complete SARS-CoV-2 virus or part of the virus to trigger an immune response from the host without causing the disease. Live attenuated vaccines stimulate both humoral and cellular immune responses, in contrast to an inactivated vaccine, which only induces a humoral response.
2. *Viral vector vaccine*: A non-SARS-CoV-2 modified virus (or vector) carrying a genomic sequence generates a viral antigen of interest (the spike protein in the case of SARS-CoV-2) using the host cell protein synthesis machinery.
3. *Protein subunit vaccine*: These vaccines use specific viral proteins (or antigens) to trigger an immune response in a host.
4. *Nucleic acid (DNA and RNA) vaccine*: RNA vaccines deploy the genetic code of a specific viral protein, most commonly as messenger RNA (mRNA), which uses the host cell protein synthesis machinery to translate into a protein (spike protein in the case of SARS-CoV-2). DNA vaccine uses a bacterial plasmid encoding the viral antigen of interest for the same purpose.
5. *Virus-like particles (VLP) vaccine*: Laboratory synthesized molecules mimicking viruses, VLP, are used for B and T cell activation in the host.

The immunological response to the current vaccines against the SARS-CoV-2 virus involves activation of T

TABLE 54.6
COVID Vaccines[49–55]

Type	Manufacturer	Dosing
mRNA vaccine	Monovalent (Pfizer, Moderna)	Two intramuscular doses given 3 to 8 weeks apart
	Bivalent - Original and Omicron BA.4/BA.5 (Pfizer, Moderna)	Single intramuscular booster dose
Viral vector vaccine	Johnson and Johnson (recombinant Adenovirus type 26 vector)	One intramuscular dose; used only in individuals who cannot receive other COVID-19 vaccines
	AstraZeneca (recombinant ChAdOx1 adenoviral vector)	Two intramuscular doses given 8 to 12 weeks apart
	Sputnik V (human Adenovirus type 5 and type 26 vector)	Two intramuscular doses given 3 weeks apart
Inactivated whole virus vaccine	Sinopharm (BBIBP-CorV)	Two intramuscular doses given 3–4 weeks apart
	Covaxin (BBV152)	Two intramuscular doses given 4 weeks apart
	CoronaVac	Two intramuscular doses given 2–4 weeks apart
Recombinant protein vaccines	NovaVax (SARS-CoV-2 recombinant spike protein nanoparticle vaccine)	Two intramuscular doses given 3 to 8 weeks apart

cells, allowing the production of cytokines and memory cells and providing an immune protection for up to six months post vaccination.[44] As of September 2022, a total of 12,659,951,094 vaccine doses have been administrated, with 63% of the global population fully vaccinated and 28.36% boosted. The vaccination rate varies significantly between countries and continents. Several countries in Africa, like Madagascar, the Republic of Congo, Mali, Senegal, and Sudan, have the lowest rates of vaccination in the world.[45]

54.12.2 Chemoprophylaxis

In December 2021, the FDA granted an EUA to EVUSHELD™ (tixagevimab co-packaged with cilgavimab) for use as pre-exposure prophylaxis. Both tixagevimab and cilgavimab are long acting, anti-SARS-CoV-2 spike protein monoclonal antibodies that are used in selected high-risk COVID-19 negative patients who are unable to mount a good vaccine response due to their underlying disease condition or due to an immunosuppressive medication. A total of 300 mg of tixagevimab and 300 mg of cilgavimab are administered as two separate consecutive intramuscular injections for individuals weighing over 40 kg. A repeat dose of 300 mg of tixagevimab and 300 mg of cilgavimab can be given every six months.[46]

54.12.3 Best Practices in Infection Control

Since the beginning of the SARS-CoV-2 pandemic, several infection control strategies have been employed to slow down the community spread of this virus. These practices include:

- Physical distancing: maintaining a distance of about 6 feet away from others to avoid spread through droplets.
- Isolation: patients diagnosed with COVID-19 are recommended to stay at home.
- Frequent hand washing with alcohol-based gel or soap and water.
- Masking: the recommendation is to wear a mask that covers mouth, nose, and chin while indoors, particularly in poorly ventilated areas.

54.12.4 Lifestyle Implications

The association of certain risk factors with the severity of COVID-19, especially progression to critical illness and mortality, has been well established.

The non-modifiable high-risk factors include:

Age: Patients aged 65 and above are more likely to develop severe COVID-19 infection, have a higher rate of hospitalization, need for mechanical ventilation, and mortality compared with younger individuals.

Race and ethnicity: Some racial and ethnic minority groups have been associated with worse outcome, likely due to barriers to healthcare access.

Other risk factors with the potential for modification with lifestyle modification are:

- Cigarette smoking
- Obesity, especially with body mass index over 30
- Diabetes
- Cardiovascular disease, including hypertension and coronary disease

Smoking cessation is associated with reduced risk of cardiovascular and respiratory conditions. Patients with limited or no physical activity are likely to progress to severe COVID-19 compared with patients who are physically active.[47] Regular exercise also helps reduce the risk of chronic conditions such as diabetes and heart disease,

which are independent risk factors for severe COVID-19. Pre-infection higher hemoglobin A1C levels and poor blood pressure control are predictors of severe COVID-19.[48] Improving blood pressure and glycemic control has been shown to decrease the progression to severe infection and hospitalization.

54.13 SUMMARY

The SARS-CoV-2 pandemic has been the seventh deadliest pandemic in human history, claiming more than 6 million reported and 17 million unaccounted deaths. The outset of the pandemic was particularly challenging due to lack of evidence-based treatment options and spread of misinformation on the social platforms, making implementation of community-based infection control strategies more challenging. The silver lining was the unprecedented global collaboration, knowledge sharing, and application of cutting-edge technology that allowed the rapid development of treatment and vaccines. We have a lot more to offer than we did at the beginning of the pandemic. We now have highly effective vaccines and potent oral and intravenous treatment options that have helped prevent hospitalizations and lower mortality from COVID-19 and its complications.

CLINICAL APPLICATIONS

- The SARS-CoV-2 pandemic has been the seventh deadliest pandemic in human history, claiming more than 6 million reported and 17 million unaccounted deaths.
- Mutation of the viral spike protein is accountable for the various emerging SARS-CoV-2 variants as well as reduced affinity to the neutralizing antibodies (natural, vaccine induced, or therapeutic).
- Vaccination, community infection control strategies, and personal hygiene are cost-effective ways to control the spread of infection.
- Antiviral therapy is most effective if given early in the infection course and helps prevent hospitalization, severe outcomes, and death from COVID-19.

55 Preconception, Pregnancy, and Postpartum Care

Nancy L. Eriksen, MD, Dip ABLM and Kristi R. VanWinden, MD

KEY POINTS

- Adopting healthy lifestyle behaviors *prior to conception* has the greatest potential impact on the health of future offspring.
- Well-balanced and predominantly plant diets prior to conception are associated with improved maternal health and pregnancy outcomes.
- Physical activity that is maintained during pregnancy reduces pregnancy complications and pregnancy-related symptoms and is associated with appropriate weight gain.
- Preconception optimization of a woman's mental health is associated with improved pregnancy outcomes and improved self-care and infant care postpartum.
- Adverse pregnancy outcomes increase the risk of cardiovascular and metabolic disease later in life and provide an opportunity for lifestyle interventions.
- Human milk is the optimal nutrition for infants and confers several maternal and neonatal benefits.

55.1 INTRODUCTION

Lifestyle behaviors of women during their reproductive years are central to their overall health as well as the health of future offspring. Broadly speaking, the reproductive years of women are a continuum of care between preconception, pregnancy, and postpartum or interpregnancy care. The goal during these years is to identify risks for the development of chronic diseases as well as to mitigate or reverse chronic diseases that have a negative impact on pregnancy, neonatal, and childhood outcomes. It is also important to optimize wellness in women who may not have overt disease but can benefit from enhanced nutrition, physical activity, and emotional wellness to enrich their reproductive health and overall well-being.

Chronic diseases are rising in younger women, increasing the risk of infertility and subfertility, adverse pregnancy outcomes, non-communicable diseases in children, and even maternal death. Additionally, pregnancy is considered a window into future health because adverse pregnancy outcomes signal increased health risks over a lifetime. Sadly, most women are not aware of the importance of optimizing their health during these pivotal years nor of the impact of lifestyle behaviors on their reproductive health. This underscores the importance of viewing every visit with a reproductive-age woman as a potential opportunity to educate her about the importance of achieving and maintaining healthy lifestyle behaviors.

This chapter reviews the principles of lifestyle medicine during the reproductive years that can enhance overall health and reduce pregnancy-related morbidity. Evidence-based strategies and practical recommendations are offered to assist women's healthcare providers in counseling their patients for optimal reproductive health and improvement of their health across their lifespan.

55.2 PRECONCEPTION HEALTH

Preconception and interpregnancy care are an integral part of the continuum of women's healthcare. The goal of preconception care (PCC) is to optimize the health of every woman to reduce pregnancy complications, improve the health of future offspring, and enhance the long-term health of the patient.

Addressing modifiable risk factors due to lifestyle prior to and between pregnancies is important for several reasons. Often, women present with infertility due to a chronic disease such as obesity, metabolic syndrome, diabetes, and renal disease. Reducing or reversing the effect of chronic disease has the potential to improve fertility and reduce the risk of adverse events during pregnancy. Additionally, pre-existing chronic diseases are increasing in younger women and account for nearly half of maternal deaths.[1,2] Chronic disease also has a reciprocal relationship with adverse pregnancy outcomes (APOs) such as preeclampsia, gestational diabetes, and spontaneous preterm birth (sPTB). Not only does chronic disease increase the risk of APOs, but APOs also increase the future risk of a variety of chronic diseases including cardiovascular disease (CVD).[3] There is also a growing body of evidence from the developmental origins of health and disease (DOHaD) theory that a variety of lifestyle factors during periconception and pregnancy has a multigenerational impact affecting the health of up to three generations.[4] These lifestyle behaviors result in epigenetic changes during pregnancy that are associated with an increase in non-communicable diseases (NCDs) in future offspring.[4,5] Consequently, it is essential to address lifestyle

DOI: 10.1201/9781003227793-65

behaviors *prior to conception* to optimize both maternal and fetal outcomes.

55.2.1 Challenges and Opportunities for Preconception Care

Most patients do not deliberately seek out PCC because they do not perceive the risks that chronic disease poses to a potential pregnancy nor understand the purpose of PCC.[6,7] Another significant barrier to PCC is that nearly 50% of all pregnancies are unplanned.[8] This coupled with fragmented healthcare[9] and that nearly a quarter of women are not seen for an annual healthcare visit[10] pose significant challenges for providers.

It is important to keep in mind that preconception care is not limited to a single provider or patient visit. Rather, it is part of the continuum of reproductive-age women's healthcare that includes multiple stakeholders. With that in mind, primary care providers, specialists, and allied healthcare professionals should look for opportunities to initiate transforming conversations during *every* patient encounter with women during their reproductive years. Additionally, there is a need for a multidisciplinary team approach to PCC, including models of intensive lifestyle management tailored to the needs of reproductive-age women.

55.2.2 Developmental Origins of Health and Disease

The theory of DOHaD originated from studies of the offspring of pregnant women who were subjected to the Dutch Winter Hunger during World War II. During the Nazi occupation of 1944–1945, pregnant women were subjected to food rations amounting to <800 kcal per day.[11] Emerging evidence from multiple cohort studies shows an association between severe caloric restriction, or undernutrition, and the risk of chronic disease in the offspring decades later, including obesity, altered lipid profiles, and CVD.[5,11] However, the effects were mainly restricted to the offspring of mothers who were exposed to starvation during periconception and early pregnancy.[11,12] Children born to women exposed to the famine later during gestation were born smaller but were less likely to be obese later in life.[11]

It is now known that in utero exposure to modifiable risk factors including overnutrition and undernutrition, chronic disease, stress, substance use, and exposure to environmental toxins all play a role in the future health of the offspring.[4] Furthermore, the lifestyle behaviors of the mother during pregnancy appear to affect the health of future children up to three generations.[4]

Mounting evidence points to fetal programming in utero through alteration in methylation of the epigenome as the most plausible explanation for the increased risk of NCDs later in life. For example, hypomethylation of the insulin growth factor 2 (IGF2) gene occurred after exposure to periconception starvation during the Dutch famine, but not for fetuses exposed late in gestation.[13] This suggests that the most critical time for epigenetic dysregulation is during periconception and early gestation.[14] This underscores the importance of adopting healthy lifestyle behaviors *prior to conception*, which is likely to have the greatest impact on the future health of the developing fetus.[15]

55.2.3 Nutrition

Preconception nutrition primarily focuses on micronutrient deficiencies without taking into consideration the dietary patterns that lead to these deficiencies. In Western countries, nutrient shortfalls occur predominantly from an overconsumption of overly processed caloric-dense food.[16]

Micronutrient deficiencies of one or more nutrients occur in 41% of reproductive-age women.[17] Micronutrient deficiencies are problematic because they increase the risk of congenital anomalies and maternal anemia. The most common shortfall nutrients are potassium, magnesium, riboflavin, and choline, along with vitamins D and E.[18] These deficiencies are more common in women of color, those of lower socioeconomic status, and women with obesity.[17,18] Additionally, more than 90% of women do not meet the RDA of 25–28 grams of fiber daily[19] averaging only 12.6 grams/day of fiber.[18] This finding reflects the highly processed food consumed in the standard American diet.

Women should be encouraged to consume a high-fiber, plant predominant diet periconceptually to reduce the possibility of micronutrient deficiencies. This is because the more dietary fiber that is consumed, the greater the number of micronutrients and vitamins consumed, excluding B12 and vitamin D.[20]

Nutrients of concern for women considering a pregnancy include folate, choline, iodine, iron, and vitamin D. Folate deficiency increases the risk of neural tube defects (NTD), so it is important for reproductive-age women to meet the daily RDA of 400 micrograms per day of folate at least one month prior to conception.[21,22] This is because the neural tube closes six weeks from the last menstrual period—before many women realize they are pregnant. Women at higher risk for folate deficiency include those with diabetes, inflammatory bowel disease, obesity, or a history of bariatric surgery. These women often need a higher daily intake of folate to maintain an adequate level. Consideration should be given to adding a supplement of 600 micrograms of folate per day for "at-risk" patients, which is the RDA during pregnancy.[23]

Choline is an important nutrient due to its role in fetal brain development. The current RDA for choline for reproductive-age women is 425 mg/day.[21] However, a recent randomized controlled trial suggests a benefit to consuming a higher dose of choline of 450–1000 mg/day because it improved cognitive outcomes in children.[24]

Iodine deficiency has become more of a problem in developed nations due to the increased use of non-iodized salt. The RDA for iodine is 150 micrograms per day, which can be achieved through a quarter to a half teaspoon of iodized salt.[25] Women planning to become pregnant should

increase their iodine intake to 220–290 micrograms/day to account for fetal requirements.[26]

Reproductive-age women require higher amounts of iron due to menstruation. The RDA is 18 mg/day[23,27] in reproductive-age women and increases to 27 mg/day[23] during pregnancy. Women contemplating pregnancy should increase their consumption of iron. Alternatively, they can begin a prenatal vitamin which contains 27 mg of elemental iron.

Vitamin D insufficiency or deficiency is extremely common in reproductive-age women.[28] This is especially a concern for women of color, women with obesity, and those with limited exposure to the sun.[29] Deficient vitamin D is associated with poor immune function, decreased fecundity, an increase in the risk of some cancers, and an increased risk of APO.[30,31] Ideally, a vitamin D level should be assessed annually with supplementation as needed. The Endocrine Society recommends a minimum of 1500-2000 international units (IU) of vitamin D per day in women with a body mass index (BMI) <30.[28] Higher doses of 6000–10,000 IU per day are needed to maintain a normal level for women with a BMI >30 or those with malabsorption issues.[28]

Foods that are considered toxic or potentially harmful should be avoided, particularly for those desiring to become pregnant within a year. Processed meats are designated as a carcinogen and red meats as a probable carcinogen by the World Health Organization and effort should be made to eliminate them from one's diet.[32]

Caffeine consumption should be <300 mg/day or roughly three cups of coffee per day.[33] Higher doses potentially increase the risk of fetal loss.[33] Additionally, the use of non-nutritive sweeteners is associated with metabolic syndrome and higher BMIs.[34]

Exposure to methylmercury is of particular concern in reproductive-age women due to fetal neurotoxicity in utero. The consumption of fish should be limited to 8–12 ounces of fish per week while avoiding fish with the highest amounts of mercury.[35–37] However, since there is no safe level of mercury consumption, if possible, women should avoid or limit their consumption of fish. An alternative to fish consumption is taking a microalgae supplement.

55.2.4 Exercise

Regular physical activity in the preconception period is an important component of a pre-pregnancy wellness plan. Maximizing physical fitness prior to pregnancy improves baseline cardiopulmonary function, leading to better tolerance of the physiologic changes of pregnancy and fewer symptoms related to increasing cardiac and respiratory demands. Regular exercise before pregnancy is also associated with less pregnancy-related back pain and pelvic pain and with fewer work absences related to pregnancy symptoms.[38–42]

Despite the known benefits of intentional physical activity during pregnancy, pregnant women often face challenges to maintaining an exercise program when pregnant—such as pregnancy-related nausea, fatigue, musculoskeletal discomforts, and societal pressures to reduce their level of activity. It is therefore not surprising that most women reduce both the frequency and intensity of their baseline physical activity level once pregnant.[43–47] Women with a higher level of physical activity prior to pregnancy tend to maintain an above-average exercise level during pregnancy and are far more likely to meet recommended activity guidelines than those who did not exercise sufficiently prior to pregnancy.[43,48]

Pre-pregnancy physical activity is also associated with improved obstetric outcomes. Increasing levels of activity prior to pregnancy are associated with a progressively reduced risk of excessive gestational weight gain (EGWG).[49,50] Pre-pregnancy physical activity is associated with improved insulin sensitivity[51] and a 22–86% reduction in the risk of gestational diabetes (GDM), with the largest reduction in risk found with more vigorous and more total hours of activity per week.[52–58] Some studies suggest a similar reduction in the risk of hypertensive disorders of pregnancy, though these data have been inconsistent.[59, 60] Pre-pregnancy exercise has also been associated with improved labor outcomes, including slightly earlier onset of term labor, 30% shorter average labor duration, and fewer operative deliveries.[48] No consistent association has been found between pre-pregnancy physical activity and the rate of Cesarean delivery, nor with neonatal birth weight.[39,48,61–63]

55.2.5 Prevention of Adverse Pregnancy Outcomes

Optimizing modifiable risk factors prior to conception has the potential to significantly reduce the incidence of APO. It is important to convey the risks of a poor lifestyle to our patients because it increases the risk of maternal and fetal complications including preterm birth, maternal mortality, and lifelong risk for chronic diseases including CVD.

Addressing modifiable risk factors preconceptually can significantly reduce the risk of GDM. Strategies for preventing GDM include obtaining a BMI <30,[64] normal HgA1C,[65] reducing insulin sensitivity with a plant predominant diet,[66] and supplementation with vitamin D.[31]

Diets higher in animal protein and eggs[67, 68] along with processed grains, sugar, and fat all substantially increase the risk of GDM.[69] In comparison, women who are most adherent to the Dietary Approach to Stop Hypertension (DASH) diet or a Mediterranean (MED) diet reduced the risk of GDM by 34% and 25%, respectively.[70] This was recently confirmed in a large prospective study (n=1900) in which those most adherent to the MED diet during periconception had a significant reduction in risk for GDM.[71] Interestingly, there is a linear dose response between consumption of dietary fiber and reduced risk of GDM. In this study for each 10g of fiber/day consumed, there was a 26% reduction in the risk of GDM, which underscores the importance of high-fiber diets in reducing APO.[72]

Physical activity is known to improve insulin sensitivity and can substantially reduce the risk of GDM. Women who exercise prior to conception can reduce the risk of GDM with the greatest benefit seen in women doing vigorous exercise and who exercise longer.[52–55,57]

Sleep disordered breathing (SDB) is associated with an increased risk of adverse pregnancy outcomes. Facco and colleagues noted that SDB more than triples the risk of GDM when present in early pregnancy after controlling for BMI, age, and hypertension.[73] There is also a linear correlation between the severity of obstructive sleep apnea (OSA) and the incidence of GDM.[74] Identifying women with SDB prior to conception and treating to improve overall sleep is important for improving overall health and may reduce the risk of GDM.

Chronic stress from adverse childhood events (ACEs) has also been associated with an increased risk for APO. In patients with depression before pregnancy, three or four or more ACEs are associated with an increased risk of GDM compared with women with no ACEs or history of depression.[75] Specifically, physical abuse had the highest correlation for risk of GDM. The Nurses' Health Study (NHS) II also found that physical abuse in childhood was associated with a 42% higher risk for GDM.[76] Additionally, forced sexual activity was associated with a 30% higher risk for GDM.[76] These findings underscore the importance of evaluating women for a history of ACEs before pregnancy so that appropriate intervention can be given that has the potential to reduce the risk of APO.

Preterm birth is a significant public health problem due to the high rate of neonatal deaths and subsequent infant morbidity.[77] Modifiable risk factors include nutrition, substance use, smoking, stress, and chronic diseases including obesity.[78,79]

In a recent large prospective trial, the risk of both spontaneous and medically indicated PTB was significantly reduced with a BMI <25 (aRR 0.58), a high-quality diet (aRR 0.68), and low to moderate stress in preconception or early pregnancy (aRR 0.60).[79] There was also a synergistic effect for more than one low risk factor compared with none and the risk of PTB. This effect was greater in women with a medically indicated PTB (RR 0.45) than for sPTB (RR 0.82).[79] These data emphasize the importance of optimizing modifiable risk factors prior to pregnancy, especially in women with preexisting chronic disease.

Periconception nutrition is an important topic to discuss with patients with a history of preterm birth or chronic diseases that increase the risk of a medically indicated PTB. Dietary patterns at periconception that are like the standard American diet, high in sugar and fat, increase the risk of PTB by 50%.[80] By comparison, a recent prospective study consisting of a multiethnic cohort showed that adherence to a MED and DASH diet during periconception significantly reduced the risk of sPTB.[71] A recent systematic review also showed dietary patterns higher in whole plant food that also included seafood with decreased amounts of fried food and red meat lowers the risk of PTB.[81] Additionally, supplementation with vitamin D reduces the risk of PTB by half.[31]

Sleep is an important vital sign for preconception health yet is typically not assessed at preconception visits.[82] In a systematic review and meta-analysis both short sleep duration and poor sleep quality were associated with a 23% to 54% increased risk for PTB.[83] Another group at risk is women who work night shifts or variable shifts—both are associated with an increased risk for PTB.[84] There also appears to be a trend in risk for PTB with moderate to severe SDB.[85,86]

Chronic stress has also been linked to lower rates of conception[87] and increased risk of PTB and infant mortality.[88,89] Specifically, an ACE score of two or more doubles the risk of PTB[88,90] Ideally, ACE screening should take place prior to conception with referral to a trauma specialist.

Preeclampsia is a disorder specific to pregnancy with the new onset of hypertension, proteinuria, and other signs and symptoms after 20 weeks' gestation.[91] The pathophysiology includes endothelial dysfunction and oxidative stress in utero and is a marker for increased risk of hypertension postpartum and a three-fold increased risk of CVD in the future.[92,93] The estimated increase in cost is over US$2 billion annually due in large part to the higher number of medically indicated preterm births.[91] Modifiable risk factors for preeclampsia include obesity, nutrition, obstructive sleep apnea, chronic stress, diabetes, chronic hypertension, and gestational diabetes.[91]

Dietary patterns greatly influence the development of preeclampsia. The Western diet consisting of increased sodium intake, processed meats, and sugar-sweetened drinks increases the risk of preeclampsia by 20%.[94] However, the reverse is true in those consuming a diet higher in whole plant food and fish and lower in refined grains and meat.[94,95] For example, a MED-type diet in Norwegian women reduced the risk of hypertensive disease by 42%.[96] And a retrospective study of women who were part of a vegan community had a very low rate of preeclampsia (0.001%).[97] This suggests there is a correlation between increased consumption of fiber from plants and a decreased risk of preeclampsia. In fact, consuming more than 21 g/day of fiber reduces the risk of preeclampsia by 67% compared with those consuming less than 12 g/day.[98] This study also noted a linear dose response to fiber. For every 5 grams/day of dietary fiber consumed, there is a corresponding 14% decrease in the risk of preeclampsia.[98] A whole food plant-based vegan diet averages greater than 50–60 g/day of fiber, which may explain why the incidence of preeclampsia is lower in that group.[20,97] Additionally, supplementation with vitamin D reduces the risk of preeclampsia by half.[31]

SDB is strongly associated with the development of hypertensive disorders in pregnancy.[73,99] Screening for OSA prior to conception is important so the patient can be referred to a sleep specialist for diagnosis and treatment. OSA typically worsens during pregnancy[100] and intervention with continuous positive airway pressure (CPAP) can reduce SDB, which has the potential to reduce APO, although more investigation is needed.

Chronic stress determined by an ACE score also increases the risk for hypertensive disease in pregnancy. A high ACE score, defined as more than three, had 60% increased odds of developing a hypertensive disorder of pregnancy after controlling for confounding variables.[90] Since ACE scores correlate with the development of chronic diseases, it is important to evaluate women prior to conception and refer for appropriate services.

55.2.6 Optimizing Mental Health

Mental health and physical health are intricately connected. Mental illness and chronic disease are strong risk factors for each other and frequently co-exist, with lifestyle factors, healthcare disparities, and secondary effects of medical treatments driving much of this relationship.[101–103] Just as it is critical to manage chronic disease prior to pregnancy, mental health should be assessed and optimized prior to pregnancy. Uncontrolled preconception mood symptoms have been linked to reduced fertility,[104,105] reduced success of in-vitro fertilization,[106] adverse pregnancy outcomes, impaired maternal self-care, and increased substance use.[107,108] Women with pre-pregnancy psychosocial risk factors including mental health conditions, substance use, health disparities, and exposure to violence or self-harm have also been found to have infants with lower mean birthweight, increased risk of neonatal injury or hospitalization, and increased infant mortality.[109] Up to 6% of women experience intimate partner violence (IPV) in the year prior to pregnancy, placing them at increased risk of depression, anxiety, posttraumatic stress, suicidality, substance use, reproductive coercion, and unintended pregnancy, in addition to physical harm.[110,111]

Women should be screened for both mood disorders and IPV in the preconception period. Any evident psychiatric diagnoses or risk factors should be identified, addressed, and managed with a pregnancy-appropriate treatment plan. Patients should be offered reliable contraception and understand the goal of timing a pregnancy once both mental and physical health have been optimized. Women with known or suspected psychiatric diagnoses should be counseled about the need to balance the risks of untreated mental illness in pregnancy against the risks of treatment in pregnancy. Non-medical strategies such as dietary modification, exercise, mindfulness, cognitive-behavioral therapy, and support groups should be employed first to reduce or eliminate the need for medical therapy in pregnancy. When such strategies are insufficient, most psychotropic medications can be continued during pregnancy when beneficial for the health of the mother. Valproate, carbamazepine, lithium, and paroxetine carry increased risks compared with other alternatives, and should therefore be avoided in pregnancy unless no viable substitute exists. Women using antiepileptic medications should be counseled to begin a daily 4 mg folic acid supplement at least two months prior to conception.[107] Multiple exposures increase pregnancy risks, so generally women planning pregnancy should be managed with the fewest psychotropic medications necessary to adequately manage their symptoms. This principle also includes exposure to comorbid substance use, which should be avoided when attempting pregnancy. Any planned initiation, discontinuation, or changes in the treatment regimen should ideally be accomplished prior to pregnancy, with the goal of achieving a period of proven stability on a stable regimen prior to conception.

If IPV is identified prior to pregnancy, the patient should be connected with a trained professional to address her safety, issues of reproductive choice, and potential psychiatric consequences; ideally utilizing a trauma-informed treatment approach.[110,111] Healthy social relationships should be encouraged, as positive social connectedness prior to pregnancy has been linked to fewer unintended pregnancies, fewer mood symptoms, and better coping skills for women with prior pregnancy complications or losses.[112] It also reduces feelings of isolation and improves self-confidence in women with mental illness, who may doubt their ability to successfully manage pregnancy and parenting.[113]

55.2.7 Optimizing Chronic Disease

Preexisting chronic disease in women poses significant maternal and fetal risks to a future pregnancy by increasing APO, severe maternal morbidity (SMM), and maternal mortality. Nearly four out of ten reproductive-age women have one or more chronic diseases, yet they are typically not aware of their risks, nor the importance of optimizing or reversing chronic disease via lifestyle changes, before trying to conceive.[114,115] Mitigating these risks is a crucial step toward reducing maternal morbidity and mortality due to chronic diseases from an unhealthy lifestyle.

Preconception counseling ideally should be integrated into *every* patient visit since nearly half of all pregnancies are unplanned. Another option for women with chronic disease who are contemplating pregnancy is to schedule a preconception consultation with a maternal-fetal specialist who can discuss specific pregnancy-related risks and contraindications for pregnancy. The goal of preconception counseling is to review maternal and fetal risks, advise on optimizing lifestyle behaviors to mitigate or reverse chronic disease, eliminate or avoid medication, avoid exposure to known toxins or recreational substances, and discuss preconception goals. An overview of maternal and fetal risks associated with the most common chronic diseases in reproductive-age women is outlined in Table 55.1.[116–118]

When feasible, lifestyle change should be employed to avoid or minimize medication exposures during the reproductive years. For women requiring ongoing medical therapy, some general principles should be followed: (1) medications with the best safety data for pregnancy should be selected; (2) known teratogens should be avoided unless no alternative exists; (3) anyone using a known teratogen during the reproductive years should be counseled about avoiding unintended pregnancy, intentional pregnancy planning with risk-mitigation measures,

TABLE 55.1
Preconception Counseling for Women with Chronic Disease[116–118]

Chronic Disease	Maternal Risks	Fetal Risks	Childhood Risks
Obesity	Infertility, miscarriage	Fetal anomalies	Childhood adiposity
	Nutritional deficiencies	(e.g. NTD, CHD)	Metabolic syndrome
	Cardiac dysfunction	Macrosomia	Developmental delay
	Obstructive sleep apnea	Birth trauma	ASD, ADHD
	Preeclampsia	Stillbirth	
	Gestational hypertension		
	Gestational diabetes		
	Failed induction of labor		
	Cesarean delivery		
	Endometritis		
	Postpartum hemorrhage		
	Venous thromboembolism		
	Maternal death		
Chronic HTN	Preeclampsia	Congenital anomalies	
	Cerebrovascular accident	Growth restriction	
	Renal failure	Preterm birth	
	Myocardial infarction		
	Gestational diabetes		
	Cesarean delivery		
	Placental abruption		
	Postpartum hemorrhage		
	Maternal death		
Diabetes	Preeclampsia	Miscarriage	ASD
	Cerebrovascular accident	Congenital anomalies	
	Myocardial infarction	Growth restriction	
	Pyelonephritis	Macrosomia	
	Urinary tract infections	Preterm delivery	
	Renal failure	Stillbirth	
	Cesarean delivery	Birth trauma	
	Maternal death	Hyperbilirubinemia	
	DKA	RDS

ADHD, attention deficit hyperactivity disorder;
HTN, hypertension;
RDS, respiratory distress syndrome;
DKA, diabetic ketoacidosis.

and vigilance for early pregnancy; (4) if a medical regimen will be modified for pregnancy, a patient should ideally be switched to and stabilized on their new regimen prior to attempting pregnancy; and (5) a preconception plan should be developed for how to manage medications once pregnancy is suspected. With a few exceptions, prescribed medications should not be reflexively discontinued on the diagnosis of pregnancy, as doing so places the mother and her pregnancy at risk of uncontrolled disease. Outside of known teratogens, most medications are neither completely safe nor unsafe for pregnancy, as each agent has an individual safety profile influenced by dose, exposure timing, and genetic and environmental influences.[119] Patients should be involved in making a shared decision about treatment in pregnancy based on the potential risks and benefits.

An overview of preconception goals for the most common chronic diseases in women is outlined in Table 55.2.[64,120]

55.3 PREGNANCY

Pregnancy is an opportunity to improve the lifestyle of women and make a multigenerational impact on the future health of their offspring. It is also a time in which underlying disease can be unmasked, especially diabetes and

TABLE 55.2
Preconception Goals and Recommendations[64,120]

Chronic Disease	Recommendations	Goals
Obesity	Counsel on maternal and fetal risks	BMI <25
	Whole food plant-based diet	
	Screen for obstructive sleep apnea	
	Diabetes screen	
Pregestational diabetes	Counsel on maternal and fetal risks	Serum Cr <1.5 mg/dl
	Whole food plant-based diet	Total urine protein < 3g
	24-hour urine for protein and Cr Cl	BMI <25
	Retinal exam	HgA1c <6
	ECG	
Chronic hypertension	Counsel on maternal and fetal risks	Avoid ACE inhibitors
	Plant predominant diet	Avoid ARBs and statins
	Consider screening for cardiac	BP <120/80 mmHg
	dysfunction and renal disease	BMI <25

BMI, body mass index;
Cr, creatinine;
Cr Cl, creatinine clearance;
ECG, electrocardiogram;
ACE, angiotensin-converting enzyme;
ARBs, angiotensin receptor blockers;
BP, Blood pressure.

CVD. Thus, early identification of CVD risk factors with lifestyle intervention has the potential to positively impact both maternal and fetal outcomes.

55.3.1 Maternal Morbidity and Mortality

Over the last few decades, there has been a shift away from pregnancy-related maternal mortality such as postpartum hemorrhage to lifestyle-related mortality secondary to NCDs. Chronic diseases are now the underlying cause for almost half of all maternal mortality in the United States with rates three times higher in African American women.[1] CVD is the single leading cause of maternal death (33%) with another 14% due to non-cardiovascular medical conditions.[2]

More than 60% of women have one or more CVD risk factors during pregnancy, placing them at greater risk for APO and SMM.[121] There is also a linear correlation between the number of CVD risk factors (BMI >25, smoking, hypertension, diabetes) entering pregnancy and the relative risk of ICU admission, preterm birth, and fetal death with the greatest risk occurring in women with hypertension and diabetes.[121] Furthermore, SMM is directly correlated to the number of comorbidities with nearly a nine-fold increased risk for women with three or more chronic diseases compared with women with none.[122] These data underscore the importance of counseling patients toward a healthier lifestyle to reduce maternal morbidity and mortality from chronic diseases.

55.3.2 Nutrition

In general, dietary advice in pregnancy has focused on macronutrient and micronutrient requirements without regard to the dietary patterns that best meet those requirements. Sadly, nearly half of all pregnant women are deficient in one or more micronutrients in the United States, primarily due to overconsumption of processed food.[16,17] Non-Hispanic blacks and women with obesity and lower socioeconomic status have the highest rate of micronutrient deficiency.[17] And women who have malabsorption issues, underwent bariatric surgery, smoke, abuse substances, or have multiple gestations are at greater risk for micronutrient deficiencies.

A recent National Health and Nutrition Examination Survey (NHANES) showed that despite meeting the recommended number of macronutrients, pregnant women overconsumed salt (3.6 g/day), sugar (21 tsp/day), and saturated fat, with an average consumption of only 17.3 g/day of fiber.[123] The NHANES study also revealed several shortfall nutrients including folate, calcium, iron, magnesium, choline, and potassium, along with vitamins A, C, D, E, K, and B6.[123] These data reflect the calorie-dense, low-fiber intake from the standard American diet which is high in processed food and animal products.

