Recently, researchers have posited that the two approaches for examining value—delay discounting and demand—are related and, when examined in conjunction, provide better prediction of disease,[93,94] as well as response to treatment.[95] Preliminary research suggests that delay discounting moderates the effects of reinforcer value,[96] such that when the value of a commodity (e.g., food) is high and future outcomes lose value quickly, behavioral disorders and maladaptive lifestyle behaviors are likely to occur. Although the majority of evidence for this effect has been obtained with adults, initial results suggest that the way children value commodities is related to lifestyle behavior and disease.[95] This approach has great potential to inform more personalized intervention for patients by identifying critical behavioral processes involved in the development and persistence of lifestyle behaviors.

64.6 SUMMARY

The development or modification of lifestyle behaviors for health and wellness during childhood provides an opportunity to sustain positive health for a lifetime. The importance of promoting healthy lifestyle behaviors early in life has become clear; though the mechanisms necessary to develop such behaviors most effectively are not fully understood, in part, because the causal nature of diseases largely impacted by lifestyle behaviors is multifactorial and often dynamic over the course of development.

Despite such challenges, interventions reviewed in this chapter and those particularly based on functional contextualism have shown significant promise in modifying lifestyle behaviors (diet, physical activity, sleep) from infancy to adolescence and young adulthood. The challenge of changing lifestyle behaviors during preventive or treatment-based healthcare is the often delayed positive health outcomes and sometimes immediate negative consequences that can undermine adherence to such interventions over time. The identification of more immediately available reinforcement to improve adherence may help address this longstanding challenge of modifying lifestyle behaviors. The principles of learning elucidated here may provide the support necessary to healthcare professionals in pediatric medicine who often struggle to change their patients' lifestyle behaviors. While considerable challenges remain in translating behavioral science into lifestyle medicine, the promise for improved pediatric health sustained into adulthood is encouraging.

CLINICAL APPLICATIONS

- Education alone is not likely to be sufficient to change behavior. When possible, have patients and families demonstrate new skills and set goals around practicing them.
- Reinforcement is fundamental to behavior change. Effective reinforcement immediately and consistently follows the target behavior over extended periods of time. Work with families to identify ways to reinforce desired behaviors of children and caregivers.
- Self-monitoring lifestyle behaviors, including context, behaviors, and consequences provides key information for goal setting and contingency management to promote behavior change.
- Referral to behavioral practitioners can facilitate the delivery of intensive family-based lifestyle interventions. Consider opportunities for establishing collaborative relationships with behavioral practitioners.

65 Cardiovascular Risk and Physical Activity in Children

Peter T. Katzmarzyk, PhD

KEY POINTS

- Physical activity levels decrease throughout childhood and adolescence, and boys have consistently higher levels of moderate-to-vigorous intensity physical activity than girls.
- Higher levels of physical activity are associated with lower levels of cardiovascular disease risk factors during childhood and adolescence.
- Childhood physical activity may be related to subclinical measures of cardiovascular disease in childhood and into adulthood.
- Children should be encouraged to meet current physical activity guidelines that call for at least 60 minutes of moderate-to-vigorous physical activity on a daily basis.

65.1 INTRODUCTION

Among adults, a physically active lifestyle is associated with a large number of health outcomes, including a lower risk of cardiovascular disease (CVD) and premature mortality.[1] Physical activity in childhood is also associated with several health benefits, including psycho-social, cardiometabolic, musculoskeletal, and cognitive outcomes.[2,3] While the health benefits of physical activity have been widely publicized, recent data indicate that 81% of adolescents globally are not sufficiently active.[4]

CVD remains a leading cause of morbidity and death in the United States and globally.[5] While children do not typically experience clinical events associated with "adult" CVD such as coronary heart disease and stroke, some children develop elevated levels of CVD risk factors and biomarkers such as blood glucose, blood lipids, and blood pressure. Some children may also begin to show subclinical signs of atherosclerotic disease. This chapter explores the association between physical activity and CVD risk in children.

65.2 DEFINITIONS AND KEY CONCEPTS

Physical activity refers to any bodily movement produced by skeletal muscles that results in energy expenditure.[6] In childhood, physical activity occurs in a variety of contexts, including the home environment, educational settings (early childhood education centers, schools, etc.), and outdoor settings, and may take the form of unstructured play activities, active transportation, structured exercise, or organized sports participation. *Aerobic activities* include forms of activity that typically use large muscle groups and are intense enough and performed long enough to maintain or improve an individual's cardiorespiratory fitness.[1] Aerobic activities include such things as walking, running, basketball, soccer, or dancing. *Muscle-strengthening activities* maintain or improve muscular strength, endurance, or power, and include behaviors such as carrying heavy items, shoveling snow, and climbing stairs, as well as the use of weight machines or free weights.[1] *Bone-strengthening activities* are those that create impact and muscle-loading forces on bone which modifies structure (shape) or mass (mineral content).[1] Bone-strengthening activities include jumping, hopping, skipping, and dancing.

Physical activity behavior is usually quantified in terms of frequency, duration, and intensity. *Frequency* refers to the number of sessions or bouts of physical activity and is usually expressed in times per week, or a similar metric. *Duration* is simply the length of time for each bout of physical activity. *Intensity* refers to the rate of energy expenditure while performing a given physical activity and is commonly reported in METs (metabolic equivalents of task), which is expressed in multiples of resting energy expenditure.[1] Physical activities are generally categorized as light (1.6 to less than 3.0 METs), moderate (3.0 to less than 6.0 METs), or vigorous (6.0 METs or greater).

The current US physical activity guidelines recommend that school-aged children and youth should accumulate 60 minutes or more of moderate-to-vigorous intensity physical activity (MVPA) each day. In addition to aerobic activity, this physical activity should include muscle-strengthening activities on at least three days each week and bone-strengthening activities on at least three days each week.[7]

Sedentary behavior has been defined as any waking behavior characterized by an energy expenditure ≤1.5 METs while in a sitting, reclining, or lying posture.[8] Sedentary behavior occurs at the opposite end of the energy expenditure spectrum as moderate-to-vigorous physical activity, and the postural component of the definition (i.e., sitting, reclining, or lying) identifies it as a potential behavioral target for interventions that are separate from physical activity *per se*.[9]

DOI: 10.1201/9781003227793-77

Physical fitness is a concept that is related to physical activity. While physical activity is a behavior, physical fitness is defined as an attained set of characteristics that relates to the ability to perform physical activity and is determined by a variety of factors, including an individual's level of habitual physical activity, heredity, and diet.[10]

Mean levels of physical activity differ across age groups, and individuals may increase or decrease their physical activity at different times and rates over the life course. A related concept is *tracking*, which refers to the maintenance of a relative rank or position over time.[11,12] Tracking is often estimated using inter-age correlations (Pearson or Spearman rank-order) between observation values measured at two or more time points in the life course.

Figure 65.1 presents a model showing the association between childhood physical activity and CVD risk. There are several pathways through which childhood physical activity can potentially impact CVD risk through the life course. For example, higher physical activity in childhood can be associated with lower levels of CVD risk factors during childhood and with improved markers of subclinical CVD in childhood and adolescence. In turn, this may reduce the risk of CVD events in adulthood. Higher levels of physical activity in childhood may be related to higher levels of physical activity being maintained into adulthood, which in turn has benefits related to reduced CVD. Finally, there may be a direct pathway whereby physical activity accumulated during childhood may have a long-term, direct effect on the risk of CVD in adulthood.

65.3 PHYSICAL ACTIVITY AND SEDENTARY BEHAVIOR DURING CHILDHOOD AND ADOLESCENCE

Levels of physical activity and sedentary behavior tend to change over the life course. In general, declines in physical activity are observed throughout childhood and adolescence.[13] Figure 65.2 presents estimates of daily MVPA obtained using waist-worn accelerometers in a nationally representative sample of US children and adolescents. It is clear that physical activity levels decrease throughout childhood and adolescence, and that boys have consistently higher levels of MVPA than girls.[14] While these results were derived from cross-sectional data, an analysis of accelerometer data from 1800 participants in the longitudinal European Youth Heart Study confirmed the overall patterns, where MVPA decreased by approximately 30 minutes per day, and sedentary increased by about 2.45 hours per day between childhood and adolescence.[15] These device-based results confirm those from studies that have relied on questionnaire data to estimate levels of physical activity. For example, recent data from the 2019 Youth Risk Factor Surveillance System (YRBSS) show that the prevalence of high-school students who are active at least 60 minutes each day of the week was 27.2%, 22.9%, 22.3, and 20% in the 9th, 10th, 11th and 12th grades, and the prevalence was higher in boys (30.9%) than in girls (15.4%).[16]

Population-level race and ethnic differences in childhood physical activity are difficult to determine.[17] Based on self-reported data, the 2019 YRBSS indicates that the prevalence of high-school students who are active at least 60 minutes each day of the week was 25.6% in White students, 20.9% in Black students, and 15.3% in Asian students.[16] However, when relying on accelerometer data from NHANES 2003–2006, Black youth have the highest levels of MVPA (60 min/day), followed by Mexican American (58 min/day), and White youth (52 min/day).[18] The reasons for the differences in trends based on self-reported versus accelerometer data are not well understood, but could potentially be explained by cultural differences in reporting, and the different contexts in which physical activity is performed in different race/ethnic groups.

As described earlier, sedentary behavior refers to activities of low energy expenditure performed while in a sitting, reclining, or lying posture. In practice, this definition is difficult to operationalize in population-based surveillance studies given that it has both energy expenditure and postural components. When accelerometer data are available, the sedentary time has been defined using cut-points that denote low levels of movement, for example, <100 counts per minute.[19] Alternatively, sedentary behavior is often assessed using questions related to screen time or specific sedentary behaviors such as TV viewing or computer use.[20] Based on data from the NHANES 2003–2006, the amount of time

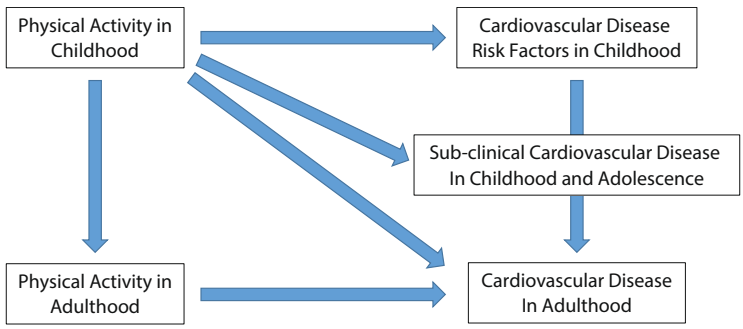

FIGURE 65.1 Association between childhood physical activity, adulthood physical activity, and cardiovascular disease (adapted from Hallal et al., 2006).[63]

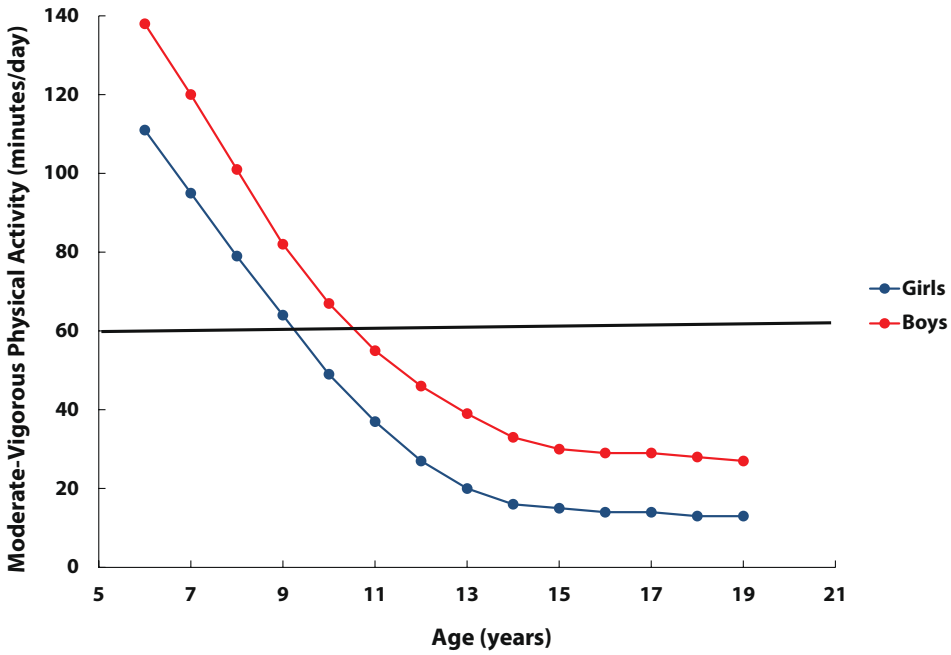

FIGURE 65.2 Levels of moderate-to-vigorous physical activity during childhood and adolescence. The markers represent age- and sex-specific 50th percentile values for accelerometer data in the US National Health and Nutrition Examination Survey, 2003–2006.[14] The solid line represents the physical activity recommendation of 60 minutes per day.

spent sedentary (<100 counts/min) increased from six hours to 7.5 hours to eight hours per day in children 6–11, 12–15, and 16–19 years of age.[19] Furthermore, 19.8% of high school students spend three or more hours per day watching television, while 46% spend three or more hours per day playing video or computer games or using a computer.[16]

65.4 PHYSICAL ACTIVITY, SEDENTARY BEHAVIOR, AND CARDIOVASCULAR RISK DURING CHILDHOOD

The 2018 US Physical Activity Guidelines Advisory Committee conducted a comprehensive review of the association between childhood physical activity and health outcomes. They concluded that there was a moderate level of scientific evidence that physical activity is positively associated with cardiometabolic health in children and adolescents in general, but that the evidence was strong for plasma triglycerides and insulin.[1] On the other hand, there was only limited evidence that sedentary behavior is related to cardiometabolic risk factors; the evidence was somewhat stronger for television viewing or screen time than for total sedentary time.[1] In this section we will explore the association between physical activity, sedentary behavior, and CVD risk factors from evidence derived from observational and intervention studies.

65.4.1 Evidence from Observational Studies

Observational studies are those where the investigator does not intervene or provide an intervention for the participants.[21] Observational studies can be cross-sectional (i.e., conducted at a single point in time) or longitudinal (i.e., follow a cohort of participants over time). Longitudinal cohort designs are important to establish temporal associations between predictors and outcomes, which can inform the cause-and-effect nature of the association.