Most pregnant women are also deficient in vitamin D. Vitamin D supplementation has been shown to halve the risk of a low birth weight neonate, preeclampsia, and GDM.[31] It can also improve bone mineralization in offspring.[124] Considering these benefits, it is prudent to assess a vitamin D level during pregnancy and supplement using current guidelines.[28]

Current recommendations for caloric intake during pregnancy are 2000 to 2200 kcal/day, which includes a 340 kcal/day and 450 kcal/day increase in the second and third trimesters, respectively.[23] The recommended daily macronutrient intake consists of 71 g protein a day (1.1 g/kg/day), 175 g of carbohydrates, and 20–35% fat.[23] Most micronutrient requirements during pregnancy are slightly higher when compared with preconception with the exception of iron (27 g/day), folate (600 µg/day), and iodine (220 µg/day).[23]Additionally, women should consume 28/34/36 g/day of dietary fiber during the first, second, and third trimesters, respectively.[19]

Nutrition counseling during pregnancy should emphasize nutrient-dense, fiber-rich plant predominant dietary patterns. A well-balanced vegetarian diet is considered safe during pregnancy and provides additional health benefits.[125]

Many providers are reluctant to endorse diets that are predominantly plant based out of concern for macro- or micronutrient shortfalls. In fact, whole food plant predominant diets meet or exceed the current DGA recommendations for micronutrients (except B12) and protein and provide more than 60 g/day of fiber.[20]

Ketogenic and low carbohydrate diets should be avoided as they lead to micronutrient deficiencies and hyperlipidemia during pregnancy.[126] Low carbohydrate diets are also associated with a higher risk of GDM,[127] and infants with an NTD, including those taking folate supplements.[128]

55.3.3 Exercise

Physical activity during pregnancy is beneficial to both the mother and fetus, as it is associated with reduced risks of excessive gestational weight gain, GDM, diabetic hyperglycemia, hypertensive disorders of pregnancy, mood disorders, preterm delivery, low birth weight, and operative and Cesarean deliveries.[47,129,130] The American College of Obstetrics and Gynecology and US Department of Public Health and Human Services guidelines for physical activity in pregnancy recommend at least 150 minutes per week of moderate-intensity aerobic activity,[47,131] a minimum standard not met by the majority of pregnant women.[132–134]

Physical activity during uncomplicated pregnancies is safe, with no associated risk of miscarriage, congenital anomalies, fetal growth abnormalities, preterm delivery, perinatal mortality, or hyperthermia.[47,130,135] Injuries from exercise during pregnancy are uncommon, with the majority related to falls.[136] Exercise techniques should account for mechanical changes such as a shifted center of gravity, and supine positioning should be avoided beyond 20 weeks of gestation to prevent aortocaval compression and hypotension. Women should wear loose-fitting clothing, ensure adequate hydration and caloric intake, and avoid high heat and humidity while exercising. Exercise should be done cautiously or avoided in women with cardiopulmonary disease, severe malnutrition, or obstetrical complications.[47,137–139]

A prescription for exercise in pregnancy should include guidelines for the frequency, intensity, type, and time (duration) of activity. These can be summarized using the pneumonic **FITT**.

(1) **F**requency: A minimum of 150 minutes of moderate-intensity exercise per week throughout pregnancy, ideally spread over four to seven days per week. For women who have been sedentary previously, they may initiate an exercise program two to three days per week and gradually increase to the goal activity frequency.[47,137]

(2) **I**ntensity: Moderate-intensity exercise, which is typically defined by a maternal heart rate no more than 60–80% of the age-predicted maximum heart rate but may also be defined by a perceived exertion scale or a "talk test" in which a woman can carry on a conversation while exercising.[47,140,141]Women who do regular vigorous-intensity exercise prior to pregnancy may continue these activities during pregnancy. Studies of fetal status during vigorous activity have been reassuring, though it is unclear if there is an absolute level of intensity or exercise duration beyond which fetal risk may occur. Elite athletes may warrant individualized counseling and close supervision, especially with frequent and prolonged duration of activity, or intensities exceeding 90% of their maximum heart rate.[142]

(3) **T**ype: Examples of safe activities in pregnancy include walking, stationary cycling, dancing, resistance work, stretching, and water aerobics. Exercises that should be avoided during pregnancy include scuba diving, contact sports, and activities with a high risk of abdominal trauma, imbalance, or falls.[47,143,144]

(4) **T**ime: The goal duration of exercise should be at least 20–30 minutes and up to 60 minutes per session.[145] Women new to exercise may begin with 10–20 minutes and gradually increase the duration of activity as tolerated.[146]

53.3.4 Emotional Wellness

Mental health conditions are common in pregnancy and are associated with increased risks, particularly when uncontrolled.[147] Women may carry psychiatric diagnoses such as depression or anxiety; may experience situational stress, pregnancy-specific anxiety, social stressors, and IPV while pregnant; or may experience long-term impacts from chronic stressors related to ACEs, societal marginalization, or trauma. Any number of these mental health and stress-related exposures may increase risks of unintended pregnancy, inadequate prenatal care, substance use, excessive or insufficient gestational weight gain, hypertensive disorders, and preterm birth.[148–155] All women should be screened in pregnancy for depression, anxiety, IPV, and psychosocial stressors using a validated screening instrument for each assessment. Specific screening tools should be adopted by each provider or practice and then incorporated into routine care in a consistent fashion.[156,157] Validated ACE questionnaires are also available to screen for adverse childhood experiences.[158]

Women with mental health conditions or significant stressors in pregnancy should be offered a multimodal approach to management, with lifestyle interventions first-line and ancillary or pharmacologic interventions as needed. Mood symptoms are more common with increased consumption of a Western-style diet pattern, processed and fast foods, added sugars, solid fats, and alcohol; in turn, symptoms tend to be reduced with consumption of more whole unprocessed and nutrient-dense foods.[159–161] Consumption of adequate macro- and micronutrient precursors and increased antioxidants and flavonoids in plant foods may prevent common nutritional deficiencies in pregnancy and reduce inflammation, both factors independently

related to mood disorders.[159,161,162] Aside from nutritional interventions, improved control of mood symptoms can be achieved with interventions such as improved sleep duration and quality, regular physical activity, mindfulness exercises, and social support. In women without an intrinsic support system or for those exposed to IPV, an unstable living situation, or prior trauma, referral for psychobehavioral interventions, trauma-informed care, social work services, or support through community partners may improve their emotional wellness and self-efficacy.[163]

55.3.5 Prevention of Adverse Pregnancy Outcomes

Gestational diabetes occurs in approximately 6% of pregnancies and contributes to increased risks of preeclampsia, macrosomia, birth trauma, Cesarean delivery, and neonatal complications.[78] GDM is more common among women who consume Western or high-protein diets,[164,165] while consumption of whole unprocessed foods and Mediterranean-style diets are associated with reduced risk.[165–167] Once diagnosed, dietary changes are the first line to manage maternal hyperglycemia. The American Diabetes Association (ADA) GDM diet, which advises a dietary composition of 40% carbohydrates, 20% protein, and 40% fat, is commonly recommended.[168] However, increased dietary fat is known to be detrimental to insulin sensitivity, and emerging data have shown that women started on the DASH diet or other diets higher in complex carbohydrates and lower in fat have improved glycemic control, lower insulin needs, and reduced macrosomia compared with those on the ADA diet.[169,170] Exercise is considered an adjunctive treatment for GDM, as it has been found to reduce maternal blood glucose levels and fetal hyperinsulinemia, and to support appropriate maternal and fetal weight gain.[129] Sleep deprivation should be avoided, as it interferes with glucose metabolism.[171] In addition, patients with OSA have an increased incidence and severity of GDM that correlates with the severity of the disorder[74,172] and management of OSA may improve insulin resistance and blood glucose control.[173,174]

Hypertensive disorders of pregnancy (HDP) affect 3–10% of all pregnancies and are responsible for a significant portion of iatrogenic preterm births, maternal morbidity, and mortality.[91] Western dietary patterns significantly increase the risk of preeclampsia,[96, 175] while Mediterranean diets and those with higher consumption of fruits, vegetables, whole grains, nuts, legumes, and fish are associated with reduced risk.[95,96] There is a strong dose-dependent reduction in the risk of preeclampsia with progressively increased daily fiber intake during pregnancy.[98] Other modifiable risk factors for HDP are low levels of physical activity and disrupted sleep, both of which are associated with an increased risk.[47,129] In patients with OSA, there is a cascade of sympathetic activation, endothelial dysfunction, altered vascular resistance, and impaired placental perfusion which is known to dramatically raise the risk of HDP.[172,176,177] Significant OSA typically requires treatment with overnight CPAP, an intervention that may reduce the likelihood of progression to preeclampsia and improve overnight blood pressure in women already diagnosed with preeclampsia.[178,179]

Preterm birth is the single most significant cause of neonatal morbidity and mortality, occurring in 10–12% of pregnancies but with notable racial and ethnic disparities.[180] One large prospective cohort study suggested the DASH diet may reduce the incidence of preterm birth by 42%, while those consuming a high percentage of processed meat, dairy, and fried and fast foods had a 53% increase in the incidence of preterm birth.[181] Other studies have demonstrated a reduction in the risk of preterm birth with adherence to Mediterranean and simple vegetarian dietary patterns.[182,183] Supplementation with omega-3 polyunsaturated fatty acids has been associated with a reduction in preterm birth in a systematic review, however, the benefit appears most substantial in women with low omega-3 consumption.[184] Some data suggest regular physical activity in pregnancy reduces the risk of preterm birth, though this impact may be stronger in overweight or obese women compared with normal-weight women.[185,186] Although OSA has been associated with an increased risk of preterm birth,[172,177,187] it is not clear if this is a direct effect or a consequence of maternal complications requiring preterm delivery.

55.4 POSTPARTUM AND LACTATION

55.4.1 Introduction

The postpartum period is a critical time of mental and physical recovery following pregnancy. Referring to the first 12 weeks postpartum as the "fourth trimester" reflects the continuum of fetal to infant development and the maternal changes that must occur to conclude a pregnancy.[188] The postpartum period carries an increased risk of maternal health complications, mood disorders, and maternal mortality; with a disproportionate number of maternal deaths occurring in women of color.[188–190] Yet, historically, the postpartum period is given little medical attention and is often devoid of adequate social and mental health support services. Shifting away from a single-visit model to a more holistic postpartum care model—one which incorporates recommendations known to improve postpartum recovery, supports the transition to parenthood, and provides risk prevention strategies—is expected to improve both short- and long-term postpartum outcomes.

55.4.2 Nutrition

Pregnancy demands increased nutritional requirements and may deplete maternal essential nutrient stores, impairing postpartum recovery and increasing the risk of mood disorders.[159,191] The largest and longest-lasting impact is on folate and iron levels, but reduced circulating levels of vitamins A, B6, B12, calcium, and zinc are also typical in the postpartum

period.[192] Postpartum caloric requirements are equivalent to those in non-pregnant individuals, but with lactation, there is an additional caloric requirement of 300–700 kcal/day necessary to maintain an isocaloric state.[19,193] In addition, a modest (100–200 kcal) caloric deficit is recommended to support early postpartum weight loss.[19] Specific caloric and nutrient recommendations for an individual patient may be calculated based on various factors (age, sex, height, weight, activity level, pregnancy or lactation status) using the USDA Dietary Reference Intake (DRI) calculator (www.nal.usda.gov/fnic/dri-calculator/index.php).[194]

Postpartum weight retention (PPWR) is the retention of gestational weight for one year or more following pregnancy. Women who lose all gestational weight by 6–12 months postpartum weigh significantly less ten years later, on average, than those who retain weight beyond one year postpartum.[195] Beyond 18 months, many women are moving into the preconception phase of their next pregnancy, and weight retained from a prior pregnancy increases their new baseline pregnancy weight. A cycle of weight gain and incomplete gestational weight loss with each pregnancy increases the risk of future pregnancy complications and later life health risks,[64,196] and pregnancy has been noted as a primary trigger for weight gain in 75% of obese women.[197] The primary driver of postpartum weight loss is nutrition. Although interventions such as physical activity, stress reduction, and adequate sleep are important for postpartum recovery and may augment weight loss, any successful postpartum weight loss program must contain a nutritional component to be effective.[64,197,198]A summary of recommendations is found in Table 55.3.[64,196,198–206]

In addition to repleting micronutrient stores, boosting satiety, and supporting gestational weight loss, consumption of a nutrient-dense diet in the postpartum period can support other healthy lifestyle behaviors. Adequate nutrient intake improves energy for physical activity, improves post-exercise recovery, promotes better sleep quality and regulation of melatonin levels, and reduces constipation.[198,207,208] Postpartum nutrition also plays a role in postpartum mental health, given the role of dietary nutrients in neurotransmitter production as well as the strong correlation between chronic diet-related diseases and mental health.[159,191]

55.4.3 Exercise

Physical activity may be resumed gradually in the postpartum period, and in most cases may be safely back to a pre-pregnancy frequency and intensity by four to six weeks postpartum.[47,198] At that point, women should aim to meet general adult activity guidelines of at least 150 minutes of moderate physical activity or 75 minutes of vigorous activity per week, as well as resistance training.[131] Exercise programs that can be done at home or those tailored to new parents may be beneficial and easier to maintain.[207,209] As an isolated intervention, postpartum physical activity is not highly effective for PPWR; but it has been shown to enhance the effectiveness of dietary interventions for postpartum weight loss.[198,207,210] It also has beneficial effects on cardiovascular and physical fitness, postpartum stress and mood symptoms, and sleep quality.[198,207,209]

55.4.4 Sleep

Obtaining sufficient sleep in the postpartum period is likely the most recognized challenge new parents face. Infant sleep patterns and overnight care lead to frequent parental sleep disruptions, short sleep duration, and poor sleep quality.[208,211,212] Impaired sleep is associated with increased postpartum mood symptoms, reduced physical activity, and more difficulty with self-care, meal preparation, relationships, and parenting.[196,208,211,213–215] Women who sleep less than five hours per night have a three-fold higher risk of PPWR at six months postpartum compared with those with a longer sleep duration.[196,211]

Cognitive behavioral therapy (CBT) focused on sleep hygiene can be an effective intervention to improve postpartum sleep.[213] Other interventions known to promote sleep quality and melatonin regulation include stress reduction techniques, exercise, sufficient intake of polyunsaturated and omega-3 fatty acids, creation of a conducive sleep environment, and modification of infant sleep routines.[208,209,213]

55.4.5 Postpartum Depression and Mental Health

Mood symptoms in the postpartum period are extremely common. Postpartum blues is a self-limited condition affecting up to 80% of women in the early postpartum period, usually resolving within two weeks without treatment.[216] Postpartum depression, on the other hand, is a major depressive episode lasting two weeks or more, seen in 10–20% of women in the postpartum period. Symptoms may be disabling and long-lasting, and often require both supportive and pharmacologic treatment.[216,217] Postpartum psychosis is rare, occurring in only 0.1% of postpartum women, but is the most potentially dangerous postpartum mood disorder and typically requires psychiatric hospitalization.[217] Postpartum depression and psychosis are associated with negative maternal and offspring outcomes[217] and warrant standardized screening and intervention. Suicidal ideation, homicidal ideation, or acute psychosis should be managed as psychiatric emergencies.[156,218] A less but increasingly recognized postpartum psychological complication is PTSD, which occurs in 1.5–7% of women, often resulting from a perception of vulnerability, danger, or trauma during the labor and delivery process – though this perception is not necessarily concordant with the actual circumstance or outcome.[219–222] PPD and PTSD frequently co-exist and effective treatment needs to address both conditions.[221]

Interventions known to be beneficial for postpartum mood disorders include simple screening and recognition, CBT, trauma-informed psychotherapy, and psychotropic medications when needed.[156,220,221,223] Healthy dietary patterns including whole and nutrient-dense foods are

TABLE 55.3

Summary of Postpartum Lifestyle Recommendations[64,196,198–206]

Nutrition Recommendations

Adequate caloric intake
- Non-lactating: 1200–1800 kcal/day
- Lactating: 1500–2300 kcal/day
  - 0–6 months: 500–700 kcal additional, target 300–500 kcal to account for modest calorie deficit/weight loss
  - 6–12 months: 300–400 kcal additional, assumes weight stability
- Use DRI calculator for individual needs
- Strict calorie counting not necessary
- Encourage portion awareness

Replenish micronutrients
- Aim for a healthy dietary pattern of whole nutrient-dense foods rather than focus on consuming specific nutrients
- Consume antioxidants and flavonoids from whole plant foods

Choose a healthy dietary pattern
- Whole food, plant-based diet
- DASH diet
- Avoid extreme carbohydrate restriction

Reduce dietary fat
- Consume ≤30% kcal from fat
- Most/all consumed fats should be polyunsaturated and omega-3 fatty acids
- Minimize intake of saturated fats
- Avoid all intake of trans fats

Increase consumption
- Whole grains (should be most or all of carbohydrates consumed)
- Fruits, vegetables, legumes, nuts, seeds
- Total and soluble fiber

Minimize or avoid
- Energy-dense foods (snack foods, fast foods, processed foods)
- Added sugars, added fats, high glycemic-load
- Red and processed meats
- Alcohol

Increase fluid intake, especially if lactating
- Primarily water
- Avoid sugar-sweetened beverages

Supplementation

Lactation
- Prenatal or multivitamin daily
- Vitamin D 1400 IU/day (4000–6000 IU/day if not supplementing infant)

Plant-based diet
- Vitamin B12 at least 2000 μg/week

Other Recommendations

Physical activity
- Minimum of 150 min/week moderate intensity or 75 min/week vigorous intensity
- Resistance training

Address mental well-being
- Manage postpartum mood disorders
- Provide strategies for stress reduction

Address sleep impairment
- Ideally target seven to nine hours per night, no fewer than five hours

Avoid smoking or substance use

Weight loss
- Target loss of gestational weight by 6–12 months postpartum
- Attempt to normalize BMI if elevated

Encourage lactation
- Aim for at least 12 months
- Exclusive for first six months if feasible

Arrange follow-up care
- GDM: GTT 4–12 weeks postpartum
- Transition from OB care to primary care
- Periodic screenings as indicated if history of APO (BP, glucose, lipids, BMI)

For all lifestyle interventions
- Start within six months of delivery
- Provide specific, actionable advice
- Intervention led by healthcare team if available
- Consider RD referral if available
- Primarily home-based interventions preferred
- Incorporate patient self-monitoring
- Involve the whole family

DRI, dietary reference intake;
DASH: Dietary Approaches to Stop Hypertension;
BMI, body mass index;
GDM, gestational diabetes;

associated with fewer symptoms of postpartum depression.[159,191] Increased mood symptoms are seen with the consumption of a Western-style dietary pattern with increased intake of processed foods, fast foods, added sugars, solid fats, and alcohol, as well as with extreme carbohydrate restriction.[159,191]

55.4.6 Adverse Pregnancy Outcomes and Long-Term Health

The postpartum period represents an opportunity to address the implications of any recent APO. Women should be counseled that APOs act as a window into their future health, as these outcomes often reveal latent disease risks that manifest clinically under the physiologic stress test of pregnancy.[64,195,197,206,224,225]

The risk of developing preeclampsia in pregnancy is strongly associated with classic cardiovascular risk indicators such as hypertension, elevated BMI, diabetes, and abnormal lipid levels; in turn, preeclampsia itself has been identified as an independent cardiovascular risk indicator. Patients with a history of preeclampsia during pregnancy are at increased risk of cardiometabolic disease, renal disease, premature cardiac death, and all-cause mortality

later in life when compared with women without this history.[197,206,224–231] These risks are highest with a history of severe, early-onset, or recurrent disease.[197,206,225,226,231,232] The cardiovascular risk is also increased with a history of other APOs, such as gestational hypertension, GDM, placental abruption, preterm birth, fetal overgrowth or undergrowth, and stillbirth; particularly when they exist in combination.[3,196,197,206,229–231] Many APOs are rooted in placental dysfunction, inflammation, and endothelial activation,[206,233] with an underlying vascular pathology similar to that seen in cardiovascular disease and supporting the closely interconnected nature of APO and cardiovascular disorders.[206,224,233] Patients with a history of GDM also have a dramatically increased risk of developing type 2 diabetes, with 5–10% of affected women meeting diagnostic criteria for type 2 diabetes immediately postpartum and 50% by ten years after delivery.[188,195,234] The risk of type 2 diabetes is also increased with a history of delivering a macrosomic infant, regardless of GDM status.[195,229,230]

Because of the associations with future chronic disease, women with a history of APO should be counseled about these risks, undergo periodic health screenings as indicated given their elevated risks, and be encouraged to consider lifestyle interventions that may not only reduce progression to clinically apparent cardiometabolic disease later in life, but also reduce the recurrence of APOs in any future pregnancy. Although news of their increased risks may be sobering to many patients, it is important to stress that the risks predicted by APOs are modifiable with lifestyle intervention. The unique preview of future health risks that pregnancy provides should be viewed as an opportunity for early intervention and as a motivating factor for change. A summary of recommendations may be found in Table 55.3.

55.4.7 Breastfeeding

Human milk is the preferred and physiologic source of nutrition for human infants.[235] The World Health Organization, Centers for Disease Control and Prevention, and American Academy of Pediatrics (AAP) recommend exclusive breastfeeding for the first six months of life, then continuing with the addition of complementary foods through one to two years of life.[235–237]

Human milk contains fats, carbohydrates, proteins, vitamins, and antibodies in a composition specific to the needs of human infants. This includes a higher whey-to-casein ratio, higher lactose content, and much lower protein content than most animal milks.[238] It is also a dynamic substance, providing a higher nutrient density during periods of rapid infant growth. The nutritional content of milk reflects the nutritional status of the mother for some nutrients, such as the content and type of fatty acids, the content of certain micronutrients (vitamins A, B1, B2, B6, B12, D, folate, iodine, selenium, choline), and of other substances such as insulin, environmental chemicals, heavy metals, and toxins.[239,240] Nutrients not significantly impacted by maternal diet include the total carbohydrate and protein content and other micronutrients (vitamins C and E, calcium, phosphorous, magnesium). Human milk is a poor source of iron, zinc, copper, and vitamin K regardless of maternal diet.[239] However, the only supplement routinely recommended for exclusively breastfed newborns is vitamin D, as all other micronutrients, including iron, are considered in sufficient supply until complementary foods are introduced around six months of age. The AAP and US Dietary Guidelines for Americans recommend infant supplementation of vitamin D 400 IU per day.[19] Although the RDA of vitamin D for lactating women is 600 IU per day, women are expected to benefit from increased supplementation of 1400 IU per day during lactation.[19,28] In addition, women who prefer to satisfy infant vitamin D requirements without supplementing their infant directly may consider high-dose vitamin D supplementation of 4000–6000 IU per day, a dose found to be safe and sufficient to enrich breastmilk adequately for infant vitamin D needs.[19,28]

There are a variety of maternal and infant benefits to breastfeeding beyond the simple provision of nutritional needs. Maternal benefits of breastfeeding include the additional caloric expenditure, which may facilitate postpartum weight loss, and reduced risks for later life type 2 diabetes, metabolic syndrome, hypertension, cardiovascular disease, and certain cancers.[64, 241] Lactation also facilitates maternal-infant bonding, reduces maternal stress, improves sleep quality, and supports natural family planning.[64,212,242] Infants fed human milk have a significant reduction in sudden infant death syndrome and develop a more favorable gut microbiome, which has been associated with improved gastrointestinal function and fewer gastrointestinal infections.[241,243–249] They also benefit from a reduction in respiratory, ear and throat infections, asthma, and atopic disease.[243] Breastfeeding promotes training of neonatal hunger and fullness cues, reducing infant and childhood overeating.[250,251] Infants fed human milk also have a lower risk of childhood leukemia,[252] improved neurocognitive development in childhood,[253,254] and reduced risks of both type 1 and type 2 diabetes and adulthood obesity.[231,241,253–255] Concerns about imperfect maternal nutrition or everyday environmental exposures should not be considered a reason to avoid or cease lactation – human milk remains the most nutritive and beneficial infant food even with a less-than-ideal diet.

Successful and sustained lactation relies not just on maternal will, but on practical needs such as social acceptance, lactation support, adequate parental leave, protected time and space for expressing breastmilk at work, and legal protections. Prenatal breastfeeding education, skin-to-skin contact at birth, infant rooming-in with the mother after delivery, and hospital policies and education supporting lactation have been shown to improve lactation initiation and continuation rates and reduce disparities.[256] Consultation with an International Board-Certified lactation consultant should be offered for any breastfeeding difficulties or maternal-infant separation. Community policies and legal protections supporting a woman's right to time and space

to lactate outside of the home should be supported by medical professionals and policymakers. Recommendations for unnecessary cessation of lactation – for example, advice to "pump and dump" after surgery or medication use – should be avoided unless supported by medical evidence. There are very few true medical contraindications to lactation, and disruption should not be advised unless a known medical contraindication exists.

55.5 CONCLUSION

Lifestyle behaviors of reproductive-age women play a significant role in the health of pregnancy and the future health of the child. Consequently, women's healthcare providers play a key role in addressing modifiable risk factors before, during, and interpregnancy. It is also important to form partnerships with other lifestyle medicine providers including dieticians, health coaches, primary care, and specialists to provide a multidisciplinary model of care that is seamless during her reproductive years.

The postpartum period represents a unique opportunity to identify and address future health risks, motivate change, and set the stage for improved outcomes in future pregnancies and later in life. Lifestyle interventions during this period are beneficial not only to the postpartum woman but also to her offspring and to the entire family unit.

CLINICAL APPLICATIONS

- Preconception goals ideally include a BMI <25, HgA1c <6.0, nutrient-dense diet with a minimum of 25 g/day of fiber, reduction or elimination of medications, and if applicable reversal of chronic disease.
- Well-balanced whole food plant-based diets are safe in pregnancy and include adequate calorie, protein, and fiber intake. Pregnant women should consume 28/34/36 g/day of dietary fiber during the first, second, and third trimesters, respectively.
- Reproductive-age women should have a vitamin D level checked annually with a goal of 40–60 ng/dl.
- Diverse plant-based diets provide all the necessary micronutrients with the exception of vitamin B12. Women consuming an entirely plant-based diet in pregnancy should intentionally consume B12-fortified foods four times per day or take a vitamin B12 supplement containing 50 µg daily or 2000 µg weekly.
- Women before, during, and after pregnancy should be advised to perform a minimum of 150 minutes of moderate-intensity exercise or 75 minutes of vigorous-intensity exercise, spread over four to seven days each week. Return to a baseline activity level should be possible for most women by four to six weeks postpartum.
- Lactation should be stimulated as soon as possible after birth. When possible, human milk should be provided as the exclusive source of infant nutrition for six months and continued along with other foods through 12 months or more. If not possible, the provision of any amount of human milk for any length of time is beneficial and encouraged.
- Adverse pregnancy outcomes should be managed as cardiovascular risk factors from the standpoint of future health screenings and risk assessment.

56 Menstrual Health and Menopause

Amanda McKinney, MD, FACOG, FACLM

KEY POINTS

- Polycystic ovarian syndrome (PCOS), and its associated insulin resistance, can cause significant abnormal uterine bleeding (AUB).
- Advanced glycation end products (AGEs) and oxidative stress have been implicated in PCOS.
- Lifestyle, particularly diet and exercise, can be used to manage or reverse PCOS.
- Later age at menopause is largely associated with improved health outcomes and can be impacted by certain lifestyle factors.
- Menopausal symptoms can often be ameliorated with dietary changes.

56.1 LIFESTYLE-RELATED MENSTRUAL DISORDERS

Polycystic ovarian syndrome (PCOS) is a constellation of obesity, insulin resistance, and oligo-ovulation, or anovulation, which can result in infertility, menstrual dysfunction, and hirsutism. It impacts approximately 10% of women of reproductive age and 40% and 85% of women with PCOS are overweight or obese. As women become obese, insulin resistance leads to elevated levels of circulating insulin which suppresses the synthesis of sex hormone-binding globulin (SHBG). This leads to a rise in free androgens that interfere with luteinizing hormone (LH) and follicle-stimulating hormone (FSH) secretion at the level of the pituitary. As such, multiple small follicles accumulate in the ovary, but none are capable of growing to a size that would trigger ovulation. This leads to infrequent ovulation characteristic of PCOS with heavy, irregular uterine bleeding.[1]

Chronic inflammation and oxidative stress have also been incriminated in the pathophysiology of PCOS. The role of advanced glycation end products (AGEs) is becoming more prominent as well. Elevated concentrations of AGEs, or glycotoxins, which exert their effects through interaction with specific AGE receptors (RAGE), have been implicated in cellular and tissue damage. Women with PCOS have almost twice the circulating AGE levels in their bloodstream and more than three times the expression of RAGE. This is true for both obese women with PCOS as well as for lean, non-insulin-resistant women with PCOS. PCOS ovaries have higher levels of AGEs within the ovary itself and have a stronger expression of RAGE, contributing to the development of PCOS and its associated abnormal uterine bleeding (AUB).[2–5]

56.2 TREATMENT

Conventional treatment for PCOS is tailored to the woman's immediate reproductive desires. For those women trying only to control the symptoms of PCOS, such as irregular bleeding, hirsutism, and acne, oral contraceptive pills are often first-line therapy. Oral contraceptives are effective for symptom amelioration, as they lower total testosterone levels and increase SHBG, however, they can have a negative impact on lipid profiles.[6] However, the two primary causative agents in PCOS are insulin resistance and AGE-induced oxidative stress, which are best addressed through diet and lifestyle changes.

A study done by Barnard and colleagues showed that SHBG is increased by 16% when women consume a low-fat plant-based diet, which could lead to improved ovulatory function.[7] Likewise, a study in the *American Journal of Obstetrics and Gynecology* revealed that replacing 5% of calories with carbohydrate or vegetable protein in lieu of animal protein is associated with a 40–50% improvement in ovulatory function.[8]

Dietary behaviors resulting in obesity and malnutrition are linked with oxidative stress and chronic, low-grade inflammation. It has been shown, repeatedly, that animal foods are associated with systemic inflammation.[9] The primary sources of AGEs implicated in the pathophysiology of PCOS are cigarette smoke and food. Reducing these dietary glycotoxins reduces the inflammatory response.[10] Foods with the highest AGEs are of animal origin and foods cooked in high temperature, dry cooking methods as compared with low heat, higher humidity cooking. Stewing, steaming, and boiling result in lower AGE production than broiling, searing, and frying. AGE tissue levels are a strong predictor of overall mortality and are consistently lower in vegetarians.[4] Reducing AGE intake improves insulin sensitivity, reduces oxidative stress biomarkers, and reduces testosterone in women with PCOS.[11]

Women with PCOS have increased serum levels of antimullerian hormone (AMH) that are two to three times higher than in women with normal ovaries. In the ovary, AMH has an inhibitory effect on follicle recruitment and on the responsiveness of growing follicles to FSH.[12] It has been shown that one hour of exercise three times per week decreases body mass index (BMI) and total and android fat mass, improves insulin sensitivity, and lowers AMH levels. This suggests that mechanisms associated with ovarian dysfunction can be improved by exercise in PCOS, possibly improving menstrual function.[13]

DOI: 10.1201/9781003227793-66

56.3 MENOPAUSE BACKGROUND

The age at which menopause occurs typically ranges from ages 48 and 55 years, with a median age of 51.4 years, and the perimenopausal transition lasts for about four years.[14] Menopause is reached when the depletion of follicles reaches approximately 1000, from 2 million at birth with a peak of 5 million during the mid-reproductive years.[15] During perimenopause, declining estrogen levels can lead to cycles with a short luteal phase or an anovulatory cycle, with unopposed estrogen leading to irregular bleeding. These cycles are common in women over the age of 40 and the bleeding can be profuse.[15]

The initial years of menopause are often accompanied by vasomotor symptoms, such as hot flashes and night sweats, somatic symptoms such as fatigue, body aches, and vaginal dryness, and psychological symptoms such as irritability, anxiety, depression, decreased libido, and difficulty sleeping.[16] Survey data indicate that 60% of women experience hot flashes, 48% experience night sweats, and 41% reported trouble sleeping. Vasomotor symptoms commonly develop one to two years before the cessation of menses. Ethnicity also plays a role with African American women having the highest frequency of hot flashes followed by Hispanic American and Euro American women, respectively, while Chinese and Japanese American women reported lower rates of vasomotor symptoms.[17]

Although menopause is a universal phenomenon among women, the timing of the onset, the duration of the menopausal transition, and the timing of the final menstrual period are not. Later age at natural menopause has been associated with greater life expectancy, reduced all-cause mortality, reduced risk of cardiovascular disease and associated mortality, and reduced risk of osteoporosis and fracture, but an increased risk of breast, endometrial, and ovarian cancers. Early menopause has also been associated with earlier cognitive decline.[15] The association of reduced bone loss with later onset of menopause is related to longer exposure to estrogen, however, this is also why there is an association with increased risks of breast, endometrial, and ovarian cancers. Despite this, there does appear to be a benefit from menstrual blood loss and a reduced risk of cancer, in general.[18]

Multiple environmental and lifestyle factors impact the age of onset of menopause. Onset varies by race and ethnicity but largely in the context of demographic and lifestyle factors. Factors that result in later natural menopause include living in developed countries and urban areas and greater parity, especially for women, with higher socioeconomic status. Factors that result in earlier onset of menopause include lower socioeconomic status, living at higher altitudes, smoking, and malnourishment. Family and twin studies suggest that heritability may impact the age of onset anywhere from 30% to 85%.[15]

56.4 MENOPAUSE MANAGEMENT

Lifestyle measures can often be used to treat menopausal symptoms. Despite this, the focus on symptom relief has largely been reliant on exogenous hormone replacement therapy (HRT). It has been well characterized since 1940 that estrogenic substances could induce carcinoma of the breast[19] with an approximate 30% greater chance of breast cancer with long-term estrogen therapy. However, there is some evidence that a diagnosis of breast cancer while taking hormone replacement therapy is associated with a better prognosis. Despite decades of accumulated observational evidence, the balance of risks and benefits of hormone use in healthy postmenopausal women remained uncertain until 2002, when the first randomized, controlled trial—the Women's Health Initiative (WHI)—was conducted. The trial halted early because the stopping boundary for invasive breast cancer (26% increased risk) was exceeded. A 29% increased risk of coronary heart disease, a 41% increased risk of stroke, and a two-fold increased risk of pulmonary embolism compared with the placebo group were also documented. While there were fewer cases of endometrial cancer, hip fracture, and colorectal cancer in the treatment group, the risk-benefit profile was not deemed consistent with the requirements for a viable intervention for primary prevention of chronic disease.[20]

Compounded bioidentical hormones, despite some claims, do carry the same risks as other synthetic or commercially produced hormone therapies. *The Medical Letter*, a non-profit, advertisement-free peer-reviewed publication stated in 2010 that, "There is no acceptable evidence that 'bioidentical' hormones are safe or effective. Patients should be discouraged from taking them".[21]

Diet-related treatments are often employed to help reduce the vasomotor symptoms of menopause including phytoestrogens like soy. There are two primary types of estrogen receptors (ERs), alpha and beta. Endogenous and synthetic estrogens act non-selectively as agonists for both types of receptors while anti-estrogen drugs like fulvestrant act as antagonists at the level of all ERs. Mixed agonist–antagonists include synthetic selective estrogen receptor modifiers (SERMs), like tamoxifen, as well as phytoestrogens that act selectively, primarily on beta-receptors.

Alpha-receptors are found mainly in the endometrium, breast cancer cells, ovarian stromal cells, and the hypothalamus, while the beta-receptor is expressed primarily in the ovarian granulosa cells, kidney, brain, bone, heart, lungs, intestinal mucosa, and endothelial cells. Because estrogens tend to act indiscriminately, they impact all these tissues simultaneously. As a result, exogenous estrogens work well to prevent both bone loss and treat vasomotor symptoms associated with menopause, however, when estrogen binds to the alpha-receptors in the breast, mammary cells proliferate, with resulting cell division and DNA replication that can lead to mutations and breast cancer development. ERs are over-expressed in around 70% of all breast cancer cases.

Conversely, phytoestrogens are plant derivatives that bear a structural similarity to 17-beta-estradiol and act in a similar manner. Phytoestrogens tend to act like SERMs and have a higher affinity for beta-receptors, which are dose-dependent. Phytoestrogens have both agonistic and

antagonistic effects, although they are strong beta-receptor agonists and weak alpha-receptor agonists. The similarities between phytoestrogens and 17-beta-estradiol allow for the displacement of estrogen. Activation of the beta-receptors in the breast inhibits mammary cell growth and the stimulatory effects of activated alpha-receptors, helping to prevent tumor growth.[22] Genistein, the phytoestrogen in soy, has been found to bind the active site of the beta-ER with an affinity of 7–30-fold greater than its affinity for the alpha-ER.[23]

Overall, clinical studies utilizing soy have revealed either a positive or neutral impact on vaginal health indices that reflect vaginal moisture, elasticity, mucosal maturation, and pH, and a positive or neutral impact on hot flashes.[24] Additionally, studies evaluating vasomotor symptoms commonly observe a significant placebo effect, with up to 30% reduction in hot flashes in the placebo group.[25] Two recent meta-analyses reported that isoflavone supplementation was associated with a 34% reduction in hot flashes and that consumption of at least 15 mg of genistein reduces hot flashes by up to 50%. This total reduction includes that provided by "the placebo effect". Additionally, a prospective population-based cohort study of 1100 Japanese women found that hot flashes were significantly inversely associated with the consumption of soy products and isoflavone intake.[26] Despite the mixed outcomes on menopausal symptoms, soy has other health benefits, including favorable effects on the vascular endothelium and protection from left ventricular hypertrophy,[27] reduced risk of endometrial[28] and ovarian cancers,[29] and nephroprotection.[27] Thus, their consumption should be encouraged.