Many observational studies have examined the association between physical activity and CVD risk factors in children. For example, Andersen and colleagues conducted a cross-sectional study of 1732 randomly selected nine- and 15-year-old children who participated in the European Youth Heart Study.[22] The odds ratios for having a high composite risk factor score (>1 SD; comprised of systolic blood pressure, triglycerides, total cholesterol/HDL ratio, insulin resistance, sum skinfolds, and aerobic fitness) decreased across successively higher quintiles of physical activity (Figure 65.3).

A cross-sectional analysis of the association between physical activity and a composite CVD risk factor score was also conducted among 3019 children aged two to nine years who participated in the eight-country IDEFICS (Identification and Prevention of Dietary- and Lifestyle-Induced Health Effects in Children and Infants) study.[23] The odds of having a high composite risk factor score (>1 SD) were higher among those with low levels of physical activity, and the association was particularly pronounced among the older (>6 years of age) children.[23]

Ekelund and colleagues conducted a cross-sectional analysis of the combined associations of MVPA, sedentary time, and cardiometabolic risk factors in a pooled analysis of data from 14 studies comprising 20,871 children (aged 4–18

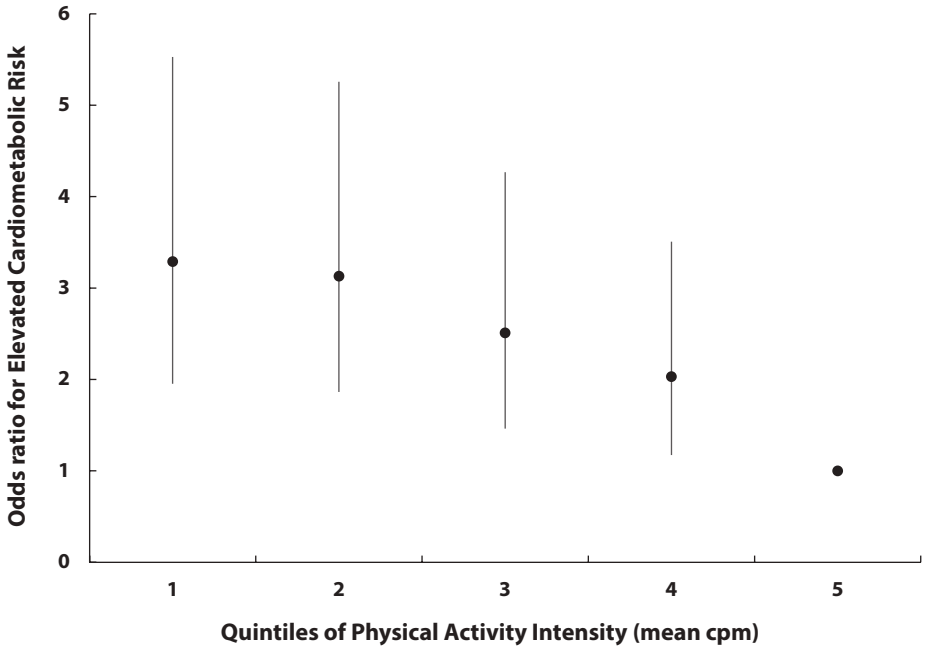

FIGURE 65.3 Odds ratios for elevated cardiometabolic risk by quintiles of physical activity intensity among 1732 nine- and 15-year-old children participating in the European Youth Heart Study.[22] Error bars represent 95% confidence intervals; cpm, counts per minute.

years) from the International Children's Accelerometry Database.[24] Higher levels of MVPA were associated with lower levels of waist circumference, systolic blood pressure, fasting insulin, and fasting triglycerides, and higher levels of HDL-cholesterol, and these associations were independent of sedentary time. On the other hand, sedentary time was not associated with any outcome independent of MVPA.[24]

In addition to studies that show associations between cardiometabolic risk factors and overall levels of physical activity in children, some studies have begun to show associations with "patterns" of activity using different statistical methods.[25,26] For example, latent class analysis of accelerometer data from youth participating in NHANES showed that those in the class with the highest average counts/minute had significantly lower systolic blood pressure, glucose, and insulin compared with youth in the class with the lowest average counts/minute.[25] Compositional data analysis has also been applied to understand the associations between different intensities of physical activity and cardiometabolic risk factors in youth participating in NHANES.[27] The results demonstrated that the composition of sedentary time, light-intensity physical activity, moderate-intensity physical activity, and vigorous-intensity physical activity was significantly associated with BMI z-score, waist circumference, systolic and diastolic blood pressures, HDL-cholesterol, and plasma glucose.[27]

As described above, the total volume of physical activity, especially MVPA, is negatively associated with CVD risk in childhood and adolescence. There is increasing interest in the role of physical activity performed at different intensities (light, moderate, vigorous) in explaining CVD risk. A growing body of literature suggests that vigorous-intensity physical activity may be an important determinant of cardiometabolic risk in children.[28] Hay and colleagues examined associations between physical activity intensities and cardiometabolic risk factors in 9–17-year-old children.[29] No significant differences in cardiometabolic risk factors were seen across tertiles of moderate- or light-intensity physical activity, but BMI z-score, waist circumference, and systolic blood pressure decreased and cardiorespiratory fitness increased across tertiles of vigorous-intensity PA.[29] Moore and colleagues examined associations between vigorous-intensity physical activity and cardiometabolic risk factors using data from the International Children's Accelerometry Database.[30] Their results indicated that substituting light-intensity physical activity with vigorous-intensity activity (adjusting for sedentary time and moderate-intensity physical activity) was inversely associated with waist circumference and insulin levels, while associations with other biomarkers were inconsistent.[30]

A recent systematic review summarized the evidence for associations between device-measured (i.e., pedometers/accelerometers) MVPA, sedentary behavior, and cardiometabolic risk factors in youth from prospective cohort studies.[31] Based on a meta-analysis of three prospective cohort studies, the authors concluded that there was a significant association between MVPA and clustered cardiometabolic risk; however, the associations between MVPA and individual risk factors were inconsistent.[31] No association was observed between sedentary behavior and cardiometabolic outcomes.

Atherosclerosis is a progressive condition that begins in early childhood. An autopsy study of children and young

adults who died of various causes showed that the prevalence of fatty streaks in the coronary arteries increased from about 50% in 2–15-year-olds to 85% in 21–39-year-olds.[32] Furthermore, the prevalence of raised fibrous-plaque lesions in the coronary arteries increased from 8% in 2–15-year-olds to 69% in 26–39-year-olds.[32] These findings are supported by data from autopsied American soldiers in the Korean War, where 77% of the soldiers had evidence of coronary atherosclerosis (mean age of 22 years).[33]

As described previously, physical activity is inversely associated with CVD risk factors in children and youth. There is also some evidence that physical activity is associated with better subclinical measures of CVD in children and youth. For example, sports participation was associated with thinner carotid intima-media thickness (cIMT) among five-year-old children.[34] Physical activity was also inversely associated with arterial stiffness in a sample of ten-year-old children.[35] In a sample of 6–8-year-old children, accelerometer-determined moderate-intensity activity, vigorous-intensity activity, and cumulative time spent in physical activity above 3, 4, 5, 6, and 7 METs were inversely associated with arterial stiffness.[36] The association between changes in physical activity and changes in arterial health (Stiffness Index) was examined in a sample of 90 six- to nine-year-old children who were followed for two years.[37] The results indicated that two-year changes in moderate-intensity, vigorous-intensity, and MVPA were inversely associated with two-year changes in the Stiffness Index.[37] On the other hand, a prospective analysis of physical activity and markers of subclinical CVD among children eight to ten years of age from the European Youth Heart Study followed for six years revealed that vigorous physical activity was associated with a cardiometabolic risk score, but not with carotid arterial stiffness.[38] Taken together, there is some emerging evidence that physical activity may be related to subclinical CVD in children and youth; however, further studies using prospective research designs are required to confirm the strength of the associations.

In summary, there is convincing evidence that physical activity is inversely associated with CVD risk factors in children and youth. There is less evidence for the detrimental effects of sedentary behavior in general, but screen time appears to be more strongly related to risk factors. In general, there is emerging evidence that physical inactivity is associated with measures of subclinical CVD in children, but more work is required to clarify those associations.

65.4.2 Evidence from Intervention Studies

Intervention studies are those in which participants receive an experimental manipulation of some sort and are typically assigned to either an intervention or a control group. While some clinical trials do not randomize the participants to study groups, the strongest design is the randomized controlled trial (RCT) in which participants are randomly allocated to the study groups. The use of randomization is an important strategy to mitigate against the results being the result of some form of bias.[39]

Trials on the effects of exercise on CVD risk factors have a long history in the field of pediatric exercise science. Table 65.1 presents a summary of meta-analyses that have described the effects of exercise interventions on CVD risk factors in children and youth.[40–46] These reviews formed part of the evidence base for the *Physical Activity Guidelines for Americans, Second Edition*.[1] This evidence led the Committee to conclude that there was "moderate" evidence that physical activity is positively associated with cardiometabolic health in children and adolescents in general, and the evidence was "strong" for plasma triglycerides and insulin. There are a number of factors that are considered when defining the levels of evidence, including applicability, generalizability, risk of bias, quantity and consistency of results, and magnitude and precision of effect.[1] In general, the assignment of "strong" evidence indicates that many studies have been published and the results are highly consistent in direction and approximate size of effect, while a grade of "moderate" indicates that a moderate number of studies have been published with some inconsistency in direction or size of effect.

In general, children have healthier levels of CVD risk factors than adults. Therefore, it is often harder to detect the effects of therapeutic interventions such as physical activity in pediatric populations. It is often easier to detect the effects of interventions among "high-risk" children and youth (i.e., with obesity, high blood pressure); however, much of the evidence base comes from trials that enrolled children with one risk factor (for example, obesity), while examining the effects of the intervention on several risk factors, which will typically dilute the effects that are observed. Future studies should be designed to study specific risk reductions in pediatric populations with elevations in specific CVD risk factors of interest.

65.5 PHYSICAL ACTIVITY IN CHILDHOOD AND CARDIOVASCULAR DISEASE RISK IN ADULTHOOD

The study of associations between childhood physical activity and CVD risk in adulthood requires long-term, prospective studies. Luckily, several such studies exist. The Cardiovascular Risk in Young Finns Study is a large population-based longitudinal study conducted in Finland, beginning with children aged 3–18 years of age in 1980.[47] This study has made several important contributions to our understanding of the epidemiology of physical activity and CVD risk over the life course. The Amsterdam Growth and Health Longitudinal Study was initiated in 1977 with approximately 600 boys and girls with a mean age of 13.1 years.[48] The initial purpose of the study was to describe the natural development of growth, health, and lifestyle of adolescents.[48] The participants have now been followed into adulthood, and many important observations have been made regarding the adolescent antecedents of adult disease.

TABLE 65.1

Summary of Meta-analyses Studying the Effects of Physical Activity on Cardiovascular Disease Risk Factors in Children and Youth from Clinical Trials

Authors	CVD Risk Factors	Number of Effects*	Results
Janssen and LeBlanc[40]	*Aerobic exercise*:	3	NS; NR

ES, effect size; CI, confidence interval.

*The number of effects reported varied from the number of studies.

**Eligibility criteria included children with obesity only.

The European Youth Heart Study is an international longitudinal study that addresses the biological, environmental, demographic, and lifestyle correlates of CVD risk factors in children and adolescents. The European Youth Heart Study was initiated as a cross-sectional study of nine- and 15-year-old adolescents in 1997 in several countries;[49] in the intervening years, there have been different follow-up assessments conducted, depending on the participating countries that have contributed data on associations between adolescent characteristics and future health outcomes.

A recent analysis of 31-year follow-up data from the Cardiovascular Risk in Young Finns Study cohort revealed that compared with those who were physically inactive between childhood and adulthood, individuals who were persistently physically active had a significantly lower risk of adult clustered cardiometabolic risk (metabolic syndrome), obesity, high waist circumference, high triglycerides high insulin, high glucose, and low high-density lipoprotein cholesterol (Figure 65.4).[50] Furthermore, physical activity in adolescents (9–15 years of age) and young adults (18–24 years of age) at baseline (1986) was negatively associated with carotid artery elasticity measured 21 years later.[51] Another recent analysis of 27-year follow-up data revealed that childhood physical activity was negatively related to adulthood systemic vascular resistance and cardiac index, and the association remained significant after adjustment for several covariates and corresponding adult data.[52] Taken together, data from the Cardiovascular Risk in Young Finns Study provide convincing evidence of the

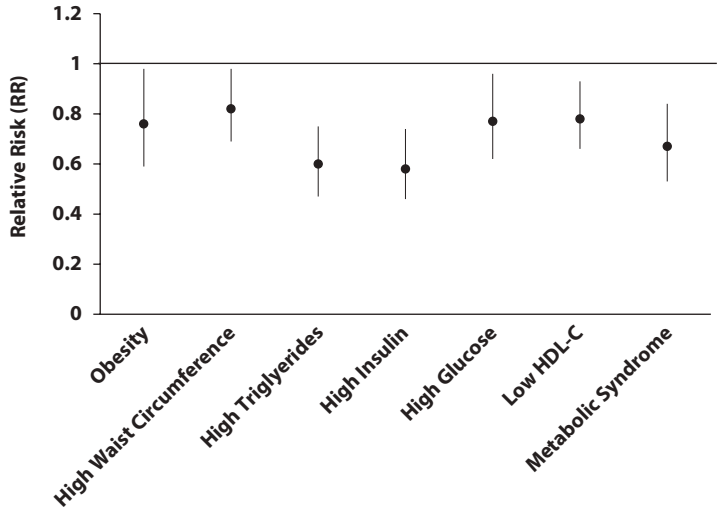

FIGURE 65.4 Relative risks of several cardiovascular disease risk factors and metabolic syndrome in adulthood comparing individuals who were persistently active from childhood to adulthood to individuals who were persistently inactive. Error bars represent 95% confidence intervals. Results are from the Cardiovascular Risk in Young Finns Study.[50]

importance of childhood physical activity in the prevention of CVD risk in adulthood.

Data from the Amsterdam Growth and Health Longitudinal Study corroborate the findings from the Cardiovascular Risk in Young Finns Study.[53] A sample of 373 participants were followed from 13 to 36 years of age, and the results demonstrated that vigorous physical activity throughout the follow-up period was associated with lower arterial stiffness.[53] An analysis of Danish adolescents approximately 15 years of age participating in the European Youth Heart Study followed for up to 12 years revealed that mean exposure to MVPA during the follow-up period was independently associated with lower levels of carotid artery stiffness in adulthood.[38] Furthermore, participants with the largest decline in MVPA between adolescence and adulthood had significantly less compliant arteries compared with the remaining sample.[38]

In summary, the available evidence from a limited number of prospective cohort studies demonstrates a significant association between levels of physical activity in childhood and adulthood CVD risk, assessed by cardiometabolic risk factors and subclinical measures such as vascular resistance and carotid artery stiffness.