CLINICAL APPLICATIONS

Lifestyle recommendations for the treatment of menopausal symptoms:

- Smoking cessation
- Moderate physical activity and weight loss for those overweight and obese
- One alcoholic beverage per day; those who do not consume alcohol should not be encouraged to start
- Consume 15 mg of the soy phytoestrogen, genistein, daily which is approximately equivalent to
  - 3 oz of tofu
  - ½ cup tofu yogurt
  - 1 cup soy milk
  - 1 oz dry, roasted soy beans
  - 2 oz tempeh
  - ½ cup boiled soy beans
  - ¼ miso
  - 1 oz aqueous-washed soy protein concentrate (85)

In addition, vaginal estrogen may be used for symptoms of urogenital atrophy in those with no prior diagnosis of breast cancer, DVT or PE, stroke, or coronary heart disease.

57 Female Breast and Gynecologic Cancer

Amber Orman, MD, Dip-ABLM, Gautam Krishna Koipallil, MD, MPH, Meghana Reddy, MD, Hari Krishna Koipallil, BS, Amy Comander, MD, DipABLM, and Michelle Tollefson, MD, Dip-ABLM

KEY POINTS

- Plant-predominant dietary patterns and physical activity are key aspects of female cancer care.
- Obesity plays a role in postmenopausal breast, endometrial, and ovarian cancer risk.
- Lifestyle interventions can be leveraged to mitigate cancer-related fatigue, pain, emotional distress, depression, anxiety, cognitive impairment, and sleep disturbances.

57.1 INTRODUCTION

In the United States, cancer remains the leading cause of death among women aged 40 to 79 years. Breast cancer is the second leading cause of death in women, with an estimated 43,250 deaths in 2022. Ovarian and endometrial cancers are the fifth and sixth leading causes of cancer death, with an estimated 12,810 deaths and 12,550 deaths in 2022, respectively.[1] Since the mid-2000s, female breast cancer incidence has been slowly *increasing* by 0.5% per year, attributable at least in part to lifestyle factors such as excess body weight and continued declines in fertility rates.[2] These lifestyle factors likely also contributed to the recent rise in endometrial cancer.[3]

57.2 ROLE OF LIFESTYLE MEDICINE IN FEMALE BREAST AND GYNECOLOGIC CANCER

Currently, 41% of men and 39% of women will develop cancer during their lifetime.[4] According to the American Cancer Society, at least 42% of newly diagnosed cancers (excluding non-melanoma skin cancer) in the United States could be prevented with positive changes in diet and lifestyle; 19% of newly diagnosed cancers may be due to smoking and 18% to a combination of excess body weight, excessive alcohol consumption, poor nutrition, and lack of physical activity. In addition, these lifestyle factors also play a key role in the health and disease outcomes of cancer survivors. Organizations such as the American Society of Clinical Oncology and the American Cancer Society have established guidelines for breast cancer survivorship.[5] What follows is a concise summary of the role of lifestyle medicine in primary and tertiary prevention of female breast and gynecologic cancers and symptom management.

57.3 PRIMARY BREAST CANCER PREVENTION

57.3.1 Nutrition

57.3.1.1 Plant-Predominant Dietary Pattern

Adherence to plant-predominant cancer prevention dietary guidelines is associated with a 19–60% decrease in breast cancer (BC) risk.[6,7] The Mediterranean diet has shown consistent empiric evidence to have protective effects against BC.[8]

57.3.1.2 Fiber

Meta-analysis revealed total fiber and soluble fiber are inversely associated with BC risk (RR = 0.92 and 0.90, respectively), with high total fiber effective in *both* premenopausal and postmenopausal women.[9] Meta-analysis has also suggested a dose-dependent response, where each 10 gram/day increase in fiber correlated with a 7% BC risk reduction.[10] This is likely due to fiber intake (irrespective of weight loss) being independently associated with reduced serum estradiol.[11]

57.3.1.3 Soy

Increased soy intake has been associated with decreased primary BC risk.[12–15] However, a 2021 meta-analysis of 18 randomized controlled trials (RCTs) did not reveal clear protective benefits (sample size was listed as a limitation)[16] The dose may account for the inconsistent findings, as a meta-analysis of prospective studies (ten years of follow-up) has suggested that increasing soy intake may be protective, with every increase of 10 mg/day correlating with a 3% decrease in BC risk[17]

57.3.1.4 Carotenoids

Pooled meta-analysis from 2012 and post-hoc analyses demonstrated that carotenoids may have varied effects on BC risk. A total of five carotenoids were independently analyzed (α-carotene, β-carotene, β-cryptoxanthin, lutein/zeaxanthin, and lycopene).[18,19] All carotenoids demonstrated protection against ER(–) (estrogen receptor negative) phenotypes, while α-carotene and β-cryptoxanthin protected against all breast cancers. All carotenoids except

DOI: 10.1201/9781003227793-67

β-cryptoxanthin protected against ER(–)/PR(+) (progresterone receptor positive) or ER(–)/PR(–) BC.[18] However, β-carotene specifically was found to increase the risk of ER(+) and ER(+)/PR(+) phenotypes specifically.[18] This is in direct contrast to an earlier meta-analysis that demonstrated that β-carotene decreased the risk of BC[20]

57.3.1.5 ALCOHOL

The 2020 American Cancer Society (ACS) guidelines for cancer prevention advise complete avoidance of alcohol, given an increased risk for BC, even with consumption of less than one drink per day[21] The prospective observational Nurses' Health Study (n = 105,986 women) revealed that increased alcohol consumption was associated with a higher risk for BC. The association was statistically significant even at low levels of alcohol intake, equivalent to three to six drinks per week (relative risk, 1.15), with every 10 grams per day of alcohol intake increasing BC risk by 10%.[22]

57.3.2 PHYSICAL ACTIVITY

Meta-analysis demonstrates that earlier onset of regular physical activity conveys a near 30% decrease in primary BC risk.[23] Exercise may exert immunomodulatory and/or anti-inflammatory effects.[24–26] Meta-analysis further demonstrates that exercise interventions (aerobic, resistance, combined, or tai chi/yoga) might be particularly effective when combined.[27]

Baseline body fat composition may alter the measured effectiveness of exercise regimens for primary BC prevention if at least part of the effect is from the loss of fat itself. Postmenopausal women experiencing significant fat loss (>2 kg) have both a significant increase in sex-hormone binding globulin (SHBG) and a significant decrease in DHEA-S. This may decrease long-term BC risk via decreased peripheral conversion of testosterone to active estrogenic compounds,[28] however, this is not supported in all studies.[29]

57.3.3 OBESITY

Obesity is a known BC risk factor, likely due to the associated increase in estrogen and estrogenic compounds.[23,30–32] It is estimated that 25% of BC incidence is influenced by a sedentary lifestyle or obesity, and obesity confers a dose-dependent (albeit non-linear) risk of BC in postmenopausal women.[33–35]

57.3.4 SLEEP

Meta-analyses of observational studies have demonstrated that high levels of artificial light at night (LAN) (but not ambient levels) have a significant correlation with increased BC risk, however, multiple studies have otherwise demonstrated either no association or a non-clinically relevant but statistically significant increase in risk with LAN exposure.[36–38]

57.3.5 PSYCHOLOGICAL STRESS

Although not consistently demonstrated, psychological stress, particularly *stressful* or *major* life events, has been implicated in increasing BC incidence.[39–46] Appropriate support and counseling for patients experiencing significant psychological stress are warranted, irrespective of the association with BC risk.

57.4 TERTIARY BREAST CANCER PREVENTION

57.4.1 Nutrition

While there is a need for more research, all major guidelines recommend a plant-predominant diet for BC survivors.[6,47,48] Nutritional educational programs for cancer survivors have demonstrated both feasibility and success in increasing self-efficacy in preparing plant-based meals, reducing barriers to eating fruits and vegetables, and significantly reducing meat intake.[49]

57.4.1.1 Dietary Supplements

There is no consensus in terms of supplement use and prognostic outcomes in BC survivors.[50] In one trial of BC patients undergoing chemotherapy (n = 1134), adjuvant and neoadjuvant use *of* any antioxidants (carotenoids, coenzyme Q10, or vitamins A, C, or E) had an *increased* risk of BC recurrence and death (adjHR = 1.41 and 1.4, respectively), although neither of these was significant at the p = 0.05 level.[50] Additionally, adjuvant/neoadjuvant B12 supplementation was significantly associated with poorer disease-free or overall survival, although no clear association with BC recurrence was found.[50] Further study is needed.

57.4.1.2 Soy

Multiple large-scale meta-analyses (n = 330,826) of prospective studies revealed that a 10 mg/day increase in soy and soy isoflavones was associated with a 9–11% decrease in BC mortality; furthermore, every 5 g/day increase in soy protein consumption reduced risk of BC death by 12%.[12, 51]

The association between soy isoflavone consumption and BC *recurrence* is less clear, with large-scale meta-analyses of RCTs, uncontrolled, and long-term observational studies generally finding soy isoflavones protective against BC recurrence, specifically at a dose of >10 mg/day.[52–54]

57.4.1.3 Carotenoids

Dietary intervention trials in BC survivors have demonstrated that increased plasma carotenoid concentration significantly reduces the risk of BC recurrence, highlighting the importance of fruit and vegetable intake.[55]

57.4.1.4 Alcohol

The American Society of Clinical Oncology and ACS recommends BC survivors be counseled to limit alcohol consumption.[21,56] In 1897 BC survivors, those who drank more than three to four alcoholic beverages per week had

a significantly higher risk of BC recurrence (HR = 1.35) and BC-specific mortality (HR = 1.51) when compared with those who reported minimal alcohol intake.[57]

57.4.2 Physical Activity

Physical activity is well-established in BC survivors as an effective method for improving quality of life (QOL), physical functioning, sleep quality, and bone mineral density, as well as preventing bone loss and reducing fatigue.[58–63] However, a large-scale meta-analysis (n = 5761) revealed no clear association between physical activity levels and BC recurrence.[64]

57.4.3 Obesity

Multiple studies purport that obesity or overweight status may be associated with a higher recurrence risk and increased all-cause mortality in BC survivors.[65–68] However, a 2020 meta-analysis (n = 2028) of RCTs of overweight and obese BC survivors undergoing weight loss intervention found that there was low-quality evidence for weight loss benefitting BC recurrence.[65] Regardless, practitioners should strive to address obesity among BC survivors due to its association with poorer QOL and increased subsequent comorbidities.[65]

57.5 SYMPTOM MANAGEMENT IN BREAST CANCER SURVIVORS

57.5.1 Physical Activity Recommendations

Physical activity benefits cancer survivors in many areas (QOL, psychosocial symptoms, pain, fatigue, lymphedema), and is an important supportive intervention to prescribe.[69–72] Meta-analysis of RCTs revealed that BC survivors benefit most from moderate to vigorous exercise (of any modality) for ~150 minutes per week.[73] Yoga (especially when combined with other meditative interventions) has been shown to reduce fatigue, depression, and anxiety and also improve sleep.[74–77]

57.5.2 Lymphedema

Exercise (particularly combined resistance and aerobic training) is well-established as an effective method to mitigate upper-extremity lymphedema secondary to surgical and/or radiotherapy interventions.[78–86]

57.5.3 Pain and Neuropathy

Upper-extremity pain, particularly chronic pain, should be targeted with a multidisciplinary approach that includes physiotherapy as well as psychological, pharmacological, and educational interventions.[87] RCTs have revealed that yoga and high-intensity interval training (HIIT) reduce overall pain sensitivity and improve fatigue.[88,89]

A multicenter RCT involving BC patients undergoing chemotherapy found that progressive moderate-intensity resistance training in a six-week home program format was associated with a significant decrease in chemotherapy-induced peripheral neuropathy.[90]

Acupuncture has been demonstrated through large-scale meta-analyses to significantly heighten pain threshold, and improve hot flashes, neuropathy, overall pain sensitivity, physical fatigue, depression, and sleep quality.[91–94]

57.5.4 Cancer-Related Fatigue

Exercise (both aerobic and resistance training) and yoga are incredibly well-established as effective in reducing cancer-related fatigue (CRF).[59,82,95–102] Notably, exercise seems to improve both physical and cognitive aspects of CRF, with benefits consistent for many years post-treatment.[103,104] Consuming a plant-based diet has also been implicated in the improvement of CRF.[105]

57.5.5 Depression and Anxiety

Depression and anxiety are prevalent in nearly one-third to one-half of BC survivors, respectively[106–109] In a meta-analysis of over 41 RCTs, non-pharmacological therapeutics (NPTs) including exercise, psychotherapy, yoga, and mind-body interventions were significantly related to a decrease in depression symptoms.[110] Meditation and mindfulness-based stress reduction (MBSR), particularly in a *group* setting, seems superior to traditional supportive-expressive group therapy in terms of longevity of improvement in psychological distress and function in cancer survivors,[111–117] and should be considered for couples as well.[118–126]

Cognitive-behavioral therapy (CBT) is very effective for psychological symptoms, including stress, depression, anxiety, sleep quality, and even hyperarousal.[127–131]

57.5.6 Cognitive Impairment

Cancer-related cognitive impairment (CRCI) is commonly experienced among BC survivors during or after chemotherapy[132] CRCI may be modified with physical activity (exercise, yoga, and Tai Chi), stress mitigation, and sleep improvement.[133–138] CRCI is exacerbated in survivors with comorbid anxiety or depression[139] Mindfulness-based interventions may improve cognition in cancer survivors, and when combined with exercise may be more beneficial than exercise alone.[140–142]

57.6 PRIMARY GYNECOLOGICAL CANCER PREVENTION

57.6.1 Nutrition

57.6.1.1 Plant-Predominant Dietary Pattern

Associations between higher-quality diets and gynecological cancer risk are inconsistent.[7,143] A 2020 meta-analysis found that high pre-diagnosis vegetable intake was associated with decreased ovarian cancer incidence (HR = 0.78), while a high pre-diagnosis fruit intake was also associated

with decreased all-cause mortality (0.82).[144] Other large-scale (n = 142,189, n = 149,177; n = 567,742) meta-analyses suggested an inverse relationship between fiber intake and ovarian cancer risk, with a linear and dose-dependent 6–12% decrease in risk for every 10 g/day increase in fiber intake.[145–148] Intake of dietary isoflavones is also associated with a 16–18% decrease in the risk of developing endometrial and ovarian cancer[149–152] A large-scale (n = 1,404,297; n = 721,429) meta-analysis found that increased total antioxidant intake and capacity were associated with a 22–27% lower risk of endometrial cancer.[153,154]

57.6.1.2 Fats and Coffee

Intake of total fats, saturated fats, cholesterol, and retinols are suggested to significantly increase ovarian cancer risk through large-scale meta-analyses[155] This is supported by a meta-analysis that found a 7% increase in ovarian cancer risk for every additional 100 g/d of whole milk versus a 5% decrease per 100 g/d of low-fat milk.[156]

A 2018 meta-analysis (n = 14,409) studying coffee intake with endometrial cancer risk demonstrated a 25% lower risk among women who drank the most versus the least coffee per day, with effect sizes being higher in women with a BMI >30[157,158]

57.6.1.3 Vitamin D and Calcium

It is suggested that lower circulating vitamin D may increase ovarian cancer incidence, while increased vitamin D has been correlated to lower mortality,[159] however, the association is not consistent.[156,160] Vitamin D has been shown to have beneficial effects of increasing total antioxidant capacity and reducing inflammatory markers in women with precarcinogenic endometrial hyperplasia.[161]

Calcium intake in multiple meta-analyses has demonstrated an inverse relationship with ovarian cancer risk, particularly epithelial ovarian cancer.[160,162]

57.6.1.4 Alcohol

Current literature has limited evidence for an association between alcohol intake and primary gynecological cancer risk.[143,163,164]

57.6.2 Obesity and Physical Activity

The International Agency for Research on Cancer (IARC) and the World Cancer Research Fund (WCRF) analysis revealed a positive association between adiposity and both endometrial and ovarian cancer,[165,166] with 57% of endometrial cancer cases attributed to obesity.[167–171] Furthermore, a large-scale meta-analysis (including 150,537 bariatric surgery patients versus 1,461,938 controls) demonstrated that bariatric surgery in obese women reduced the risk of ovarian and endometrial cancer by 53% and 67%, respectively.[172]

Total lifetime physical activity is inversely associated with (RR = 0.77) endometrial cancer, notably augmented in postmenopausal women.[23,173,174] More than two hours of moderate exercise per week or less than three hours of sitting per day are associated with a decreased risk of ovarian cancer.[175]

57.7 TERTIARY GYNECOLOGICAL CANCER PREVENTION

57.7.1 Obesity

Meta-analysis of obesity in endometrial cancer survivors demonstrated an increase in all-cause mortality (HR = 1.34) and cancer recurrence (HR = 1.28) if BMI was greater than 30 at the time of diagnosis.[176] Small RCTs have demonstrated the ketogenic diet to be effective for weight loss in ovarian and endometrial cancer survivors, with no adverse effects or significant alteration to blood lipid and ketones after only 12 weeks, however, longer-term follow-up is needed to assess association with recurrence risk and potential development of comorbidities.[177–179]

57.8 SYMPTOM MANAGEMENT IN GYNECOLOGIC CANCER PATIENTS

57.8.1 Pain and Cancer-Related Fatigue

More than one-half of all gynecological cancer survivors report suffering from CRF.[180] Home-based physical activity interventions effectively reduce CRF in ovarian cancer patients for long-term periods (up to nine months) and are further augmented by concurrent behavioral counseling.[181] Small-pilot studies also demonstrate that short-term fasting may significantly improve fatigue and QOL in gynecologic patients undergoing chemotherapy.[182]

57.8.2 Emotional Distress, Depression, and Anxiety

Exercise is associated with decreased self-reported depression and decreased serum brain-derived neurotrophic factor (BDNF) (a depression-related biomarker), as well as improved quality of life, pain, and distress in endometrial or ovarian cancer survivors.[183–186]

CBT and positive psychology interventions, particularly in a nurse-led format significantly improve CRF, depression, cognitive functioning, subjective well-being, mood, and sexual functioning in gynecological cancer survivors.[187–190]

57.8.3 Sleep Disturbance

CBT in addition to regular physical activity and a healthy diet can help improve sleep and quality of life in endometrial cancer patients.[191] MBSR has also been shown to significantly improve sleep time and quality among cervical cancer patients, however, the effect waned over time.[192]

57.9 CONCLUSIONS

Healthcare practitioners caring for women can share the primary cancer prevention information in this chapter with

their patients, thereby decreasing their risk of a breast cancer or gynecologic cancer diagnosis. For healthcare practitioners treating breast or gynecologic cancer survivors, educating patients about the potential for lifestyle medicine to decrease recurrence risk and manage symptoms can improve their quality of life while also helping them lead longer and healthier lives.

CLINICAL APPLICATIONS

- Plant-predominant dietary pattern has a role in both primary and tertiary prevention of breast cancer. The role in gynecologic cancer is less defined.
- Physical activity has a clear role in primary breast cancer prevention.
- Obesity increases the risk of postmenopausal breast, endometrial, and ovarian cancers; early intervention is encouraged.
- Cancer-related fatigue, pain, emotional distress, depression, anxiety, cognitive impairment, and sleep disturbances may be mitigated with a variety of exercise and mindfulness-based practices.

58 Cardiovascular Disease, Diabetes, Obesity, and Lifestyle Medicine Considerations in Women

Neha Pathak MD, FACP, DipABLM

KEY POINTS

- Cardiovascular disease (CVD) is the number one cause of mortality for women in the United States.
- A lifestyle medicine approach should be utilized for all women to address prevention, management, and reversal/remission of CVD and related risk conditions such as diabetes and obesity.
- Women have sex- and gender-specific differences that uniquely affect CVD, diabetes, and obesity risk, presentation, diagnosis, and treatment.
- Metabolic risk factors, such as waist circumference, and lipid levels have different threshold values for women compared with men while others, such as hypertension, may have distinct implications for CVD.
- Unique considerations can differentially impact a woman's ability to perform healthy lifestyle behaviors and lifestyle factors can have different impacts on CVD, diabetes, and obesity risk.

58.1 INTRODUCTION

Cardiovascular disease (CVD) is the leading cause of death for women in the United States, accounting for more than 300,000 deaths in 2019.[1] Annually, CVD mortality is greater for women, a consistent trend over two decades.[2] Conditions such as hypertension (HTN), ischemic heart disease (IHD), myocardial infarction, and stroke are included within the umbrella of CVD. Stroke, itself, is the third most common cause of death for women, affecting more women than men every year.[3]

Data show that metabolic changes, for example, abdominal obesity and blood pressure elevation, have distinct effects on women versus men.[4] Women living with metabolic syndrome, defined by the presence of risk factors including high blood pressure, lipid abnormalities, glucose intolerance, and visceral adiposity are at elevated risk for CVD compared with men.[4,5]

Even with advances in awareness about the CVD burden in women, only a little more than half of women in the United States recognize the risk, and progress to further reduce CVD has plateaued, especially in women younger than 55 years old.[1,5]

Relative to men, research shows that women may not be given counseling about lifestyle interventions or preventive care at the same rate, even with similar risk factors.[4] Health professionals may also not be aware of unique considerations that differentially impact a woman's ability to perform healthy lifestyle behaviors or the different impacts of lifestyle factors on CVD, diabetes, or obesity risk.

This chapter will discuss sex and gender differences that contribute to 1) distinct prevalence and impacts of traditional CVD risk factors (e.g., metabolic syndrome, HTN, dyslipidemia), 2) special considerations about lifestyle risk factors for women, and 3) the impact of risk factors unique to women (e.g., preeclampsia, gestational diabetes) on the development of diabetes, overweight/obesity, and ultimately, CVD. Health professionals must understand these differences in order to specifically tailor risk stratification, management, and lifestyle medicine counseling to improve chronic disease care for women.

58.2 CARDIOVASCULAR DISEASE, DIABETES, AND OVERWEIGHT/OBESITY IN WOMEN

Due to differences in reproductive stages, genetics, epigenetics, social determinants, and environmental exposures over their lifetimes, risk factors for acquiring diabetes, overweight/obesity, and CVD can vary in women compared with men.[5] Over time, these chronic conditions impact a woman's health across the lifespan, potentially causing secondary complications and impacting future generations.[5]

Sex differences are related to biological differences in the expression of particular genes and hormones. These can result in variations in the prevalence of traditional and sex-specific risk factors, different cardiovascular impacts, and distinct pathophysiology and presentation of CVD. Gender differences generally are the result of varied cultural, environmental, or psychosocial factors that may impact behaviors related to cardiovascular health.

An understanding of particular considerations across a woman's life allows health professionals to optimally

DOI: 10.1201/9781003227793-68

prescribe lifestyle medicine interventions that can prevent, manage, and sometimes lead to the remission or reversal of CVD, diabetes mellitus (DM), and overweight/obesity in women.

58.2.1 Cardiovascular Disease Pathophysiology in Women

CVD may be more difficult to diagnose in women because the underlying pathophysiology and presentation of acute coronary syndrome (ACS) may be different. Research from studies, including the Women's Ischemia Syndrome Evaluation (WISE), has found that IHD in women may be linked with abnormal coronary reactivity, distal plaque microembolization, and microvascular dysfunction, distinct from obstructive coronary artery disease (CAD) more common in men.[5,6] Differences in the burden of obstructive disease, which is more traditionally seen as synonymous with IHD, may play a role in lower rates of lifestyle counseling for prevention, barriers to effective treatment and management, and worse CVD outcomes and mortality rates for women compared with men.[5,6]

Below is a discussion of traditional, lifestyle, and sex-specific risk factors for CVD with an emphasis on the differences in prevalence, distinct impact on risks, and differing threshold values for diagnosis (where applicable) for women. A detailed discussion is also presented for diabetes and overweight/obesity.

58.3 TRADITIONAL RISK FACTORS

58.3.1 Metabolic Syndrome

The presence of metabolic syndrome can double the risk for CVD.[4,5] This is of particular concern because of gender disparities in the management and outcome of care.[7] The National Cholesterol Education Program's (NCEP) Adult Treatment Panel III (ATP III) defines the diagnosis of metabolic syndrome in women as the presence of three or more of the following findings:[8]

1. Waist circumference of more than 35 inches (88 cm).
2. Triglyceride level greater than or equal to 150 mg/dL.
3. HDL cholesterol less than 50 mg/dL.
4. Blood pressure of 130/85 mmHg or higher.
5. Blood glucose greater than or equal to 110 mg/dL after fasting for at least eight hours; revised ATP III criteria include plasma glucose greater than or equal to 100mg/dl.[9]

Though the age-adjusted prevalence of the metabolic syndrome is similar for both men and women, Mexican American and African American women have higher rates of metabolic syndrome (57% more African American women compared with African American men and 26% more Mexican American women compared with Mexican American men).[4,5,10]

The prevalence of some components of the metabolic syndrome and the effect on CVD risk is also distinct in women. Elevations in central obesity, triglycerides, and blood pressure may be responsible for much of the increased prevalence among women.[4,5,11] Examples of different impacts on women from components of the metabolic syndrome include:[4,5]

- Waist circumference: greater waist circumference increases the risk of metabolic syndrome to a higher degree compared with men.[4]
- Dyslipidemia: causes a higher risk of CAD compared with men; and higher triglyceride levels (particularly when combined with low HDL levels) have a greater impact on CAD risk in women.[4]
- Hypertension: higher risk of congestive heart failure (CHF) with HTN in women.[4]
- Hyperglycemia: elevated glucose levels after glucose load more common than elevated fasting blood glucose in women.[4]

58.3.2 Hypertension

Hypertension is a major cause of MI, stroke, and kidney failure. Women commonly develop hypertension ten years later than men because of the role of endogenous estrogen in maintaining blood pressure control through vasodilation before menopause.[6,12] However, data show that elderly women may have a higher prevalence of more poorly controlled HTN, with 23% of women over 80 with a BP <140/90 mm Hg compared with 38% of men over 80 years old.[13]

58.3.3 Dyslipidemia

Among all cardiovascular disease risk factors, lipid abnormalities pose the highest attributable risk for CVD in women.[5,6] It is important to note that dyslipidemia increases the risk for CVD in postmenopausal women, as this risk is not observed in premenopausal women with elevated cholesterol levels.[6] Notably, sex-specific guidance for primary prevention has been incorporated into the 2013 ACC/AHA Guidelines on the Treatment of Blood Cholesterol to Reduce Atherosclerotic Cardiovascular Risk in Adults and the American Heart Association (AHA)/American College of Cardiology (ACC) pooled cohort formula for CVD risk stratification includes sex in the calculation.[14]

The interpretation of a variety of biomarkers and imaging tests for CVD risk stratification in women continues to be studied. High-sensitivity CRP (hsCRP) levels are associated with CVD risk and aid with the predictive value of lipid levels[15] Research suggests that women have higher CRP levels than men (with Hispanic and African American women found to have the highest CRP levels).[16,17] According to one study, women with the largest baseline elevations of

CRP levels were found to have a five-fold increased risk for any vascular event and a seven-fold increased risk for stroke or MI over three years.[18]

Other tests including coronary artery calcium measurements and advanced lipid tests such as lipoprotein-associated phospholipase A2 (Lp-PLA2) are also being studied as potential tools for CVD risk stratification in women.[6]

58.3.4 Diabetes

Diabetes affected an estimated 34.2 million people in the United States (10.5%) of all ages, including 16.2 million (48%) women, according to the National Diabetes Statistics Report of 2020.[19]

The risk of developing type 2 diabetes (T2DM) in women is impacted by a multitude of factors including epigenetics, genetics, hormonal interplay, reproductive stage, body composition, fat metabolism, and a vast array of unique social, environmental, and lifestyle factors.[5,20]

From birth, children of mothers with gestational diabetes or T2DM carry an increased risk for CVD, T2DM, and obesity.[21,22] Female infants born to mothers with diabetes are at risk for metabolic syndrome, hyperglycemia, and increased body fat.[23] Birth weights designated as high or low are also connected to a future risk of T2DM and obesity.[24,25]

Over the lifespan, the hormonal interplay of estrogens and androgens plays an important role in energy metabolism, body composition, lipid homeostasis, and glucose levels.[26] Menopause, along with chronic hyperglycemia, may diminish the protective effects of estrogen, potentially playing a role in worsening a woman's metabolic profile as she ages.[27,28]

Diabetes in women may lead to worse CVD outcomes due to several underlying differences in pathophysiology. Studies show sex differences may factor into impairment of endothelium-dependent vasodilation, presence of hypercoagulable state, higher risk of atherosclerosis with dyslipidemia, and higher rates of co-occurring metabolic abnormalities and metabolic syndrome.[6,29–31] There is also growing evidence that women with prediabetes may also have higher rates of other metabolic abnormalities, suggesting higher CVD risk at lower glucose levels compared with men.[5,6,32,33]

Diabetes complications in women include 1) a higher risk of earlier MI and higher MI mortality, 2) lower revascularization rates, 3) a higher risk of developing congestive heart failure, 4) a higher risk of stroke, and 5) a higher risk of claudication with PAD compared with diabetic men.[5,6]

58.3.5 Obesity

Obesity is the result of excess accumulation and storage of body fat.[5,34] Over the past few decades, there has been a large increase in the percentage of overweight or obese individuals.[35] Data from 2017–2018 showed the incidence of obesity (body mass index [BMI] ≥30) was 42% among adults in the United States, with no significant differences between genders or different age groups. However, extreme obesity (BMI ≥40) was higher in women (11.5%) compared with men (6.9%).[36]

BMI is a well-established measure of overweight and obesity. Adults with a BMI ≥25 are at increased risk of developing CVD, insulin resistance and diabetes, and obstructive sleep apnea and are at higher risk for certain cancers.[34] Additionally, waist circumference, which can be used as a correlate for abdominal fat, is an independent risk factor for cardiometabolic risk, CVD events, and mortality.[34,37]

Overweight/obese women are also at an increased risk of many sex-specific cancers, including endometrial, cervical, breast, and ovarian cancer, with the risk of death from all cancers being 62% higher among women with a BMI greater than 40 versus normal weight.[5,38] Obese women also have a disproportionate increase in the risk of CAD, with data from the Framingham Heart Study showing that obesity increased the relative risk of CAD by 64% in women compared with 46% in men.[6,39]

Taken together, data show that the pathophysiology, health impacts, counseling considerations, and medical management of visceral fat accumulation and overweight/obesity in women are distinctive from men as a result of a combination of female sex-specific influences including reproductive stage and pregnancy.[5]

Obesity risk is influenced by hormonal regulation, developmental exposures, energy balance, genetic predisposition, and environmental exposure to toxic substances.[41] It is particularly important to address and manage overweight and obesity in women because exposure to maternal obesity increases the risk of obesity in the offspring.[5] Of note, epigenetic variations linked to obesity risk have been found to be sensitive to diet, exercise, and weight loss over the lifespan. [40–42]

58.4 LIFESTYLE-RELATED RISK FACTORS

58.4.1 Physical Inactivity

Clear evidence demonstrates the link between physical activity and lower risk for CVD, with greater benefits derived from greater levels of activity.[5,6] There is a moderate level of evidence that aerobic activity is beneficial for reductions in LDL cholesterol, non-HDL cholesterol, and BP.[43] Physical activity rates may be lower in women compared with men, according to survey data from the Centers for Disease Control (CDC), displaying that physical activity counseling in women can be improved.[42]

58.4.2 Diet

Data suggest that, compared with men, women consume more fruits, vegetables, and less meat.[44] However, women may also consume more sugar, with a higher glycemic index diet in general, increasing the risk of abdominal

obesity, particularly when combined with a sedentary lifestyle.[45]

58.4.3 Tobacco Use

Compared with men, data show that smoking in women is linked to a 25% increased risk of CAD.[46] Smoking, in combination with oral contraceptive use, increases the risk of stroke, MI, and venous thromboembolism.[6,47] Additionally, exposure to tobacco smoke increases the T2DM risk in both men and women.[48]

58.4.4 Exposure to Toxic Substances

Some studies demonstrate a potential link between moderate alcohol consumption and a lower risk of stroke, heart disease, and improved insulin sensitivity in non-diabetic women.[49,50] Alcohol counseling for women should explain that the reasons behind the possible benefit of moderate drinking on heart disease are not clearly known. Additionally, moderate drinking is linked to violence, injuries, and breast cancer, therefore women should not be advised to start drinking alcohol for possible health benefits.[5]

More and more data are elucidating the link between environmental toxic substance exposure with higher risk for CVD, T2DM, and obesity. Many studies have linked air pollution with a higher risk for MI and stroke.[5] Endocrine disruptors from the environment may mimic estrogen, leading to higher insulin resistance and hyperinsulinemia.[5,51] Given the advancement in available data, health professionals should consider counseling women about these environmental risks as part of a complete lifestyle medicine intervention.

58.4.5 Sleep

Because of the increased risk for sleep loss for reasons unique to women, a focus on addressing sleep disorders plays a role in CVD, DM, and obesity management. Sleep apnea raises the risk for hypertension, stroke, and MI.[79] Women with sleep apnea may present with different symptoms compared with men. In addition to snoring, the most common symptom in men, women may present with morning headaches, insomnia, or excessive daytime sleepiness as their prevailing symptoms.[52]

Insomnia alone has been linked with CVD morbidity and mortality, including CAD, HTN, and CHF.[53] Chronic sleep deprivation, defined as sleeping five hours or less, is associated with weight gain relative to people sleeping seven or more hours.[5] Weight gain may be due to sympathetic nervous system activation, dysregulation of the hypothalamic-pituitary axis, combined with higher levels of inflammation.[53] For peri- and postmenopausal women, sleep disturbance may be linked to nocturnal vasomotor symptoms, low-estrogen state, and mood changes associated with menopause.[54]

58.5 Stress Management/Social Connectedness/Positive Psychology

Robust evidence suggests an association between higher levels of psychological stress and worse CVD outcomes in women.[55] Stress from work, finances, and home and life events doubled the risk of acute MI in the INTERHEART study.[56] Women appear to be more negatively affected by psychological stress, sleep disturbances, and occupational stress.[5] Socioeconomic factors such as lower incomes, lower levels of educational attainment, food insecurity, and low childhood socioeconomic status also impact T2DM risk in women more than men.[5,9] Additionally, racial disparities exist with higher stress scores and lower ideal cardiovascular health metrics among African American women compared with Caucasian and Asian American women.[5]

Depression is also associated with the development of CAD and poorer outcomes after CAD events.[6] Young women have higher rates of depression than men, therefore addressing mental health concerns beginning at an early age may be beneficial in improving CVD development and outcomes in women.[5,6]

According to studies, the stress response may have distinct manifestations in women that may ultimately impact cardiovascular health. Women may be more sensitive to the hypothalamic-pituitary-adrenal (HPA) axis, one of the command centers to control cortisol, catecholamine, and inflammatory cytokine levels.[5] Evidence also suggests higher levels of ghrelin and neuropeptide Y may mediate stress-driven "emotional eating" and less ability to suppress hunger leading to stress-related weight gain. [5,57,58] Additionally, women with visceral adiposity may have higher cortisol levels when challenged with acute stressors, allowing chronic stress to cause sympathetic overactivity, abdominal obesity, and insulin resistance.[59]

Stress management must be an integral part of the care of women to reduce CVD risk. The American Heart Association has widened the focus on lifestyle by including measures of well-being in their 2030 Impact Goals.[5,60] This suggests an increasing understanding that factors such as "security, prosperity, sense of connection, and purpose" are linked to ideal cardiovascular health and longevity.[5, 60]

58.6 SEX-SPECIFIC RISK FACTORS

58.6.1 Pregnancy-Related Disorders

Hypertensive disorders in pregnancy, including gestational HTN, preeclampsia, and chronic HTN, may drive future CVD risk.[5,6] According to data from one meta-analysis, women with preeclampsia had a 3.7-fold relative risk (RR) of HTN 14 years post-pregnancy, a 2.16-fold RR of IHD 12 years post-pregnancy, and 1.81-fold RR of stroke ten years post-pregnancy compared with women with normotensive pregnancies.[5,6,61] Women with earlier onset preeclampsia had worse outcomes, and preeclampsia severity was also linked with long-term CVD severity.[5,6]

Preterm delivery (PTD) is also an independent risk factor for CVD, with higher risks for women who deliver before 34 weeks of gestation.[5,6]

Diabetes impacts approximately one in every six pregnancies: 13% with known T1DM or T2DM and 86% with GDM.[5,62] Diabetes during pregnancy raises the risk for CVD and T2DM in women. GDM increases the risk of future CVD, independent of risk from developing type 2 diabetes, with a two-fold increased risk for stroke and a four-fold increased risk for MI.[5,6,63]

Women with a healthier lifestyle (no tobacco, ≥ 150 min/wk of moderate to vigorous physical activity, healthy diet, BMI <25 before pregnancy) had a 52% lower risk of GDM compared with women who did not follow these components of a healthy lifestyle.[64]

58.6.2 Lactation and Weight Gain after Pregnancy

Breastfeeding is protective and can decrease the risk of the development of metabolic syndrome.[5] For women who breastfed longer than one month, the odds ratio for metabolic syndrome decreased by 22% compared with women who did not breastfeed or who breastfed for less than one month.[65] Lactation also plays a role in weight post-pregnancy weight loss.[66] According to some studies, women who do not lose pregnancy weight between 3 and 12 months postpartum, may begin to show metabolic abnormalities even within the first year after pregnancy.[6,67]

58.6.3 Menopause

After menopause, the CVD gap between men and women narrows. Before menopause, endogenous estrogen, in particular, is thought to be cardioprotective based on studies showing the favorable effects of the hormone on vascular endothelium and lipid levels.[5,6] Postmenopausal women who are obese (BMI ≥ 30) have four times higher risk of CVD death compared with those with a BMI of 29 or less.[5,68]

Aging is linked with greater increases in total fat and abdominal obesity in women compared with men, beginning in midlife independent of baseline weight.[5,69,70] This midlife weight gain may be the result of a combination of factors including postmenopausal estrogen deprivation, sleep disturbance, "stress eating", or decreases in physical activity levels.[71–75] Although menopause itself is not a significant cause of weight gain, fat distribution may shift to more abdominal adiposity.[69] Mood changes seen in close to 25% of peri- and postmenopausal women may also be linked to weight gain as a result of disruptions to healthy behaviors.[76]

58.7 CONCLUSION

CVD is the number one cause of mortality for women in the United States. Women have sex- and gender-specific differences that uniquely affect CVD, T2DM, and overweight/obesity risk presentation, diagnosis, and treatment. In order to achieve ideal cardiovascular health, a focus on lifestyle medicine should be utilized for all women to address prevention, management, and disease reversal and remission. Understanding unique considerations in the care of women across the lifespan is key to providing intensive therapeutic lifestyle change (ITLC) in the most effective manner as part of the standard of care.

CLINICAL APPLICATIONS

- CVD is the number one cause of mortality for women in the United States and a lifestyle medicine approach should be utilized for all women to address prevention, management, remission, and reversal.
- Women have sex- and gender-specific differences that uniquely affect CVD, DM, and obesity risk, presentation, diagnosis, and treatment.
- Traditional metabolic risk factors, such as waist circumference, and lipid levels have different threshold values while others, such as hypertension, may pose different hazards for cardiovascular disease in women compared to men.
- Lifestyle and factors unique to women may have distinct implications for lifestyle medicine interventions.

59 Using Digital Health Technology to Promote Cardiovascular Disease Risk Reduction in Secondary Prevention

Neil F. Gordon, MD, PhD, MPH, FACC, Richard D. Salmon, DDS, MBA, Mandy K. Salmon, MD, and Prabakar Ponnusamy, MS

KEY POINTS

- A broad spectrum of hybrid and alternative secondary prevention delivery models that incorporate novel digital health technologies have been proposed for rectifying barriers to low rates of utilization of traditional cardiac rehabilitation (CR) programs, and for the provision of ongoing, evidence-based, secondary prevention interventions.
- The COVID-19 pandemic has created a digital health technology inflection point by accelerating the widespread acceptance and adoption of virtual/remotely delivered interventions, and this momentum is likely to continue in the era of COVID-19 and beyond.
- Despite the flaws and limitations of existing research, the preponderance of evidence to date is highly supportive of the great potential of digital health technologies to facilitate lifestyle modification and cardiovascular disease (CVD) risk reduction.
- Digital health interventions appear to be most effective when integrated with evidence-based behavioral change strategies and direct interaction between participants and healthcare providers.
- Additional research and healthcare policy change are needed to move the promise of new digital health technologies for CVD risk reduction toward reality.

59.1 INTRODUCTION

Cardiovascular disease (CVD) remains the leading cause of death globally and is projected to account for over 23.6 million annual deaths by 2030.[1] Although sound clinical reasons exist for emphasizing secondary prevention in day-to-day medical practice, studies indicate that physicians often fail to provide recommended CVD risk reduction interventions and, even when provided, patients often fail to comply with the prescribed lifestyle and pharmacologic interventions.[2] Moreover, the COVID-19 and CVD pandemics have interacted to create a so-called "perfect storm" in which each pandemic is contributing to the worsening of the other.[3] Clearly, to achieve the American Heart Association's (AHA) 2030 Impact Goal of equitably increasing healthy life expectancy from 66 to at least 68 years of age across the United States and from 64 to at least 67 years of age worldwide by 2030, and to reduce premature CVD mortality, increased emphasis is needed on CVD risk reduction through evidence-based management of health behaviors and risk factors.[1]

Traditional center-based outpatient CR reduces morbidity, hospital readmissions, and mortality versus usual care.[2,4–8] Every recent secondary prevention guideline from the AHA and American College of Cardiology (ACC) provides a Class I level recommendation (i.e., there is evidence for and/or general agreement that the intervention is beneficial, useful, and effective; the intervention should be performed) for CR referral.[2,4–8] However, despite the proven benefits, the use of CR remains dismally low.[2,4–8] Multiple strategies have been proposed for rectifying barriers to participation in, and completion of, traditional center-based CR programs. These include a broad spectrum of hybrid and home-based alternative secondary prevention delivery models that incorporate novel technologies to facilitate CVD risk reduction.[2,4–11]

Modern-day cardiovascular medicine is a "high-tech" industry.[12] According to a 2017 report of the ACC Task Force on Health Policy Statements and Systems of Care,[13] key recent technological innovations of paramount importance for the future transformation of CVD care include the following: (1) digital health, with smartphone, wearable, sensor-based, and other electronic technologies; (2) big data, comprising the aggregation of large quantities of structured and unstructured health information and sophisticated analyses with artificial intelligence (including machine learning and natural language processing techniques); and (3) precision health, using approaches aimed at the identification of individual-level risks and determinants of wellness and pathogenicity. The intra- and inter-connections among emerging innovations and developments in digital health, big data, and precision health, as summarized by the ACC, are shown in Figure 59.1. In this chapter, we focus primarily on the use of digital health to promote CVD risk reduction.

A 2015 scientific statement from the AHA on the consumer use of mobile health for CVD prevention defines eHealth (also referred to as digital health) as the use of emerging communication and information technologies, especially the Internet, to improve health and healthcare and mHealth as a subsegment of eHealth that involves the use of mobile computing and communication technologies for health services and information (see the glossary of commonly used terms in Table 59.1).[14] While digital technologies have revolutionized broad sectors of our society and economy, ranging from entertainment to dating, travel, news, and finance, the healthcare industry generally has been slower to respond.[12,13] However, given the ubiquity of mobile devices and Internet access, digital health interventions that incorporate various technologies (such as telemedicine, videoconferencing, text messaging, mobile phone apps, and data from electronic medical records, blood pressure monitors, digital scales, blood glucose monitors, heart rate monitors, activity trackers, and other wearable/monitoring devices) are now rapidly emerging as an integral component of traditional CR programs and, especially, hybrid and home-based alternative CR/secondary prevention delivery models. Moreover, COVID-19-related lockdowns and other disruptions have created a digital health technology inflection point by accelerating the widespread acceptance and adoption of virtual/remotely delivered interventions.[3] This momentum is likely to continue for the foreseeable future in the era of COVID-19 and beyond.

59.2 EFFECTIVENESS AND THE ROLE OF HOME-BASED ALTERNATIVE CR AND SECONDARY PREVENTION DELIVERY MODELS

A 2017 Cochrane systematic review of data from 23 randomized controlled trials involving 2890 participants compared the effect of home-based and supervised center-based CR in adult patients who were post-myocardial infarction or had angina, heart failure, or underwent coronary revascularization.[15] For the review, home-based CR was defined as a structured program (including exercise training) with clear objectives for the participants, including monitoring, follow-up visits, letters or telephone calls from staff, or at least self-monitoring diaries. The review found no evidence of a significant difference between home- and center-based CR, either in the short-term (3 to 12 months) or longer-term (up to 24 months), for total mortality, cardiac events, exercise capacity, multiple modifiable CVD risk factors, or health-related quality of life.

Similarly, a 2019 scientific statement from the American Association of Cardiovascular and Pulmonary

TABLE 59.1
Glossary of Commonly Used Digital Health Terms

Term	Explanation
eHealth	eHealth, or digital health, is the use of emerging communication and information technologies, especially the use of the Internet, to improve health and healthcare.
mHealth	A subsegment of eHealth, mHealth is the use of mobile computing and communication technologies (e.g., mobile phones, wearable sensors) for health services and information.
Smartphone	A handheld personal computer with a mobile operating system and an integrated mobile broadband cellular network connection for voice, SMS, and Internet data communication; most if not all smartphones also support Wi-Fi.
SMS	A text messaging service component of mobile devices. It uses standardized communications protocols to allow mobile phone devices to exchange short text messages. The terms text messaging and texting are used interchangeably to refer to both the medium and messages, and the term text message refers to the individual message sent.
MMS	The next evolutionary step from SMS. MMS allows mobile phone users to exchange pictures with sound clips on their handsets or digital cameras.
App	App is short for application, which is the same thing as a software program. Although an app may refer to a program for any hardware platform, it is most often used to describe programs for mobile devices such as smartphones and tablets.
Wireless	Being wireless means not using wires to send and receive electronic signals (i.e., sending and receiving electronic signals by using radio waves).
Wi-Fi	A wireless networking technology that allows computers and other devices to communicate over a wireless signal.
Bluetooth	This wireless technology enables communication between Bluetooth-compatible devices. It is used for short-range connections between desktop and laptop computers, a mouse, digital cameras, scanners, cellular phones, earphones, headsets, and printers.
Operating system	An operating system, or OS, is software that communicates with the hardware and allows other programs to run. Common mobile OSs include Android, iOS, and Windows Phone.
iOS	A mobile OS developed by Apple. It was originally called the iPhone OS but was renamed to iOS in June 2009. The iOS currently runs on the iPhone, iPod Touch, and iPad.
Android OS	A Linux-based open-source platform for mobile cellular handsets developed by Google and the Open Handset Alliance. Android 1.0 was released in September 2008.
Bandwidth	In computer networks, bandwidth is used as a synonym for data transfer rate, the amount of data that can be transmitted from one point to another in a given time period (usually a second). Network bandwidth is usually expressed in bits per second (bps); modern networks typically have speeds measured in the millions of bits per second (megabits per second or Mbps) or billions of bits per second (gigabits per second or Gbps).

MMS indicates multimedia messaging service; OS, operating system; and SMS, short messaging service. (From Burke LE et al., *Circulation* 2015;32:1157–213. Adapted with permission.)

Rehabilitation (AACVPR), AHA, and ACC reported on the findings of a systematic review of 23 published studies of home-based compared with center-based CR.[16] Interestingly, from a safety and wearable technology perspective, only three of the 23 studies utilized heart rate monitors and only two others used electrocardiographic telemetry monitoring for home-based CR. Consistent with the findings of the abovementioned Cochrane systematic review, the AHA scientific statement concluded that home- and center-based CR programs can achieve similar improvements in three- to 12-month clinical outcomes, and that home-based CR may be a reasonable option for selected clinically stable low- to moderate-risk patients who are eligible for CR but cannot attend a traditional center-based program. The scientific statement further recommended that prioritization be given to the testing and implementation of evidence-based hybrid approaches to CR that combine the positive and complementary aspects of both center- and home-based CR to personalize and optimize services for each patient, and to promote long-term adherence and favorable behavioral change. Regarding the latter (i.e., hybrid approaches), the Million Hearts Cardiac Rehabilitation Think Tank: Accelerating New Care Models has subsequently proposed a new model for describing CR delivery that: (1) includes a variety of modes of CR service delivery, namely, in-person (i.e., synchronous CR where patients and clinicians are in the same location at the same time and with in-person/direct patient observation during an exercise session), virtual (i.e., synchronous CR delivered with real-time audiovisual communication technology to facilitate patient and clinician interaction during an exercise session), and remote (i.e., CR delivered with asynchronous activities without real-time communication between patients and clinicians at the time of an exercise session); and (2) provides the option for an individual program to offer ≥1 mode of delivery and an individual patient to participate through ≥1 mode of delivery.[8]

Wongvibulsin et al. conducted a systematic literature review of 31 studies published from January 1990 to October 2018 that deployed digital health interventions for CR.[17] For this review, the authors defined digital as the technology employed to deliver virtual/remote care beyond

the use of the telephone (e.g., the delivery of care using the Internet, wearable devices, and mobile apps). The reviewed interventions primarily targeted physical activity counseling (100% of studies), baseline assessment (97% of studies), and exercise training (87% of studies). Approximately one-third of the studies addressed the CR core components of nutrition counseling, psychological management, and weight management, and less than a third of the studies addressed other CR core components, such as smoking cessation and lipid, diabetes, and blood pressure management. The most commonly used modalities were smartphones or mobile devices (65% of studies), web-based portals (58% of studies), and email/text messaging (35% of studies). The authors concluded that digital CR was feasible and as effective as traditional CR in improving outcomes, whether as an adjunct or an alternative to traditional CR.

In 2022, Nkonde-Price et al. reported on a retrospective cohort study of 2556 demographically diverse patients, including those who were medically complex, from a large integrated healthcare system who participated in a center-based (n = 1315) or technology-enabled home-based (n = 1241) CR program.[18] After adjusting for demographic and clinical characteristics, patients who received home-based CR had a lower odds of all-cause hospitalization at 12 months of follow-up (OR, 0.79; 95% CI, 0.64–0.97) compared with patients who received center-based CR. The authors concluded that their study strengthens the evidence supporting home-based CR, including in previously understudied patient populations.

In a multi-center study involving 12,984 patients who completed a traditional center-based CR program, very few patients had all CVD risk factors at levels currently recommended for ideal cardiovascular health at program completion.[19] These data emphasize the need for ongoing surveillance and intensive intervention aimed at residual CVD risk reduction in most patients who complete traditional center-based CR programs. In addition to their use as an alternative to center-based programs, home-based programs that incorporate novel digital health technologies can be leveraged to provide ongoing secondary prevention intervention after completion of center-based CR.

59.3 EFFECTIVENESS OF DIGITAL HEALTH TECHNOLOGIES FOR LIFESTYLE INTERVENTION AND CVD SECONDARY PREVENTION

The global smartphone penetration rate is estimated to have reached over 78% in 2020 and, according to a Deloitte survey, in the United States, the smartphone market penetration rose from 82% in 2017 to 85% in 2018.[20] The survey further indicated that the growth in smartphone penetration was strongest among older age groups (particularly those aged 45–54 and ≥55 years). From the perspective of addressing existing disparities in the provision of CR and CVD secondary prevention services, it is especially important to note that according to 2021 statistics from the Pew Research Center, 76% of individuals with an annual household income below $30,000 owned a smartphone.[21] Moreover, smartphone ownership was similar among Whites (85%), Blacks (83%), and Hispanics (85%). Thus, unlike the initial digital divide that placed Internet access and computer use beyond the reach of many disadvantaged populations, smartphones have been widely adopted across demographic groups, including ethnic minorities and older, lower socioeconomic status, and/or other currently underserved populations who may be most in need of secondary prevention interventions.[14]

The 2015 AHA scientific statement on consumer use of mobile health reviewed the scientific literature on mHealth tools related to CVD prevention.[14] Key findings pertaining to the use of mHealth to improve weight management, physical activity participation, smoking cessation, self-management of diabetes, hypertension care, and management of dyslipidemia were evaluated together with gaps in knowledge, and suggestions were made for future research. Several common themes and concerns were noted, including: (1) study design concerns such as the use of pre-post designs without concurrent control groups or randomized comparison groups, reliance on self-reported data, failure to use intention-to-treat analyses, evaluation in motivated participants and selected settings, and short duration of the studies; (2) evaluation of a single digital health technology compared with usual care rather than head-to-head studies comparing various digital health technologies with each other; (3) unanswered questions about product safety; (4) inability to demonstrate which components in an intervention are pivotal to success or whether the impact of a specific digital health product varies depending on the mode of use or delivery; and (5) absence of meaningful data on how best to incorporate the digital health technologies into a broader collaborative model of healthcare. Even with the abovementioned flaws, limitations, and unanswered questions, the authors concluded that their review of the evidence clearly demonstrates the great potential that mobile technologies can have to aid in lifestyle modification and that the current absence of sufficient evidence should not be interpreted as evidence of an absence of effectiveness. The authors encouraged healthcare professionals to rise to the challenge of producing the needed evidence on the effectiveness of digital health technologies and how best to adopt them in daily clinical practice.[14]

In a 2016 publication, Afshin et al. systematically reviewed the scientific evidence on the effectiveness of novel information and communication technologies to reduce non-communicable disease risk.[22] The authors searched PubMed for studies evaluating the effect of the Internet, mobile phones, personal sensors, or stand-alone computer software on diet, physical activity, adiposity, tobacco, or alcohol use among generally healthy adults. From 8654 abstracts, 224 relevant reports were identified. The authors concluded that Internet and mobile interventions improve important lifestyle behaviors for up to one year and that

their review supports the need for long-term interventions to evaluate sustainability. Interestingly, the authors also observed that: (1) using evidence-based behavioral change strategies could increase the effectiveness of Internet and mobile phone interventions (for example, in studies of diet/adiposity, interventions were more effective if adopting multiple modes of communication, using tailored messages, and integrating goal setting and self-monitoring; and in studies of physical activity, developing the Internet intervention content based on psychological theories of behavioral change increased both effectiveness and participant retention); and (2) interaction with healthcare providers could increase the success rate of the interventions.

In a 2017 publication, Khan et al. reviewed studies addressing digital health technologies to promote lifestyle change and medication adherence, including text messaging, smartphone apps, and wearable devices.[23] They concluded that: (1) the current literature indicates that digital health technologies will likely play a prominent role in future CVD management, risk reduction, and delivery of healthcare in both resource-rich and resource-limited settings; (2) additional clinical research and healthcare policy change are needed to move the promise of new digital health technologies toward reality; and (3) with many new digital health interventions bypassing clearance from the Food and Drug Administration, academic medical centers and professional medical organizations should provide broader guidance to consumers/patients. The authors also expressed concern that, because the development of digital health technologies is often driven by non-clinicians, unique challenges exist related to integration into daily clinical workflows. Moreover, because clinicians are increasingly burdened by the time-consuming use of electronic medical records and data overload, there may be limited capacity for them to take on additional responsibilities by processing and reacting to digital health-related data.

Through a comprehensive search of databases from 2002 to 2016, Park et al. conducted a quantitative systematic review of mobile phone interventions for the secondary prevention of CVD.[24] A large majority of studies (22 of 28, or 79%) demonstrated that text messaging, mobile apps, and telemonitoring via mobile phones were effective in improving outcomes. Key factors associated with successful interventions included personalized messages with tailored advice, greater engagement (e.g., two-way text messaging and higher frequency of messages), and the use of multiple digital health modalities. Overall, text messaging appeared more effective than smartphone-based interventions. Based on their observations and experiences, the authors speculated that future mHealth interventions will likely use a combination of different technologies (e.g., basic cellular phones, smartphones, computers, and tablets) and that with the widespread proliferation of smartphones, mHealth apps will likely expand on their connectivity with social media to maximize consumer engagement. However, in doing so, concerns of privacy and security issues will need to be adequately addressed.

A 2019 AHA scientific statement on harnessing mobile health technology for secondary CVD prevention in older adults, reported on the findings from a systematic review of 26 studies that used mHealth for secondary CVD prevention focusing on lifestyle behavior change and medication adherence in cohorts with a mean age ≥60 years.[25] Improvements in multiple health behaviors and medication adherence were observed, particularly when there was a text message component involved. In studies with app-only interventions, the majority of patients reported ease of use (>60%), patients found the app helpful, and self-reported use of the app was high. However, many of the apps tested were intended for very specific purposes. Although mobile technologies are becoming more mainstream and starting to blend more seamlessly with standard healthcare, the scientific statement concluded that there are still distinct barriers that limit implementation, including affordability, usability, privacy, and security issues. The scientific statement further emphasized that: (1) future studies on the type of mHealth that is the most effective are essential; and (2) as our population ages, identifying and implementing widely accepted, cost-effective, and time-efficient mHealth interventions to improve cardiovascular health should be a top priority.

59.4 HEALTHCARE TRANSFORMATION IN THE ERA OF DIGITAL HEALTH

Newly developed and rapidly evolving technological innovations have the potential to play a pivotal role in the shift from volume- to value-based healthcare. However, as emphasized in the 2017 report of the ACC Task Force on Health Policy Statements and Systems of Care[13] technological transformation often occurs too rapidly for existing healthcare practice to keep pace, thus creating a mismatch between the rate of development of novel technologies and preparedness of the healthcare system for effective integration and utilization of novel technologies. Thus, despite billions of dollars of investment in digital health technologies, there are numerous reasons why the digital transformation of healthcare still lags the rate of transformation that has occurred in other industries.[12,13]

Simultaneous with the publication of the 2017 ACC Task Force report, Walsh and Rumsfeld[12] proposed the following concerns among key reasons for healthcare lagging other industries in the adoption of potentially transformative new technologies: (1) healthcare is not entertainment; the healthcare system is extremely complex and simply not set up to rapidly absorb innovation; (2) the stakes in healthcare are very high, often involving life-or-death decisions and, thus, rightfully requiring convincing evidence for technology solutions before widespread clinical adoption; (3) many technology companies lack the necessary clinical insights; (4) while electronic medical records were a first step in the digital transformation of healthcare, dissatisfaction and criticism abound, with many physicians considering the introduction of electronic medical records a significant

misstep; (5) digital health companies have often been fearful of entering the healthcare regulatory process, and many have chosen not to aim innovation at the clinician-patient interface, instead solely developing consumer products; and (6) for the most part, there are non-aligned incentives or payment models in place to support digital health transformation of care delivery.

When deploying digital health technologies as a component of alternative CVD secondary prevention models, the following key policy recommendations from the AHA should be considered: (1) CR and secondary prevention programs should be reengineered to include an array of service options that meet the needs of individual patients and provide more flexible programs within and beyond the traditional clinical center to enhance access, adherence, and effectiveness; (2) such alternative approaches should not replace traditional programs, but should be used to engage the many patients who currently do not participate, and to provide ongoing monitoring and treatment after completion of traditional center-based CR programs; (3) alternative approaches should meet reputable quality standards, and existing standards may need to be customized for each model accordingly; (4) any new approach should not be widely implemented until it has been shown to be effective as evidenced by results of clinical studies published in peer-reviewed journals; and (5) third-party payers should cover the costs of evidence-based alternative models of delivery, such as hybrid programs and technology-enabled home-based models, that have been shown to be effective in peer-reviewed published clinical trials.[4,16] Regarding the latter, as a result of the COVID-19 pandemic, the Centers for Medicare and Medicaid Services (CMS) in the United States provided waivers to expand CR reimbursement to include virtual, synchronous (but not remote, asynchronous) service delivery. While the future of reimbursement for virtual CR is unknown at this time (September 2022), there is great enthusiasm to make the CMS waivers permanent.[8] It should also be noted that, in certain instances, there is currently the ability to leverage other newly reimbursable options for the provision of virtual/remote CVD secondary prevention services (e.g., chronic care management, principal care management, and remote patient monitoring) in the United States.

59.5 CASE STUDY OF AN EVIDENCE-BASED, DIGITAL HEALTH TECHNOLOGY-ENABLED, CVD RISK REDUCTION PROGRAM

We have spent over 25 years developing, testing, and implementing an evidence-based lifestyle management and CVD risk reduction telehealth coaching intervention that utilizes a variety of digital health technologies and has been shown to be effective in individuals with or at heightened risk for CVD.[26] The primary objectives of the digital technology-enabled telehealth coaching program are to help participants: (1) make and adhere to meaningful, evidence-based lifestyle changes (especially, regular exercise/physical activity, healthy nutrition, weight management, stress management, and tobacco cessation); (2) learn about CVD, CVD risk factors, and comorbidities, and acquire appropriate self-management skills (including use of relevant wearables/monitoring devices for remote patient monitoring, understanding untoward symptoms/signs, knowing when to contact their physicians/providers, and avoiding re-hospitalization); (3) address gaps in preventive care (e.g., complying with recommended preventive screenings/tests/vaccinations); and (4) comply with prescribed medications and other aspects of their regular medical care. To accomplish these objectives and help ensure the attainment of clinically meaningful/reproducible outcomes, telehealth coaching is delivered using a formal, structured, systematic approach together with rigorous continuous quality improvement protocols. The core components of the program and the key steps involved in their delivery are summarized in Figure 59.2.

There is no one single innovation that makes the telehealth coaching intervention novel; rather, it is due to the synergistic manner in which multiple novel approaches and digital health technologies have been incorporated into a single program to facilitate the provision of comprehensive CVD risk reduction services and the achievement of reproducible outcomes. A few of the many innovative aspects of the telehealth coaching intervention include the use of:

(1) A home-based program that was originally based on the protocols/procedures deployed in the Stanford Coronary Risk Intervention Project,[27] subsequently enhanced over more than 25 years and addresses not only prescribed physical activity/exercise training but also the other important core components of comprehensive CR/secondary prevention as part of a single integrated intervention. These other core components include modification of multiple CVD risk factors via education and behaviorally oriented health coaching, stress/mental health interventions, symptom management, and compliance with prescribed evidence-based CVD risk reduction medications, recommended preventive tests/vaccinations, and other aspects of regular medical care. The program is in daily use throughout the United States and Canada in a variety of real-world settings, including in English, Spanish, and French.

(2) Multiple novel digital health technologies, including telemedicine, videoconferencing, text messaging, online smartphone apps, game-based learning, and integration of data from electronic medical records, laboratories, blood pressure monitors, digital scales, blood glucose monitors, heart rate monitors, activity trackers, and other wearable devices/sensors. While the telehealth

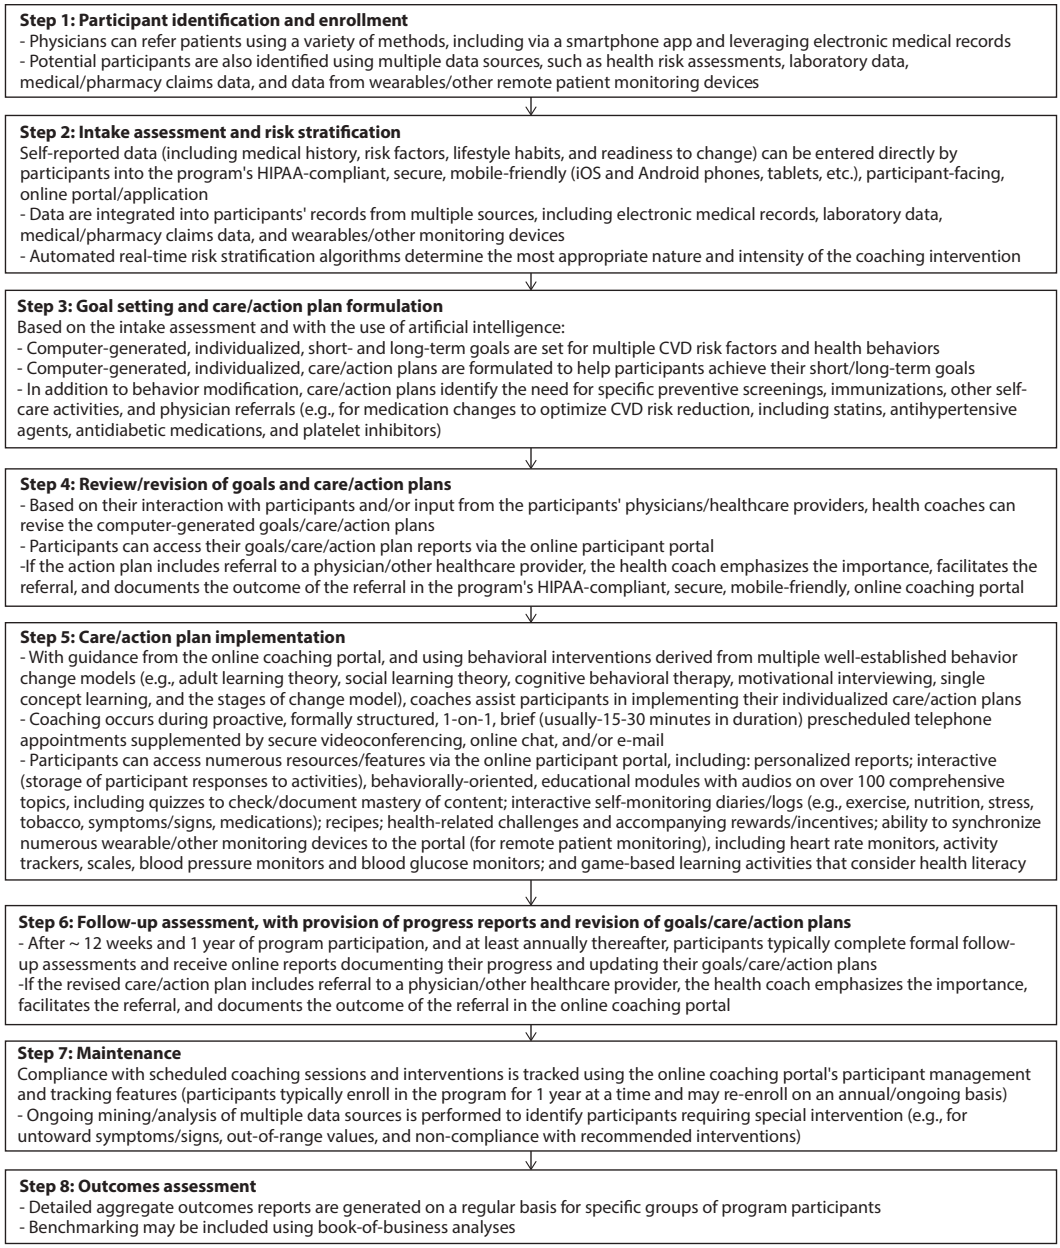

FIGURE 59.2 Summary of core components and key steps involved in an evidence-based, technology-enabled, lifestyle management and cardiovascular disease risk reduction program. Abbreviations: CVD, cardiovascular disease; HIPAA, Health Insurance Portability and Accountability Act of 1996

coaching program incorporates multiple digital technologies, individuals who are unable to use such technologies are still able to participate and achieve meaningful clinical benefits, making the intervention suitable for use with a broad spectrum of underserved populations. In fact, the minimum needed for participation is telephone access. All core participant educational materials are available in hard copy format, interactive online format (including health coaches having access to online activities completed by participants), and audio formats (for verbal learners and individuals who, for example, are illiterate or visually impaired). No special resources (e.g., exercise equipment or fitness center membership) are required but participants can elect to use and synchronize a variety of wearable/monitoring devices to the program's online portal.

(3) A sophisticated online coaching portal that provides professional health coaches access to the resources, data, and automated guidance they need to provide evidence-based, behaviorally oriented, coaching aimed at helping participants acquire the skills, motivation, and support needed

TABLE 59.2
Case Study of an Evidence-Based, Digital Health Technology-Enabled, CVD Risk Reduction Program: Key Published Randomized Clinical Trials

Reference, Objectives; Study Design/Duration	Results, Conclusions, and Implications
Gordon et al.[35] This randomized clinical trial compared the clinical effectiveness of two, less-costly and potentially more accessible, approaches to CVD risk reduction with that of a contemporary phase 2 center-based CR program. Low- or moderate-risk coronary artery disease patients (n = 155) were randomly assigned to 12 weeks of participation in a contemporary phase 2 CR program (n = 52), a physician-supervised, nurse-case-managed CVD risk reduction program (n = 54), or a comprehensive health coaching program administered by exercise physiologists guided by a computerized participant management system based on reputable national clinical guidelines (n = 49); 142 patients (91.6%) completed testing at baseline and after 12 weeks of intervention.	For patients with abnormal baseline values, statistically significant ($p \leq 0.05$) improvements were observed with all three interventions for multiple CVD risk factors. With the exception of maximal oxygen uptake, no statistically significant risk factor differences were observed among the three programs. For patients with a baseline maximal oxygen uptake <7 METs, maximal oxygen uptake increased to a greater degree in patients in the contemporary phase 2 CR program and the health coaching program versus the physician-supervised, nurse-case-managed program. These data demonstrate that an evidence-based, technology-enabled health coaching program can be at least as effective as other more costly and potentially less accessible interventions (including traditional center-based CR) in low- and moderate-risk coronary artery disease patients. The data have important potential implications for cost-containment and for increasing accessibility to clinically effective comprehensive CVD risk reduction services.
Maron et al.[36] This randomized clinical trial evaluated how the intensity of intervention after the provision of a health risk assessment affects CVD risk; 133 employees with CVD risk factors were randomly assigned for one year to a health risk assessment plus comprehensive health coaching group (higher-intensity intervention; HC group) or a health risk assessment plus information about worksite health promotion programs group (lower-intensity intervention; HRA group). The HC group participated in a one-year technology-enabled, health coaching program, whereas the HRA group received one feedback session about their CVD risk factors and information about free worksite health promotion programs. The primary outcome measure was the change in Framingham ten-year coronary heart disease risk scores.	In the HC group, the mean Framingham ten-year coronary heart disease risk score decreased by 22.6% (relative risk reduction); in the HRA group, the mean score rose by 4.3% ($p = 0.017$ for the difference between groups). The data demonstrate that a health risk assessment followed by participation in an evidence-based, technology-enabled, health coaching program can be more effective than a health risk assessment followed by one feedback session and the provision of information about free worksite health promotion programs. The data also serve to highlight that not just any kind of lifestyle management program done in any way at all will produce high levels of clinical benefit. It is evident from this study that lifestyle management programs must be appropriately designed and executed effectively to significantly impact multiple clinical variables and facilitate CVD risk reduction.
Derdeyn et al.[30]; Turan et al.[31]; Turan et al.[32]; and Turan et al.[33] This study, conducted at 50 medical centers in the United States, randomly assigned 451 patients with recent transient ischemic attack or stroke related to 70–99% stenosis of a major intracranial artery to aggressive medical management (including anti-platelet therapy, intensive management of vascular risk factors, and participation in an evidence-based, technology-enabled, telehealth coaching program) or aggressive medical management plus intracranial stenting with the Wingspan stent. The primary endpoint was any of the following: stroke or death within 30 days after enrollment, ischemic stroke in the territory of the qualifying artery beyond 30 days of enrollment, or stroke or death within 30 days after a revascularization procedure of the qualifying lesion during follow-up. Patients were followed for a median of 32.4 months.	In the medical management-only group, 15% of patients had a primary endpoint event, while 23% of patients in the stenting group had a primary endpoint event. The primary endpoint rate in the medical management-only group (14.1% at two years) was much lower than was projected based on the results of the WASID trial (24.7% at two years), an observation that was attributed to differences in medical treatment in these trials, including use of telehealth coaching in SAMMPRIS but not WASID. Throughout the duration of the study, there were continued improvements in CVD risk factor control. Multivariate analyses demonstrated that of the various CVD risk factors, physical inactivity was by far the most important predictor of poor outcomes—greater physical activity decreased the likelihood of a recurrent stroke, myocardial infarction, or vascular death by 40% (odds ratio 0.6, confidence interval 0.4–0.8). The investigators attributed increases in physical activity to compliance with the telehealth coaching program, which also contributed to the high percentage of patients achieving other risk factor targets. The study highlights the potential benefits of physical activity for the prevention of recurrent stroke and the role that evidence-based, digital technology-enabled, telehealth coaching can play in helping patients achieve CVD risk factor goals. The study also helps allay concerns regarding the long-term sustainability of CVD risk factor control.

CR, cardiac rehabilitation; CVD, cardiovascular disease; SAMMPRIS, Stenting and Aggressive Medical Management for Prevention of Recurrent Stroke in Intracranial Stenosis; WASID, Warfarin Aspirin Symptomatic Intracranial Disease (adapted, in part, from Gordon NF et al., *Am J Lifestyle Med* 2017;11:153–166).

to implement and adhere to their individualized care/action plans.

(4) Multiple features to facilitate provider engagement and interaction with participants to improve adherence to evidence-based secondary prevention interventions. For example, using artificial intelligence, evidence-based, individualized goals and care/action plan reports and progress reports are automatically generated for program participants. Healthcare providers are able to access these reports, recommend changes, and, in certain instances, provide electronic input to their patients' health coaches. Where indicated on the basis of reputable clinical guidelines, including optimizing CVD risk reduction medication management, coaches facilitate the referral of participants to their healthcare providers.