65.6 TRACKING OF PHYSICAL ACTIVITY AND SEDENTARY BEHAVIOR FROM CHILDHOOD TO ADULTHOOD

Given that both physical inactivity and sedentary behavior are related to CVD incidence and mortality in adults,[54,55] one pathway whereby childhood physical activity and sedentary behavior may impact this risk is through the tracking, or stability, of these behaviors over time. In order to assess tracking, data from at least two points are required, which necessitates a longitudinal study design where the same individuals are followed over time.

In general, the tracking of physical activity is highest over short periods of time and decreases the further apart the two measurements are obtained.[11] Based on the available evidence, tracking appears to be lower in early childhood than in adolescence or adulthood, and lower in transitional periods of the lifespan, such as the transition between childhood and adolescence or from adolescence to young adulthood.[12]

A recent study was conducted using a large, unique dataset from the Netherlands Twin Registry (n = 43,889).[56] The results demonstrated moderate-to-high tracking over two years (median r = 0.57), whereas stability decreased over time, with a median of 0.38 for 22-year tracking. The long-term tracking from childhood into adulthood was modest, but shorter-term tracking across the lifespan was moderately to highly stable.[56]

The moderate tracking for physical activity observed in many studies suggests that behavioral patterns established in childhood may carry over into adulthood to a limited extent; however, the explained variance remains low, which suggests that there are opportunities for intervention and the potential to change an individual's physical activity trajectory.

65.7 TRACKING OF CARDIOVASCULAR DISEASE RISK FACTORS FROM CHILDHOOD TO ADULTHOOD

The stability of CVD risk factors between childhood and adulthood is an important consideration in the primordial prevention of CVD. In general, there is generally good stability of CVD risk factor clustering between childhood and adulthood, with inter-age correlations of risk factor cluster scores ranging from ~0.4 to 0.7.[57] For example, there was moderate stability in the Quebec Family Study between childhood and adulthood (12 years of follow-up)

for indicators of metabolic syndrome, as well as a composite metabolic syndrome score (r = 0.51 and 0.46 in males and females, respectively).[58] Results from long-term follow-up of participants (16 years) in the Bogalusa Heart Study showed that cardiometabolic risk factors coexist in terms not only of their levels in childhood and adulthood but also of long-term rates of change.[59]

Obesity is an important risk factor for the development of future CVD. Measures of adiposity, including BMI, show relatively strong tracking between childhood and adulthood. Indeed, the odds of having obesity in young adulthood based on having obesity as a child range from 1.3 at one to two years of age to 17.5 at ages 15–17 years.[60] A recent systematic review revealed that childhood obesity is significantly and positively associated with adult blood pressure and triglycerides and negatively associated with HDL-cholesterol.[61] Further, having obesity in addition to multiple CVD risk factors during adolescence is associated with an almost 15-fold increased risk of developing CVD before the age of 50 years.[62]

The results from tracking studies suggest that the maintenance of healthy risk factor levels during childhood will predispose individuals to have better risk factor profiles as adults. However, changes in dietary and physical activity patterns between childhood and adulthood may counteract these effects to some extent.

65.8 CONCLUSIONS

This chapter has explored the topic of CVD risk and physical activity in children. As described in the model presented in Figure 65.1, there are several pathways through which physical activity can influence CVD risk during childhood as well as into adulthood. There is good scientific evidence that physical activity is related to CVD risk factors during childhood and that physical activity may be related to subclinical measures of CVD in childhood and adulthood. The evidence for sedentary behavior is weaker, however, many studies have documented associations between higher levels of screen time and poorer CVD risk factors in children. Further longitudinal studies are needed to clarify these relationships. In general, children and youth should be encouraged to avoid extended periods of sedentary behavior and strive to meet the physical activity guidelines, which call for at least 60 minutes of MVPA daily.

CLINICAL APPLICATIONS

Age Range	Physical Activity Guidelines
3–5 years	• Preschool-aged children (ages three through five years) should be physically active throughout the day to enhance growth and development. • Adult caregivers of preschool-aged children should encourage active play that includes a variety of activity types.
6–18 years	• It is important to provide young people with opportunities and encouragement to participate in physical activities that are appropriate for their age, are enjoyable, and offer variety. • Children and adolescents ages six through 17 years should do 60 minutes (one hour) or more of moderate-to-vigorous physical activity daily: • Aerobic: Most of the 60 minutes or more per day should be either moderate- or vigorous-intensity aerobic physical activity and should include vigorous-intensity physical activity on at least three days a week. • Muscle-strengthening: As part of their 60 minutes or more of daily physical activity, children and adolescents should include muscle-strengthening physical activity on at least three days a week. • Bone-strengthening: As part of their 60 minutes or more of daily physical activity, children and adolescents should include bone-strengthening physical activity on at least three days a week.

66 Cardiovascular Risk and Diet in Children

Carly Faulkner, MS, RD, Sarah Couch, PhD, RD, and Jessica Hemingway, MS, RD

66.1 INTRODUCTION

Compelling evidence shows that the atherosclerotic process begins in early childhood and progresses slowly into adulthood.[1–5] Later in life, this often leads to coronary heart disease, the leading cause of death in the United States.[6] Several risk factors are important for the development of cardiovascular disease (CVD), including family history of CVD, obesity, elevated blood pressure, dyslipidemia, diabetes, and cigarette smoking. Diets high in saturated and trans fats, excessive energy intake, and physical inactivity are lifestyle-related behaviors that can increase the risk of CVD.[7, 8]

Childhood obesity remains a major public health crisis, both nationally and internationally, placing many youths at greater risk for serious health problems. What have previously been considered adult metabolic disorders related to obesity, such as hypertension, dyslipidemias, type 2 diabetes, metabolic syndrome, and non-alcoholic fatty liver disease, are now increasingly prevalent among children.[9–11] This continues to make prevention and treatment of childhood overweight and obesity an important public health focus.

Based on data from the National Health and Nutrition Examination Survey (NHANES) 2011–2014, approximately one in five youths had high total cholesterol, low high-density lipoprotein cholesterol (HDL-C), or high non-HDL- C.[12] Youth with obesity had a greater prevalence of high total cholesterol, low HDL-C, and high non-HDL-C than their normal weight counterparts. Additionally, more than one in ten children and adolescents had borderline high or high blood pressure.[13]

While genetics can play a role in the development of disorders of lipid metabolism and blood pressure regulation in children, these CVD risk factors are largely influenced by lifestyle-related factors, primarily overnutrition, poor diet quality, and inadequate physical activity. In this chapter, we discuss the consequences of suboptimal diet quality regarding CVD risk factors and approaches to achieving optimum nutrition in children and adolescents.

66.2 OBESITY

Childhood and adolescent overweight and obesity in the United States remain major health problems. It is estimated that approximately 19.3% (or 14.4 million) of US children between the ages of 2 and 19 years meet the criteria for obesity, with 6.1% having severe obesity, and another 16.1% meeting the criteria for overweight.[7] Non-Hispanic black and Hispanic children have higher prevalence rates (24.2% and 25.6%, respectively) than non-Hispanic white (16.1%) and non-Hispanic Asian children (8.7%)[7]. Lower-income children and adolescents are more prone to obesity than their higher-income counterparts, but the relationship is not consistent across race and ethnicity groups.[14] There is an increased risk of obesity for children if one or both of their parents have obesity.[15] Additionally, children with obesity are more likely to carry obesity into adulthood.[16]

Overweight and obesity in childhood are strongly associated with increased cardiovascular mortality in adulthood.[17–19] Pediatric obesity is associated with an increased risk of a broad range of health problems including hypertension,[20, 21] elevated serum lipid levels,[22] low HDL-C,[12] elevated hepatic enzyme levels or fatty liver disease,[23] type 2 diabetes,[24] respiratory problems including sleep apnea and asthma,[25, 26] and joint and musculoskeletal problems.[25,27]

Weight status in children is defined using body mass index (BMI), an anthropometric measurement of weight in relation to height, calculated by taking body weight in kilograms (kg), divided by the square of the height in meters. Percentile distributions relative to age and sex in the 2000 Centers for Disease Control and Prevention (CDC) growth charts are used as reference points.[28] BMI has been accepted as a useful tool to screen for possible weight-related health issues and to assess body fat, as increasing BMI levels correlate with excess body fat.[29] Children ages 2–20 years with a BMI-for-age greater than the 85th percentile but less than the 95th percentile for age and sex meet the criteria for overweight. BMI-for-age at or above the 95th percentile for age meets the criteria for obesity, and BMI-for-age greater than or equal to the 120th percentile of the 95th percentile meets the criteria for severe obesity. For children under the age of two years, the World Health Organization (WHO) sex-specific weight-for-recumbent-length charts are used.[30] Weight-for-lengths at or above the 98th percentile meet the criteria for overweight in this age group.

Fat accumulates in excess when total energy intake exceeds total energy expenditure. This creates an energy imbalance caused by a complex interplay of various

DOI: 10.1201/9781003227793-78

genetic, hormonal, behavioral, and environmental factors. Excessive caloric intake from food and beverage choices, and/or a low-energy expenditure from a sedentary lifestyle, can result in overweight or obesity. While some genetic conditions and hormonal disorders may increase a person's susceptibility to weight gain, environmental factors such as lack of physical activity and an overabundant food supply are required to develop overweight or obesity. Lack of adequate sleep and excessive use of electronic device screens can also contribute to excessive weight gain in children and adolescents.[31,32] For more details on the etiology and pathophysiology of pediatric obesity, see Chapter 68.

Weight loss in children with overweight or obesity is associated with significant changes in cardiometabolic outcomes including HDL-C, triglycerides (TG), and systolic blood pressure. A 1 kg weight loss can help reduce serum TG by 5 mg/dL and increase HDL-C by approximately 1.5 mg/dL. Decreasing BMI by one unit in adolescents is expected to reduce systolic blood pressure by 6 mm/Hg.[33] Adopting a healthy lifestyle to manage weight and lower CVD risk includes incorporating a healthful dietary pattern, engaging in regular physical activity, limiting recreational screen time, getting adequate quantity and quality of sleep, and managing stress.[34] Therefore, behavior changes in these key areas should be considered as targets for intervention. Treating obesity in children and adolescents should include parental involvement, as parents serve as role models and authority figures and can impact behaviors around eating habits and activity levels.[15]

Dietary factors that can contribute to excessive energy intake relative to energy expenditure include regular intakes of sugar-sweetened beverages (SSB), greater intakes of fast food, increased intakes of dietary fats and added sugars, and eating larger portions of food. These factors are positively associated with childhood overweight.[35] Additionally, some observational research indicates that low intakes of dairy and calcium-rich foods may increase obesity risk.[35] Breakfast skipping has been indicated as a dietary behavior that is associated with obesity, whereas eating breakfast daily is associated with weight loss and weight maintenance, in addition to improving nutrient intake.[36] Increased intake of fruits and vegetables may be associated with a decreased risk of obesity in children.[35] Family meals, especially those with positive family-and-parent-level interpersonal dynamics (i.e., warmth, group enjoyment, parental positive reinforcement) and with positive parent-level food-related dynamics (i.e., positive food communication, parental food positive reinforcement) are associated with a reduced risk of childhood overweight and obesity.[37]

Lack of physical activity and a sedentary lifestyle play key roles in the development of pediatric obesity (see Chapter 65). Shorter sleep duration and poor sleep quality can increase the risk of obesity[31] (see Chapter 67).

Excessive use of electronic device screens including high amounts of television viewing, playing video games, and recreational use of computers and cell phones can contribute to excessive weight gain in children and adolescents.[32] Screen time exceeding two hours per day increases childhood obesity risk.[35] Additionally, foods high in total calories, sugars, salt, and fat, and low in nutrients are highly advertised, marketed through media, and targeted to children and adolescents.[38] This can influence food choices and increase overall caloric intake.

Emerging research suggests that formula-fed infants may be at higher risk for increased weight trajectories and increased odds for overweight/obesity later in life when compared with breastfed infants.[39] Low access to healthful foods may have unfavorable impacts on food choices and eating behaviors among children and adolescents, although it is unclear if household food insecurity is related to pediatric overweight or obesity.[35]

Furthermore, recent literature suggests that children and adolescents with high stress levels may be more susceptible to increased body weight because of biological changes, increased food consumption as a coping mechanism, and engaging in less physical activity.[40] However, the associations between economic status, food security, stress, and obesity remain areas for further research.

Regarding family climate, parental dietary dis-inhibition and restraint, negative aspects of family functioning (such as lack of parental support or over-possessiveness), and parental concern about weight status are associated with a higher risk of childhood overweight or obesity. Conversely, positive aspects of family functioning (such as family cohesion, expressiveness, democratic style, parental support, and cognitive stimulation at home) are associated with a lower risk of childhood overweight or obesity[35].

The Expert Committee Recommendations Regarding the Prevention, Assessment, and Treatment of Child and Adolescent Overweight and Obesity have established recommendations for practitioners working with pediatric patients and their families in all areas of obesity care.[15] Interventions are categorized into different stages according to the severity of obesity, and the appropriate stage of treatment is based on age, BMI-for-age percentile, and the presence of other health risks. The Academy of Nutrition and Dietetics Evidence-Based Pediatric Weight Management Nutrition Practice Guidelines, 2015, provide complimentary guidelines.[35] These stages of obesity treatment are outlined below.

66.2.1 Stage 1: Prevention Plus

A family-centered approach focusing on healthful eating and activity behaviors is aimed at improving BMI status. The involvement of the child's parent or caregiver is recommended, and especially important for children ages 6–12 years, along with involving the whole family in lifestyle changes. Targeted behaviors for Stage 1 obesity treatment include minimizing consumption of sugar-sweetened beverages and juice, encouraging diets with adequate fruit and vegetable consumption, limiting television and other screen time to $\leq$2 hours per day, eating a healthy breakfast daily, limiting eating out at restaurants, encouraging family meals

in which parents and children eat together, consumption of diets rich in calcium, consumption of diets high in fiber, limiting consumption of energy-dense foods, eating a diet with appropriate portion sizes and balanced macronutrients (energy from fat, carbohydrates and protein in proportions for age as recommended by USDA 2020 Dietary Guidelines for Americans), encouraging exclusive breastfeeding for six months of age with maintenance of breastfeeding after introduction of solid food to 12 months of age and beyond (consistent with American Academy of Pediatrics recommendations)[41, 42] and promoting moderate-to-vigorous physical activity for at least 60 minutes each day.