(5) Big data mining to provide business intelligence to enhance participant engagement and optimize the nature and intensity of CVD risk reduction interventions. Data sources include health risk assessments, electronic medical records, laboratory data, medical/pharmacy claims data, and data from wearables/other monitoring devices.

The program's effectiveness has been evaluated as part of numerous formal research initiatives. The telehealth coaching program was successfully deployed as part of the aggressive medical management component of the National Institutes of Health (NIH)-funded Stenting and Aggressive Medical Management for Preventing Recurrent Stroke in Intracranial Stenosis (SAMMPRIS) multi-center clinical trial,[28–33] and is currently being used as part of the aggressive medical management components of the multi-center NIH-funded Carotid Revascularization and Medical Management for Asymptomatic Carotid Stenosis Study (CREST-2)[34] and Comparison of Anti-coagulation and Anti-Platelet Therapies for Intracranial Vascular Atherostenosis (CAPTIVA) clinical trials. The telehealth coaching program is also being used by participants in the Canadian Diabetes Prevention Program (CDPP) clinical trial (funded, in part, by the Public Health Agency of Canada) and the Telehealth-Enhanced Assessment and Management after Stroke-Blood Pressure (TEAMS-BP) multi-center clinical trial (funded by the Patient Centered Outcomes Research Institute). Results of several of the key published randomized clinical trials are summarized in Table 59.2.[28–33,35,36]

CLINICAL IMPLICATIONS

1. Newly developed and rapidly evolving technological innovations, including digital health, have the potential to play a pivotal role in the shift from volume- to value-based healthcare.
2. Hybrid and home-based digital health technology-enabled lifestyle management and CVD risk reduction programs are a viable alternative to traditional center-based CR programs.
3. Such alternative approaches should not be used to replace center-based CR but rather to engage the many patients who currently do not participate and provide ongoing, evidence-based, CVD secondary prevention interventions post-CR.
4. Healthcare professionals should rise to the challenge of producing the needed evidence on the long-term effectiveness of digital technologies and determine how best to adopt them in daily practice to help optimize patient health.

DISCLOSURES

Neil Gordon, Richard Salmon, and Prabakar Ponnusamy are members and/or employees of a population health management company (INTERVENT International, LLC).

60 Psychosocial Risk Factors as Modulators of Cardiovascular Outcomes in Secondary Prevention

Joel W. Hughes, PhD and David Ede, PhD

KEY POINTS

- Many patients with heart disease experience psychosocial comorbidities, such as depression, anxiety, social isolation, and anger/hostility.
- These moderate risk in secondary prevention, and, for example, patients with depression have a greater risk of a poor outcome.
- Treatments for psychosocial comorbidities have generally not been shown to reduce the associated risk.
- Outpatient cardiac rehabilitation improves psychosocial comorbidities, improves quality of life, reduces risk factors, and reduces risk of mortality.

60.1 SECONDARY PREVENTION AND PSYCHOSOCIAL FACTORS

Cardiovascular disease (CVD) causes nearly one out of every three deaths in the United States, and every year, over 1.1 million Americans have a first or recurrent coronary event.[1,2] Advances in cardiology have resulted in many more patients surviving their first encounter with heart disease, leading to an increase in the population of patients requiring secondary prevention, as well as a growing number of patients living with heart failure (HF).

Secondary prevention is attempting to reduce the risk of acute cardiac syndrome (ACS) and cardiac mortality in people with established CVD. The cornerstone of secondary prevention is risk reduction in multiple areas including smoking, BP control, lipid management, physical activity, weight management, type 2 diabetes management, antiplatelet and anticoagulant agents, renin-angiotensin-aldosterone system blockers (e.g., ACE inhibitors), beta-blockers, influenza vaccination, depression screening, and cardiac rehabilitation.[3] In 2011, the most recent American Heart Association/American College of Cardiology (AHA/ACC) guidelines for secondary prevention listed cardiac rehabilitation as a class 1-A recommendation.[3] Furthermore, screening patients who are potentially at risk for depression is now recommended. These are changes from the earlier 2006 guidelines.[4] The role of psychosocial factors, like depression, in moderating risk in secondary prevention is increasingly recognized, and the importance of cardiac rehabilitation as part of secondary prevention is now well established.

Some see cardiac rehabilitation as synonymous with secondary prevention for heart disease, but it is only one of 12 areas for intervention.[3] True, cardiac rehabilitation is a comprehensive approach to secondary prevention that addresses or monitors many of the other 11 areas, and it is particularly effective when delivered in a manner that includes all the core components. Psychosocial management is a core component of outpatient Phase II cardiac rehabilitation programs in the United States (here we write from the perspective of the United States of America with respect to definitions, statutes, official statements, and business models; we recognize that the implementation and models of CR differ by country and that an international perspective on psychosocial management is important, but beyond the scope of this review)[5] and has been identified as one of the components contributing to the effectiveness of cardiac rehabilitation.[6]

60.2 PSYCHOSOCIAL FACTORS IN HEART DISEASE

Psychosocial factors have long been recognized as moderators of outcomes in secondary prevention, meaning that patients with known heart disease who have certain psychosocial characteristics may have better or worse outcomes. For example, the Type-A behavior pattern was first recognized in the 1950s,[7] prompting decades of research into coronary-prone personality types and the role of anger and hostility in primary and secondary prevention. Currently, the most prominent example of a moderating role of psychosocial factors is that patients with comorbid heart disease and depression have worse outcomes than those without depression.[8–13] In the early 2000s, excellent reviews of the broader topic of psychosocial factors in heart disease were published. For example, Smith et al.[8] described how psychosocial influences could influence the pathophysiology of coronary heart disease and identified a number of psychosocial risk factors. Those relevant to secondary prevention included hostility, depression, anxiety, social isolation, interpersonal conflict, and occupational stress.

DOI: 10.1201/9781003227793-71

Psychological interventions attempting to mitigate these risks were conducted, such as the landmark Enhancing Recovery in Coronary Heart Disease (ENRICHD)[14] and Sertraline and Depression Heart Attack Randomized Trial (SADHART)[15] trials for post-MI patients with depression (or social isolation in the case of ENRICHD). The mixed results of these trials were widely discussed, and this only underscored the need for physicians to be aware of the role of psychosocial factors in secondary prevention.[13] The call to screen for and intervene with psychosocial risk factors increased. What some called the field of "behavioral cardiology"[12, 13] emerged to examine the application of behavioral, pharmacological, and rehabilitative interventions on cardiac outcomes.

In this chapter, we focus on the more recent literature and important developments. In secondary prevention, psychosocial factors such as depression[12, 16] and anger/hostility[17] are associated with poorer prognosis. Furthermore, the contribution of behavioral and psychosocial factors to risk is commensurate with that conferred by more traditional risk factors (e.g., cholesterol). Depression is the only psychosocial risk factor included in the AHA/ACC position statement,[3] and no clinical consensus has emerged for how cardiology practitioners should approach behavioral and psychosocial factors in the clinical management of coronary heart disease. However, some have recommended a "stepped care" approach in which physicians are the front-line clinicians, followed by behavioral health interventions (e.g., cardiac rehabilitation) and behavioral health specialists (e.g., psychologists) in the second and third tiers, respectively.[12]

Fortunately, cardiac rehabilitation or structured exercise programs reduce anger/hostility, anxiety, depression, and stress.[9] In our view, cardiac rehabilitation is a particularly appropriate context for addressing psychosocial factors in secondary prevention. Heart disease and psychosocial factors are profoundly affected by lifestyle, and cardiac rehabilitation is a lifestyle intervention that can address both synergistically. In our view, some targets for intervention are more amenable to addressing during physician visits than others (e.g., blood pressure control, lipid management, antiplatelet agents/anticoagulants, renin-angiotensin-aldosterone system blockers, beta-blockers, influenza vaccination), and some are more effectively targeted by the increased intervention frequency and intensity of comprehensive cardiac rehabilitation (e.g., smoking, physical activity, weight management, type 2 diabetes mellitus management, depression). Furthermore, few alternatives to cardiac rehabilitation exist besides treatment-as-usual.

60.3 WHAT ARE THE PSYCHOSOCIAL FACTORS THAT MODERATE OUTCOMES IN SECONDARY PREVENTION?

60.3.1 Anger/Hostility

Anger and hostility remain important psychosocial factors for prognosis in primary and secondary prevention of cardiovascular disease.[8,12,13] In one meta-analysis, the association between anger/hostility and outcomes was stronger for men than for women.[17] However, psychosocial interventions for hostility have been rare, and it has been suggested that the widespread adoption of pharmacological interventions acting on the putative biological mechanism (i.e., beta-blockers) has resulted in a less prominent role for hostility in secondary prevention in recent decades. For example, a more recent study reported that hostility predicted all-cause mortality, but not recurrence of acute coronary syndromes (e.g., emergency department visits that resulted in hospitalization).[18]

60.3.2 Anxiety

Anxiety also worsens prognosis in secondary prevention of cardiovascular disease.[9,19] For example, anxiety predicts mortality in stable heart disease, and the risk may be shared with depression or potentiate the risk associated with depression.[20]

60.3.3 Social Support

A classic study reported that patients who were socially isolated or who lacked a close confidant were at greater risk for mortality after a myocardial infarction (MI) than those with better social support.[21] A systematic review reported that loneliness and social isolation predict incident cardiac disease and stroke,[22] and it is generally recognized that adequate social support is necessary for recovery from acute coronary events. For example, heart transplant candidates are typically required to identify a support person during the eligibility evaluation before transplantation. Medicare guidelines for cardiac rehabilitation also require an evaluation of social support (i.e., "aspects of family/home situation") that affects treatment, although screening procedures were not specified. However, the treatment of loneliness is not merely structural, as shown in a broader population meta-analysis, which demonstrated that interventions targeting social cognition were more effective than those that merely increased opportunities for interaction.[23]

60.3.4 Depression

The fact that depression worsens prognosis in secondary prevention is now well established,[9] and screening for depression has been incorporated into the most recent AHA/ACC statements.[11] The relationship between depression and heart disease is complex, as depression is also a risk factor for the development of cardiovascular disease and cardiovascular mortality.[24,25] In primary prevention, depression has been associated with approximately a 65% increase in the risk of developing cardiovascular disease among persons initially free from heart disease.[26] In secondary prevention, depression contributes to a two- to fivefold increased risk of mortality.[10,11]

Depression is also very common in cardiac patients, with perhaps 15% to 20% of patients qualifying for a

diagnosis of major depressive disorder and an additional 15% to 20% exhibiting clinically significant symptoms of depression without meeting diagnostic criteria. Depression can be exacerbated by the stress of ACS but can also predate the cardiac event or emerge later. For example, half of the patients enrolled in SADHART were depressed prior to their ACS.[15] Therefore, depression has become an important consideration in secondary prevention for patients with cardiovascular disease, but efforts to reduce the risk of mortality by alleviating depression have not been very successful.

60.4 ADDRESSING DEPRESSION IN SECONDARY PREVENTION

60.4.1 Screening for Depression

Although screening for depression in secondary prevention is recommended[11,27,28] and has become common, there has not been an evaluation of the impact of depression screening on patient outcomes in cardiovascular care.[29] Methods for screening for depression (and anxiety) are not consistent, and recommendations in international guidelines vary.[30] Thus, one research priority is evaluating whether or not screening patients for depression improves patient care or outcomes for patients with CVD. [31]

60.5 TREATING DEPRESSION IN SECONDARY PREVENTION

A 25-year review of interventions for depression in heart disease concluded that many cases of depression remit "spontaneously" and that there is no strong evidence that either antidepressants or psychotherapy influence prognosis.[32] The conclusion of this literature is that the first-line treatments for depression in heart disease are newer antidepressants (e.g., SSRIs) or psychotherapy (e.g., cognitive behavioral therapy), that the effectiveness of these approaches is moderate at best, that these treatments do not improve cardiac prognosis much, if at all, and that patients whose depression persists continue to have elevated risk of poorer outcomes. The often-overlooked option is exercise, a key component of cardiac rehabilitation, which, as we will see, both reduces depression and improves prognosis.

60.5.1 Antidepressant Medication

Concerning antidepressants, they are often the first treatment option, and SSRIs, in particular, appear to be safe for use in patients with CVD.[33,34] However, in the SADHART trial, sertraline was only effective for patients with a history of depression.[15] In the Canadian Cardiac Randomized Evaluation of Antidepressant and Psychotherapy Efficacy (CREATE) trial, citalopram had a small to medium effect relative to placebo in reducing depression.[35] Again, most of this benefit was limited to those patients with recurrent depression.[36] In the Myocardial Infarction and Depression-Intervention (MIND-IT) trial, antidepressants improved neither depression nor prognosis.[37,38] Antidepressants have also been administered prophylactically, and escitalopram was reported to prevent depression episodes following ACS relative to placebo.[39] A recent meta-analysis reported a pooled effect size of second-generation (e.g., SSRI, SNRI) antidepressants for depression in patients eligible for CR was small ($g = 0.15$). In patients with heart failure, antidepressants are not more effective than placebos for reducing depression symptoms.[40,41]

Thus, evidence for the effectiveness of antidepressants in secondary prevention is mixed and may not match patient preference. Specifically, among the general population of patients experiencing their first episode of major depression, 41% prefer psychotherapy and 31% prefer antidepressants.[42] Furthermore, in recent years, some cardiovascular safety concerns regarding newer antidepressants have been articulated, suggesting that prescribers should carefully weigh the risks and benefits.[43–45] However, the disappointing effectiveness of antidepressants for patients with heart disease may be better understood by appreciating recent revelations on the shortcomings of antidepressants more broadly.

Fairly recently, it has become clear that much of the effect of modern antidepressants on depression is due to psychological factors like *hope*, a *sense of efficacy in doing something* about depression, and the *expectation* of getting better.[46,47] In fact, antidepressants appear to have a greater effect on depression if the patient experiences more side effects, as the side effects apparently remind the user that they are taking the medication and imply that the medication must be working.[48] It has been argued that fluoxetine would not have received approval from the Federal Drug Administration (FDA) had the studies with negative results been reported.[47] A less charitable way of saying this is that a substantial part of the effectiveness of antidepressants is a placebo effect.[46,49,50] Between the years 2002 and 2010, this erupted into a public controversy. Some associates within the field of psychiatry were not amused.[51]

Of course, there are caveats and vigorous debate,[52,53] and it must be acknowledged that antidepressants do "work", whatever the mechanism may be. For example, the response curve for both placebo and active drugs appears robust, and drug trials rarely include a study arm of patients receiving no treatment at all. The small effect of antidepressants may only be relative to the placebo, and untreated patients may not improve at all. Furthermore, in clinical practice, it is strongly recommended that patients not abruptly discontinue antidepressants without medical supervision because some patients have discontinuation symptoms and the chance of relapse into another depressive episode is high.[54] Even for antidepressants-as-placebo, the therapy infrastructure is often so poor that, for many patients, the only option may be antidepressants. However, lifestyle cognitive and behavioral habits, rather than taking medication, will be a

more enduring solution for most cases of depression and anxiety.

Why is there so little effect of antidepressants that can be attributed to the medication itself? It is not known for certain. It is suspected that the chemical imbalance theory of depression (really a metaphor) is overly simplistic.[55,56] Furthermore, treatment cannot inform etiology. For example, a headache is not caused by an aspirin deficiency. The fact that aspirin works (anti-inflammatory medications reduce prostaglandins) does not suggest an "aspirin imbalance" in a patient's brain. This is not to suggest that the serotonergic systems of the central nervous system are not involved in depression, but the chemical imbalance metaphor appears to be dramatically oversimplified. Whatever the mechanism of action for antidepressant medication, they appear more effective in patients with recurrent depression and they do not appear to influence prognosis in secondary prevention.

60.5.2 Psychotherapy

With respect to psychotherapy, cognitive behavioral therapy (CBT) used in the ENRICHD trial modestly reduced depression relative to control and did not reduce mortality rates.[14] Patients whose depression persisted continued to have a worse prognosis.[57] One alternative to CBT, interpersonal psychotherapy for depression, was evaluated by the CREATE trial but was not more effective than clinical management for depression in patients with coronary artery disease.[35] In the more recent Comparison of Depression Interventions after Acute Coronary Syndrome (CODIACS) trial, stepped care (as suggested by Rozanski[12,13]) was compared with treatment-as-usual (e.g., locally determined care by the patient's healthcare provider).[58] Those allocated to stepped care initially received problem-solving therapy via telephone followed by the option to receive antidepressants. Reductions in depression were greater for stepped care than for treatment-as-usual, potentially suggesting that patient preference (e.g., choice, agency) is important for the effectiveness of treatment. However, improvement in depression was not associated with better secondary prevention in the areas of aspirin adherence, diet, exercise, use of tobacco, or blood pressure control.[59] A Cochrane review of psychological interventions for patients with heart disease concluded that reductions in depression are small to moderate and that they are not accompanied by improved prognosis.[60] However, a subsequent Cochrane systematic review and meta-analysis reported that psychological interventions for patients with coronary heart disease led to a reduction in cardiovascular mortality. [32]

Given the disappointing effectiveness of both antidepressants and psychotherapy for addressing psychosocial factors that moderate risk in secondary prevention, alternative approaches are needed. In our view, the most promising resource for addressing depression is existing secondary prevention that includes participation in cardiac rehabilitation.

60.6 CARDIAC REHABILITATION

Outpatient (Phase II) cardiac rehabilitation is a multi-faceted secondary prevention program for patients that includes up to 36 sessions (e.g., 12 weeks) of exercise and education on lifestyle risk factor management and is reimbursed by Medicare and other insurance carriers.[61] Because cardiac rehabilitation lowers rates of reinfarction and mortality,[62] it is an evidence-based treatment recommendation for eligible patients with CVD following cardiac events such as MI, percutaneous coronary intervention (PCI), coronary artery bypass graft (CABG), and cardiac valve surgery.[3,63] The goals of cardiac rehabilitation are to improve fitness, biomarkers such as lipids, and quality of life, and engage in and maintain secondary prevention behaviors including exercise, diet, smoking cessation, and medication management. These goals are broadly consistent with the premise of lifestyle medicine.

There is no question that cardiac rehabilitation is effective for secondary prevention. However, many eligible patients do not enroll in outpatient cardiac rehabilitation,[64–66] and, for example, only 28.6% of Medicare beneficiaries who had an event that made them eligible for cardiac rehabilitation enrolled, and only 27.6% of these completed 36 sessions.[67] Furthermore, health disparities persist in cardiac rehabilitation participation, driven by social determinants of health,[68] such that lower participation rates are observed among the elderly, sicker patients, women, minorities, and persons of lower socioeconomic status (SES).[69–71] Depression also reduces adherence to cardiac rehabilitation.[72]

Cardiac rehabilitation reliably reduces depression.[9] For example, although women starting cardiac rehabilitation have higher depression scores, they also experience a greater reduction in depression.[73] Exercise is at least as effective as antidepressant medication for depression,[74] and combined exercise and antidepressants appeared to have greater benefits on a biomarker of risk (heart rate variability) than either intervention alone.[75] Combining psychological interventions with cardiac rehabilitation reduced depression more than cardiac rehabilitation alone.[76] A small trial integrating 12 weeks of stress management training with cardiac rehabilitation reduced mortality relative to cardiac rehabilitation alone, suggesting that combining psychosocial interventions with cardiac rehabilitation may provide even better secondary prevention.[77] Finally, a program of research in the UK has reported promising results for integrating metacognitive therapy into cardiac rehabilitation. [78]

Given that cardiac rehabilitation is effective in reducing both mortality and depression, combined with the disappointing results of decades of attempts to ameliorate the poorer prognosis of cardiac patients with comorbid depression, it is our view that future efforts should focus on increasing the utilization of cardiac rehabilitation, integrating psychosocial interventions with cardiac rehabilitation or other structured exercise programs, and extending secondary prevention of CVD to include alternatives to cardiac

TABLE 60.1
Treatments for Depression in Cardiovascular Disease

Antidepressants	Antidepressants are not very effective for patients with heart disease, except for patients with a history of recurrent depression. Antidepressants do not reduce the risks associated with depression.
Psychotherapy	Cognitive behavioral therapy is somewhat effective, but does not reduce the risk associated with depression. Newer psychotherapies such as acceptance and commitment and mindfulness-based cognitive therapy have not yet been evaluated. Metacognitive therapy may be effective when integrated into cardiac rehabilitation, and possible improvements in cardiovascular prognosis have not been evaluated.
Cardiac rehabilitation	Cardiac rehabilitation, which includes exercise, is effective for depression and reduces the risk of mortality. Enhancing cardiac rehabilitation with stress management or other psychosocial interventions has promise. Extending cardiac rehabilitation with innovative delivery models or alternatives is suggested.

rehabilitation (e.g., remotely delivered secondary prevention) (see Table 60.1).

60.7 DEPRESSION IN HEART FAILURE

In the past, secondary prevention efforts primarily targeted coronary heart disease and patients experiencing ACS. The success of modern cardiology has led to an increased prevalence of patients with HF, as they survive the initial MI and live longer with heart disease. Now this population has received increased secondary prevention efforts, and stable systolic HF is an approved indication for cardiac rehabilitation. Currently, over five million Americans have HF, and nearly one million new cases are diagnosed each year.[1,2] The prevalence of HF is expected to increase 46% by 2030, and more than eight million US adults will have HF.[79]

Mortality in HF remains high, as one out of two HF patients die within five years of diagnosis.[79–81] As with other forms of heart disease, many individuals with HF experience depressive symptoms or clinical depression. At least 20–40% of patients with HF experience depression symptoms during their illness,[82] which doubles the risk of all-cause mortality.[82,83] Depression undermines disease management programs for HF[84] and is a barrier to effective patient self-management. For example, medication non-adherence increases the risk of mortality in depressed patients with HF.[85]

Some of the lessons from other heart disease conditions about psychosocial factors in secondary prevention are being repeated in patients with HF. For example, neither sertraline[86] nor escitalopram[87] is efficacious for depression in patients with HF; and although both were safe, they did not improve clinical status.[86,87] Furthermore, as with the broader population of depressed individuals,[88,89] HF patients tend to prefer behavioral treatments to antidepressants.[90]

CBT for depression and self-care in HF reduced depression symptoms at six months and showed superior remission of depression relative to the control condition (46% vs. 19%), but the trial was not powered to detect improved prognosis.[91] As with cardiac patients more broadly, exercise also reduces depression in systolic HF.[92] The HF-ACTION trial randomized 2322 patients with HF to exercise or education and usual care. Depression scores were reduced at three months and 12 months, but the clinical significance of the improvement could not be demonstrated. The effect of exercise training on depression was a 40% reduction in symptoms, and those who remained depressed continued to have an elevated risk of mortality.[93] Intriguingly, depressed patients who completed exercise training had almost a 60% reduction in mortality.[93]

60.8 FUTURE DIRECTIONS

The public health burden of CVD is likely to increase as the population ages and advances in cardiology result in more patients being appropriate for secondary prevention. Psychosocial factors are known to moderate cardiovascular outcomes, but efforts to ameliorate this risk have been challenging. Here we argued that addressing psychosocial factors in the context of cardiac rehabilitation is a promising approach, making increasing utilization of cardiac rehabilitation a critical focus.[94] There are several other directions for future research that merit comment, specifically integrating psychosocial interventions with cardiac rehabilitation or other structured exercise programs, and extending secondary prevention of CVD to include innovative delivery models and even alternatives to cardiac rehabilitation.

60.8.1 Integrating Psychosocial Interventions with Cardiac Rehabilitation

Another promising future direction is integrating psychosocial interventions with cardiac rehabilitation. Integration would result in the broader dissemination of treatments for psychosocial factors in secondary prevention and will require the development of behavioral interventions that are easier to implement. The front-line treatments at this point are antidepressant medications, which are not particularly effective, and psychotherapy, which is time- and labor-intensive. The mental health infrastructure is poor in many communities, and it would be valuable to have interventions that can be provided to more patients.

The evolution of psychotherapy to include more acceptance of distress and more mind–body interventions such as meditation may facilitate the integration of interventions

with cardiac rehabilitation. The so-called "third wave" of psychotherapy departs from cognitive behavioral therapy[95–97] by de-emphasizing the focus on dysfunctional or depressogenic cognition, instead, asking patients to accept and tolerate some distress. The major therapies in this tradition are acceptance and commitment therapy[98] and those which incorporate mindfulness meditation.[99] A meta-analysis and systematic review of mindfulness-based interventions for patients with vascular diseases included nine clinical trials (three in heart disease) and reported effects for psychological but not medical outcomes.[100] If newer therapies continue to grow in popularity and availability, it will be important to evaluate their suitability for secondary prevention. There is great enthusiasm for incorporating some of the techniques (e.g., meditation) into cardiac rehabilitation, but the research is currently lacking. Another promising new approach developed in the UK involves integrating metacognitive therapy into cardiac rehabilitation, which can be delivered in a group or self-help format.[78]

60.8.2 Innovative Delivery Models and Alternatives to Cardiac Rehabilitation

Currently, there is an emphasis on increasing the utilization of cardiac rehabilitation and developing innovative models of delivery, which has great merit. The onset of the COVID-19 pandemic temporarily shuttered cardiac rehabilitation sites, and many rapidly transitioned to remote delivery. There is great hope that new delivery models will increase enrollment in cardiac rehabilitation. Although some barriers to participation can be overcome using telehealth or other means, some patients have chosen not to participate due to competing life demands, personal priorities, or other volitional forms of non-participation.

It is our view that secondary prevention of CVD could be extended beyond cardiac rehabilitation by offering self-management programs that are alternatives (e.g., remotely delivered secondary prevention). That is, for patients who do not enroll in cardiac rehabilitation, the *de facto* provider of secondary prevention is the patient's medical provider (e.g., cardiologist, primary care physician). The success of cardiac rehabilitation and the fact physician prescribed and monitored exercise defines cardiac rehabilitation by statute (i.e., 42 CFR §§ 410.47)[61] may have resulted in many conflating secondary prevention with cardiac rehabilitation. This is not accurate, as cardiac rehabilitation is one of 12 targets for intervention. Thus, it should be possible to develop approaches that fall between physician visits and center-based outpatient cardiac rehabilitation with respect to intensity, frequency, and patient burden. This would be consistent with the spirit of the guidelines for secondary prevention.[3] This suggestion does not disparage the importance of exercise training, as patients having a good experience with a more comprehensive secondary prevention program might be subsequently willing to enroll in cardiac rehabilitation. Furthermore, physical activity (i.e., moderate-intensity aerobic activity) is a recommendation independent of that for cardiac rehabilitation. Our suggestion is to increase the intensity of secondary prevention using structured programs that are more accessible than outpatient cardiac rehabilitation to achieve more widespread dissemination of secondary prevention broadly construed. Ultimately, this could provide opportunities to address psychosocial factors that modulate cardiovascular outcomes in secondary prevention.

60.9 CONCLUSION

Many patients with heart disease experience psychosocial comorbidities, such as depression, anxiety, social isolation, and anger/hostility that moderate risk in secondary prevention. Depression is the most prominent risk factor, and decades of research have concluded that first-line treatments (antidepressants and/or psychotherapy) are only moderately effective and generally do not reduce the associated risk associated with depression. Comprehensive cardiac rehabilitation, which includes psychosocial management, is the most promising approach for addressing psychosocial risk factors and is aligned with the spirit and aims of lifestyle medicine.

CLINICAL APPLICATIONS

Psychosocial considerations in secondary prevention:

- Social support/social isolation confer greater risk of mortality: isolated patients or those with low social support.
- Anger/hostility: patients high in anger or hostility have poorer outcomes and interventions are rare. Beta-blockers may directly target the physiological mechanism responsible.
- Anxiety: high anxiety increases risk of mortality independently of depression, and comorbid anxiety and depression may have a greater effect than either alone.
- Depression: depression is common in heart disease and confers a two- to five-fold increased risk of mortality. Patients should be screened for depression.

61 Lipid Management in Secondary Prevention

Antonio B. Fernandez, MD and Stephanie J. Saucier, MD

KEY POINTS

- The benefit of lipoprotein (LDL)-cholesterol (C) reduction appears to have no lower boundary.
- Our treatment goal in managing patients with atherosclerotic cardiovascular disease (ASCVD) is to lower the LDL-C as much as possible without producing side effects.
- Most patients cannot achieve sufficiently low levels with dietary intervention alone.
- High-intensity statin treatment is the cornerstone of secondary prevention and LDL–C management in patients with ASCVD.
- Non-statin lipid-lowering drugs should be considered in patients intolerant of statins or in whom the LDL-C levels are not at goal on maximally tolerated statin therapy.

61.1 INTRODUCTION

The initiation and progression of atherosclerotic cardiovascular disease (ASCVD) is driven by low-density lipoprotein (LDL)-cholesterol (C) and reducing LDL-C reduces the incidence of both primary and secondary cardiovascular events. The benefit of LDL–C reduction appears to have no lower boundary. GLAGOV (the Global Assessment of Plaque Regression with a PCSK9 Antibody as Measured by Intravascular Ultrasound) trial randomized 968 statin-treated patients with angiographic coronary artery disease to the proprotein convertase subtilisin kexin type 9 (PCSK9) inhibitor, evolocumab, or to placebo. LDL–C at 78 weeks was 93 and 37 mg/dL in the placebo and evolocumab subjects, respectively[1] The percent atheroma volume measured by intracoronary ultrasound increased by 0.05% with placebo but decreased by 0.95% with evolocumab ($p<0.001$). Analysis of the regression curve demonstrated increasing reductions in atheroma volume with decreasing LDL-C down to LDL-C levels of 20 mg/dL.[1] Similarly, FOURIER or the Further Cardiovascular Outcomes Research with PCSK9 Inhibition in Subjects with elevated risk demonstrated that evolocumab added to a statin reduced cardiovascular events at 48 weeks when compared with placebo. LDL-C levels decreased from 92 mg/dL to 30 mg/dL with evolocumab treatment.[2] Both GLAVOV and FOURIER suggest that greater LDL-C reduction produces greater reductions in cardiovascular events and both trials support the hypothesis that lower LDL-C is better in patients with established ASCVD. This chapter will describe our rationale and approach for treating LDL-C in ASCVD patients.

61.2 TREATMENT GOALS

Our treatment goal in managing patients with ASCVD is to lower the LDL-C as much as possible without producing side effects. This goal varies from present guidelines for LDL–C reduction in ASCVD patients, and there is also variation among the available guidelines. The American College of Cardiology/American Heart Association 2018 guidelines recommend high-intensity statin treatment for all patients with ASCVD and moderate-intensity statin treatment for those not suitable for high-intensity treatment. High-intensity statin treatment limits the medication choices to rosuvastatin ≥20 mg or atorvastatin ≥40 mg daily. If on maximal statin therapy LDL-C >70 mg/dL, then the addition of ezetimibe or PCSK9i is considered reasonable. [3] In contrast, the American Association of Clinical Endocrinologists (ACCE) 2017 guidelines recommend an LDL of <70 mg/dL for very high-risk patients and <55 mg/dL for those considered at extreme risk.[4] These ACCE guidelines suggest that writing groups are also appreciating the benefit of even lower LDL-C levels.

61.3 DIETARY THERAPY

Such LDL values can rarely be obtained by dietary therapy alone. Strict vegans and vegetarians can achieve low LDL-C levels, but most patients cannot achieve sufficiently low levels with dietary intervention alone. We strongly recommend that patients follow low-saturated fat diets, exercise, and practice calorie control, but do not depend on these interventions to achieve their LDL-C goals. Many clinicians cite the Lifestyle Heart Trial as evidence that diet alone can reduce atherosclerotic cardiovascular disease.[5] This trial design precludes an accurate estimation of the risk reduction based on diet alone. Therefore, we recommend a combination of pharmacologic and dietary interventions to optimize LDL-C reduction.

DOI: 10.1201/9781003227793-72

61.4 STATIN TREATMENT

High-intensity statin treatment is the cornerstone of secondary prevention and LDL–C management in patients with ASCVD. Statins reduce secondary events by both LDL-C reduction and decreasing inflammation.[6] Patients with acute coronary syndromes (ACS) or recent interventions should be started on high dose statins such as atorvastatin 80 or rosuvastatin 40 mg daily. Such treatment should be continued as long as possible, but we consider decreasing the dose to atorvastatin 40 or rosuvastatin 20 after two years of higher dose therapy. We specify two years because approximately two years of aggressive therapy is the duration frequently observed in trials demonstrating atherosclerotic regression.[7] Also, aggressive lipid treatment produces maximum atherosclerotic plaque reduction within two years of treatment (Figures 61.1 and 61.2).[8] We routinely add ezetimibe to high-intensity statin treatment since the IMPROVE-IT (or Improved Reduction of Outcomes: Vytorin Efficacy International Trial) demonstrated a 2% absolute reduction in cardiovascular events in patients with ACS treated with the combination of statin and ezetimibe vs. statin alone (p=0.016). [9]

61.5 MANAGING STATIN-ASSOCIATED MUSCLE COMPLAINTS

Approximately 10% of patients treated with moderate to high dose statins report muscle complaints that they attribute to the statin.[10] Our double-blind, placebo-controlled study demonstrated that 9.4% of subjects treated for six months with atorvastatin 80 mg daily developed muscle complaints compared with only 4.6% of placebo-treated subjects.[11] This suggests that approximately 5% of patients have true statin-associated muscle symptoms (SAMS). These patients do not generally demonstrate objective evidence of muscle injury such as elevated CK levels or documented muscle weakness. Whether or not SAMS are real, and we believe they are,[12] it is a moot point for clinicians because clinicians cannot ignore a patient's complaints and expect to maintain a good patient relationship.

We have described our approach to managing SAMS.[13,14] We determine whether the patient can tolerate the symptoms and measure CK to make sure that it is not elevated to >10 times the upper limits of normal. We reassure the patient that SAMS are almost always reversible and not progressive. We stress the importance of statin treatment in secondary prevention and the lifesaving role of statin therapy. Nevertheless, we stop the statin until the patient has no symptoms if the patient remains concerned or intolerably symptomatic. Reversal of the symptoms within several weeks of statin discontinuation supports the diagnosis of SAMS.[15] We next try the same or another statin at a comparable or lower dose. If rechallenge with a statin also produces symptoms, we try ezetimibe alone. Ezetimibe produces approximately a 20% average reduction in LDL-C levels. We then retry the statin at very low doses such as rosuvastatin 2.5 or 5 mg, atorvastatin 5 or 10 mg, or pitavastatin 1 mg—Monday and Friday. These agents are not approved for intermittent dosing, but the

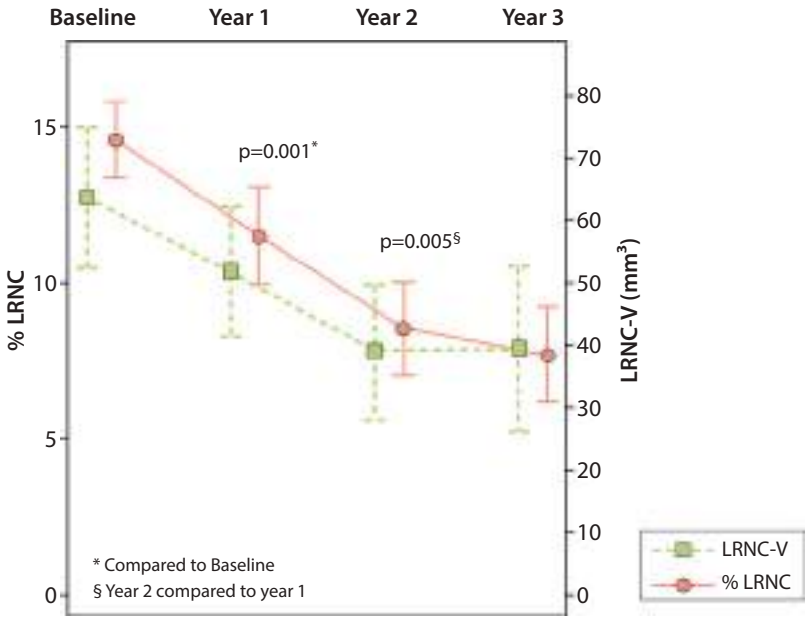

FIGURE 61.1 Carotid plaque lipid depletion and time course during three-year lipid therapy. After three years of intensive lipid therapy, lipid-rich necrotic core volume (LRNC-V) (squares) significantly decreased from 60.4 mm^3 to 37.4 mm^3. Percent LRNC (%LRNC) (circles) also significantly decreased from 14.2% to 7.4%. The plaque lipid depletion time course over three years showed that %LRNC for pooled slices containing lipid at any time point significantly decreased by 3.2% in the first year, significantly decreased by 3.0% in the second year, and decreased by 0.9% in the third year (the change from year two to three was not statistically significant). Bars around the estimates are standard error bars (taken with permission from Zhao et al. *JACC Cardiovasc Imaging* 2011).

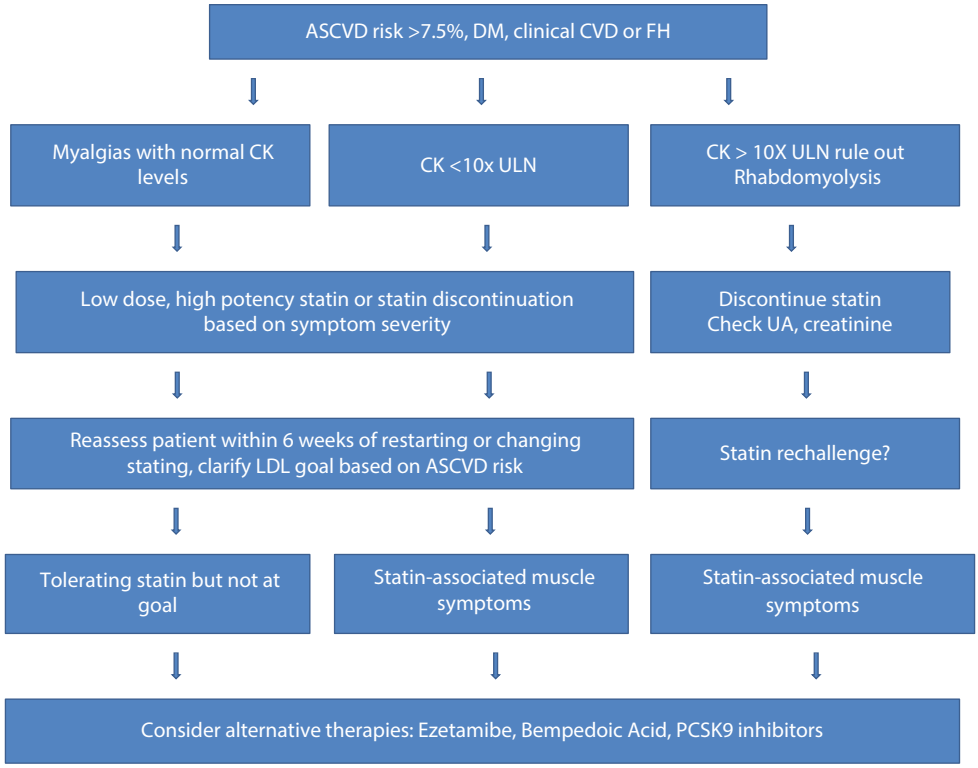

FIGURE 61.2 Clinical applications flow chart—our approach to lipid management in statin-intolerant patients.

long half-lives of these statins produce a ≈20% reduction in LDL-C with such intermittent dosing.[16] Clinicians often forget that the largest percent reduction in LDL-C per mg of statin occurs with the lowest doses. The combination of ezetimibe and low-dose statin is often able to normalize LDL-C levels in many patients. Co-Q10 supplementation is often recommended for patients with SAMS for several plausible reasons,[17] but our studies[18] and a systematic review[19] did not demonstrate that Co-Q10 supplementation is effective in SAMS. Nevertheless, we occasionally use it in selected patients. We discuss the absence of effect in controlled studies but also emphasize that some patients have had remarkable responses to Co-Q10 supplementation. We will occasionally try Co-Q10 supplementation even though its effectiveness may be only a placebo effect.

In patients who are truly intolerant to statin therapy, we use other agents such as PCSK9Is, ezetimibe, and bempedoic acid.

61.6 PCSK9 INHIBITORS

PCSK9 inhibitors are our go-to drugs in patients intolerant of statins or in whom other lipid-lowering agents cannot reduce their LDL-C levels to a sufficiently low level. PCSK9 inhibitors are approved for use in patients with familial hypercholesterolemia and in patients with documented ASCVD who do not achieve sufficient LDL-C reductions by dietary and statin therapy. FDA approval of PCSK-9 inhibitors was provided before IMPROVE-IT documented that ezetimibe, when added to a statin, reduces ASCVD events more than statins alone.[9] Present best practice, therefore, would require that ezetimibe be included in the treatment before progressing to the more expensive PCSK9 inhibitors. What level of LDL-C warrants PCSK9 therapy is the clinician's decision but as mentioned earlier, we aim for an LDL-C of at least <70 mg/dL in patients with established ASCVD.

PCSK9 inhibitors will likely be more widely used to achieve low LDL-C levels in patients with ASCVD. We do not use them prematurely, however, because they are expensive. We restrict the use to those individuals who cannot achieve a sufficiently low LDL-C level using statins, ezetimibe, niacin, fibric acid derivatives, or bile acid sequestrant resins. We do not necessarily try all these agents in patients with ASCVD before proceeding to a PCSK-9 inhibitor, but do consider these other drugs as part of our therapeutic regimen. We do proceed directly to PCSK-9 inhibition in patients with such high LDL levels that it is unlikely that other agents will be effective.

The combination of statin, ezetimibe, and PCSK9 inhibitor therapy has the potential to markedly reduce recurrent rates of ASCVD events in patients with documented disease by reducing LDL-C so low that recurrent events become extremely unlikely. Such aggressive therapy has the potential to enhance further the already excellent survival of ASCVD patients.

Patients within one year of their most recent myocardial infarction (MI) have a higher risk of ASCVD and thus may have a greater absolute ASCVD risk reduction. In FOURIER,

patients with a recent MI had an absolute risk reduction of 3.2% compared with patients who have had a more distant MI history.[20] More recently, the EVOPACS trial evaluated the effectiveness of administering evolocumab in-hospital in the acute phase of acute coronary syndrome on LDL-C lowering. In this investigator-sponsored study conducted in Switzerland, 308 patients with an ST elevation myocardial infarction of less than 24 hours or a non-ST segment elevation of less than 72 hours were randomized to receive evolocumab 420 mg every four weeks and atorvastatin 40 mg daily versus placebo every four weeks and atorvastatin 40 mg daily. The investigators demonstrated a 41% additional LDL reduction in the evolocumab group from baseline to week eight. This afforded the opportunity to achieve an LDL of <70 mg/dL (the AHA threshold) in 95% of those patients, compared with only 37% of the patients randomized to placebo and atorvastatin.[21] These data suggest that in patients with established ASCVD and recent myocardial infarction, adding a PCSK9I to a statin may help prevent another event. However, this should be interpreted cautiously since the EVOPACS trial was not designed to assess a correlation between LDL-C reduction and ASCVD events.

The PACMAN-AMI trial showed that the use of alirocumab 150 mg biweekly within 24 hours after PCI for acute myocardial infarction leads to a greater reduction in plaque burden and plaque regression at 52 weeks in the nonculprit vessel.[22]

61.7 EZETIMIBE

Ezetimibe works by inhibiting the absorption of cholesterol from the gut leading to a reduction in the amount of cholesterol that comes to the liver via the portal circulation, thus decreasing hepatocyte cholesterol content and an increase in LDL-C receptor production by the liver. Ezetimibe produces about a 20% reduction in LDL-C when used alone and a larger reduction, about 24%, when used in conjunction with a statin. IMPROVE-IT randomized patients with acute coronary syndromes to simvastatin 40 with or without ezetimibe.[9] The combination of statin plus ezetimibe produced a 2% absolute reduction in ASCVD events.

61.8 BEMPEDOIC ACID

Bempedoic acid works by inhibiting ATP-citrate lyase (ACLY), an enzyme upstream from HMG-CoA reductase. Bempedoic acid is administered as a pro-drug that must be activated by being converted into its active form, bempedoyl-CoA. [23] This enzyme is not abundant in skeletal muscle; therefore, un-acetylated bempedoic acid does not affect the skeletal muscle as it cannot be activated. The LDL-C reduction is robust (17–18% reduction), but it is not as potent as the statin lowering effect. The combination of bempedoic acid and ezetimibe can reduce LDL-C by 38%.[24] Bempedoic acid can increase uric acid levels and can also increase creatinine by interfering with renal tubular excretion. The glomerular filtration rate itself is not altered. Bempedoic acid has not yet demonstrated a reduction in ASCVD events, however, outcomes studies are ongoing.

61.9 INCLISIRAN

Inclisiran is a small interfering RNA (siRNA) directed to PSCK9 mRNA, interfering with the degradation of the LDL receptor, resulting in higher LDLR expression. It is administered as a subcutaneous injection at zero and three months and then every six months thereafter. ORION-9 randomized patients with LDL >100 mg/dL at screening to either inclisiran vs. placebo and found a reduction of 39.7% in the inclisiran group compared with an increase in LDL-C of 8.2% in the placebo group.[25] ORION-10 randomized patients with ASCVD and LDL >70 mg/dL to either inclisiran vs. placebo and found a reduction of 51.3% in LDL compared with a 1% increase in the placebo group.[26] ORION-11 randomized patients with ASCVD or ASCVD-risk equivalent and LDL >70 mg/dL to inclisiran vs. placebo and found a 45.8% reduction in LDL levels compared with a 4% increase in LDL in the placebo group.[26] Ongoing outcome trials are also underway. We recently started using inclisiran in patients who have demonstrated a suboptimal response or an allergy to PCSK9Is. It is FDA-approved along with diet and maximally tolerated statin therapy in adults with heterozygous familial hypercholesterolemia or ASCVD who require additional lowering of LDL-C.

61.10 EVINACUMAB

Evinacumab is an antihyperlipidemic angiopoietin-like protein 3 (ANGPTL3) inhibitor. It is a recombinant human monoclonal antibody that binds to and inhibits ANGPTL3; allowing lipoprotein lipase (LPL) and endothelial lipase (EL) to enhance the clearance of VLDL remnants via remnant receptors in the liver. This leads to the reduction in LDL-C, HDL-C, and triglycerides in an LDLR-independent manner. It is FDA approved for use as an adjunct to other LDL-lowering therapies for patients with homozygous familial hypercholesterolemia. ELIPSE-HoFH showed a substantial 47% reduction in LDL levels in patients with HoFH randomized to evinacumab, regardless of the degree of LDLR function compared with placebo.[25]

61.11 PELACARSEN

Lipoprotein (a) is a genetically determined, independent risk factor for cardiovascular disease. PCSK9i has been found to provide risk reduction in recurrent ASCVD events with each 5 mg/dL reduction in Lp(a) predicted event rate reduced by 2.5%. Pelacarsen is a hepatocyte-directed antisense oligonucleotide targeting the LPA gene. Pelacarsen has been demonstrated to lower Lp(a) by 35–80%, lower oxidized phospholipids by 30–90%, reduce apo(a) and apoB, and lower LDL by 20% in patients already on lipid-lowering therapy in its phase 2 trial.[27] Phase 3 RCT (HORIZON) is ongoing to evaluate the effect of pelacarsen

on major adverse cardiovascular events in patients with a history of ASCVD and Lp(a) >70 or >90 mg/dL.

CLINICAL IMPLICATIONS

1. ASCVD is primarily driven by LDL-C. Reducing LDL-C reduces the incidence of both primary and secondary cardiovascular events.
2. The benefit of LDL–C reduction appears to have no lower boundary. Some of the different professional society prevention guidelines follow a trend targeting lower LDL-C levels for secondary ASCVD prevention. This opens the window for an aggressive lipid-lowering therapy in high-risk individuals to decrease LDL-C as low as possible.
3. It is also important to understand the cost of newer drugs, such as PCSK9 inhibitors, to maintain cost-effective care. These emerging lipid-lowering agents will continue to reduce recurrent ASCVD events.

62 Counseling Coronary Heart Disease Patients about Their Body Weight: Implications Regarding the Obesity Paradox

Nadia Isabel Abelhad, MD, Peter G Pantlin, MD, Sergey Kachur, MD, and Carl J. Lavie, MD, Richard V Milani, MD

KEY POINTS

- The obesity epidemic continues to grow and counseling on appropriate lifestyle changes is more important than ever. In an age of misinformation, topics such as the "obesity paradox" and "metabolically healthy obese" can be interpreted to show that excess body weight may not be harmful.
- The obesity paradox is present in those with chronic disease, advanced age, and low cardiorespiratory fitness. Those with higher fitness have not been shown to benefit from excess mass. In younger individuals, obesity accelerates the onset of chronic disease and may shorten overall lifespan.
- The concept of the metabolically healthy obese is confounded by increased levels of fitness found in obese individuals without metabolic syndrome. When adjusted for fitness, studies show that excess weight in this group confers some (albeit smaller) cardiovascular risk and mortality.
- Recent data highlights abdominal obesity defined by waist circumference as an independent marker of poor cardiovascular outcomes.
- Improved imaging modalities can better quantify visceral adiposity.
- Clinical trials of medical weight loss have not demonstrated a reduction in coronary artery disease rates.
- Previously, lifestyle recommendations were recommended, however, current prospective studies signal a reduction in coronary artery disease rates when combined with bariatric surgery.

62.1 INTRODUCTION

The obesity epidemic and its associated chronic diseases are increasing due to the availability of high-calorie foods and a sedentary environment at home and work. Counseling on lifestyle interventions is a clinician's primary tool in combating obesity because the mechanisms of harm are multifactorial, making medical monotherapies largely ineffective.[1] Although the concept of decreasing caloric intake while increasing expenditure is a simple one, the changes needed to modify harmful behaviors are counter-intuitive, as overeating and a sedentary lifestyle are linked to neurochemical reward systems. Complicating matters further are recent discoveries of the obesity paradox (OP) and the "metabolically healthy obese" (MHO) phenotype, which can be interpreted by the layperson to mean that obesity and its associated sedentary behaviors are beneficial. Thus, any discussion or counseling session initiated to prevent or treat obesity needs to be comprehensive in its scope—addressing data on risks, benefits, and modifying associated lifestyle behaviors. Here, we will define obesity, discuss the data behind MHO and the OP, and touch on newer imaging modalities to quantify excess visceral adipose tissue. We will review the outcomes of non-invasive lifestyle changes and bariatric surgery as they relate to coronary artery disease. This chapter will serve as a summary of the key points in a discussion on this topic with a patient.

62.2 EPIDEMIOLOGY

The World Health Organization defines overweight as a body mass index (BMI) greater than or equal to 25 kg/m^2 and obesity as a BMI greater than or equal to 30 kg/m^2.[2] Worldwide obesity has more than doubled between 1980 and 2014 to a level of 600 million (13%). The trend is projected to worsen due to the epidemic of childhood obesity; 41 million obese children under age five as of 2016, projected by the WHO to increase to 70 million by 2025. This is a growing health problem because of obesity's associations with cardiovascular (CV) disease (CVD) and stroke, accounting for a combined 15 million global deaths in 2015 (Figure 62.1).[3]

DOI: 10.1201/9781003227793-73

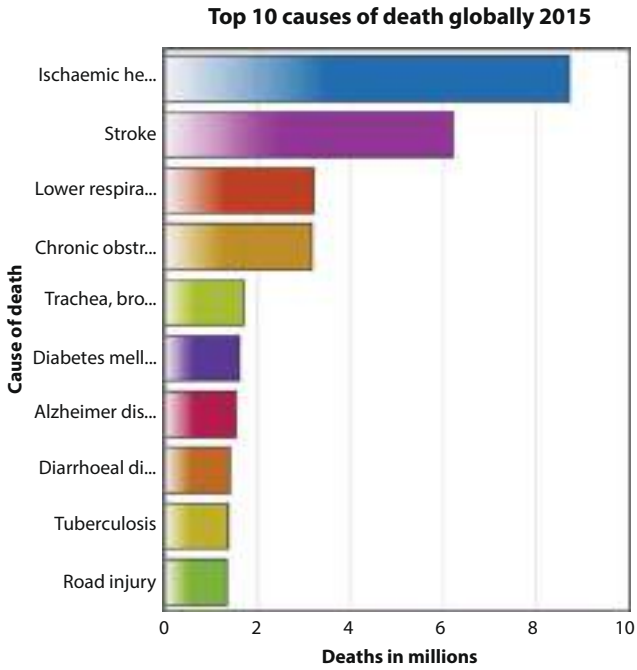

FIGURE 62.1 Leading causes of death.

62.3 MEASURING OBESITY

The BMI metric has its origins in the Quetelet index. It was derived from the heights and weights of French and Scottish armies as a means to normalize anthropometric measurement. It is an imperfect measure of adiposity because of confounding factors, such as excessive muscular development and fluid retention, among others.[4] Traditionally, body weight (and by relation BMI) is divided into body fat (BF) and lean mass (LM). Out of a cohort of 95 patients, BMI had a good correlation with both BF% ($p = 0.66$, $p < 0.001$) and LM ($p = 0.41$, $p < 0.0001$) and failed to discriminate between both ($p = 0.72$). A BMI $\geq$ 30 kg/m^2 had a good specificity (95%; 95% CI, 83–100) but a poor sensitivity (43%; 95% CI, 32–54) while a BMI $\geq$ 25 kg/m^2 had a good sensitivity (91%; 95% CI, 84–97) but a poor specificity (65%; 95% CI, 42–88) at detecting adiposity defined by excess BF.[5]

Recent data highlights abdominal obesity as an independent marker of poor CVD outcomes.[6–8] Thus, high waist circumference (WC) even in individuals with normal weight may unmask higher CVD risk.[9] As such, several organizations and expert panels have recommended that WC measures be assessed along with BMI in clinical evaluations.[1]

The development of imaging modalities such as computed tomography (CT) and magnetic resonance imaging (MRI) have served as more precise tools to quantify visceral and ectopic adipose tissue deposition.[3] With these methods, volumetric measurements can be made of subcutaneous vs intra-abdominal adipose tissue including stores found in liver, pancreas, heart, and skeletal muscle.[2] As much, a wide variation of adiposity distribution has been observed for a given BMI.[2] Importantly, in the overweight and obese subgroups, low levels of visceral abdominal tissue represent a more favorable CVD risk profile,[10] possibly representing MHO patients. When compared with patients with excess visceral abdominal tissue, the highest CVD risk was observed, regardless of BMI.[2] With the improved imaging of ectopic fat, the question remains as to whether isolated excess adipose liver deposition is associated with higher CVD risk. Previous randomization studies have not shown associations despite its known role in the pathogenesis of dysmetabolic state.[11] Other adipose measurements such as WC-to-height and WC-to-hip ratio may be a better predictor of CVD and have been shown to predict CVD mortality independently of BMI.[12]

62.4 DOES MHO EXIST?

The mechanisms of pathology (Figure 62.2) in the obese suggest that most, if not all, of the increased risk associated with obesity could be attributable to associated metabolic derangements characterized by impaired glucose tolerance, dyslipidemia, and hypertension (HTN)—collectively diagnosed as metabolic syndrome (MetS).[13] The presence of MetS is often used to differentiate obesity into those with metabolically healthy obesity (MHO) and metabolically around this issue, as the results of older studies on the effect of MHO on coronary heart disease (CHD) and heart failure (HF) were conflicting.

In a regional health registry of 2074 individuals, metabolically abnormal obese (MAO), but not MHO, had increased CVD mortality over a 15-year follow-up.[14] Similarly, in a review based on the Norwegian Nord-Trøndelag population of 61,299 men and women over a 30-year time span, Mørkedal et al. found that increased CVD risk was present in MAO (HR = 2.0, 95% CI 1.7–2.3), but not MHO (HR = 1.1; 95% CI 0.9–1.4).[15] However, in the same study, MHO was associated with significantly more HF events.[16] In The Health Improvement Network (THIN), 3.5 million individuals were followed for 20 years; obesity was associated with significantly higher risks of HF, CHD, and stroke.[17] Also, a large meta-analysis by Fan et al. (n = 299,059; 12,125 incident cases of CVD, 2130 deaths associated with CVD, and 7071 cases of all-cause mortality) found that in patients followed for >15 years, there was an additional risk of CVD events in the MHO group, and these patients had an increased risk of mortality.[18] This latter finding was supported by another meta-analysis of eight studies conducted by Kramer et al. (n = 61,386; 3988 events) where in subjects followed for ≥10 years, MHO individuals had a 24% increased risk of major CVD events compared with the metabolically healthy lean subjects, but the risk of CVD events increased 2.65–3.14-fold in MAO individuals when compared with the MHO.[19] Although the above trials failed to adjust for confounders of mortality (age and sex), and did not include effects of cardiorespiratory fitness (CRF), they support other data stratified by CRF and LM.[20]

Of note, more recent studies have demonstrated an association between central adiposity and CHD and CVD

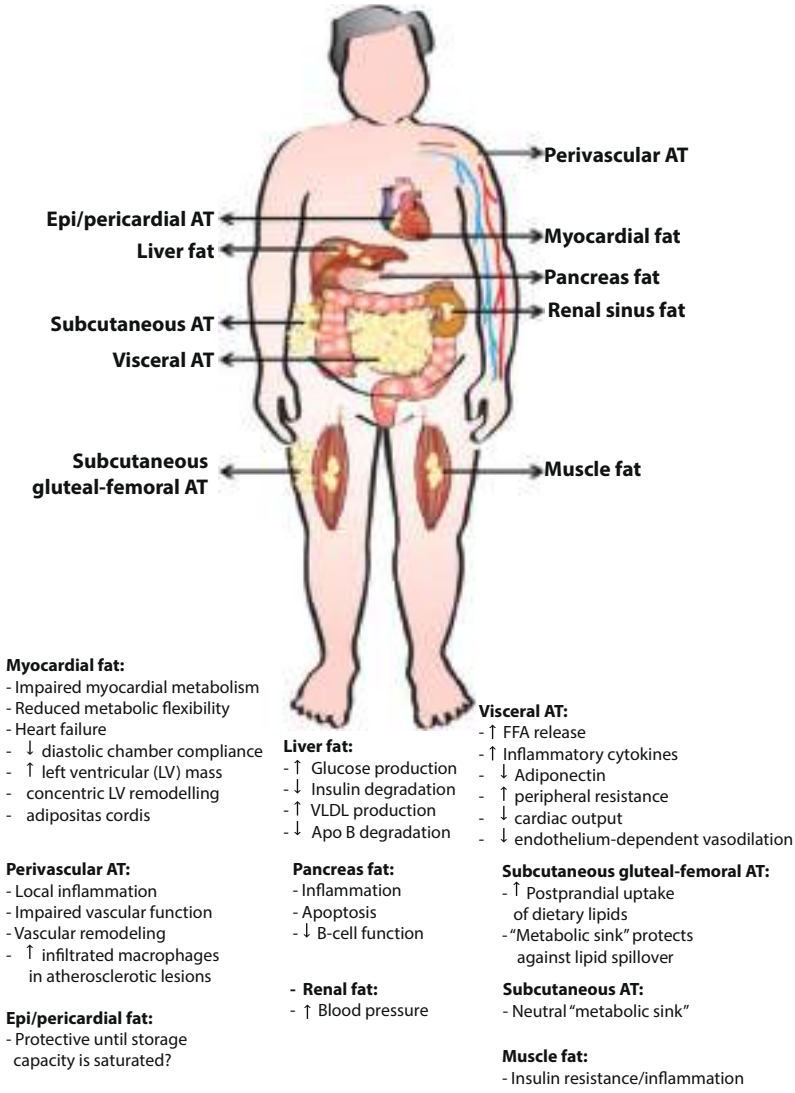

FIGURE 62.2 Mechanisms of cardiovascular risk related to adiposity in the obese.

mortality including subgroups with normal weight and BMI.[21,22] Furthermore, the degree and duration of obesity, measured by total lifetime exposure to excessive visceral adiposity, measured by WC years, has been shown to be a much stronger predictor of CHD events beyond BMI alone.[23]

Although the fitness hypothesis does explain some of the findings of the "fat-but-fit" phenomenon, variable metabolic effects from both fat distribution (visceral versus subcutaneous) and fat composition (white versus brown) lend credence to a benign adipose phenotype. Both subcutaneous distribution of fat and increasing proportions of brown fat have been associated with better metabolic profiles and lend support for a benign adiposity phenotype.[24] As of now, there are no known mechanisms for stimulating subcutaneous adiposity, exercise does preferentially reduce visceral fat and has been shown to increase fat "browning", thus modifying the metabolically harmful effects of white adipose tissue.[25,26]

Based on current data, CRF and adiposity in the case of the MHO phenotype are closely interrelated, with significant evidence for amelioration of the risks of CVD related to excess BMI with higher levels of CRF found in the MHO population. When discussing the MHO phenotype, it is thus important to note that the interpretation of MHO as a "preserved state of health associated with excess BMI" is a fallacy, and to use available data to focus on the health benefits related to higher CRF[27–29] and reduced visceral adiposity.[2]

62.5 THE OBESITY PARADOX

There is a growing body of evidence of survival benefits associated with obesity (as measured by BMI) in populations with chronic disease—a phenomenon termed the OP. Despite a shorter life expectancy in many large cross-sectional trials, those who are obese and overweight have been found to have decreased mortality risks in chronic disease populations when compared with normal-weight

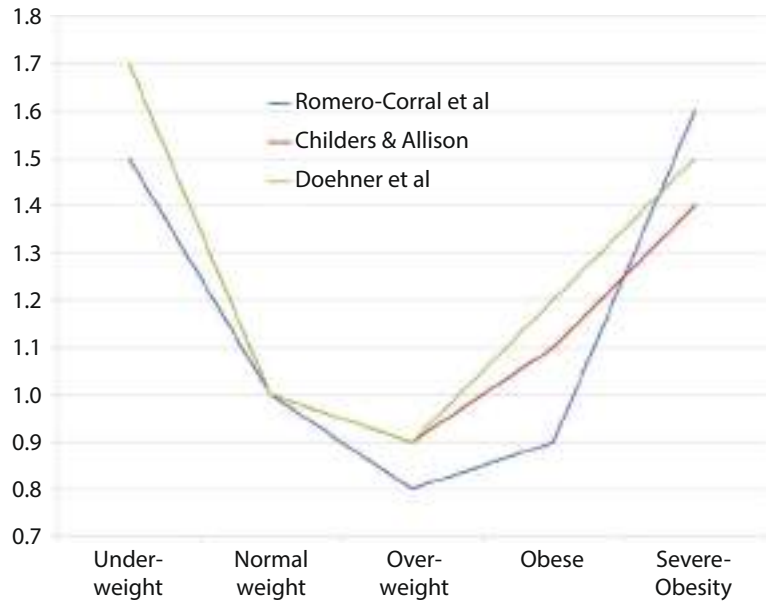

FIGURE 62.3 Mortality modification based on BMI in populations with CHD.

TABLE 62.1
Postulated Mechanisms of the Obesity Paradox

BMI is a poor measure of adiposity	
	Protective effects of lean mass confound deleterious effects of BF
	Higher BMI is associated with higher fitness due to increased muscle mass
Lean mortality	
	Catabolism of chronic disease benefits disproportionately from metabolic reserves of BF
Selection bias	
	Obese individuals enter the health system at a younger age and receive treatment earlier in the disease process
Anti-inflammatory	
	Adipose tissue secretes soluble TNF-R which provides an anti-inflammatory effect

individuals.[30–33] In the majority of these studies, the nadir of mortality occurs in the overweight group, with a U and/or reverse-J-shaped distribution of increasing mortality as BMI values diverge in the positive and negative directions (Figure 62.3).[34–36]

There are several proposed causes for the existence of the OP (Table 62.1). One view is that obesity changes neuro-endocrine profiles in a manner that may be protective.[37] Adipose tissue produces soluble tumor necrosis factor-α receptors which may be protective as a method of sequestration of free TNF-α in obese patients.[38] When it comes to hypertensive mechanisms, overweight and obese patients appear to have lower levels of circulating atrial natriuretic peptides, have attenuated sympathetic nervous system and renin-angiotensin responses, and their higher circulating volume and levels of sympathetic activation may allow tolerance of higher doses of cardio-protective medications (leading to a better prognosis in HF patients).[39] Another postulated mechanism is that higher circulating lipoproteins in obese patients may bind and detoxify lipopolysaccharides (super-antigens that trigger innate immunity cascades), serving as a protective mechanism against inflammation-mediated damage.[40] The most commonly cited argument for the existence of the OP is the one of metabolic reserve; that in the catabolic state characterized by chronic disease, additional body mass serves as a metabolic reserve that delays the catabolism of vital metabolites such as proteins. Conversely, the "lean paradox", a term used to describe individuals with low body fat and BMI, may identify more pertinent predictors of poor reserve and CVD outcomes.[41]

In order to better understand the effects of weight on mortality when discussing the OP, it is prudent to focus on weight trajectory rather than a static reading of BMI. In doing so, chronically ill individuals can be divided into two distinct groups: those with increasing BMI and those with decreasing BMI. On the positive end of the spectrum, the effects of increasing weight are divided between beneficial aspects of increased LM and deleterious effects from excess BF. As mentioned earlier, increases in LM are often accompanied by higher CRF and improvements in metabolic reserves, without the deleterious effects of excess BF.[42,43] In a study of nearly 10,000 patients with known or suspected CHD, only those in the bottom 20th percentile for age and gender levels of CRF demonstrated an OP, which was present by BMI, %BF, and even with WC.[44] In those with lower CRF, such as the morbidly obese, increasing BF (usually visceral adiposity) is closely linked with increases in the markers of MetS and associated CVD risks and mortality.[45,46] The OP was significantly observed in a large cohort of 6500 CHD patients from Norway followed for 13 years.[47] The OP was only present in those who did not meet the

international PA guidelines, and in this group, higher BMI was protective against mortality. However, in those who met the PA guidelines, survival was much better and BMI did not impact survival.[12] In a Norwegian follow-up study over 16 years, 3300 CHD patients were assessed for changes in BMI and PA. This study showed that changes in PA were much more predictive of survival than changes in BMI.[48] In no group was weight loss associated with improved survival. In fact, in those with "normal" BMI, weight gain was associated with improved survival and weight loss with reduced survival. Maintaining or increasing PA was associated with better survival in CHD.[13]

On the other end of the BMI spectrum, individuals who are losing mass do so in terms of either adiposity alone or adiposity with concomitant losses in LM. Evaluating the effects of weight loss on mortality has been challenging as many studies have shown higher mortality with observational weight loss, especially in the elderly population.[49,50] Yet, others have demonstrated that intentional weight loss leads to lower all-cause and CVD mortality risks.[51,52] This variability in results implies confounding factors, which have been explored in a series of studies. These categorize weight loss by categories that help discriminate between individuals who are losing BF as the result of increasing CRF, and those with unintentional weight loss characteristic of end-stage disease. The Tecumseh Health and Framingham did this based on weight loss versus fat loss and found that weight loss increased risk of death by 29–39%, while fat loss reduced risk of death by 15–17%.[53] An alternative approach has been to define intentional versus unintentional weight loss. In a nine-year follow-up of subjects enrolled in the National Health Survey, intentional weight loss lowered the mortality rate by 24% (HR 0.76; 0.60–0.97), while unintentional weight loss had a 31% higher mortality rate (HR 1.31; 1.01–1.70).[54] Wannamethee and colleagues further delineated intentional weight loss into medically prescribed weight loss and elective weight loss, finding that those losing weight intentionally had a significantly higher risk for mortality when medically prescribed than when adopted as an elective lifestyle change (RR, 0.59; 95% CI, 0.34–1.00; p = 0.05) vs (RR, 1.37; 95% CI, 0.96–1.94).[51] When measured in the setting of cardiac rehabilitation (CR), weight loss was associated with a significantly lower rate of CVD regardless of baseline BMI (HR = 0.62; p = 0.018).[55] Hamer and O'Donovan studied weight loss in the elderly in the framework of sarcopenia as measured by grip strength, thus comparing those in the lowest handgrip tertile with those in the highest. The lowest risks of mortality were in populations with stable weight and/or grip strength, whereas those losing either weight or grip strength had a significantly higher risk than the former (HR: 2.21; 95% CI: 1.32, 3.71), and the highest risks were found in elderly individuals with both weight loss and reduced strength (HR: 3.77; 95% CI: 2.54, 5.60).[56]

In regard to CHD, interventional trials of medical weight loss have not demonstrated a clear reduction in rates.[12] In contrast, reduced CHD risk has been demonstrated in prospective studies comparing obese patients undergoing bariatric surgery with non-surgical management. Statistically significant decreased rates of CVD events were seen in the surgical arm with an average reduction of 10–40 kg versus 5–10 kg (medical arm).[57,58] It has been postulated that modest short-term weight loss may not be sufficient to overcome the long-term negative effects of obesity as it pertains to the vasculature.

Farnaz and colleagues used a meta-analysis to evaluate the relationship of diabetes mellitus and obesity by BMI to HF-free survival. Men and women with no risk factors lived on average an additional three years to 15 years longer free of HF than those with risk factors, and in subgroup analyses, the authors found that obese individuals had shorter overall survival but lived significantly longer with HF than those without obesity.[59] Recent data has also suggested that higher BMI is more strongly associated with the risk of heart failure with preserved ejection fraction,[60] independent of other CVD risk factors. In subgroups with severe obesity, weight loss after bariatric surgery increases NT-proBNP levels concomitantly with improved left ventricular diastolic dysfunction. [61]

In summary, the OP is most apparent in the unfit elderly population, a group that is characterized by increasing sarcopenia as a manifestation of declining function and metabolic reserves.[62] As chronic disease develops, increased BMI is beneficial for survival in populations where BF offsets losses in LM and CRF.[63] Thus, BF is a double-edged blade, accelerating the process of developing chronic diseases, but allowing more time as CRF is eroded by the catabolic strain of chronic disease. Data supports that increases in LM are beneficial regardless of age and disease status and that the ultimate modulator of morbidity and mortality effects (i.e., biological age) appears to be bariatric surgery[12,13] and CRF.[64] When counseling the younger individual, there is increasing evidence for the long-term risks associated with excess body weight.[11] As such, younger patients should be counseled on the benefits of aggressive weight loss, especially in conjunction with physical activity (PA).[11] Since the data on weight loss is more circumspect in the elderly population, focusing counseling sessions on increasing PA would avoid the uncertainties associated with the effects of weight loss entirely.

62.6 PHYSIOLOGIC EFFECTS OF EXERCISE

As discussed above, CRF modulates the adverse effects of adiposity and MetS. CRF is maintained through PA, which in today's largely sedentary societies commonly stems from voluntary (rather than occupational) exercise training (ET). The benefits of ET are derived from modulating inflammation, decreasing adrenergic tone, and facilitating metabolic homeostasis across multiple organ systems.

ET modifies the deleterious effects of increased sympathetic tone by increasing sympatho-vagal signaling and associated parasympathetic activation. This manifests as increasing heart rate variability and decreasing blood

pressure (BP), which confer a better CVD prognosis.[65] Furthermore, ET-associated antioxidant production reduces systemic inflammatory markers in physically active people with CHD and reduces HTN by reducing oxidation-mediated nitric oxide scavenging.[66–68] Both BP and heart rate also benefit from decreased resting sympathetic activation by decreasing angiotensinogen II-mediated increases in systemic vasoconstriction and through noradrenaline suppression by plasma adrenomodullin, renalase, and atrio-natriuretic-peptides.[69,70]

Mitochondria provide energy and antioxidant capacity in most human tissues. Age-related impairment of function and decreasing numbers of these organelles results in damage to existing proteins and DNA and reduces the ability of myocytes to counter stress, such as myocardial infarction. Increased metabolic demands during exercise, and upregulation of signaling molecules such as insulin-like-growth-factor-1 increase mitochondrial division and modify energy pathways within the organelles to improve metabolic efficiency.[71,72]

Higher levels of PA have been shown to reduce the development of HF and improve prognosis in HF, regardless of BMI.[73] For those with advanced HF, Class III obesity is a relative contraindication for heart transplantation and in some institutions, ventricular assist devices (VAD). In those respective individuals who do on to get a VAD, adverse drive-line associated events are commonly observed.[74] Furthermore, advanced HF is typically a contraindication for bariatric surgery, leading to a "Catch-22". Of note, a recent retrospective study showed reduced HF hospitalizations in HF patients who underwent bariatric surgery.[75] Limitations in this study were the lack of representation of the most at-risk populations including the elderly and those with advanced HF.[17] For elderly obese subgroups at risk for HF, more studies are needed to identify methods for maintaining weight and improving functional outcomes as opposed to weight loss alone.