66.2.2 Stage 2: Structured Weight Management

This stage includes targeting the behaviors mentioned in Stage 1 but with more specific eating and activity goals, and the support of a registered dietitian nutritionist (RDN). Balanced hypo-caloric diets with a mild energy deficit are prescribed to achieve a healthier weight or promote weight stabilization. Nutrition prescriptions are used to help guide the clinician and are not always disclosed to the parent or the patient but can be translated into an eating plan. A planned meal and snack schedule and one hour of supervised and planned daily physical activity are included. Self-monitoring is implemented by the family, with staff support using motivational interviewing techniques to help set healthful lifestyle goals and identify barriers to behavior change.[43]

66.2.3 Stage 3: Comprehensive Multidisciplinary Intervention

The intensity of behavior changes and frequency of visits are increased in this intervention. This stage includes an interdisciplinary team of specialists with experience in pediatric overweight or obesity. During this phase, medical nutrition therapy should be provided for a minimum of three months or until baseline weight management goals are reached. More successful weight loss and weight maintenance may be achieved by increasing the frequency of contact between the patient and practitioner.

66.2.4 Stage 4: Tertiary Care Intervention

This stage may be appropriate for children and adolescents with severe obesity who have attempted the Stage 3 intervention. Interventions are more aggressive in this stage and can include the use of medications, very low-energy diets, and bariatric surgeries with standard clinical protocols.

Nutrition plays a vital role in the healthy growth and development of children. A healthful diet and regular physical activity are important to prevent and treat obesity in children and can help to lower the risk of CVD. Eating patterns established in childhood often track into adulthood, so it is important to set healthful habits early in life.

66.3 DYSLIPIDEMIA

Early identification and treatment of dyslipidemia in youth is considered the cornerstone of primary prevention for CVD.[44] Reducing atherogenic lipoproteins to recommended target levels (see Chapter 69) with a healthy diet and lifestyle including daily physical activity, tobacco smoking cessation, and maintaining a healthy body weight is the primary intervention for youth to lower lifetime risk of CVD.[45] Current pediatric dietary recommendations for treating identified dyslipidemia include a two-step approach called the Cardiovascular Health Integrated Lifestyle Diet or CHILD-1 and CHILD-2.[46] Nutritional components of the CHILD-1 and CHILD-2 diets for low-density lipoprotein (LDL)-C and non-HDL-C reduction are summarized in Table 66.1. CHILD-1 is appropriate for all children over the age of two years and is, for the most part, consistent with the 2020–2025 Dietary Guidelines for Americans.[36] The CHILD-1 is considered the first-line approach to managing elevated LDL-C and non-HDL-C levels. For children with persistently high elevated LDL-C and non-HDL-C, e.g., after three to six months of compliance with CHILD-1, the CHILD-2 diet is recommended. For both CHILD-1 and CHILD-2, weight management is recommended for children with a BMI ≥85th percentile. According to CHILD guidelines, weight-reduction approaches should focus on decreasing the child's weight-for-height (BMI) percentile while maintaining linear growth.[46]

TABLE 66.1
Comparing the Nutritional Intervention Approaches in the Cardiovascular Health Integrated Lifestyle Diet-1 and -2 for Lipid lowering in Children >2 Years of Age

Nutrient target for LDL-lowering	CHILD-1	CHILD-2
Total dietary fat	25–30% of calories	25–30% of calories
Saturated fat	< 10% of daily calories	<7 % of daily calories
Trans fat	Avoided	Avoided
Monounsaturated fat	Up to 10–15% of calories	Up to 10–15% of calories
Polyunsaturated fat	Up to 10% of calories	Up to 10% of calories
Cholesterol	300 mg or less	200 mg or less
Dietary fiber	Child's age + 5 g up to 14 g/1000 calories	Child's age + 5 g up to 14 g/1000 calories
Simple Carbohydrates	Reduction of sugar-sweetened beverages	Reduction of sugar-sweetened beverages

Approaches to achieving the total and saturated fat limits of CHILD-1 and -2 include early transition (between one and two years) to a low-fat diet.[47] This advice is supported by dietary safety data from the Special Turku Risk Intervention Program (STRIP) study that showed that dietary counseling to reduce saturated fat and cholesterol to Dietary Guidelines for Americans levels from six months of age to age 20 years could be done safely under medical supervision.[48] In the STRIP study, indicators of diet safety included optimal growth and pubertal development, nutrient adequacy, and favorable cardiovascular health metrics (lowering of LDL-C and blood pressure) in infants, children, and adolescents.

To achieve the reduced fat goals of CHILD-1, which include a minimum of 30% of energy for children aged two to three years and a minimum of 25% of energy for older children, emphasis should be placed on dietary patterns high in fruits, vegetables, and whole grains.[49] Unprocessed forms of these foods are low in fat and high in fiber and will help to add bulk to the diet. Consumption of high fiber foods has been shown to be an effective means of displacing calorie-dense, nutrient-poor foods.[47] Transition to reduced fat, unflavored milk, and lean protein sources are also recommended by age two years with special consideration given to gender and age-specific calorie and nutrient requirements for growth and development.[46]

In a systematic review of randomized controlled trials aimed at reducing dietary saturated fat to modify CVD risk factors in children, the greatest lowering of LDL-C was achieved by replacing saturated fats with polyunsaturated fats (PUFA) or a mixture of PUFA and monounsaturated fats.[50] Top sources of saturated fat in diets of children 2–18 years of age include whole milk dairy products, sweet bakery products, mixed grain-based dishes, and processed meats and poultry.[51] Counseling families to switch from whole milk to low-fat varieties or fortified plant-based milks and from red meat to skinless white meat poultry may be a useful means of lowering saturated fat without lowering energy intake.[52] Also, switching out high-fat desserts and snacks for low-fat fruits, vegetables, nuts, and seeds and substituting solid cooking fats like butter with liquid cooking oils or spreads may be effective strategies to add PUFA while lowering saturated fat in the diets of children.

The Dietary Approaches to Stop Hypertension (DASH) diet is comparable to the CHILD-1 food plan.[49] A Mediterranean-type diet, if appropriately planned, may also conform to CHILD-1.[53] These dietary patterns emphasize whole, unprocessed fruits, vegetables and whole grains, unsaturated forms of fats, and lean animal and plant sources of protein. These food patterns have been recognized as effective in modifying cardiovascular risk factors including lowering blood pressure, improving blood lipids, and promoting weight loss.[45] Greater improvement in vascular function was reported in adolescents with obesity and hypercholesterolemia on a 12-week Mediterranean-type diet intervention compared with a control group.[54] Meal plans for different calorie levels have been published for these food patterns[36] and can be modified for progressive saturated fat lowering and calorie and nutrient adequacy for children.[49] The expected LDL-C reduction for children with hypercholesterolemia on CHILD-2 (LDL) is on average 12%.[47]

Plant sterols given in the form of prepared muffins, margarines, or chews in combination with a low-fat diet contributed to average LDL-C reductions of 5 to 9%[55] in children with familial hypercholesterolemia. Concern has been raised about the potential for the malabsorption of fat-soluble vitamins in children consuming plant sterols chronically.[56] For this reason, it is recommended that food preparations with plant sterols should be reserved for children with moderate to severe elevations in cholesterol with appropriate monitoring for fat-soluble vitamin status.[46] Soluble fiber given as psyllium in a dose of up to 10 g/day with a low-fat diet provided an additional 5 to 10% reduction in LDL-C in children with familial hypercholesterolemia.[56]

A dietary pattern called CHILD-2 (TG) is recommended for children with dyslipidemia characterized by high triglyceride (TG) and/or low HDL-C.[47] This diet emphasizes a dietary pattern low in saturated fats, trans fats, and refined carbohydrates. CHILD-2 (TG) emphasizes substituting saturated fats and trans fats with unsaturated fats, decreasing intake from sugar-sweetened beverages and desserts, and substituting refined carbohydrates from highly processed breads, rice, and pasta with whole grain sources of these same foods. CHILD-2 (TG) guidelines to minimize added sugars are consistent with a scientific statement from the AHA for children to consume $\leq$25 g (100 calories or six teaspoons) per day to lower cardiovascular risk factors.[57] Processed foods high in sugar are generally high in calories, which may contribute to weight gain and elevate serum TG and lower HDL-C. Modest weight loss for children with a BMI $\geq$85th percentile should favorably modify serum TG and increase HDL-C.[36]

An increase in long-chain omega-3 fatty acids from fish or fish oil products may decrease serum TG[58] Prescription fish oil capsules as a source of long-chain omega-3 fatty acids have been shown to reduce TG levels and have been used safely in children.[59] However, they lack approval for use in children and should be used in consultation with a lipid specialist. For children with very high TG, such as those with hyper-chylomicronemia, a CHILD-2 (TG) diet and fat restriction as low as 15% of daily calories may be helpful in lowering TG and avoiding pancreatitis. Medium chain triglyceride oils (MCT) may also be considered as a source of calories in these cases as they are beneficial for disorders that have defects in bile secretion or chylomicron aggregation or clearance processes.[60]

66.4 HYPERTENSION

Non-pharmacologic approaches for the treatment of elevated blood pressure/hypertension are recommended as the first-line approach in children and adolescents with elevated blood pressure (see Chapter 70).[61] Obesity and

overweight are some of the strongest predictors of elevated blood pressure in children.[62] Lifestyle interventions that achieve weight loss have consistently been found to favorably impact pediatric blood pressure and other cardiometabolic risk factors.[63] A recent review of treatment outcomes of over 6000 children of two to 19 years enrolled in a US consortium of multicomponent pediatric weight management programs that include diet, exercise, and behavior modification showed that a modest decrease in BMI after 12 months was associated with significant improvement in diastolic blood pressure, TG, HDL-C, and fasting blood glucose in children with obesity.[64] Reinehr et al.[65] prospectively analyzed results from a one-year weight loss intervention in children with overweight and obesity between the ages of 5 and 17 years. Participants who were able to reduce their BMI by >0.25 standard deviation score (SDS) in one year (equivalent to a BMI reduction of 0.5 kg/m^2 in a seven-year-old child and 1.0 kg/m^2 in a 13-year-old) achieved an average reduction in systolic blood pressure of −3.2 mm Hg and diastolic blood pressure of −2.2 mm Hg. In this same study, a BMI-SDS reduction of >0.5 more than doubled the response in lowering both systolic and diastolic blood pressure. Given the benefits of weight loss on cardiovascular risk factors in youth, weight reduction is recommended as a primary intervention for blood pressure lowering in children with hypertension, overweight, and obesity.[61] Importantly, findings in young adults suggest that it is not necessary to achieve one's ideal body weight to gain significant blood pressure benefits.[66] Slow, gradual weight loss may be recommended for some children depending on the severity of obesity and the presence of co-morbidities.[67]

An evidence-based, best practices model regarding pediatric weight management[45] recommends calorie intake to match growth demands and physical activity needs with a focus on plant-based foods as a low-calorie source of nutrients; intake of excess fat and sugar-sweetened beverages are discouraged. A DASH dietary pattern can be so planned to accommodate the needs of the growing child.[49] The diet is prescriptive in food group serving recommendations based on daily calorie targets, and per 2000 calories, includes eight to ten servings of fruits and vegetables, two to three servings of low-fat or non-fat dairy, six to eight servings of mostly whole grain foods, two or fewer servings of lean protein foods, two to three servings of fats and oils, and five weekly servings of nuts, with limited sweets.[45] The pattern emphasizes a complement of nutrients including potassium, calcium, and magnesium that have been shown in single-nutrient studies to favorable impact blood pressure and is advocated in current blood pressure treatment guidelines as a recommended eating style to lower blood pressure in children.[61] In a recent randomized control trial, the effectiveness of a six-month diet intervention emphasizing the DASH dietary pattern was examined on blood pressure and vascular health among youth 11–18 years of age.[68] Adolescents (n=159) received face-to-face counseling with an RDN at baseline and check ins at three months, six months, and one year focused on knowledge and skills necessary to comply with a DASH dietary pattern. Fifteen behaviorally focused telephone calls were provided, teaching adolescents about healthful food selection, preparation, meal planning, handling high-risk eating situations, and setting progressive DASH-compliant dietary goals weekly. The DASH diet intervention group experienced a greater reduction in systolic blood pressure (−2.7 mm Hg) and improvement in flow-mediated dilation (+2.5%) compared with the routine care group at the six-month assessment. While blood pressure benefits at six months were not fully sustained at 18 months, flow-mediated dilation showed greater improvement (+3.1%) in the DASH group compared with routine care, suggesting long-term benefits of DASH-style eating on vascular health in adolescents with elevated blood pressure.

Reducing salt intake may also aid in blood pressure lowering in youth. Dietary salt, and its main constituent sodium, is one of the most studied food components related to blood pressure as it plays a central role in regulating fluid balance in the body. In children as in adults, excessive sodium intake leads to the expansion of blood volume and can potentially lead to the development of arterial hypertension.[69] A pooled analysis of nine randomized controlled trials of reduced salt diets compared with usual intake showed a significant blood pressure lowering in children.[70] In this analysis, a median net reduction of salt intake of 42% over four weeks correlated with a decrease in systolic and diastolic blood pressure of 1.17 mm Hg and 1.29 mm Hg, respectively. The 2017 AAP Clinical Practice Guidelines recommends lowering salt intake to 2300 mg/day, especially in children with hypertension and those with overweight or obesity, as these at-risk subgroups frequently exhibit increased blood pressure response to changes in dietary sodium.[61]

The median sodium intake of children and adolescents in the United States exceeds current guidelines with current estimates of 2840 mg/day in children four to 17 years.[70] Therefore, reducing dietary sodium to the recommended levels may be challenging. Focusing on key sources of sodium in the diets of children and working collaboratively with the family to limit those foods is an important first step. In the United States, an average of 83% of total sodium consumption comes from pre-prepared foods purchased from grocery stores and restaurants.[71] Pizza, breads and rolls, and processed meats and poultry are the greatest sources of sodium in the diets of children.[72] Therefore, teaching children and their parents how to read nutrition facts panels on product labels for sodium content and choosing products that have lower sodium would be a useful strategy for lowering sodium in children's diets. Using fresh rather than packaged meats and avoiding instant foods such as pasta, rice, and cereals, which usually contain salt, will help to reduce daily sodium intake. Foods cooked from scratch are naturally lower in sodium than most instant and boxed meals and take-out foods. To aid families in sodium reduction, their food literacy should be assessed, and they should be counseled accordingly on food-shopping skills, their ability to read food labels, and

their capacity to cook and flavor foods using low sodium methods.

66.5 STRATEGIES TO PROMOTE EATING BEHAVIOR CHANGE

A behavioral approach to dietary modification provided by an RDN is the most consistently effective approach to evoke dietary change.[45] In the pediatric population, the child and his/her family should be engaged in the counseling efforts with an RDN. To be most effective, the RDN should gather a comprehensive assessment of the child's current nutritional and weight status, current dietary intake, and eating patterns along with the family's readiness to change. This information can be a valuable resource in estimating success in implementing and sustaining lifestyle changes. Particular attention should be given to potential barriers to dietary behavior change that are rooted in social determinants of health.[73] Assessing information on food access and availability including food insecurity, availability of grocery stores in the neighborhood, transportation to grocery stores, and financial barriers should be considered to better align meal planning and dietary considerations within the specific contexts of the child and family's needs.

Modifying eating behaviors can be challenging, particularly if the food environment of a child is not conducive to making healthy food selections. Children eat like their parents in large part due to a shared food environment, shared meals, and the influence of parent modeling, particularly in young children.[74] Therefore, teaching parents how to plan, shop, and prepare heart-healthy meals for their family and engage their children in the process will help to create a home food environment that is likely to have a favorable impact on their children's health. Enhancing food planning, selection, and preparation knowledge and skills has been shown to increase fruit and vegetable intake[75] and was negatively associated with unhealthy food choices, including soft drink consumption.[76]

66.6 CONCLUSION

Diet plays a very important role in first preventing the emergence of cardiovascular risk factors, and second, in treating risk factors, such as obesity, dyslipidemia, and hypertension, when they develop in young individuals. Identifying risk-factor development in children and adolescents is important for the implementation of appropriate treatment and interventions. Unfortunately, children and adolescents do not usually live in an environment that makes healthy food choices an easy one. This means that behavior change interventions must focus on changing the home environment to encourage healthier choices. Often the best approach is for the entire family to work together to make improved lifestyle choices. This may be broadly beneficial, as often cardiovascular risk factors will cluster in families because of shared environment and shared genetics. Identification and management of cardiovascular risk factors in children and adolescents require a team of healthcare professionals, including physicians, nurses, dietitians, and exercise physiologists. Appropriate management can be successful, which should provide a sense of optimism. On the other hand, the prevention of the development of risk factors in the first place is by far the best strategy.

CLINICAL APPLICATIONS

- Identifying CVD risk-factor development in children and adolescents is important for the implementation of appropriate diet and lifestyle interventions.
- Encouraging dietary patterns emphasizing plant sources of protein rich in soluble fiber will promote weight loss, manage lipids, and lower blood pressure.
- Placing emphasis on the creation of a healthy home food environment, including the provision of ample fruits and vegetables and family meals will encourage healthful eating behaviors.
- Assess information on food access and availability to better align meal planning and dietary considerations within the specific contexts of the child and family's needs.

67 Sleep and Obesity Prevention in Children and Adolescents

Jill L. Kaar, PhD and Stacey L. Simon, PhD

KEY POINTS

1. Early intervention and treatment of childhood obesity is advised; therefore, screening a child's growth is essential.
2. Education regarding healthy diet, engaging in physical activity, limiting screen time, and appropriate sleep hygiene is encouraged for both the family and the children.
3. Although the mechanism relating sleep behaviors to obesity risk remains unknown, establishing healthy sleep habits at an early age is advised.
4. Adolescents tend to have very poor health behaviors including short sleep duration, high sedentary activities, and poor diets, which together lead to early indicators of dysfunctional metabolism.

67.1 OBESITY EPIDEMIC IN CHILDREN AND ADOLESCENTS

Obesity among children and adolescents remains a problem in the United States, with a significant increase in severe obesity over the past several years.[1,2] Although the impact of the COVID-19-related school and community closures on pediatric obesity is not yet fully understood; recent evidence has started to shed light on the unique lifestyle challenges presented to families and children, including loss of healthy school meals, playground and recreation center closures, and canceled school activities that may have further exacerbated obesity risk.[3,4]

Recent data has shown a steady increase in diagnosis of severe obesity, defined as a body mass index (BMI) greater than 120% of the 95th percentile for age and sex, among preschool-aged children (two to five years).[1] The highest prevalence of obesity continues to be among racially and ethnically minoritized subgroups of children and adolescents, i.e., African American, Hispanic, and those classified as other race, compared with White and Asian American.[1] Twice as many non-Hispanic Black, preschool-age children meet the criteria for obesity, compared with non-Hispanic White children (18.2% vs. 9.2%, respectively) in the United States. Children with obesity are at a higher risk for many short- and long-term health consequences, as well as a decrease in their overall life span as adults.[5]

Economists have predicted an additional $19,000 per capita medical care costs for a child with obesity versus a child of normal weight throughout their lifetime.[6] As childhood obesity has been found to progress into adolescence and adulthood, there is a larger societal burden, including reduced income at an individual level, decreased productivity at the employer level, and reduced tax revenues at the government level,[7] all of which may further increase the estimated societal cost of childhood obesity.[8] In addition, children with obesity often have poorer psychosocial functioning related to body image disorders, lower self-esteem, higher levels of stress and anxiety, and increased risk of depression.[9–12] Additionally, children with obesity are at a greater risk of being bullied or teased at school, which leads to poorer social skills and increased difficulties with social situations.[9]

The combined impact of the psychosocial and sociocultural determinants of health problems associated with obesity, as well as the increased risk of cardiovascular disease, diabetes, and other comorbidities of obesity are present throughout the lifespan.[13,14] The early years of life may present a critical window of time during which interventions to prevent childhood obesity could have profound effects. For the last several decades, the major focus has been on increased activity and improving dietary intake; however, these programs have yet to change the trajectory as the prevalence continues to rise, indicating a need for the consideration of additional factors to prevent and treat obesity in children.[15–17]

67.2 POOR SLEEP HEALTH IN CHILDREN AND ADOLESCENTS

Chronic short sleep patterns are becoming an alarming issue in all ages. Findings from the 2016–2018 National Survey of Children's Health (NSCH) show that approximately one-third of children aged four months to 17 years of age obtained insufficient sleep for age per parent-report.[18] Youth from racially and ethnically minoritized groups and with low socioeconomic status had the highest rates of short sleep duration.[18] Young children are at particular risk, as sleep problems are one of the most common parental complaints to pediatricians,[19] and preschool-age children are more likely to be diagnosed with a sleep disorder than any other age group.[20] Poor sleep patterns in childhood tend to

DOI: 10.1201/9781003227793-79

persist into adulthood and develop into chronic sleep problems.[21,22] Adolescence is another unique period of risk for poor sleep health due to a combination of physiological, environmental, and psychosocial factors that increase the propensity for delayed and short sleep.[23] Approximately 60% of middle-school-age students and 70% of high-school-age students report obtaining insufficient sleep on school nights according to data from the Youth Risk Behavior Surveys.[24] Evidence is also emerging of the impact of the COVID-19 pandemic on childhood sleep due to factors including reduced structure and variable schedules with school shutdowns and the transition to online learning.[25]

Poor sleep health, including short sleep duration, has been posited to increase risk for obesity due to changes in physical activity, dietary intake, and impact on metabolic hormones, including leptin, ghrelin, cortisol, and growth hormones.[26–33] Short sleep duration may also decrease metabolic rate (i.e., resting energy expenditure) and is linked to insulin resistance and increased risk for type 2 diabetes.[34–36] Notably, there is strong evidence that short sleep duration is associated with an increased risk of childhood obesity.[37–40]

67.3 SLEEP ASSOCIATED WITH OBESITY AND OTHER HEALTH BEHAVIORS

The association between sleep and obesity will be discussed in the next section. As the specific mechanism linking sleep and obesity is unknown, literature exploring the possible metabolic dysfunction, as well as associated changes in diet and activity behaviors, will be explored.

67.3.1 Sleep and Obesity

The impact of sleep health on obesity has been proposed as the missing link to improved health behaviors, leading to improved health outcomes including many obesity-related comorbidities (i.e., insulin resistance, type 2 diabetes).[41–55] The association between short sleep duration and obesity/adiposity has been well documented, with the majority of studies using self-report measured sleep and a cross-sectional design.[46,56–60] More specifically, short sleep duration (compared with recommended sleep duration for age) has been shown to increase risk of obesity, especially among 3–13 years of age, whereas sleep duration in line with recommended amounts has been found to be protective against obesity.[61] In the Heartfelt Study of almost 400 adolescents, the odds of obesity increased by 80% for each hour of lost sleep.[59] Similarly, in a sample of over 300, four- to ten-year-olds, children with obesity slept less than children without obesity and showed more variability in their sleep on the weekends, compared with school days.[60] In a cross-sectional study, short sleep duration (less than nine hours per night) at age seven years was associated with obesity, independent of TV watching and time spent in sedentary activities (examined by accelerometry).[57] Of the few longitudinal studies conducted, results have been inconsistent, with some finding an association with shorter sleep duration in early childhood and increased weight during later childhood and others showing no association.[62–64] Over 300 children (aged three years) were followed through age six with annual assessments of sleep, physical activity, and television viewing.[42] Longer sleep duration at age three was found to predict decreased BMI percentiles from age three to six years. In a birth cohort in New Zealand (n = 244), sleep and other health behaviors were measured from age three to seven years, and short sleep duration at ages three to five years was found to predict higher adiposity at age seven years. However, in a similar study conducted in the United States with over 800 Hispanic children aged 4–19 years, self-reported sleep duration did not predict increased weight gain one year later.[62] In a more recent study conducted in Denmark with 8–11-year-olds, sleep duration was also not found to be predictive of weight gain over time.[63] The inconsistencies in results could be attributed to methodological issues with the sleep data, as the majority of studies used self-report sleep duration data versus objective measures such as actigraphy. Together, these data suggest the link between sleep and obesity may be "beyond sleep duration" and other components of sleep need to be explored.[65] One such component is the timing of sleep and its relationship with obesity. Although less studied, research to date has found that late bedtimes are associated with adiposity and weight gain in both children and adolescent populations.[65–67] These findings have been concluded independent of sleep duration, indicating that the timing of sleep may be as important as the number of hours of sleep.

Sleep duration has been associated with metabolic regulation, in particular insulin sensitivity, within pediatric populations. In a sample of youth ages 10–19 years, self-reported sleep duration was associated with insulin sensitivity measured with a hyperglycemic clamp.[68] In adolescents with obesity, sleep duration, measured by actigraphy, was found to be inversely associated with glucose, triglycerides, HDL, and other metabolic markers in one study, even after controlling for other lifestyle factors and body composition,[69] and associated with HOMA-IR in another.[70] Similarly, another study found that adolescents who slept 7.75 hours per night had the best insulin sensitivity compared with adolescents who slept less (five hours/night) or more (ten hours/night),[71] though these findings were no longer significant after adjusting for markers of adiposity. In another study of youth ages 2–15 years, abdominal adiposity mediated the relationship between insulin sensitivity and self-reported sleep duration.[72] In a large sample of adolescents, actigraphy-measured longer sleep duration was associated with lower metabolic risk scores including HOMA-IR.[57] However, these studies are limited by the use of either only fasting glucose and insulin rather than more sensitive measurements, or subjective assessment of sleep duration.

Two studies have examined sleep and insulin sensitivity in youth utilizing both objective sleep measurement and more sensitive measures of insulin sensitivity. Shorter actigraphy-measured sleep duration was significantly associated with oral glucose tolerance tested insulin resistance in a sample of

adolescents with overweight and obesity assessed during the academic year.[54] A randomized crossover laboratory study found that adolescent boys had lower HOMA-IR following three nights of four hours in bed compared with three nights of nine hours in bed.[31] Further work is needed in this area, as much of the literature is conflicted, which may be due to various methods of data collection as well as factors included or not included in analyses (i.e., adiposity, pubertal status, and other health behaviors like diet and activity).

67.3.2 Sleep and Diet

The relationship between sleep and diet behaviors is limited in children and adolescent populations. Sleep restriction has been found to alter dietary intake in adolescents in experimental studies.[73,74] Adolescents were found to have diets composed of higher glycemic index, two times higher consumption of sweet/dessert foods, and more calories and carbohydrates after five nights of sleep restriction (6.5 hours in bed/night) compared with consumption after healthy sleep (10 hours in bed/night).[73,74] Adolescents also rated pictures of sweet/dessert foods more appealing than other foods following sleep restriction compared with after healthy sleep.[74] Adolescents performed more poorly on a food-related inhibitory control task and exhibited higher food reward following one week of sleeping five hours per night compared with one week of sleeping nine hours per night, suggesting that insufficient sleep may impact dietary choices by increasing the reward value of foods.[75]

Sleep timing has also been associated with dietary habits, independent of sleep duration. Children and adolescents with later bedtimes (i.e., after midnight for adolescents) compared with those that go to bed early (i.e., before midnight) have been shown to consume larger quantities of sugary or caffeinated beverages.[76–79] Similarly, individuals falling asleep after midnight also report consuming more sugary, salty, and fatty foods throughout the day.[76,77,80]

Adolescents are more likely to skip breakfast and eat the majority of their meals toward the end of the day, which may be related to adolescents' tendency to prefer to stay up late and sleep late.[81,82] Moreover, healthy foods may be less easily available late at night. In an experimental study of adolescents, a "morningness" preference was protective against evening caloric intake when randomized to increase sleep duration by moving bedtime earlier, while no such effect was shown for "night owls".[83] While research is limited in youth, irregular timing of meals and meal frequency has been linked to poor health consequences in adults, including cardiovascular disease, type 2 diabetes mellitus, and obesity.[84] Given that teens are at high risk for irregular eating behaviors, future research should focus on sleep and meal timing in adolescence.