In summary, ET reduces resting systolic BP and heart rate, increases physical work capacity via decreased myocardial oxygen demand (i.e. rate-pressure product) at fixed submaximal workloads, and is associated with modest reductions in total cholesterol and low-density lipoprotein cholesterol. In HF, ET improves prognosis and confers risk reduction and bariatric surgery has been shown to reduce HF hospitalizations. Together, these effects translate into lower rates of CVD.[76,77]

62.7 MODIFYING LIFESTYLE

Although obesity may be associated with survival benefits in those with chronic disease, the combination of altered hemodynamics, endocrinopathy, and inflammatory effects of free fatty acid metabolism combine to significantly shorten life expectancy in the healthy population.[59] As discussed previously, both intentional weight loss and maintenance of CRF have been shown to reduce CVD risk factors associated with obesity, and as a result, PA/ET is highly recommended for health maintenance and CVD prevention.[54,77–79]

Dietary control is one of the cornerstones of modern weight-loss approaches. All diets, regardless of macronutrient composition, can produce clinically meaningful weight loss (>5%) if they induce a deficit of ≥500 kcal/d.[80] However, these have to be accompanied by appropriate macronutrient supplementation to prevent pro-arrhythmic adverse effects.[81]

Health maintenance through ET has been another cornerstone of managing body weight. Although the benefits of weight loss are scrutinized closely because of the OP and MHO, maintenance of CRF through PA/ET has unequivocally shown health benefits. In addition to improvements in mortality, PA/ET is associated with dose-response reductions in HF and CHD, with additional benefits to functional metrics like grip strength, balance, and cognition.[82–84]

In counseling patients on ET, the mode and duration of therapy should be discussed in order to maximize benefits and tailor recommendations to a patient's lifestyle. Modes of ET currently fall into one of two major approaches: moderate-intensity continuous training (MICT) and high-intensity interval training (HIIT). MICT has been the gold standard of CR ET programs and involves continuous maintenance of workload at an intensity of 50–65% of the peak, often measured as peak O_2 uptake or peak heart rate. HIIT protocols consist of shorter high-intensity intervals (75–95% of maximal effort) interrupted by periods of rest.[60] Over the last decade, HIIT has been shown to have significant metabolic advantages to MICT therapy. Specifically, HIIT protocols produce greater improvements in CRF and have comparatively beneficial effects on metabolic derangements, such as insulin resistance, and some data suggest mortality improvements are greater with HIIT regimens.[85–88]

When discussing the duration and frequency of ET, more has not been shown to be better. Although there is evidence of a linear improvement in HF risk with increasing ET, most studies suggest a plateau of benefits. For CHD the plateau is at about 5000 metabolic equivalent unit (MET) minutes per week.[82,89] Likewise, continuous exercise exceeding 9–10 METs was not shown to improve all-cause mortality in comparison with lower intensities.[90] In women, exceeding exercise frequency of two to three times per week had significantly higher associations with CVD events.[91]

In terms of duration, 50 minutes per session appears optimal for moderate-intensity endurance exercise.[92] This is even lower for HIIT, as such protocols have shown improvements in muscle metabolism, CRF (based on oxygen uptake), and insulin sensitivity in a fraction of the exercise time (as little as ten minutes) of MICT protocols.[93–95]

Current American Heart Association (AHA) guidelines for regular PA summarize this data well: ≥30 minutes of moderate-intensity aerobic PA at least five days per week for

a total of 150 minutes/≥25 minutes of vigorous aerobic PA at least three days per week for a total of 75 minutes along with moderate- to high-intensity muscle-strengthening activity at least two days per week for additional health benefits.[96] These recommendations are delineated simply in an infographic that can be found on the AHA website (www.heart.org/HEARTORG/HealthyLiving/PhysicalActivity/American-Heart-Association-Recommendations-for-Physical-Activity-Infographic_UCM_450754_SubHomePage.jsp).

Most successful lifestyle modification approaches have revolved around persistent (≥14 treatment visits), supervised high-intensity lifestyle interventions that combine dietary counseling and planning, scheduled moderate-to-vigorous PA, and behavior therapy.[80] In many cases, obese individuals can lose between 6% and 8% of initial weight after six months, which decreases the risk of MetS, HTN, and dyslipidemia.[97] Greater than 150 minutes per week of PA alone usually yields modest short-term weight loss compared with diet but still provides significant benefit to obesity-related conditions.

Although regaining weight after lifestyle intervention is common, it can be prevented by continued participation in monthly weight loss maintenance sessions and regular PA/ET.[86]

62.8 CONCLUSIONS

Obesity causes alterations in homeostasis through numerous mechanisms affecting most organ systems. Thus, the most effective therapies are preventive—taking the form of lifestyle modification. In patients with CHD and HF, these measures when combined with bariatric surgery have been shown to improve CVD outcomes. Counseling persons on the dangers of obesity along with the necessity for weight loss and PA/ET has been somewhat confounded by the concepts of MHO and OP. In evaluating the root causes, mechanisms, and patterns associated with both MHO and OP, obesity is detrimental and benefits are closely related to low CRF and increased visceral adipose tissue. In counseling individuals, it is important to review the role of CRF in modifying disease states and to emphasize that healthy weight loss (increases in PA/ET/CRF with concomitant decreases in BF and increases in LM) is the best way to improve outcomes related to chronic diseases and reducing mortality risk (Table 62.2).

TABLE 62.2
Clinical Applications

Counseling the controversies	
Effects of excess mass are deleterious from:	
Increased sympathetic tone causing hypertension	
Increased inflammation and cholesterol dysregulation predisposing to CHD	
The obesity paradox predisposes to chronic disease:	
Protective in chronic disease associated with low CRF	
Associated with shorter disease-free and cumulative lifespan	
The Metabolically Healthy Obese	
Predisposes to CVD and HF, though to a lesser degree than alone metabolic syndrome	
Exercise Recommendations	
	≥ 30 min MICT for ≥5 days per week for ~150 min
OR	≥ 25 min HIIT for ≥3 days per week for ~75 min
AND	moderate/high-intensity muscle-strengthening activity at least 2 days per week
Dietary Recommedations	
Calorie deficit ≥500 cal per day with balanced diet	
Effective strategies	
Supervised dietary and exercise program consisting of multiple weekly sessions over several months and monthly reinforcement thereafter

63 Vitamins and Supplements: Evidence in the Prevention and Treatment of Cardiovascular Disease

Jenna M. Holzhausen, PharmD, BCPS and Aaron D. Berman, MD, FACC

KEY POINTS

- Unlike prescription drug products, dietary supplements are not required to be proven safe or effective prior to reaching the consumer.
- Despite a lack of quality evidence supporting benefit, it has been reported that approximately one-half of US adults take a dietary supplement.
- In instances in which randomized trials are available, data is often conflicting and left to the patient and/or clinician to interpret.
- Clinicians may assist patients with supplement selection by becoming familiar with current evidence and national organization recommendations, evaluating potential drug-drug interactions, and educating the patient to look for over-the-counter products with a "seal of approval", indicating more stringent quality testing has been performed.

63.1 INTRODUCTION

Cardiovascular disease (CVD) is the leading cause of mortality worldwide, accounting for 18.6 million deaths in 2019.[1] In an attempt to prevent or treat CVD, many patients have turned to vitamins and supplements as an easily accessible option. Despite the valuation of the 2021 global supplement market at over $150 billion,[2] the clinical benefits of available formulations remain unclear due to a paucity of controlled clinical trials and heterogeneity among study populations. Additionally, the benefits observed with dietary intake are often inappropriately assumed to extend to supplementation in tablet or capsule form. In this chapter, we summarize existing evidence regarding the use of common vitamins and supplements for primary and secondary prevention of CVD to assist the clinician with assessing the appropriateness of supplementation.

63.2 MULTIVITAMINS

Multivitamins (MVIs) are the most commonly utilized dietary supplement in the United States, with approximately 40% of adults aged 60 years or older reporting use during 2017–2018.[3] The combinations of vitamins, minerals, and/or herbs are intended to promote adequate nutritional intake while preventing or correcting nutritional deficiencies secondary to poor adherence to dietary guidelines. Several potential benefits to MVI use have been suggested, including a reduction in cancer rates, mortality, and risk of cardiovascular disease. Despite annual MVI sales in the billions,[2] the evidence regarding cardiovascular benefit is contradictory.[4–15] The US Preventive Services Task Force (USPSTF) recently published a recommendation statement[16] regarding MVI use in which they conclude evidence is insufficient to determine the benefits and harms of MVI supplementation for the prevention of cardiovascular disease. Available randomized controlled trials[5,6,13,14] have demonstrated no difference in CVD outcomes compared with placebo, despite one trial reporting a trend toward reduction in fatal myocardial infarction (MI) with MVI use.[13] Notably, the largest of these trials[14] only followed patients for a median of 3.6 years, which was likely too short to see an effect. Several observational studies have suggested an inverse association between MVI use and coronary artery disease (CAD) incidence and/or CAD-associated mortality,[4,7,11,15] whereas others have found no association.[8–10,12] Randomized controlled trials evaluating extended MVI use in subjects representative of the general population are needed before MVIs may be routinely recommended for primary prevention of cardiovascular disease.

63.3 INDIVIDUAL VITAMINS

Vitamins that have been postulated to play a role in the primary and secondary prevention of cardiovascular disease include folic acid, niacin, and vitamins C, D, and E.

63.3.1 Folic Acid

Folic acid (vitamin B9) is Food and Drug Administration (FDA) approved for the treatment of megaloblastic anemia and supplementation has been shown to be dramatically beneficial for preventing neural tube defects when administered to pregnant women.[17,18] Folate is a cofactor in the only methyl-donating pathway in humans, facilitating homocysteine remethylation to methionine and synthesis of DNA,

DOI: 10.1201/9781003227793-74

phospholipids, proteins, and neurotransmitters.[19] Inborn errors of metabolism and/or dietary vitamin deficiencies may result in excess serum levels of homocysteine. Extreme homocysteine elevations (>100 μmol/L) are associated with premature vascular disease and may be caused by homozygous genetic defects in one of three enzymes: cystathionine beta-synthase, methionine synthase, or methylenetetrahydrofolate reductase.[19,20] Whether the heterozygous condition of these abnormalities or moderate homocysteine elevation is associated with the development of premature vascular disease has been studied extensively with conflicting results.[21,22] Meta-analyses have suggested a 25% lower plasma homocysteine level decreases the risk of ischemic heart disease by 11% and stroke by 19% among individuals in prospective trials (following adjustment for known cardiovascular risk factors)[23] and that a folic acid dose of 0.8 mg daily is sufficient to maximally reduce homocysteine levels.[24] Unfortunately, early secondary prevention trials failed to define any benefit of homocysteine-lowering by vitamin supplementation, although it has been suggested they lacked sufficient statistical power to detect an association between B-vitamin treatment and decreased cardiovascular endpoints.[25] Results may have also been confounded by the 1996 FDA-mandated supplementation of grain products in the United States, which resulted in a 7% reduction in homocysteine in middle-aged and older adults, rendering additional folic acid supplementation less effective.[26]

In addition to lowering homocysteine levels, folic acid may exert a direct effect on endothelial function. In a double-blind crossover study of post-MI patients, folic acid 10 mg daily improved flow-mediated arterial dilatation (FMD) as measured by forearm brachial reactivity. Interestingly, improvement in FMD persisted after crossover with placebo but did not correlate with baseline homocysteine levels or reductions in homocysteine.[27] A subsequent meta-analysis of 611 participants in eight studies confirmed these findings.[28]

Despite average homocysteine reductions of 25% with folic acid supplementation,[29] a CVD or mortality benefit has not been consistently demonstrated when utilized for primary or secondary prevention. The largest meta-analysis to date[30] included 30 randomized trials incorporating 82,334 participants and identified a 10% lower risk of stroke and 4% lower risk of CVD with folic acid supplementation of 0.5 to 15 mg daily (with one study of end-stage renal disease patients receiving 40 mg/day). Among patients without pre-existing CVD (ten trials), folic acid supplementation reduced the risk of CVD by 10% in patients with renal disease and 20% in patients without cardiovascular or renal disease, suggesting a primary prevention effect. Findings in earlier meta-analyses of chronic kidney disease patients, however, were conflicting, with two observing no stroke, CVD, or mortality benefit with supplementation,[31,32] while another suggested a 10% CVD risk reduction.[33] Meta-analyses in patients with pre-existing CVD suggest decreased stroke risk with supplementation,[34,35], with greater benefits observed in populations with no or partially fortified grain, those achieving homocysteine reductions of ≥25%, and in individuals receiving <2 mg folic acid per day. No benefit has been observed in terms of cardiovascular events or mortality.[29,35] Importantly, no signal of harm has been noted with folic acid, with the exception of a potential increase in late diameter loss and increased restenosis in patients with bare metal coronary stents.[36]

In summary, the evidence for the cardiovascular benefits of folic acid supplementation remains inconclusive, but use has been suggested for both primary and secondary prevention. The absence of large randomized controlled trials makes recommendations for folic acid supplementation speculative, though risk of harm seems low.

63.3.2 Niacin

The finding that reduced high-density lipoprotein (HDL) and elevated low-density lipoprotein (LDL) cholesterol levels increase CVD risk dates back to the Framingham study.[37] Niacin (nicotinic acid, vitamin B3) has been found to raise HDL cholesterol while decreasing LDL and triglycerides. In addition, it lowers lipoprotein(a) levels by approximately 23%.[38] The Coronary Drug Project (1966–1975) assessed the effect of five drugs, including niacin, on the prevention of cardiovascular events in men with previous MI.[39] Although no survival benefit was noted with niacin 3 g/day vs. placebo, the incidence of non-fatal MI was reduced. Interestingly, mortality was 11% lower in the niacin group at a 15-year follow-up, despite discontinuation at study end.[40] In 2001, niacin plus simvastatin was shown to decrease angiographic CAD progression and hard endpoints.[41] Other early niacin trials also described angiographic benefits and decreased clinical endpoints without concomitant statin therapy. Given its beneficial effects on lipid profile and early encouraging studies, high-dose niacin has historically been widely used for patients with vascular disease and primary prevention in high-risk patients with adverse lipid profiles.

More recent studies, however, have cast doubt on niacin's ability to decrease cardiovascular morbidity and mortality. The AIM-HIGH study[42] examined the effects of niacin in patients already on simvastatin therapy with or without ezetimibe. Despite favorable lipid profile changes, niacin had no effect on the composite endpoint of death from coronary heart disease, non-fatal MI, ischemic stroke, hospitalization for unstable coronary syndrome, or coronary or cerebral revascularization. Of note, the mean treatment time was only three years, which perhaps was not long enough to show benefit. The HPS2-THRIVE study,[43] which compared niacin plus laropiprant (to reduce flushing) with placebo in over 25,000 patients with vascular disease, further brought the use of niacin into question. Patients receiving lipid-lowering therapy more potent than in AIM-HIGH (simvastatin 40 mg with ezetimibe 10 mg) were excluded. Again, no effect on cardiovascular outcomes was observed, but treatment was associated with an increased risk of adverse effects. Recent meta-analyses have also failed to

demonstrate a benefit to niacin for primary or secondary prevention with regard to all-cause or cardiovascular mortality, stroke, or fatal/non-fatal MI, with the exception of a potential decrease in non-fatal MI in patients not receiving statin therapy.[44,45]

Are we done with niacin? A recent review points out several issues with the newer studies.[46] One reason cited for niacin failure is that all patients were treated with background statin therapy in the two most recent trials. In addition, patients in the AIM-HIGH and HPS2-THRIVE trials had relatively good baseline lipid levels and may not represent the dysmetabolic population that is generally considered for niacin use. On the other hand, both trials used simvastatin instead of atorvastatin or rosuvastatin, which are the "high-intensity" statins recommended by current guidelines.[47] The use of more potent agents may further diminish any additional niacin benefit.

Niacin clearly has beneficial effects on LDL, HDL, triglycerides, and lipoprotein(a). It may be that the proper target population, with severe atherogenic dyslipidemia (low HDL with high triglycerides and small dense LDL), may benefit from niacin therapy. These trials have yet to be done, and at least for now, niacin therapy may be relegated to patients who have excessively high (> 500 mg/dL) levels of triglycerides or who are unable to tolerate statins (or more preferred alternatives) and considered for those with severe dysmetabolic atherogenic lipid profiles.

63.3.3 Vitamin C

Vitamin C (ascorbic acid) is an essential water-soluble vitamin that must be obtained from dietary sources. Mechanisms by which vitamin C has been proposed to reduce cardiovascular risk include: reducing atherosclerotic lesion formation by inhibiting low-density lipoprotein oxidation; acting as an antioxidant in the plasma; and enhancing endothelial nitric oxide synthase activity to increase circulating nitric oxide levels.[48–50] It has been suggested vitamin C intake of approximately 100 mg/day is sufficient to confer cardiovascular protection for non-smoking individuals.[51] The use of vitamin C and other antioxidants for the prevention of CVD remains controversial, as results of clinical trials have been conflicting.

Observational studies have demonstrated inverse relationships between vitamin C concentrations or intake and blood pressure[52,53] and some evidence suggests vitamin C supplementation may reduce the risk of cardiovascular-related death in patients with low dietary intake.[54–58] However, supplementation has not been shown to reduce cardiovascular events or mortality in randomized controlled trials[59–61] and large population-based studies evaluating the effect of vitamin C intake on mortality have yielded conflicting results.[54,62–70] Recent meta-analyses have concluded vitamin C supplementation, alone or in combination with other antioxidants, does not significantly affect mortality in healthy subjects or those with pre-existing disease states[71] or reduce CVD risk in healthy participants or in those at increased risk of CVD[72] suggesting lack of benefit for primary prevention. Of note, the findings of the second meta-analysis were based solely on one trial of male physicians, which limits generalizability. Although there is limited data regarding vitamin C supplementation in patients with pre-existing CVD, the majority of evidence suggests it does not prevent CVD progression or events.[69,73,74] Therefore, although vitamin C supplementation is unlikely to cause harm, it is not anticipated to be beneficial for patients with sufficient dietary intake.

63.3.4 Vitamin D

Vitamin D (25-hydroxy vitamin D) is primarily involved in calcium metabolism and bone homeostasis, but has been implicated in more wide-ranging effects, including the renin-angiotensin-aldosterone axis, and therefore hypertension and cardiovascular health. In addition, it has a role in diabetes mellitus, hyperparathyroidism, inflammatory response, and depression. Although vitamin D deficiency is prevalent worldwide, it remains unclear whether it is causative or simply associated with these conditions, and whether supplementation can reduce risk.

Several studies have linked deficiency to cardiovascular disease, including NHANES[75] which found an association between cardiometabolic disease and low vitamin D levels regardless of ethnic background, and the Framingham Offspring Study[76] in which low vitamin D levels were associated with a 53–80% increased risk of CVD development. A recent meta-analysis of prospective trials confirmed serum vitamin D concentrations were inversely associated with total CVD events and CVD-associated mortality.[77]

Basic animal and human research have suggested salutary effects of vitamin D supplementation, such as inhibition of the renin-angiotensin-aldosterone system and improved endothelial function in patients with low vitamin D levels.[78] However, beneficial effects of vitamin D supplementation on cardiovascular endpoints have not been demonstrated in the prevention of hypertension,[79] patients with heart failure[80] or individuals with vitamin D deficiency.[81] A meta-analysis of 21 randomized controlled trials including 83,291 patients found no benefit to vitamin D supplementation on the incidence of major adverse cardiovascular events, myocardial infarction, stroke, or cardiovascular or all-cause mortality.[82] The long-awaited VITAL trial,[83] a 25,871 patient 2×2 study of vitamin D 2000 IU per day and marine fatty acids, may have closed the door on the idea of vitamin D supplementation as a potentially beneficial intervention. After a median follow-up of 5.3 years, vitamin D supplementation failed to demonstrate benefit compared with placebo in terms of major cardiovascular events (with or without coronary revascularization), myocardial infarction, or death from cardiovascular causes.

Unlike efficacy of vitamin D supplementation, safety is well established. Increased cancer risk at very high vitamin D levels has been suggested, although studies have

been inconsistent. The Institute of Medicine[84] has defined a serum 25-hydroxyvitamin D level of over 50 ng/ml (125 nmol/L) as "potentially harmful" and it is felt supplementation of 2000 IU daily is well within safe limits. While generally agreed upon that vitamin D deficiency of <20–30 ng/ml (<50–75 nmol/L) should be treated for the prevention of bone disease, treatment for cardiovascular health, especially in patients without risk factors of deficiency, should not be recommended at this time.

63.3.5 Vitamin E

Vitamin E is a fat-soluble antioxidant that exists in several different forms (alpha-, beta-, gamma-, and delta-tocopherol and -tocotrienol). Although gamma-tocopherol is the most abundant formulation found in the human diet, many vitamin E supplements contain synthetic alpha-tocopherol, which is the most biologically active and the only formulation considered necessary to meet human dietary requirements.[85,86] It has been suggested vitamin E may slow or prevent the development of atherosclerosis via inhibition of LDL oxidation,[87] though it is unclear whether individual formulations may confer varying degrees of clinical efficacy.[88]

Despite the proposed mechanism by which vitamin E may be beneficial, the majority of available evidence suggests it is not effective for primary prevention of CVD in healthy or high-risk patients.[89–98] One exception is an analysis from the Women's Health Study (WHS), which found 600 IU of vitamin E (RRR-alpha-tocopherol) taken every other day for up to ten years reduced the risk of cardiovascular death by 24% in healthy women age ≥45 years.[92] However, there was no difference observed in the risk of other cardiovascular events, such as myocardial infarction or stroke, and a separate analysis of the WHS demonstrated the same vitamin E dose does not prevent the development of heart failure in this population.[99]

Existing clinical trial data also suggests vitamin E is not beneficial for secondary prevention of cardiovascular disease or events, including myocardial infarction, stroke, or death.[93,100,101] Supplementation has failed to demonstrate reduced progression of atherosclerosis in patients with pre-existing coronary artery disease or an ability to improve quality of life or functional indices of heart failure.[100–103] Additionally, a meta-analysis[71] conducted in 2012 found vitamin E supplementation, alone or in combination with other antioxidants, significantly increased mortality in healthy subjects and those with pre-existing disease states, though more recent meta-analyses have not reached this conclusion.[95,104] Based on the available evidence, the American Heart Association (AHA) and USPSTF currently recommend against utilizing antioxidants, such as vitamin E, for the primary or secondary prevention of cardiovascular disease.[16,105] Given the lack of proven benefit and potential increase in mortality with use, routine vitamin E supplementation should be advised against at this time.

63.4 DIETARY SUPPLEMENTS

The Dietary Supplement Health and Education Act of 1994[106] defines dietary supplements as products containing a dietary ingredient intended for ingestion to supplement the diet. In addition to vitamins, dietary ingredients may include amino acids, herbs, minerals, or other substances meant to add nutritional value. Supplements commonly touted as beneficial for cardiovascular health include coenzyme Q10, fish oil, red yeast rice, and selenium.

63.4.1 Coenzyme Q10

Coenzyme Q10 (CoQ10), or ubiquinone, is an endogenously produced fat-soluble antioxidant found in the mitochondria of the heart in high concentrations. It plays a role in the Kreb's cycle, serving as a cofactor in oxidative phosphorylation to enhance adenosine triphosphate (ATP) production, and has been demonstrated to have membrane stabilizing properties.[107] CoQ10 levels decrease with age and deficiency is associated with muscle weakness, fatigue, and soreness.[108] Additionally, it has been demonstrated that serum and myocardial CoQ10 levels are inversely associated with the degree of heart failure.[109–111]

There is low-quality evidence regarding the utilization of CoQ10 in healthy subjects for the primary prevention of cardiovascular disease. A Cochrane Review from 2013 identified only six small (n = 20–52) trials of CoQ10 100–200 mg taken daily for approximately three months, none of which reported cardiovascular events or mortality.[112] Meta-analyses evaluating the effect of CoQ10 supplementation on blood pressure have yielded conflicting results, with one reporting CoQ10 has the potential to lower systolic blood pressure by up to 17 mmHg and diastolic blood pressure by up to 10 mmHg and others reporting lesser or no benefit.[113–115] At this time, CoQ10 cannot be recommended for the primary prevention of CVD or hypertension treatment.

Although CoQ10 has been studied for secondary prevention of several cardiovascular disease states, the most evidence is available for use in the setting of acute MI and heart failure. When administered within the first 48–72 hours following myocardial infarction, CoQ10 120 mg/day has been found to reduce the incidence of angina, arrhythmias, and poor left ventricular ejection fraction (LVEF) compared with placebo after four weeks of treatment.[116] CoQ10 has also been demonstrated to reduce cardiovascular death, non-fatal MI, and total cardiac events at one year compared with placebo.[117] Reported fatigue was 6.8% in the CoQ10 group, as opposed to 40.8% in the placebo group, which may be due to CoQ10's role in ATP production. Large randomized controlled trials with a longer duration of follow up are required to confirm these results before CoQ10 may be routinely recommended following acute MI.

When added to conventional therapy, CoQ10 has been demonstrated to improve NYHA classification and symptoms of heart failure, decrease hospitalization rates, and improve quality of life in patients with NYHA Class II–IV

heart failure.[118–126] It has also been demonstrated to improve LVEF, cardiac output, and systolic wall thickening when 100–300 mg is taken daily for up to seven months, although data is conflicting.[127–131] It remains unclear whether CoQ10 may reduce heart failure-associated mortality.[132,133] While it may be considered as adjunctive therapy for heart failure, CoQ10 should not replace guideline-recommended therapies.

63.4.2 Fish Oil

Fish oil is a dietary source of omega-3 fatty acids. The two most commonly studied omega-3 fatty acids are eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), which are polyunsaturated long-chain fatty acids. The role of pharmaceutical-grade EPA/DHA for the treatment of hypertriglyceridemia (triglycerides >500 mg/dL) is well-established, with doses of 2–4 g/day associated with serum triglyceride reductions of 20–60%.[134] Despite several proposed mechanisms for benefit,[135] including triglyceride and blood pressure reduction, decreased inflammation, improved vascular function, and reduced platelet aggregation, the effect of supplementation on cardiovascular outcomes remains unclear.

The AHA currently recommends one to two 3.5-ounce servings of non-fried seafood per week based on evidence suggesting consumption of fish oil from dietary sources is associated with reductions in congestive heart failure, coronary heart disease (CHD), ischemic stroke, and sudden cardiac death, especially if replacing intake of less healthy foods.[136] This concept is echoed by the 2020–2025 Dietary Guidelines for Americans,[137] which recommend adults with and without CVD consume 8–10 ounces of seafood per week (based on age and target caloric intake), to provide an average of 250 mg or more per day of long-chain omega-3 fatty acids. Despite the benefits observed with dietary intake, however, fish oil supplementation of 1–4 g/day has not been shown to be beneficial for primary prevention of CVD in randomized controlled trials of patients without prior events, including those deemed to be at high cardiovascular risk.[138–141] Recent meta-analyses have also failed to identify a clear benefit of fish oil supplementation in individuals without pre-existing CVD.[142,143] Therefore, fish oil supplementation should not be routinely recommended for primary prevention.

An AHA scientific advisory regarding fish oil supplementation and the prevention of cardiovascular disease was recently published, which included analyses of secondary prevention of CHD and sudden cardiac death in patients with prevalent CHD.[144] The review included five randomized controlled trials (24,499 patients) utilizing an average omega-3 dose of approximately 1 g/day for a mean duration of two years (range 1–6.2 years). Two of the trials demonstrated a mortality benefit with omega-3 supplementation when administered following a recent myocardial infarction, whereas the other three trials did not observe a CVD benefit. A meta-analysis[145] of 20 RCTs of patients with prevalent CHD, at high risk for CVD, or with an implantable defibrillator (n = 68,680) was also included in the review and demonstrated a reduction in CHD death with supplementation. Based on this data, the AHA statement[144] concludes that omega-3 supplementation is reasonable for the secondary prevention of CHD death, but likely will not reduce the incidence of non-fatal myocardial infarction. Notably, the most convincing evidence supporting this recommendation was from trials conducted prior to 2002 and more recent meta-analyses have demonstrated little to no benefit of omega-3 supplementation for secondary prevention of CVD.[142,143,146]

In addition to considering omega-3 supplementation for secondary prevention, the AHA also concludes it is reasonable in patients with heart failure with reduced ejection fraction (HFrEF),[144] based on the results of the GISSI-HF trial.[147] This randomized controlled trial of ~7000 NYHA class II–IV heart failure patients demonstrated a 9% reduction in all-cause mortality and an 8% reduction in cardiovascular-related death or hospitalization with omega-3 1 g daily vs. placebo when taken for a median duration of 3.9 years. Of note, the majority of patients had an ejection fraction <40%, which limits generalizability to the entire heart failure population. A subsequent meta-analysis evaluating omega-3 supplementation in heart failure patients failed to identify reductions in first heart failure hospitalization or cardiovascular mortality with use but did observe a reduction in recurrent heart failure hospitalizations compared with placebo.[148]

63.4.3 Red Yeast Rice

Red yeast rice (RYR) has been incorporated into alternative medicine practices for centuries. Red yeast is the product of rice fermentation with the fungus *Monascus purpureus*, which results in the production of monacolins. Monacolins are known to inhibit HMG-CoA reductase, an enzyme involved in cholesterol synthesis. One of the monacolins produced, monacolin K (lovastatin), is available as a prescription medication. As a result, the FDA announced in 1998 that the products were subject to regulation, which prompted RYR product reformulations in the United States to remove monacolin K, though variable amounts may remain.[149–151]

Red yeast rice has been reported to reduce total cholesterol, LDL cholesterol, and triglycerides in a manner similar to statin therapy.[152] Favorable all-cause and cardiovascular mortality reductions have been reported when used for primary prevention and red yeast extract 1.2 g/day has been shown to significantly reduce coronary events, non-fatal MI, and all-cause and cardiovascular mortality in patients with a history of myocardial infarction compared with placebo when taken for an average of 4.5 years.[153–155] Of note, products utilized in these trials contained monacolin K and results cannot be extrapolated to products currently available in the United States. Therefore, RYR cannot be routinely recommended at this time.

63.4.4 Selenium

Selenium is a trace mineral that is a key component of several selenoproteins, including glutathione peroxidase and selenoprotein P.[156] It has been shown to increase enzymatic antioxidant activity and decrease lipid peroxidation at a dose of 100 µg/day,[41,157–159] and may play a role in neutralizing peroxide intermediates, resulting in the decreased production of inflammatory prostaglandins and leukotrienes.[160] Based on these known mechanisms, it has been hypothesized selenium may be beneficial for the treatment and prevention of CVD. However, the majority of clinical research suggests selenium is not beneficial for the primary prevention of CVD at doses of 100–800 µg/day.[161–163]

There is no data supporting selenium alone for the secondary prevention of CVD except in individuals with a severe deficiency at baseline, as has been observed in patients with Keshan disease, a cardiomyopathy found in areas of China with selenium-deficient soil.[164,165] In patients with pre-existing CVD, a combination of beta-carotene 25 mg, vitamin C 1000 mg, vitamin E 800 IU, and selenium 100 µg daily did not reduce the frequency of clinical cardiovascular events compared with placebo and actually reduced cardioprotective HDL-2.[41] Additionally, a prospective randomized controlled trial of 443 elderly patients (age 70–88 years) reported taking 200 µg of organic selenium yeast in combination with CoQ10 200 mg daily for an average of 5.2 years reduced cardiovascular mortality by 53% compared with placebo.[166] A multivariate analysis confirmed statistical significance following adjustment for several risk factors and a significant reduction in NT-proBNP was observed in the treatment group at 24 and 48 months. Although extensive prior cardiac history was not reported for the participants, 74% of the study population had a past medical history of hypertension, 23% had ischemic heart disease, and 48% were reported to have NYHA Class II or III heart failure. Interestingly, a mortality benefit continued to be observed in the treatment group at 10- and 12-year follow-ups, despite stopping therapy following the initial four-year intervention period.[167,168] Unfortunately, it is not able to be discerned whether the benefits observed were due to the selenium, CoQ10, or the combination. Therefore, selenium

TABLE 63.1
Main Adverse Effects and Considerations for Vitamins and Supplements Commonly Touted as Beneficial for Cardiovascular Disease Prevention or Treatment[171]

Vitamin/ Supplement	Main Adverse Effects and Considerations
Coenzyme Q10	The most common adverse effects are gastrointestinal, including nausea, diarrhea, heartburn, and appetite suppression. Hepatic insufficiency or biliary obstruction may cause accumulation. Insulin requirements in diabetic patients may be reduced.
Fish oil (omega-3)	Avoid use in patients with known fish or shellfish hypersensitivity. Gastrointestinal symptoms are common (burping, indigestion, altered taste). May increase LDL levels. May prolong bleeding time, resulting in increased bleed risk. Liver function test elevations have been reported; monitor if used in patients with hepatic impairment. There is a potential association between fish oil use and an increased risk of prostate and other cancers, although evidence remains inconclusive.[172–175]
Folic acid (vitamin B9)	Doses >0.1 mg may obscure pernicious anemia, which may allow the progression of irreversible nerve damage. Possible risk of late diameter loss and increased restenosis in patients with bare metal coronary stents.[36]
Niacin (vitamin B3)	Skin flushing/pruritis is common; increasing the dose slowly, administering with food, using slow-release formulations, and/or taking aspirin 30 minutes prior to a dose may help. May increase fasting blood glucose (generally <5%). Increases uric acid levels; use with caution if history of gout. Risk of myopathy increases when combined with statin therapy. Other adverse effects include atrial fibrillation, abdominal discomfort, loose stools, and hepatotoxicity (rare, but severe).
Red yeast rice	Contents of available products are highly variable. US formulations may or may not contain monacolin K (lovastatin)[149–151] Monacolin K-containing products may cause statin-like adverse effects, including myopathy, rhabdomyolysis, and hepatic toxicity. Some red yeast rice products contain citrinin, a contaminant that has been associated with the development of renal failure.
Selenium	Gastrointestinal adverse effects (abdominal cramps, diarrhea, nausea, vomiting) have been reported.
Vitamin C	May cause acidification of urine, leading to precipitation of cysteine, urate, or oxalate stones. Doses >2000 mg/day may cause serum glucose elevations and interfere with glucose monitoring. Individuals with glucose-6-phosphate dehydrogenase deficiency may experience hemolysis following administration.
Vitamin D	Avoid use in the setting of hypercalcemia. Toxicity may occur with excessive doses. Symptoms may last two or more months after discontinuation and include nausea, vomiting, loss of appetite, constipation, fatigue, dehydration, irritability, confusion, weakness, and/or weight loss.
Vitamin E	Some data suggest vitamin E may increase bleed risk. Other adverse effects associated with long-term use include headache, dizziness, weakness, and fatigue.

TABLE 63.2

Drug-Drug Interactions of Common Vitamins and Supplements Taken for Cardiovascular Disease Prevention or Treatment[171]

Vitamin/ Supplement	Interacting Drug(s)	Anticipated Effect(s)	Proposed Mechanism
Coenzyme Q10	Warfarin	Reduced anticoagulant effectiveness	Coenzyme Q10 has a similar chemical structure to vitamin K2
Fish oil (omega-3)	Anticoagulant and antiplatelet agents	Increased risk of bleeding	Decreased platelet aggregation due to decreased thromboxane A2 levels
Folic acid (vitamin B9)	Barbiturates/primidone	Decreased folic acid serum levels and decreased barbiturate/primidone effectiveness	Decreased folate absorption and increased barbiturate/primidone metabolism
	Fosphenytoin/phenytoin	Decreased folic acid serum levels and decreased phenytoin effectiveness	Decreased folate absorption and increased phenytoin metabolism
	Pafolacianine	Decreased detection of malignant lesions	Reduced binding of pafolacianine to folate receptors overexpressed on ovarian cancer cells
	Pyrimethamine	Loss of pyrimethamine efficacy	Pharmacodynamic antagonism of antiparasitic effects
	Tea (green or black)	Decreased folic acid exposure	Decreased folate absorption
Niacin (vitamin B3)	Bile acid sequestrants	Decreased niacin exposure	Decreased niacin absorption
	HMG-CoA reductase inhibitors ("statins")	Increased risk of myopathy or rhabdomyolysis	Unknown
	Insulin	Decreased blood glucose lowering effect	Unknown
	Warfarin	Increased risk of bleeding	Additive anticoagulation effect and decreased CYP450-mediated warfarin metabolism
Red yeast rice	Cyclosporine	Increased risk of elevated creatine phosphokinase; rhabdomyolysis	Inhibition of CYP3A4-mediated lovastatin metabolism
Selenium	Baloxavir marboxil	Decreased baloxavir concentrations	Chelation
	Eltrombopag	Decreased eltrombopag concentrations	Chelation
Vitamin C	Aluminum antacids	Aluminum toxicity (personality changes, seizures, coma)	Increased aluminum absorption
	Amphetamine	Decreased amphetamine levels and efficacy	Lower GI and urinary pH; increased renal excretion of amphetamine
	Amygdalin	Increased amygdalin metabolism, leading to increased cyanide levels	Increased amygdalin hydrolysis and hydrogen cyanide formation; reduced cysteine levels (detoxifies cyanide)
	Cyanocobalamin (Vitamin B12)	Reduced cyanocobalamin concentrations	Unknown
	Deferoxamine	Impairment of cardiac function	Increased iron availability for chelation
	Erythromycin	Decreased erythromycin efficacy	Unknown
	Indinavir	Decreased indinavir plasma concentrations	Increased CYP3A4-mediated indinavir metabolism
Vitamin D	Aluminum antacids	Aluminum toxicity (personality changes, seizures, coma)	Increased aluminum absorption
	Bile acid sequestrants	Decreased vitamin D exposure	Reduced vitamin D absorption
	Carbamazepine	Decreased vitamin D exposure	Increased vitamin D elimination
	Cimetidine	Decreased vitamin D exposure	Increased vitamin D elimination
	Fosphenytoin/phenytoin	Decreased vitamin D exposure	Increased vitamin D elimination
	Mineral oil	Decreased vitamin D exposure	Reduced vitamin D absorption
	Orlistat	Decreased vitamin D exposure	Reduced vitamin D absorption
	Phenobarbital	Decreased vitamin D exposure	Increased vitamin D elimination
	Thiazide diuretics	Decreased vitamin D exposure	Increased vitamin D elimination
Vitamin E	Bile acid sequestrants	Decreased vitamin E exposure	Reduced vitamin E absorption
	Orlistat	Decreased vitamin E exposure	Reduced vitamin E absorption
	Warfarin	Increased bleed risk	Unknown

cannot be routinely recommended at this time, except in individuals with (or at risk for) severe deficiency.