67.3.3 Sleep and Physical Activity and Screen Time

The relationship between physical activity levels and sleep is limited due to a small number of studies and primarily relying on self-report measures. Some studies have found a relationship between short sleep duration and less physical activity, higher electronics use, and greater sedentary behaviors in youth,[85–88] while one study found that longer self-reported sleep duration was associated with more screen time and lower physical activity levels.[89] A study of over 1200 six- to ten-year-olds in Sweden showed that objectively measured total sleep time did not change after moderate-to-vigorous physical activity (MVPA); however, sleep efficiency did improve for each additional bout (minute) of MVPA.[90] In contrast, in a cohort of 275 eight-year-olds, for every unit of increase in PA (counts/minute) during the day, objectively measured sleep duration that night was decreased along with sleep efficiency.[91] Lastly, the link between short sleep duration and higher sedentary activity was shown in a sample of over 3000 European adolescents, with short sleep duration (defined as less than eight hours per night) associated with higher sedentary time and TV time.[92]

Two experimental studies have examined changes in sleep duration and physical activity. In a within-subject counterbalanced design, 37 8–11-year-old children were randomized to either increase or decrease their average bedtime by 1.5 hours/night for one week[93] During this time, the children wore wrist accelerometers and completed a physical activity recall questionnaire. During the week of decreased sleep, children had lower mean physical activity levels and reported watching more television the next day compared with the week of increased sleep. An experimental study with adolescents objectively measuring sleep and activity found that time spent in sedentary behaviors was increased during two weeks of habitual short sleep duration (five to seven hours per night) compared with two weeks of increasing sleep duration by 1.5 hours.[94] In this study, no difference was found for light or moderate-to-vigorous physical activity, suggesting that the extra wakefulness during insufficient sleep is comprised of sedentary time.[94]

67.3.4 Influence on Health Behavior Patterns

As health behaviors co-occur, it is important to understand how patterns of health behaviors predict obesity. For example, obese children tend to report having two or more poor eating and activity behaviors (e.g., high consumption of sugared sweetened beverages and low activity levels).[95] One possible reason for the discrepancy in findings for the studies described earlier could be the potential relationships that exist between each of the health behaviors (i.e., diet, physical activity, screen time). To date, few studies have examined the possible influence of multiple behaviors patterning together[96–99] and, to our knowledge, few have included sleep in conjunction with other health behaviors. One approach to that would be person-centered and encompass multiple behaviors using novel statistical methodologies, like pattern analysis.[100] In a secondary analysis of over 1000 young children, the bi-directionality of the relationship between sleep duration and health behavior (i.e., diet, activity, screen

time) patterns were examined using a latent class analysis approach.[41] This study found that sleep duration acted as a mediator between the relationship between health behavior patterns and obesity. As research continues to disentangle the relationship between these obesity-related health behaviors, future work should consider examining the potential pathway in which these behaviors co-occur.

67.4 PEDIATRIC OBSTRUCTIVE SLEEP APNEA AND OBESITY

Children and adolescents with obesity are at increased risk for obstructive sleep apnea (OSA): prevalence of OSA is approximately 1–5% in otherwise healthy children but increases to upwards of 30% in children with obesity.[101,102] OSA is characterized by repeated partial or total obstruction of the upper airway during the night resulting in multiple arousals from sleep. Untreated, OSA can have severe negative consequences, including cardiovascular morbidity, cognitive deficits, and mood and behavior problems.[102,103] Greater severity of OSA has been associated with fat distribution, exercise function, and insulin resistance.[47] In a study of 31 obese children ages 5–18 years, visceral fat distribution assessed with MRI/MRS was associated with OSA severity measured by polysomnography (PSG).[104] Children with OSA ages 7–12 years, compared with weight-matched children without OSA, had lower cardiac output and oxygen consumption at peak exercise capacity independent of weight status.[105] Despite similar levels of obesity, adolescent patients with moderate or severe OSA had higher fasting insulin and HOMA-IR compared with patients with mild or no OSA.[106] Similarly, in a sample of 62 children ages 5–16 years referred for snoring, severity of OSA correlated with fasting insulin, independent of BMI.[107] Gozal and colleagues[108] conducted a study of 260 children ages 4–11 years and found that children with both obesity and OSA had the lowest levels of G protein-coupled receptor 120 (GPR 120), a long-chain free fatty acid receptor that plays a role in energy homeostasis and protects against insulin resistance and systemic inflammation, potentially contributing to food intake, weight, and glucose metabolism in youth with OSA. The extant studies are limited in the use of non-standard criteria for defining OSA and variable measurement of OSA ranging from full polysomnography to parent-report of symptoms. Future research is needed to further understand the role that OSA may play regarding weight, exercise function, energy balance, and glucose metabolism.

67.5 IMPROVING SLEEP IN CHILDREN AND ADOLESCENTS

67.5.1 Assessment of Sleep Behaviors and Symptoms

A comprehensive evaluation of sleep behaviors is necessary to thoroughly assess for both medical and behavioral sleep disorders and disruption. Input from both youth and their parents can be helpful, as each may have a unique perspective about sleep difficulties. A clinical interview should inquire about typical bed and wake times, any bedtime routine or preparation, and what activities the child performs before bed while attempting sleep, and during night wakings (e.g., getting out of bed, seeking parents, reading, watching TV, using a tablet). Any medications (over-the-counter or prescription) or recreational drugs the child or teen uses to help with sleep should be queried. Lastly, it is helpful to ask about any strategies the family has tried previously to help with sleep and their perceptions of what has been helpful or not. A range of sleep assessment tools are also available to help supplement the clinical interview (Table 67.1).

67.5.2 Treatment of Sleep Disorders

Recommendations for the treatment of sleep problems and disorders vary depending on type. Many children and adolescents have poor sleep habits and practices that contribute to insufficient sleep and daytime sleepiness in the absence of a specific sleep disorder or diagnosis. For these youth, sleep hygiene recommendations may help to improve sleep and daytime functioning. Sleep hygiene is the habits and conditions that generally promote healthy sleep. Patients with sleep difficulties often engage in sleep-related habits that can inhibit adequate sleep, for example, the use of caffeine or other stimulants in an attempt to increase alertness during the day, which inadvertently reduces sleep drive and prolongs sleep onset at night.[112] While sleep hygiene is not a standalone treatment for insomnia, these strategies are necessary to lay a foundation for healthy sleep practices in children and adolescents. Sleep hygiene recommendations encourage sleep practices that promote sleep, including engaging in a bedtime routine, avoiding electronics at least one hour before bedtime to avoid bright light and stimulation, following a consistent sleep/wake schedule (e.g., not varying bed or wake times by more than two hours throughout the week), and maintaining a quiet, dark, and cool sleep environment. Simultaneously, it is necessary to reduce practices that inhibit sleep, including caffeine consumption, exercise within two hours of bedtime, daytime napping, and an uncomfortable sleeping environment.

Cognitive-behavioral therapy for insomnia (CBT-I) is considered the first-line treatment for adults,[113] and while less studied, evidence exists supporting CBT-I for adolescents.[109,114] Key components of CBT-I for adolescents include sleep hygiene (described above), stimulus control, sleep restriction, and cognitive restructuring.

- *Stimulus control* involves using the bed and bedroom only for sleeping in order to strengthen the association between the bed/room and sleep while weakening the association between the bed/room and wakefulness.[115] For adolescents, this may mean no longer doing homework, watching TV,

TABLE 67.1
Available Tools to Assess a Patient's Sleep Behavior

Sleep Assessment Tool	Description
Polysomnography (PSG)	PSG is the "gold standard" for measuring sleep and involves the measurement of multiple physiological channels (brain activity, respiration, heart rate, eye movements, and limb movements) and is usually completed in a sleep laboratory. PSG is clinically indicated if there are concerns about sleep-disordered breathing (loud snoring, pauses in breathing, gasping for air during sleep) or unusual movements during sleep. PSG is not recommended for insomnia.
Actigraphy	A watch-like device worn on the non-dominant wrist that provides estimates of sleep based on motor activity using an accelerometer. The advantages of actigraphy include the ability to monitor sleep in the home environment in real time over a prolonged duration (one to two weeks). Unfortunately, actigraphy is not readily available to many clinicians.
Sleep diary	A sleep diary completed by the child and/or parent is a simple and inexpensive way to obtain prospective information about sleep patterns and practices. Ideally completed upon awakening each morning, a sleep diary provides critical data regarding typical sleep/wake patterns, including attempted bedtime, perceived sleep onset time, frequency and duration of night wakings, and morning wake time. Information from the sleep diary can then be used to help guide the clinician's questions regarding sleep practices.
Sleep questionnaires	Dedicated sleep questionnaires can also be helpful to screen for sleep problems or gain additional information for further queries. A variety of questionnaires are available for a multitude of sleep problems. For example, the Pediatric Insomnia Severity Index (PISI) is a brief, six-item measure available in both child- and parent-reports that assesses sleep domains relevant to insomnia, including sleep onset problems, sleep maintenance difficulties, daytime sleepiness, and nocturnal sleep duration.[109,110] For symptoms of breathing difficulties during sleep, the Pediatric Sleep Questionnaire (PSQ) is a parent-report measure for youth 2–18 years and yields four subscales including snoring, excessive daytime sleepiness, inattention/hyperactive behavior, and sleep-related breathing disorders.[111]

using tablets and cell phones, eating, or reading in their bed/room.

- *Sleep restriction* sets a strict amount of time that the teen is allowed to spend in bed each night that more closely aligns with the amount of sleep they are currently obtaining with a goal of reducing the amount of time spent in bed awake. Similar to stimulus control, the goal of sleep restriction is to reduce associations between the bed/room and being awake. Sleep restriction is accomplished by delaying bedtime while maintaining wake time, resulting in partial sleep deprivation, and increasing the homeostatic drive to sleep so teens can fall asleep more quickly and have reduced night wakings. After sleep has become more efficient, bedtime can slowly be moved earlier to allow for a healthy sleep duration. Caution should be used with sleep restriction to avoid the negative effects of insufficient sleep on daytime functioning (e.g., academic performance, operating an automobile) or in certain medical conditions (e.g., bipolar disorder).
- *Cognitive restructuring* aims to modify the negative thoughts and cognitive distortions about sleep that may serve as perpetuating factors maintaining insomnia symptoms. Negative cognitions about sleep can result in increased arousal, support behaviors that interfere with sleep, and strengthen negative associations with the sleep environment.[116] The goal of cognitive restructuring is to break the cycle of negative thoughts about sleep in order to decrease arousal and improve sleep by identifying and replacing negative beliefs with more adaptive thoughts and attitudes. Relaxation strategies such as diaphragmatic breathing and imagery, done in conjunction with cognitive restructuring, can also help to reduce arousal and disruptive thoughts.

There are a number of empirically supported behavioral treatments for younger children with insomnia, aimed at helping with difficulties such as bedtime resistance and difficulty falling asleep or returning to sleep independently.[117,118] The American Academy of Sleep Medicine Practice Parameters provides guidance on recommended behavioral treatments for young children.[119] Parent education on sleep and sleep hygiene is recommended, with a focus on helping the child develop positive sleep habits. Parents are encouraged to devise a bedtime routine that includes a set of enjoyable and calming pre-bedtime activities leading up to sleep onset. After putting the child to bed at a designated bedtime, parents should then try to reduce the child's dependence on external cues (e.g., parent presence) to fall asleep. This may be done by ignoring the child until morning while monitoring for safety, doing brief check-ins at pre-determined periods (e.g., every five minutes, or at five minutes, then ten minutes), or remaining in the child's room as they fall asleep but providing minimal attention and limiting interaction. Positive reinforcement (e.g., rewards, sticker charts) may be used in conjunction with these strategies. For any sleep intervention, it is important to work together with families to find a treatment that is both evidence-based and acceptable to parents.[120]

For obstructive sleep apnea, the first-line treatment in children is typically surgical removal of tonsils and

adenoids. However, pre-operative sleep appears to be a risk factor for obesity in youth, and getting the right amount of sleep at the right time may have important implications for dietary intake, physical activity, sedentary activity, and metabolic function. More research is needed to understand the mechanisms behind the sleep and obesity relationship, particularly experimental studies, in order to demonstrate causality, along with the use of rigorous methodological procedures. Pediatric obesity is a significant public health concern, coinciding with an increase in chronic sleep restriction in today's youth. Thus, new obesity prevention and treatment targets, such as sleep, are strongly needed.

CLINICAL APPLICATIONS

Presenting Problem	Possible Diagnoses	Recommended Treatment
All ages		
Snoring, pauses in breathing, gasping for air during sleep	Obstructive sleep apnea	Polysomnography; referral to pediatric sleep clinic
Irregular sleep/wake times	Poor sleep habits in the absence of a discrete sleep disorder	Scheduled, consistent, bed/wake times
Poor sleep habits (e.g., use of electronics at bedtime and/or to fall asleep)	Poor sleep habits in the absence of a discrete sleep disorder	Sleep hygiene recommendations
Younger children		
Difficulty falling asleep independently (need for a parent's presence to fall asleep or return to sleep after night wakings)	Insomnia	Behavioral treatments for independent sleep; referral to pediatric behavioral sleep medicine specialist
Bedtime resistance	Insomnia	Bedtime routine; positive reinforcement; referral to pediatric behavioral sleep medicine specialist
Older children/adolescents		
Difficulty falling asleep	Insomnia	Cognitive-behavioral therapy for insomnia (CBT-I); referral to pediatric behavioral sleep medicine specialist
Frequent night wakings	Insomnia	CBT-I; referral to pediatric behavioral sleep medicine specialist

In addition to the sleep difficulties and disorders discussed in this chapter, many other sleep symptoms and disorders (such as parasomnias, restless leg syndrome, and circadian rhythm sleep disorders) were not able to be mentioned due to space constraints. Referral to a pediatric sleep specialist is recommended to rule out a sleep disorder. The Pediatric Sleep Council maintains a list of American Academy of Sleep Medicine-accredited sleep centers specializing in pediatrics: www.babysleep.com. The Society of Behavioral Sleep Medicine offers a list of behavioral sleep medicine providers, including pediatric specialists: behavioralsleep.org.

68 Childhood Obesity

Jaime Moore, MD, MPH and Matthew Haemer, MD, MPH

KEY POINTS

- Universally screen all children in primary care at least annually for excess weight gain using age- and sex-specific BMI percentiles (≥2 years) or weight-for-length percentiles (<2 years), and for lifestyle factors that may contribute to obesity.
- Tailor obesity interventions to the severity of obesity and the family's readiness to change.
- Use motivational interviewing techniques to help families identify factors that they value and select attainable lifestyle change goals.
- When goals for lifestyle change have been identified, work with families to use developmentally appropriate cognitive behavioral strategies including self-monitoring, accountability, and positive reinforcement to engrain new healthy habits.
- When available, connect families to intensive multidisciplinary family-centered interventions (≥26 contact hours/year have the strongest evidence for enduring BMI and lifestyle changes) and consider advanced interventions like pharmacotherapy or bariatric surgery for youth with severe obesity with complications.