63.5 OVER-THE-COUNTER DIETARY SUPPLEMENT SELECTION

Unlike prescription drug products, dietary supplements do not undergo an FDA-approval process requiring proof of safety and efficacy prior to reaching the consumer. In fact, once a supplement is on the market, the FDA has to prove the supplement is *unsafe* in order to restrict its use or remove it altogether. Although the FDA issued a guidance on Current Good Manufacturing Practices in 2007[169] requiring dietary supplement manufacturers to establish quality standards for manufacturing, packaging, storing, and testing of ingredients, the FDA does not perform quality control testing or define what is considered "appropriate". Unfortunately for consumers, the lack of FDA regulation allows for varying degrees of quality control, which are largely manufacturer dependent, and makes it difficult to determine an individual product's quality based on its label alone. Educate patients intent on taking a dietary supplement to look for products with a "seal of approval" indicating the manufacturer voluntarily subjected the product to more stringent quality testing. Available approvals include the Consumerlab.com Approved Quality Product Seal, the NSF Mark, and the United States Pharmacopeia (USP) Verified Mark.

63.6 CONCLUSION

Although recent surveys have revealed approximately half of US adults take a dietary supplement,[3,170] there is little evidence supporting their use for the primary and secondary prevention of cardiovascular disease. In the rare instances in which well-designed randomized controlled trials are available, evidence is often conflicting. Although guidance statements or scientific advisories from national organizations are published for some of the supplements, it is often the patient and/or clinician who is left to interpret the available evidence. In addition to the clinical data presented, the main considerations and adverse effects should be reviewed prior to recommending therapy (Table 63.1). Although patients often view over-the-counter (OTC) supplements as benign due to their ease of availability, the potential for drug-drug interactions still exists (Table 63.2). Consistent with the mantra to "first, do no harm", the use of supplements must not distract the patient from adhering to optimal guideline-directed medical therapy. However, discretionary use of supplements that have no (or minimal) adverse effects may be considered in select patients.

CLINICAL APPLICATIONS

- Although evidence is inconclusive, folic acid may be beneficial for the primary and secondary prevention of cardiovascular disease.
- Niacin should be reserved for patients who are intolerant of statins (and more preferred alternatives), those with triglyceride levels >500 mg/dl, and individuals with severe dysmetabolic atherogenic lipid profiles.
- Vitamin E, alone or in combination with other antioxidants, has been associated with a potential increase in mortality and should be avoided for primary and secondary prevention of cardiovascular disease.
- Coenzyme Q10 may be reasonable to consider as adjunct therapy for heart failure patients but should not replace guideline-directed therapy.
- Omega-3 supplementation may be considered for the secondary prevention of cardiovascular disease, in the setting or HFrEF, or for the treatment of hypertriglyceridemia. If utilized, prescription products are preferred over OTC options.
- Despite favorable effects on cholesterol and evidence suggesting reductions in mortality, coronary events, and non-fatal myocardial infarction, red yeast rice supplementation cannot be recommended at this time due to the reformulation of US products to remove monacolin K.
- There is currently insufficient evidence to recommend for or against multivitamins, vitamin C, or selenium for the primary or secondary prevention of cardiovascular disease. Increasing evidence suggests vitamin D supplementation may not be beneficial.

64 Pediatric Preventive Medicine: An Introduction

Richard E. Boles, PhD, Jonathan R. Miller, PhD, and Stephen R. Daniels, MD, PhD

KEY POINTS

- Lifestyle medicine in pediatric populations has expanded from the prevention of future diseases to the treatment of diseases acquired during childhood and adolescence.
- Prevention and treatment efforts require behavior change on the part of the caregiver and child, which can be supported by healthcare practitioners.
- Behavior change strategies with the greatest empirical support stem from functional contextual approaches, such as operant psychology.
- A better understanding of behavioral principles will inform more effective strategies to promote lifestyle change.

Pediatricians have traditionally had a strong emphasis on prevention. Early in the history of pediatrics, these preventive efforts concentrated on infectious diseases, both by improved public health measures and immunizations. More recently, pediatricians have focused their attention on the prevention of chronic diseases. With the work of David Barker and others, it has become clear that the risk for the development of chronic disease starts in utero and is determined by exposures to the fetus and, subsequently, the child, as well as exposures through adolescence and into young adult life.[1,2] Many of these environmental exposures are often a result of lifestyle factors. This presents a tremendous opportunity, but also a tremendous challenge to change the trajectory of risk, by changing lifestyle behaviors.[3]

Although a traditional focus for the prevention of chronic disease has been on risk factors, with primary prevention being the approach to treating risk factors once they develop, the work of Dr. Stamler and others has shifted the focus to health factors or ideal health. Stamler and others have shown that if individuals can reach age 50 in ideal cardiovascular health, their subsequent risk of atherosclerotic cardiovascular disease is quite low.[4] Of interest is the fact that individuals with ideal cardiovascular health, defined as normal body mass index, normal blood pressure, normal cholesterol, no type 2 diabetes, and no cigarette smoking also have a quite low risk of cancer and other illnesses and have a greatly expanded life expectancy.[5,6] Beyond this, the quality of life and freedom from morbidity are also higher than for those who have lost ideal cardiovascular health.[7] In addition, the cost of healthcare is reduced in individuals with favorable cardiovascular health.[8–10] This approach to the prevention of the development of risk factors in the first place has been referred to as primordial prevention.[11]

An important consideration is the extent to which ideal cardiovascular health is determined by genetics versus environmental influences, such as diet, physical activity, and sleep.[12] Studies have shown that ideal cardiovascular health is only about 12–18% heritable.[11,13] This means that approximately 80–85% of ideal cardiovascular health is related to maintaining a healthy lifestyle through a healthful diet, regular physical activity, and quality sleep. These data create an imperative for those healthcare providers focused on children and adolescents. Most individuals are born with ideal cardiovascular health, as well as a healthy heart, vascular system, and other organ systems. However, this ideal health status is lost by many individuals during childhood and adolescence. Disturbingly, an increasing proportion of the pediatric population is exhibiting sufficiently poor lifestyle behaviors that diseases previously only seen in adulthood are presenting in childhood,[14,15] requiring efforts not just to prevent but also to treat. This is in part why so few individuals are able to reach the age of 50 in ideal health. Most estimates indicate that fewer than 5% of individuals at 50 years have maintained ideal cardiovascular health[14] Micha et al. have shown that dietary factors are associated with a substantial proportion of deaths from heart disease, stroke, and type 2 diabetes.[16] This means that it is the pediatrician's job and the job of other child health professionals to deliver as many individuals as possible into young adulthood with ideal health status. This goal can only be accomplished by promoting a healthy lifestyle for fetuses, infants, school-age children, and adolescents.

This section focuses on lifestyle medicine related to the pediatric population, including issues related to diet, physical activity, sleep, obesity, cardiovascular health, and bone health. This chapter focuses on the behavioral principles that can be utilized to promote optimum health behaviors and change health behaviors when necessary to improve lifestyle and health.

64.1 LIFESTYLE BEHAVIORS

Lifestyle behaviors, including diet, physical activity, sedentary behavior, and sleep, are often central to the prevention

DOI: 10.1201/9781003227793-76

or progression of multiple non-communicable diseases, including obesity, heart disease, cancer, obstructive sleep apnea, and diabetes. While the specific contributions of a single healthy behavior can have a positive impact on health (e.g., regular consumption of vegetables), optimal health outcomes will most likely result from maximizing the number of healthy lifestyle behaviors. Although there may be some overlap, the development of healthy lifestyle behaviors may be different than modifying an existing maladaptive lifestyle behavior. Moreover, a particular behavioral strategy used to maintain a healthy lifestyle behavior may differ from the method used to establish it in the beginning. The evidence to date for lifestyle interventions suggests targeting multiple behaviors over one behavior in isolation.[17–19] For adults, comprehensive lifestyle modification programs targeting obesity produced a 7–10% reduction in weight and meaningful changes in CVD risk factors.[17,19] Similarly, the strongest evidence to date for improving childhood obesity includes comprehensive and intensive behavioral interventions (>25 hours of contact) that target multiple lifestyle behaviors, engage both children and their caregivers, and result in typical BMI z-score reductions of 0.20 or more.[20]

The development or modification of healthy lifestyle behaviors has been studied across the spectrum of disease progression from pre-pregnancy to adulthood. Fostering healthy lifestyle behaviors early in life is a goal that has been well supported by the evidence showing increasing difficulty in reversing obesity once established in childhood that generally tracks into adulthood.[21–23] Systematic reviews on the prevention of childhood obesity have identified non-significant or small effect sizes for interventions, of which most study settings were school-based.[24] Notably, the most effective prevention programs included a home-based component with the school environment that suggests the effect of modifying lifestyle behaviors is maximized when multiple settings and agents of change are targeted.[24,25]

Conceptualizing relevant health behaviors within testable models remains a core task in the pursuit of preventing and treating diseases that are impacted by lifestyle behaviors. In the following section, we review models and principles of behavior related to lifestyle behaviors.

64.2 MODELS OF BEHAVIOR

Human behavior is complex, with a multitude of factors contributing to any given instance of behavior. While multiple theoretical models have been developed to understand behaviors, the evidence supporting each model varies in terms of behavioral changes, maintenance of changes, and health outcomes.[26,27]

64.2.1 Social-Ecological Model

Bronfenbrenner's social-ecological model has been extensively tested and adapted for understanding lifestyle behaviors.[28] The theory is founded on the principle that behaviors cannot be understood without considering their context. An individual, including the individual's biological environment, lies at the center of the model in which levels from the immediate external environment (family members and the home environment) are surrounded by more distal levels of influence such as peers and school environments. Finally, outer levels of influence are depicted, including neighborhoods, communities, regions, and policies that may influence behaviors.[29] Given that obesity and related comorbidities is a multifactorial disease in which preventive and treatment approaches are based on multiple components, the social-ecological model provides a well-matched, comprehensive view of the exposures and targets for such interventions to be tested.

However, a significant limitation of the social-ecological model is that, while useful for placing the development and progression of disease in the contexts that influence an individual's health, it does not directly identify interventions on how to modify these contexts to prevent or ameliorate disease and therefore lacks a practical quality.[30] Presumably, the ultimate goal of medicine is not just to understand health and disease but to act in order to improve the human condition. With lifestyle medicine, this is accomplished primarily through changing the behaviors of those in the contexts most proximal to health-related events (e.g., child *and* caregiver behaviors).[31] It seems a framework that incorporates the pragmatic goals of medicine and the explanatory benefits of examining behavior in context would be ideally suited to providing a foundation for the advancement of lifestyle medicine. Indeed, such an approach does exist[32] and has been central to many of the most successful strategies for behavior change, health-related and otherwise.

64.2.2 Functional Contextualism

Functional contextualism[33,34] is the philosophical framework that underlies operant psychology (learning theory) and the related field of behavioral economics, as well as psychotherapeutic practices, including acceptance and commitment therapy (ACT). It is founded on a pragmatic approach to knowledge and action, with a focus on predicting and influencing behavior by examining it relative to the context in which it occurs. Within this framework, behavior is conceptualized as an interaction between an individual and their environment—both internal (biological, psychological) and external (physical, social). In accordance with its pragmatic goal, principles of behavior are defined functionally, in terms of the effects of environmental events on behavior. This results in principles that are derived from effective action and are therefore readily applied to behavior change.

This framework is distinct from other models of behavior that have been applied to lifestyle medicine (e.g., theory of reasoned action/theory of planned behavior, stages of change), which often utilize correlational designs and cross-sectional data rather than experimental methods,[35,36] due to its emphasis on function. However, functional contextualism remains compatible with models that share a

context-based approach to examining behavior, such as the social-ecological model.

Although functional contextualism per se has not been widely discussed in relation to lifestyle medicine, the impact of approaches aligned with this philosophy is well documented. For example, patient adherence to recommendations is essential for effective intervention, as the behaviors needing to change typically occur outside of contexts where the provider directly interacts with the patient. In 2003, the World Health Organization (WHO) published a report on adherence to long-term therapies that, among other things, outlined patient-level interventions for improving adherence.[37] The report stated that "the most effective adherence-enhancing interventions directed at patients aim to enhance self-regulation or self-management capabilities" and that "such approaches are grounded in basic principles of learning" (p. 143). As such, we will review some of the fundamental principles developed within the functional contextual framework and highlight their relevance to behavior change in lifestyle medicine to inform readers' perspectives when reading subsequent chapters of this section and when practicing lifestyle medicine.

64.3 PRINCIPLES OF BEHAVIOR

The principles of operant psychology described below were empirically derived and validated through hundreds of experiments that methodically manipulated environmental events and observed consistent changes in behavior. This inductive approach has produced a robust, tightly interwoven conceptual system that is defined by its ability to predict and influence behavior.

The most fundamental and powerful concept of operant psychology for understanding and changing behavior is *reinforcement*. Reinforcement is the process by which a behavior is strengthened due to the consequence (environmental change) that follows it. Strengthening can occur as increased probability, duration, or magnitude of a behavior or as decreased latency for the behavior to occur in response to a stimulus. A critical feature of this definition is that it defines a functional relation—if a consequence does not strengthen the behavior, reinforcement, by definition, has not occurred. For example, if a child with diabetes was experiencing hypoglycemia (and its accompanying aversive physiological effects) ate some sugar (behavior), and then began to feel better soon after (consequence), eating sugar would likely be reinforced by the alleviation of the unpleasant symptoms; however, it would only meet the definition of reinforcement if the child's future behavior related to sugar intake (the behavior that produced the consequence) was strengthened, such as the child eating sugar more quickly when beginning to feel hypoglycemic or eating sugar more often to avoid symptoms of hypoglycemia.

A functional definition of reinforcement maintains the pragmatic goal of behavior change when applying this principle. Additionally, a number of structural distinctions have proven valuable when describing reinforcement and applying it to change behavior. First, the reinforcement process defining the environmental change that reinforces behavior can be considered in terms of the addition or subtraction of stimuli. When reinforcement occurs due to a stimulus being added to or increased in the environment following behavior, it is referred to as *positive reinforcement*. For example, if a parent was not paying attention to their child at a meal, the child began spitting out vegetables and then the parent started paying attention to the child, this would be positive reinforcement if the child became more likely to spit out vegetables during that or future meals. When reinforcement occurs due to a stimulus being decreased, removed, or avoided following behavior, it is referred to as *negative reinforcement*. The previous example of alleviation of hypoglycemia would be considered negative reinforcement.

Furthermore, categorizing consequences into two general classes based on the source of the event has also proved valuable in application. Social reinforcement involves events mediated by another person, such as the attention of the parent in the previous example about spitting out food (social positive reinforcement) or a patient who has been non-adherent to their lifestyle regimen canceling their doctor's appointment to avoid being admonished by their provider (social negative reinforcement). Automatic reinforcement occurs when the behavior itself produces the reinforcing event, such as when eating sugar automatically produces alleviation of hypoglycemia (automatic negative reinforcement) or eating palatable food produces pleasant stimulation (automatic positive reinforcement). A single instance of behavior can produce multiple environmental changes simultaneously, such that more than one form of reinforcement can occur concurrently. For example, spitting out food may produce both social positive reinforcement via gaining parental attention and automatic negative reinforcement via removing the disliked taste. Still, these distinctions are useful because they can help inform how one should alter the environment to produce behavior change.

Generally, when preferred events are presented following behavior it is likely to produce positive reinforcement and when unpleasant or aversive events are removed following behavior it is likely to result in negative reinforcement. However, assuming what an individual prefers or finds unpleasant is where therapeutic attempts to use reinforcement often fail. Strategies for identifying reinforcement for maladaptive behaviors (known as functional analysis or functional behavior assessment; see Beavers et al., 2013[38] and subsequently modifying reinforcement to increase adaptive skills (known as function-based treatment) have been developed elsewhere,[39] but have yet to be applied to lifestyle medicine, though examples of application exist.[40,41] Collaborations between current lifestyle medicine practitioners and applied behavior analysts (practitioners trained in operant psychology) may provide avenues by which such work and new clinical strategies could be accomplished.

For simplicity, the examples thus far have described reinforcement in terms of a single instance of a reinforcing

consequence following a behavior. Although a single behavior-consequence experience can reinforce behavior, repeated and ongoing association over time is typically needed to maintain behavior change long term. When a behavior continues to occur and the reinforcing consequence no longer follows, this will eventually lead to the *extinction* of the behavior, such that the behavior no longer occurs. Preventing a reinforcing consequence from following behavior (implementing the principle of extinction) is one of the most fundamental means of changing behavior; however, this can be challenging in application, as the availability of the consequence may not be readily altered (particularly with automatic reinforcement) and the individual may initially engage in increased or varied behavior in an attempt to obtain the consequence (known as an extinction burst). When the consequence intermittently follows behavior, this can lead to highly persistent behavior that is more difficult to change.

Another important concept is *punishment*. Punishment is the process by which a behavior decreases in strength due to the consequence that follows it. Like reinforcement, punishment takes positive and negative forms. In positive punishment, a stimulus is added or increased in the environment following behavior such that the behavior is weakened. In negative punishment, a stimulus is decreased or removed following behavior such that the behavior is weakened. Although we do not advocate for the use of punishment in lifestyle medicine, understanding that this process may already be impacting the health-related behaviors of patients is important. For example, teasing by peers (or concerns about this) may punish attempts to engage in group sports or other physical activities at school. Additionally, many medical procedures and lifestyle behaviors can automatically produce aversive stimulation for patients—whether it be medication side effects, blood draws, or the discomfort of physical exertion during exercise—which may punish the behaviors that produce these consequences, thereby contributing to non-adherence.

In addition to altering the strength of behavior, functional consequences (those that reinforce or punish behavior) can also affect the relation between other environmental stimuli and behavior.

As an individual engages in a behavior over time, they may learn that some stimuli are predictive that reinforcement is more likely and therefore become more likely to engage in that behavior when such stimuli are present. *Stimulus control* describes the increased probability of a behavior in the presence of a specific stimulus or set of stimuli (discriminative stimuli) due to a history of greater reinforcement following the behavior in the presence of those stimuli relative to their absence. For example, a child initially throws a tantrum when presented with non-preferred food at mealtime by either parent. Over time, Parent A occasionally gives in and lets the child choose another food to eat at a meal whereas Parent B never lets the child choose a more preferred food after a tantrum. Stimulus control for the child's tantrums is likely to develop so that they will be more likely to tantrum when Parent A presents a non-preferred food than when Parent B does because tantrums in the presence of Parent A are more likely to be reinforced with a more preferred food to consume.

Stimulus control can be a powerful way to influence behavior. Under strong stimulus control, the behavior may not occur unless the discriminative stimulus is present, such that the occurrence of behavior can be changed by altering when or how often the discriminative stimuli are presented. For example, when watching television, viewers are frequently presented with advertisements for energy-dense foods, which signal that these items are available at the sponsoring restaurant. The more frequently these advertisements are seen the more likely that the individual is to consume such items or similarly energy-dense foods.[42]

Essentially, any stimulus or event can participate in stimulus control if it is differentially associated with the probability of reinforcement for a behavior. In particular, reinforcing events themselves can often serve as discriminative stimuli, as their presence tends to be associated with an increased likelihood of additional reinforcement. For example, the presence of highly palatable food (stimulus) is often discriminative for the ability to eat it (behavior) and thereby experience the pleasant taste (consequence). Rules, instructions, and other verbal statements can also function as discriminative stimuli and can often quickly establish stimulus control if the individual has well-developed language skills and the behavior (or component skills for the behavior) is in the individual's repertoire. However, the ability of such stimuli to function as discriminative stimuli is highly dependent on a person's history of reinforcement following similar events. Simply telling a parent or child to do something obviously does not guarantee that they will, but they will be more likely to follow new recommendations if they have experienced reinforcement for following other recommendations. Additionally, stimulus control can be highly specific, as any change in the context may disrupt this process. For example, learning how to take a blood glucose test in the provider's office may not generalize to home. In fact, generalization (learning from a training environment being expanded to a natural environment across individuals, settings, or behaviors) ideally should be programmed into an intervention and not simply be expected to occur.[43]

Other environmental events that precede behavior can also influence their occurrence. *Motivating operations* (MOs) are events or conditions that alter the efficacy of a given consequence for strengthening (or weakening) behavior, as well as influence the likelihood that behavior will occur.[44] Deprivation from a preferred stimulus will typically increase the value of that stimulus and make behaviors to obtain it more likely. When a lifestyle change involves restricting preferred foods, the deprivation from these items is likely to act as an MO that increases their value in that barring other MOs that work to reduce their value (e.g., access to foods that adequately substitute) or punishing consequences for eating these foods (e.g., allergic reaction),

a person may be more likely to consume these foods if given the opportunity. MOs can also reduce the value of otherwise reinforcing events, as when being tired decreases the value of physical activity with peers for a child.

The principles described thus far participate interactively in a fundamental unit of analysis within operant psychology known as the four-term contingency. The four-term contingency is comprised of the context prior to the behavior (discriminative stimuli, motivating operations), the behavior of interest, and the environmental change following the behavior (consequences). From these concepts, a wealth of other behavioral processes, phenomena, and procedures have been identified that further refine the ability to predict and influence behavior, many of which have great relevance to lifestyle behavior. However, it is beyond the scope of this chapter to detail each of these and we encourage the interested reader to consult with professionals trained in these behavioral concepts.

64.4 APPLYING BEHAVIORAL PRINCIPLES TO LIFESTYLE MEDICINE IN CHILDREN

The treatment literature has shown that modifying lifestyle behaviors is supported by delivering intensive, comprehensive programs that include education but also behavioral skills training. Some of the most effective strategies for changing lifestyle behaviors include self-monitoring, goal setting, stimulus control, behavioral rehearsal, corrective feedback, behavioral contracting, commitment enhancement, creating social support, reinforcement, and relapse prevention, all of which are derived from or concordant with operant behavioral principles[37,45] For example, when done well, goal setting establishes a discriminative stimulus by indicating that reinforcement will be available if certain behaviors occur (e.g., meeting the goal of walking for 15 minutes on at least five days this week will result in earning an "app" download).

Unfortunately, these strategies can be time-consuming to implement. However, despite a desire for brief, low-intensity interventions, the overwhelming evidence suggests that lifestyle changes require more versus less intensity and that specialization of treatment content may enhance the maintenance of treatment effects over time.[20,45] For example, the Look AHEAD and Diabetes Prevention Programs tested intensive lifestyle treatments and showed moderate overall reductions in initial weight in adults but found treatment response differences were generally explained by the adoption of key treatment components such as dietary self-monitoring and reaching physical activity goals.[46] Additionally, research on obesity has found that education-only and low-dose interventions (less than 26 hours of contact time) have generally not produced significant changes in behavior or reductions in overweight or obesity in children.[47] Pediatric obesity treatments with the most available evidence have been family-based behavioral treatments and have shown clinically significant short- and long-term (ten years) reductions in weight for primarily school-aged children.[48] This approach incorporates many of the behavioral principles previously described in the intervention design.

64.4.1 Family-Based Behavioral Treatment

Family-based behavioral weight loss treatment (FBT) for pediatric obesity has been extensively evaluated in research settings.[49–55] The primary components include participant utilization of the Stoplight Eating Plan in which a daily energy intake goal is set and adapted for child age and baseline weight.[56,57] Specifically, the Stoplight Eating plan targets increasing nutrient-dense foods ("green" foods) while lowering the intake of calorie-dense foods and those high in fat and sugar content ("red" foods). Moderate intake of "yellow" foods (i.e., nutritional values between the red and green foods) is monitored. Children are given individualized goals to reduce caloric intake to achieve about a 0.5-pound weight loss each week until BMI weight status has been significantly improved (greater than 5% body weight loss).[56]

Recommendations are made to increase physical activity and reduce sedentary time based on defined minimum and maximum time duration goals (e.g., <15 hours per week engaged in screen time)[56] Activity goals are also set to increase physical activity to reach the recommended 60 minutes of daily moderate or vigorous physical activity and at least three days a week of vigorous activity.[58] Sedentary behavior goals are set to reduce daily sedentary time to no more than 60 minutes. Parents complete dietary intake and physical activity monitoring for themselves and their child during the intervention.

Additional primary components include implementing behavior modification strategies, including self-monitoring (e.g., dietary intake), stimulus control (e.g., modifying the home food environment for greater availability of nutrient-dense foods and a reduction in high-calorie foods), and goal setting with motivating rewards for positive reinforcement (e.g., provide a preferred social activity for reaching dietary intake goals). Parents receive skills training to learn how to set specific goals and give effective directions to young children. Goal setting can often be a challenging task for parents when it becomes important to avoid setting unclear or unobtainable goals. Effective goal setting begins by first understanding the behavior in specific, positive terms (e.g., to eat more vegetables at mealtimes versus eating less healthfully) and under what conditions the behavior is expected to occur (e.g., during mealtimes with family members). Next, the initial performance of the desired skill needs to be defined to set an attainable goal. Discrete, intermediate steps may be necessary to define if a child is far from producing the desired behavior. For instance, before a child regularly takes a bite of vegetables, it may first be necessary to begin with a goal of positively interacting with it, such as touching, smelling, or tasting (without actual consumption). Each of these interactions can be followed with positive consequences and mastered before transitioning to the next step of the desired behavioral goal. As this example

demonstrates, the process of goal setting often becomes a collection of smaller goals and a process that facilitates goal achievement more effectively than setting unrealistic goals from the beginning. Additionally, parents learn to implement differential reinforcement of alternative behaviors (i.e., combined use of praising positive behaviors and ignoring mild negative behaviors) and effective discipline for the management of more intensive negative behaviors (e.g., time out for behaviorally disruptive tantrums). Contingency management procedures are also taught to reward positive dietary and activity behavior changes and weight loss success each week. Rewards include verbal (i.e., immediate, descriptive praise) and tangible consequences (e.g., stickers). Inappropriate rewards include the use of food, which can place value on specific foods that can become difficult to manage, particularly when a child has unlimited access to the "reward" food. Child caregivers are encouraged to also participate in setting healthy eating and activity goals to model desired child behaviors.[49]

The effectiveness of FBT has been tested during multiple randomized controlled trials with significant reductions in child BMI associated with clinically significant reductions in child health problems related to weight.[49–52,59–62] The durability of these effects has also been demonstrated based on the five- and ten-year maintenance of treatment effects.[51] Criticisms of FBT access remain, however, given that FBT studies have generally focused on school-aged children, have not included low-socioeconomic status or minority families, have rarely been tested in clinical settings for effectiveness, and have not usually included children with greater severity in obesity.[49–51] More recent investigations have helped to address these FBT limitations, however, by using technology to help deliver FBT to lower-socioeconomic status (SES) families via primary care partnerships[63,64]

64.4.2 Motivational Interviewing

Additional approaches to behavior change not rooted in functional contextualism have been developed and evaluated for weight management, including motivational interviewing (MI). Briefly, the model for MI is based on patient-centered counseling designed to determine a patient's readiness to change, identify, and resolve any ambivalence for changing relevant health behaviors, and elicit self-motivational statements or change talk.[65] The efficacy of MI as a stand-alone approach to change lifestyle behaviors and reduce overweight and obesity among children and adolescents has been limited—although the American Academy of Pediatrics recommends it as a behavior change strategy[66, 67] In contrast to these studies showing limited outcomes, Resnicow et al. showed that a ten-session MI intervention delivered over a two-year period was most effective for reducing BMI percentile when compared with a less intensive MI intervention (four sessions) and usual care.[68] Additional evidence continues to accumulate in support of the use of MI as a treatment for lifestyle interventions, including those aimed at treating obesity.[69]

Given the strong foundation of empirical support for behavioral skills training (BST) within FBT, one alternative consideration may be using MI as a complementary approach to the standard prescribed approach. For instance, in a randomized clinical trial, 72 families all received traditional behavioral skills training for the first five weeks, followed by randomization for 15 sessions that compared the continued use of skills in traditional FBT to a self-directed treatment condition utilizing principles of MI. The results showed no group differences in child BMI z-score change from baseline to post-treatment and follow-up two years later[70] While MI may not be sufficient to change child and adolescent lifestyle behaviors and high weight status, this counseling method may be an alternative approach when combined with BST and implemented with moderate to high intensity (>25 contact hours).[20]

64.4.3 Skill versus Motivation Deficits

A challenge specific to pediatric lifestyle medicine is identifying whose behavior needs to change to accomplish the goals of prevention/intervention. In younger children, parents are primarily responsible for carrying out lifestyle recommendations, but as children age and eventually transition to adulthood they are expected to be increasingly responsible for these behaviors. Lifestyle interventions for obesity have been conducted with preschool, school-age, and adolescent youth with varying levels of child involvement. Results of parent-only and family-based interventions have been equivalent, with stronger effects observed with children relative to adolescents.[71]

The issue of whose behavior needs to change brings with it a consideration of the current abilities of the person of interest. Part of child development includes learning new skills, such as the ability to tell time and plan ahead, which may be needed to engage in lifestyle behaviors. When a disease is already presenting in youth, children may also need to learn new skills specific to the conditions they are helping to manage (e.g., self-monitoring). When these skills are deficient or absent from the child's repertoire, important lifestyle behaviors may not occur. Although easily overlooked, the same is true for parents or caregivers. Skill deficits in parenting skills (e.g., setting/enforcing expectations, using reinforcement for desired behaviors) or other relevant life skills (e.g., identifying/preparing nutritious food) will likely lead to failures in promoting healthful behaviors. As evidenced by the poor outcomes of education-only interventions,[72] correcting such skill deficits will often require more than simply telling the parent or child what to do differently. The use of BST within FBT has proven effective in addressing such skill deficits in lifestyle behaviors related to obesity.

However, the ability to engage in behavior is necessary but not sufficient for behavior change to occur. The lack of engagement in healthy lifestyle behaviors may be due

to motivational deficits. Motivational deficits occur when the outcomes for a behavior are not sufficiently valuable to reinforce that behavior. This can be when the costs (e.g., effort, resources needed) to engage in a behavior are too high relative to the value of the outcomes, when potentially reinforcing events are too delayed in time, or when other behaviors produce relatively more valuable outcomes and therefore displace the desired behavior. For example, although a teen may find sleep valuable, the outcomes for going to bed on time are delayed as staying up to engage with peers on social media at that time is both more valuable and immediately available, resulting in a motivation deficit for going to bed. Additionally, for parents, the behaviors of their children can serve as powerful outcomes for reinforcing behavior.[73] Parents may experience motivation deficits when attempting to enforce healthy lifestyle behavior for their child results in unpleasant outcomes (e.g., child tantrums when told to go to bed) or when engaging in unhealthy lifestyle behavior produces preferred outcomes (e.g., child accepts energy-dense foods and is therefore not going to starve). MI is aimed at increasing motivation for engaging in healthy and/or stopping unhealthy behaviors. This method, however, relies on verbal processes that may not be sufficiently robust to overcome the delays or costs of engaging in healthy lifestyle behaviors or compete with the long history of reinforcing outcomes parents or children have experienced for engaging in unhealthy lifestyle behaviors.

Although skill and motivation deficits have significant potential to influence the occurrence of lifestyle behaviors, research in this area remains significantly limited. The ability to quickly identify the events contributing to an individual's existing patterns of behavior has the potential to substantially improve the efficacy of behavior change programs. More extensive application of concepts and principles from operant behavior to pediatric lifestyle medicine is therefore warranted for research.

64.5 PREDICTORS OF DISEASE AND RESPONSE TO TREATMENT

Multiple difficult-to-change or non-modifiable characteristics have been linked with diseases that are affected by lifestyle behaviors. For instance, childhood obesity has been shown to have associations with race/ethnicity, genetics, and SES factors.[74] Disparities between race and ethnicity have not been fully explained by behavior differences and remain an understudied area of lifestyle research, particularly across developmental time periods.[75]

While this knowledge can be useful for clarifying contributing factors to disease prevalence, development, and response to treatment, it does not provide a direct target on which to intervene to change lifestyle behaviors. Approaches stemming from functional contextualism tend to focus on modifiable factors related to lifestyle behaviors to predict and influence disease, and therefore may more readily inform prevention and treatment strategies. Behavioral economics is one such approach that has received increased attention in recent years.

64.5.1 Behavioral Economics

In everyday life, the outcomes of one's behavior can be delayed and probabilistic, and a variety of behaviors are often concurrently available to produce alternative outcomes and the costs, in terms of the time, effort, or resources needed to obtain any of these outcomes, can vary widely. These variables have long been known to influence the value of outcomes and microeconomics has developed concepts and methods for describing their effects on the consumption of commodities. Behavioral economics integrates microeconomic concepts with the basic principles of operant psychology, allowing quantitative assessment of the interaction between environmental constraints and the value of commodities that may serve to reinforce the behavior of individuals. This approach expands the ability to describe the context in which behavior occurs, thereby establishing additional means to predict and influence behavior. Over the last several decades, the application of this approach to health-related behaviors and conditions has shown value in examining the possible contributions of these contextual factors to the development of disease, predicting response to treatment, and, in some cases, directly informing intervention.

A behavioral process that has been well-described by behavioral economic assessment is *delay discounting*. Delay discounting is the process by which a commodity loses subjective value due to the delay of its receipt. For example, $10 now is generally more valuable than $10 next week, which is more valuable than $10 next year. The rate at which delayed outcomes lose value is well-described by a hyperbolic equation[76] and, more importantly, it has shown robust associations with numerous lifestyle behaviors and health conditions, with higher rates of discounting (future outcomes lose value more quickly) associated with poorer health habits.[77] It is believed that this process influences decision-making involved in all choice behavior, with particular importance for lifestyle behaviors due to the often delayed nature of health consequences.[78] Additionally, although delay discounting changes across development,[79] it has shown trait-like qualities in its relative consistency over time for an individual.[80] In children, delay discounting has largely been examined with respect to current adiposity or predicting future weight gain. A meta-analysis of these data found a medium effect size ($d = 0.61$) for the relation between delay discounting and childhood obesity.[81] Furthermore, delay discounting has shown to be a significant predictor of drug use, such as smoking[80,82] which can negatively impact cardiovascular function and other health-related outcomes.

Despite the trait-like nature of delay discounting, recent research has demonstrated that this process can be modified, at least temporarily, through intervention.[83] Daniel et al. (2015) implemented a procedure known to improve

delay discounting and found that it resulted in reduced energy intake in children with overweight and obesity, suggesting the potential utility of targeting this behavioral process to facilitate improved lifestyle behavior.[83] However, this work is still preliminary, and more research is needed before treatment recommendations can be made[84,85]

As shown by delay discounting, understanding how people value commodities may improve efforts to predict disease risk and response to treatment, and potentially inform lifestyle intervention. Other behavioral economic assessments have also examined the value of commodities relevant to lifestyle medicine. A common method is to make a commodity (e.g., food) available at a range of costs, such as monetary price or amount of effort (completing a specified task) and examining how consumption of the commodity changes as its cost increases. When the value of a commodity is examined in isolation, it is referred to as a demand curve analysis (after the microeconomic concept of supply and demand).[86] If another commodity with a fixed cost is concurrently available, it is referred to as an assessment of relative reinforcing value.[87] Similar to delay discounting, these assessments with children and teens have been primarily examined with respect to lifestyle behaviors related to obesity and drug use. Results suggest an association between the value of food and food intake,[88] current weight,[89,90] and prospective weight gain in children.[91,92] Although the value of food, drugs, and other commodities can be modified in numerous ways, information from behavioral economic assessments of commodity value has not been directly integrated into treatments to date.