68.1 INTRODUCTION

Childhood obesity represents a relatively new chronic disease epidemic from medical and public health perspectives. The prevalence of childhood obesity has increased markedly since the 1980s, paralleling the increase of obesity in adults over the same period[1,2] Multisector population-level responses have been evaluated for obesity prevention over the last two decades,[3,4] but the healthcare system still struggles to implement evidence-based treatment interventions broadly or to offer interventions that effectively reach Black, Hispanic, and Native American populations that face great health disparities related to childhood obesity[5,6] In the decade prior to the COVID-19 pandemic, the rate of increase in the prevalence of childhood obesity had slowed compared with prior decades[7] However, the lifestyle sequelae of the COVID-19 pandemic resulted in rapid increases in childhood obesity prevalence and severity in the United States, affecting low-income and minority groups most dramatically.[8] Comorbid conditions such as type 2 diabetes are projected to increase significantly as generations of children carry obesity into adulthood.[9]

Because the costs in terms of quality of life, direct medical costs, and indirect societal costs of this epidemic are very high, dissemination of evidence-based interventions within the healthcare system is urgently needed, especially for the highest-risk groups. Medical providers want to help children who suffer from reduced quality of life and health consequences of excess weight gain and help families prevent these problems but have historically encountered obstacles to doing so. There has been a lag in responding to this emergent epidemic by the US healthcare delivery[10] and medical education systems.[11,12] Thus, many practicing clinicians report that they lack adequate training, have low self-efficacy in weight management counseling for children, and lack access to or awareness of appropriate resources for evidence-based treatment.[13]

The overall purpose of this chapter is to serve as a reference for medical providers who wish to incorporate the prevention and treatment of childhood obesity into their practice. Specifically, the chapter emphasizes lifestyle-change approaches that support families in changing nutrition, physical activity, sleep, and other habits to maintain or achieve healthy child growth. A range of lifestyle approaches is discussed within a staged approach to childhood obesity treatment that matches treatment intensity to the severity of obesity and the readiness of individual families. Treatment options discussed also include pharmacotherapy or surgical interventions that should be considered for children who have severe obesity and comorbid conditions.

68.2 KEY RESOURCES

When considering the prevention, assessment, and treatment of childhood obesity, there are a few key resources that are helpful to be familiar with: 1) The 2007 *Expert Committee Recommendations* focused on primary care practice.[14] An update to these American Academy of Pediatrics recommendations will be published in 2022 in the form of a *Clinical Practice Guideline for Childhood Obesity* with accompanying extensively referenced *Technical Reports*. 2) The *2013 Scientific Statement on Severe Obesity in Children and Adolescents from the American Heart Association* addressed the etiology and comorbidities of severe obesity in detail[15] 3) The 2017 *Endocrine Society's Clinical Practice Guideline for Pediatric Obesity* represents a contemporary clinical management guideline.[16] 4) The *United States Preventive Service Task Force (USPSTF) 2017 Recommendation Statement on Screening for Obesity in Children and Adolescents* sought to identify the treatment

DOI: 10.1201/9781003227793-80

intensity required for effectiveness based on a comprehensive review of interventions.[17]

68.3 DEFINITIONS

The term obesity refers to excess adiposity. BMI (weight[kg]/height[m^2]) is the accepted clinical surrogate of adiposity for children aged two years and older, and weight-for-length is the appropriate measure for children under two years:[18]

≥2 years of age (reference standard to use: CDC BMI Growth Charts 2–20);[19] <2 years of age (reference standard to use: WHO Weight-for-Length Growth Charts Birth–24 months[20]); "overweight" (weight for recumbent length for age and sex ≥97.7th percentile):[16]

Overweight (BMI ≥85th percentile through the 94th percentile for age and sex)
Obesity (BMI ≥95th percentile for age and sex)
Severe obesity (BMI ≥120% of the 95th percentile or ≥35 kg/m^2)[15]

68.4 ETIOLOGIES

Childhood obesity results from the complex interactions of genetic, epigenetic,[21] lifestyle, biopsychological, and socioenvironmental factors. The major etiologies for childhood obesity are presented in Table 68.1. In addition to the etiologies listed, any pediatric condition that impairs energy balance (e.g., poorly controlled asthma or musculoskeletal conditions limiting mobility) may also contribute to excess weight gain.

68.5 COMORBID CONDITIONS

Obesity in childhood and adolescence can affect numerous organ systems. In some cases, the effects of a given degree of obesity on the body systems of a growing child can differ from the effects seen in an adult. For example, obesity may worsen respiratory conditions in children due to their smaller airway diameter, increasing the risk of collapse from external pressure. Some orthopedic problems such as Blount disease or slipped capital femoral epiphysis (SCFE) occur prior to the fusion of the growth plates. Considerations for the role of lifestyle-based weight management of important comorbid conditions are described in Table 68.2. While lifestyle-change strategies represent a foundation of childhood obesity treatment, the risk of harm to the child posed by a comorbid condition and the severity of the obesity may prompt more intensive intervention as noted in Table 68.2.[14,16,22–37]

68.6 PREVENTION OF CHILDHOOD OBESITY

68.6.1 Risk and Protective Factors

Risk factors for the development of childhood obesity are now widely accepted to arise in the preconception and prenatal stages of life.[38] Postnatally, evidence-based risk factors associated with childhood obesity include sugar-sweetened beverage intake, increased screen time, decreased sleep duration, early adiposity rebound (the point where BMI begins to increase from its nadir in early childhood), and adverse experiences including violence or abuse. Protective factors include increased physical activity and increased family, school, and/or community involvement in prevention.[16,39,40] These represent attractive targets for potential prevention efforts across multiple settings and at individual and public health levels. In a recent meta-analysis, breastfeeding of any duration decreased the odds of obesity onset by age six years, with each month of breastfeeding decreasing the odds of early child obesity by 4% and the greatest benefit (one-third reduction in odds of obesity) seen from six months of exclusive breastfeeding.[41] For its many benefits, exclusive breastfeeding has been recommended for the first six months of life, continued thereafter along with complementary foods through 12 months of age.[42]

68.6.2 Screening

Early recognition of accelerated weight gain paired with early intervention strategies may prevent the progression to overweight or obesity. We recommend universally screening all children in primary care at least annually for excess weight gain using age- and sex-specific BMI percentiles (≥2 years) or weight-for-length percentiles (<2 years)[14,17]

68.6.3 Effectiveness of Prevention Interventions

A 2011 Cochrane review of interventions for preventing childhood obesity found strong evidence to support that these interventions as a whole produce small meaningful reductions in BMI.[43] The authors identified six policies and strategies believed to be influential in successful obesity prevention programs. Four were school-based (curricula inclusive of healthy eating, physical activity, and body image topics; improved nutritional quality of school-provided food; more physical activity time; and support for teachers and staff to execute health-promoting activities), one was home-based (parent support and a home environment that fosters healthy eating, physical activity, and decreased screen time), and one transcended any one setting (environments and cultural practices that consistently support healthy eating and physical activity). A comparative effectiveness meta-analysis of obesity prevention programs by setting showed that the strongest evidence for obesity prevention came from combined diet-physical activity interventions delivered in schools with both home and community components, and from physical activity-only interventions delivered in schools with a home component.[3] These results support a collaborative approach across settings to prevent obesity.

TABLE 68.1
Etiologies of Childhood Obesity

	Key Clinical Features	Examples
Social determinants	Resource limitations are important targets for screening and intervention Mediated by toxic chronic stress	• Poverty • Food insecurity, low access to healthy foods • Lack of neighborhood safety, lack of open spaces for exercise/play • Adverse early childhood events • Interpersonal and structural racism • Barriers to accessing healthcare (e.g., distance, transportation, loss of wages)
Lifestyle	Normal linear growth Generalized distribution of excess adiposity	Individual and family-level choices influencing nutrition, physical activity, sedentary behaviors, and energy balance including: • Nutritional quality • Daily screen time • Sleep quantity
Endocrinologic	Decreased linear growth	• Hypothyroidism (untreated) • Growth hormone deficiency • Cushing syndrome
Hypothalamic dysfunction	Pituitary hormone deficiencies Increased hunger/poor satiety Decreased resting energy expenditure	• Treatment of hypothalamic/pituitary tumors (e.g., surgery/radiation for craniopharyngioma) • Direct effects of a tumor, trauma, or inflammatory disease
Medications	Weight gain temporally associated with medication initiation	• Atypical antipsychotics, systemic corticosteroids, depo-medroxyprogesterone, select mood stabilizers, antidepressants, and anticonvulsants
Genetic syndromes[16]	Severe obesity before age five, developmental delay, dysmorphic features, and/or hyperphagia	*Developmental delay + dysmorphic features* • Prader–Willi syndrome • Bardet–Biedl syndrome • Albright hereditary osteodystrophy *(+) Hyperphagia without developmental delay or dysmorphic features* • MC4R deficiency • Leptin/leptin receptor deficiency • POMC deficiency

MC4R, melanocortin 4 receptor;
POMC, proopiomelanocortin.

68.7 TREATMENT OF CHILDHOOD OBESITY

68.7.1 Overview of Treatment Goals

A holistic view of the child and family should guide the weight management treatment plan. Overarching goals include improving quality of life, family functioning, and healthy child development while achieving meaningful BMI change that will yield physical and mental health benefits. This should be accomplished in a manner that encourages shared decision-making between families and providers and incorporates their values, cultural beliefs, and socioeconomic challenges.

68.7.2 Clinical Weight Loss Goals

Weight loss goals should be guided by the child's age, degree of excess weight at baseline, presence of comorbidities, and the patient/family's readiness to change. For all children, an ideal endpoint is at least a BMI <95th percentile, based on the compelling opportunity to reverse cardiometabolic risk[44] And, in some children, a BMI less than the 85th percentile is advisable. This is in recognition of the fact that within the overweight BMI range (85th–94th percentile), the correlation between BMI and excess adiposity is not as strong (~50% specificity compared with 95% specificity for a BMI in the obesity range).[18] There are also important differences in the relationship between BMI and body adiposity that should be considered on an individual basis.[45] Thus, an endpoint less than the 85th percentile may be appropriate in children with additional risk factors (e.g., personal or family history of obesity-related comorbidities) but may be overly restrictive for a child with healthy lifestyle habits, normal screening labs, and benign family history. For children with obesity, the recommended rates of weight loss by age group are as follows: 2–5 years: weight maintenance or up to 1 lb/month; 6–11 years: 1 lb/month–2 lb/week; 12–18yo: 1–2 lb/week.[14] More rapid losses should prompt investigation for unhealthy weight loss methods. Predicting the amount of weight loss that might occur and be maintained with a given change in energy balance can guide weight management. Unfortunately, many fitness software applications do not account for the body's

TABLE 68.2
Select Conditions Comorbid with Childhood Obesity

Conditions by System	Prevalence and Diagnostic Considerations	Treatment Considerations
Pulmonary		
Obstructive sleep apnea (OSA)	Occurs in 19–61% of youth with obesity; risk increases with increasing BMI.[22] Diagnosed by polysomnogram, which is indicated for children with obesity and frequent snoring.	Tonsillectomy is the first-line treatment when there is tonsillar hypertrophy but is less effective when obesity is present.[23] Positive pressure therapy is often needed for moderate to severe OSA. Severe OSA should prompt stage 4[a] treatment of obesity.
Cardiovascular		
Hypertension	Prevalence 4–25% in youth with overweight and obesity. Hypertension is diagnosed based on auscultated BP ≥95th percentile for sex, age, and height or ≥130/80 (whichever is lower) at three different visits. See updated tables in the 2017 AAP Clinical Practice Guidelines.[25]	Elevated BP (≥90th to <95th percentile or ≥120/80, whichever is lower) should be treated with lifestyle management; stage 1 hypertension (≥95th to <95th percentile BP + 12 mmHg or ≥130/80) in children with obesity may be treated with lifestyle weight management (including DASH diet) for three months, then antihypertensive medication added if needed; Treatment of stage 2 hypertension (≥95th percentile + 12 mm Hg or ≥140/90 mm Hg) begins with combined lifestyle and medication management within stage 4[a] obesity treatment.[25]
Lipid abnormalities	Universal screening recommended by sexual maturity rating 2 (Tanner 2). Non-fasting non-HDL or fasting LDL can be used to screen for familial hyperlipidemia. Mild-moderate hypertriglyceridemia with low HDL is the most common abnormality.[26]	Treatment decisions are based on the average of two fasting samples. LDL >100 mg/dL and <160 mg/dL and triglycerides <400 mg/dL are typically treated with lifestyle modification in children. Statins are considered by lipid management experts for children above eight years with LDL >160 mg/dL or >130 mg/dL if cardiovascular risk factors are present such as diabetes. The risk for pancreatitis increases if fasting triglycerides exceed 400 mg/dL.
Orthopedic		
Blount disease (tibia vara)	This stress injury to the medial tibial growth plate creates bowing of the legs. Two peaks of incidence occur in toddlers/preschoolers with overweight and adolescents with severe obesity.[27]	This potentially disabling condition is treated with either bracing or surgery, which impair mobility for prolonged periods. Any orthopedic condition that impairs the mobility of a child with obesity should be treated urgently with lifestyle-based weight management, and stage 4[a] treatment could be considered based on severity.[28]
Endocrine	Elevated HgA1c 5.7–6.4%	Lifestyle-based weight management is the primary treatment.
Impaired glucose metabolism or prediabetes	Elevated fasting glucose = 100–125 Screening beginning at Tanner stage 2 for children with severe obesity may identify those at the highest risk of T2DM[29]	Metformin is not supported by long-term studies for weight loss or diabetes prevention.[30] The Endocrine Society recommends against using metformin in children with prediabetes.[16] Risk for insulin resistance peaks mid-puberty and often resolves by Tanner stage 5.[31]
Type 2 diabetes (T2DM)	Prevalence in adolescents has increased in recent decades but remains a rare diagnosis. The incident rate is 12.5 cases per 100,000 US youth per year, but is higher in black, Hispanic, and Native American youth.[32]	Management by a pediatric endocrinologist is recommended. Lifestyle management plus stage 4 treatment of obesity should be considered. Bariatric surgery is particularly efficacious for T2DM in adolescents.[104]
Polycystic ovary syndrome (PCOS)	PCOS is the most prevalent endocrinopathy affecting women of reproductive age (8–13%). It is associated with overweight/obesity and metabolic disease, especially type 2 diabetes. Diagnostic criteria for adolescents include irregular menstrual cycles (starting one year after menarche) + clinical or biochemical hyperandrogenism without another etiology identified. Note: ultrasound is *not* recommended until eight years post-menarche.[105]	First-line treatment includes multicomponent lifestyle modification (including sleep, mood, quality of life, and other sources of insulin resistance including high glycemic diets and low physical activity). Weight loss improves hormone abnormalities and symptoms of PCOS (hirsutism, menstrual irregularity) and mitigates metabolic risk. Pharmacotherapy for PCOS is used to treat signs of hyperandrogenism (combined oral contraceptive ± anti-androgens), insulin resistance (e.g., metformin), and obesity (anti-obesity medications).[106]
Hypothyroidism	Not recommended as part of routine screening of every child with obesity, but test in the setting of thyroid symptoms, family history, or linear growth faltering.[14]	Subclinical TSH elevations can be seen in children with obesity. Treatment decisions are guided by a pediatric endocrinologist.[34] Reassessment of thyroid function could be considered if diligent efforts fail to yield success in weight management for a child with a family history of thyroid disease.

(*Continued*)

TABLE 68.2 (CONTINUED)
Select Conditions Comorbid with Childhood Obesity

Conditions by System	Prevalence and Diagnostic Considerations	Treatment Considerations
Gastrointestinal		
Non-alcoholic fatty liver disease (NAFLD)	NAFLD is present in 29–38% of children with obesity. The screening test is alanine aminotransferase (ALT): >22 units/L in females or >26 units/L in males, which suggests NAFLD, per 2017 NASPHGAN guidelines. Diagnosis is a spectrum that may progress from fatty infiltration, to steatohepatitis, to fibrosis, and cirrhosis.[35]	In adults, 10% weight reduction resolves 90% of cases of steatohepatitis. Lifestyle-based weight management including reduced sugar intake is the primary treatment. ALT as a surrogate marker of liver inflammation is inexpensive but correlates less with histology than liver elastography, CT, or MRI. If ALT is persistently (>3 months) above twice the upper limit of normal, assess labs for autoimmune, infectious, and genetic causes of liver disease in consultation with a pediatric hepatologist.[35]
Dermatology		
Acanthosis nigricans	Most children with acanthosis have normal blood glucose. This darkened, thickened skin found at the neck, axillae, and/or groin is a sign of insulin resistance and hyperinsulinemia.[36]	Fades with successful lifestyle-based weight management. Parents should avoid scrubbing away acanthosis because melanocytes reside in the deepest layer of the epidermis.[37]
Mental Health		
Depression, anxiety, disordered eating, low self-esteem, body dissatisfaction, impaired quality of life	Youth with obesity have a ~34% higher risk of developing depression. Of those seeking treatment, up to 50% have depression or anxiety.[107] Universal screening using validated tools is recommended.[16] These psychological conditions have complex interactions with an individual's experiences of bullying, stigma, external and internalized bias, and discrimination.[78,108]	Professionally structured/delivered multicomponent lifestyle interventions have been shown to improve depression and anxiety[107] and are not associated with increased eating disorder risk.[109] Screening should guide referral to intensified interventions including psychotherapy or medication management.

[a] Stage 4 treatment of obesity is indicated when BMI is very high (>99th percentile or >140% of the 95th percentile) or for severe comorbidities. These weight management interventions, including restrictive diets, medications, and surgery, are typically offered by pediatric weight management experts at referral centers.

reduction of resting energy expenditure after weight loss. One noteworthy exception is the NIH Body Weight Planner,[46] which accounts for this metabolic adaptation (found at www.niddk.nih.gov/health-information/weight-management/body-weight-planner)[47] If available, indirect calorimetry is a useful tool to quickly and non-invasively measure resting metabolic rate, allowing calorie goals to be tailored to factors that affect metabolism including body composition, sleep quality/duration, prolonged fasting, and recent weight fluctuations.[48]

68.7.3 Interpreting Treatment Effects

Outcome measures reported in obesity studies have been poorly standardized, which can make it difficult to compare conclusions across heterogeneous interventions and populations. The most widely reported measure in the last two decades has been the change in BMI z-score. However, there are important limitations to using the BMI z-score. First, it is difficult to apply clinically. Second, the BMI z-score is an inaccurate and statistically invalid measure of adiposity for children and adolescents with severe obesity.[49] BMI for youth with severe obesity should be expressed relative to the age- and sex-specific CDC growth chart's 95th percentile, either as a percent above the 95th percentile or the distance (in kg/m^2) from the 95th percentile. For example, a 14-year-old girl with an actual BMI of 36 kg/m^2 and a 95th percentile BMI of 27 kg/m^2 is 132% above the 95th percentile or +9 kg/m^2 from the 95th percentile. Clinically, an "extended" BMI growth chart can facilitate the monitoring of weight trends for patients with severe obesity[50] The CDC has defined a new metric called the "Extended BMI z-Score" that overcomes the statistical limitations of the historical CDC BMI z-score, and for which new growth charts are currently in development.[51]

68.7.4 2007 Expert Committee's Staged Intervention Framework

The 2007 Expert Committee Guidelines proposed a structure for healthcare delivery of pediatric obesity interventions in four stages, which provide increasingly intensive interventions, beginning with structured weight management in the primary care setting and advancing to comprehensive, multidisciplinary management in a tertiary care center[14] Movement through these stages is based on the severity of the patient's obesity, comorbidities, age, the family's motivation to change, available resources, and treatment progress. The primary goal of treatment is permanent, healthy lifestyle habits, which may be achieved using the following strategies: 1) patient/family-driven identification of priority behaviors reflective of their values

and preferences, and paired with goal setting; 2) motivational interviewing; 3) implementation of self-monitoring and planned reinforcement; 4) optimization of multidisciplinary expertise to address the physical and psychosocial needs of the family; and 5) excellent communication with the primary care provider (in stages 3 and 4). A few salient models of implementing treatment that have been tested are described below.

68.7.5 Behaviorally Based Multicomponent Lifestyle Treatment

68.7.5.1 Overview

Behaviorally based lifestyle interventions are recommended as a first-line treatment for childhood obesity.[14–16] Most behaviorally based interventions target more than one behavior (e.g., nutrition, physical activity, sleep) and are variably referred to as "multimodal", "multicomponent", or "multidisciplinary" interventions.

A series of 2016–2017 Cochrane reviews for children from preschool through 17 found that multicomponent lifestyle interventions had modest, positive effects on weight status. The overall quality of evidence ranged from very low to moderate and was limited by a high risk of bias, heterogeneous assessments of diet, physical activity, and behavior, and poor ethnic diversity. Gaps for future study include strategies to achieve post-intervention maintenance of effect and stronger data on comorbidities and cost.

68.7.5.2 Family-Based Behavioral Treatment

The most extensively tested behavioral pediatric weight management is an approach developed by Epstein and colleagues called family-based behavioral treatment (FBT)[52] FBT is an intensive intervention originating from family systems theory and traditionally has simultaneously treated the parent(s) and child. Standard FBT is delivered in 16 weekly sessions that target *nutrition* (using the traffic light diet paradigm), *behavior* (e.g., self-monitoring including documentation of caloric intake/exercise/weight, goal setting, and preplanned rewards for meeting self-determined goals), and recommendations for *physical activity.*[53] FBT has demonstrated efficacy in improving weight status up to 25 years after program involvement.[54] Despite FBT's impact on weight, lack of insurance coverage and significant training, resources, and participant time have been barriers to its widespread adoption. Additionally, the efficacy of FBT has been inadequately studied in youth with severe obesity, adolescents, and those of lower socioeconomic status. One strategy to ease dissemination barriers is to deliver a similar program only to parents of young children, which can be as effective.[55,56]

68.7.5.3 Mindfulness

Mindfulness is an emerging intervention strategy in pediatric obesity that aims to enhance self-regulation of targets including child and parent stress response and lifestyle behaviors[57–59] In one RCT, adolescent girls with overweight/obesity, risk for type 2 diabetes, and depressive symptoms who received a six-week (1 hour/week) group intervention, with activities teaching breath awareness, mindful eating, mindful movement (yoga), and meditation, had greater improvements in depression and insulin resistance compared with a cognitive behavioral control[59]

68.7.6 Office-Based Interventions: Motivational Interviewing

Motivational interviewing (MI) is an effective and versatile evidence-based tool, which can be used one-on-one, or with groups, in multiple weight management prevention and treatment settings. MI is a patient-centered counseling style that encourages families to take the driver's seat in identifying and exploring potential behaviors that may be modified to improve health. As few as three visits with MI-trained PCPs plus two to three phone calls by MI-trained dietitians over 2 years significantly improved BMI in the Brief Motivational Interviewing for Body Mass Index (BMI^2) study.[60] MI paired with point-of-care electronic clinician decision support may also be an effective approach for dissemination.[61] Specific MI techniques that healthcare providers can master to help families move from a place of ambivalence include: asking open-ended questions and using reflective listening to elicit change talk from the patient/family (e.g., "I want to…because", "I can…"). The AAP's "*Change Talk: Childhood Obesity*" is a free online resource that can help providers develop MI skills[62] (found at: https://ihcw.aap.org/resources/).

Next Steps: A Practitioner's Guide of Themed Follow-up Visits to Help Patients Achieve a Healthy Weight[63] is a tool designed by the National Initiative for Children's Healthcare Quality and the AAP to help clinicians conduct pediatric weight management visits around evidence-based targets. Topics include meal patterns and snacks, portion sizes, screen time and sleep, and bullying and teasing. It also includes counseling materials for providers and self-directed activity books for families. The *Next Steps* guide and flip chart is available for purchase on the AAP's website.

68.7.7 Nutrition Interventions

68.7.7.1 Balanced Hypocaloric Reduction

The first nutrition intervention in a staged weight management treatment approach is often a balanced reduction in calories, accomplished through individualized small changes, matched to a family's readiness to change. This approach is relevant across practice settings (from primary care to referral weight management centers) and is commonly delivered through weekly to monthly multidisciplinary visits using techniques including motivational interviewing and collaborative goal setting. Common dietary targets include reducing sugar-sweetened beverages, calorie-dense/nutrient-poor snacks, and portion sizes, increasing intake of home-cooked meals, vegetables, fruits,

whole grains, and lean protein, improving meal routine (not skipping meals, avoidance of grazing), and increasing awareness of hunger and satiety cues.[14,16]

68.7.7.2 Traffic Light Diet

The Traffic Light Diet is a widely used schema that can similarly achieve balanced, moderate hypocaloric restriction. It was developed by Epstein et al. and serves as the core nutrition component of multidisciplinary FBT programs.[64] This system divides foods into green (low-calorie, no limit), yellow (intermediate calories, eat in moderation), and red (high calorie + all sugar-sweetened beverages, avoid). Families are instructed to stay under a specified daily caloric limit and to limit red foods to fewer than five per week.[54]

68.7.7.3 Ideal Macronutrient Composition

For children and adolescents with overweight and obesity, there is not one specific dietary macronutrient composition (i.e., relative proportion of protein, carbohydrates, and fat) that is clearly superior to achieve significant and sustained improvements in BMI.[65] Existing evidence supports that a low-carb, high protein diet may be most effective for moderate *short-term* weight loss compared with a low-fat diet, but long-term results are similar at two years.[65] Thus, a reduction in total energy intake, through any macronutrient combination, may improve weight-related outcomes. On a practical note, when implementing a low carb (<60 g/d), high protein diet, patient selection for adherence and tolerance and supervision by a medical provider and dietitian are key for success.

68.7.7.4 Very-Low Calorie Diets and Meal Replacement

Very-low calorie diets (VLCDs) typically provide 500–800 kcal/day in the form of a formulated high protein, low carb, low fat micronutrient-enhanced liquid/soup/bar (i.e., meal replacement), high protein, low carb whole foods, or a combination. Meal replacement products can reduce the burden and increase the accuracy of self-monitoring and may facilitate healthy eating through stimulus narrowing.[66] Among 5–18-year-olds with obesity, VLCDs result in a mean initial 10.1 kg weight loss (after 3–20 weeks of intervention) and 5.3 kg weight loss at longer-term follow-up (5–14.5 months from baseline).[67] Adherence to this diet is difficult. In practice, the initial phase of a VLCD should be delivered under close medical supervision, followed by a supervised transition to a balanced low-calorie diet. Adult studies demonstrate that VLCDs do not result in greater, long-term (at two years) weight loss than moderately calorically restricted diets (1000–1500 kcal/day), chiefly because of greater weight regain following the VLCD, and are more costly.[68] Meal replacement as part of a moderate caloric restriction (1300–1500 kcal/day) in adolescents may be a tool to achieve short-term weight loss (at ~4 months), but sustained BMI reduction (at one year) compared with an isocaloric diet from conventional foods is similar[66]

68.7.8 Physical Activity and Sedentary Behavior Interventions

68.7.8.1 Physical Activity

Evidence supports physical activity as an adjunct to nutritional and behavioral lifestyle interventions to achieve small, short-term reductions in weight outcomes with very low risk[69–71] While the independent effect of physical activity on BMI is less clear, well-supported benefits of physical activity in children and adolescents with obesity include improvements in vascular function, cardiorespiratory fitness, and cardiometabolic risk factors.[72] The 2018 Physical Activity Guidelines for Americans recommend that 6–17-year-olds engage in at least 60 minutes per day of moderate to vigorous activity through a combination of aerobic (e.g., fast walking, biking), muscle-strengthening (e.g., playing on a jungle gym, resistance exercises), and bone-strengthening (e.g., jumping rope) activities[73] Nationally recognized guidelines for physical activity for children five and younger[74] recommend that one to five-year-olds get at least 60 minutes (and up to several hours per day) of unstructured activity *plus* daily structured activity for at least 30 minutes (one to three-year-olds) and 60 minutes (three to five-year-olds); one to five-year-olds should not be sedentary for more than one hour, except during sleep. Physical activity at this age is focused on developing motor skills.

While an hour or more per day of physical activity is the goal for most children, there is data to support that as few as 10–20 minutes of high-intensity interval activity may result in meaningful physical and cognitive health benefits in youth with overweight and obesity.[75,76] Additionally, physical activity interventions for children with obesity are more likely to be successful if they 1) are individualized to match baseline fitness/exercise tolerance levels[77] and 2) address stigma (particularly weight-based teasing), which can have significant adverse effects on a child's body image, motivation, and desire to participate in any physical activity[78]

68.7.8.2 Sedentary Behavior

Reduction of sedentary behavior is an essential, independent behavioral target of obesity treatment programs. Screen time is a ubiquitous example of a sedentary behavior. Increased duration and frequency of screen time among 5–17-year-olds of any weight status have been associated with higher cardiometabolic risk scores, lower fitness, and lower self-esteem[79] The AAP's 2016 media use policy statements[80,81] recommend the following by age: <18 months: no screen media except for limited video chatting; 18–24 months: evidence-based educational shows/apps *with* parent interaction; two to five years old: ≤1 hour of high-quality programming, ideally with an adult to promote learning; 5–18 years old: no specific maximum, but parents are encouraged to place consistent limits they choose; emphasis is placed on ensuring sleep and physical activity goals are reached and creating media-free family time. For all ages,

screens should not be accessed while eating or in the hour before bedtime, and no screens should be kept in the bedroom. The free AAP Family Media Use digital planning tool can help families design an individualized plan[82] (www.healthychildren.org/English/media/Pages/default.aspx).

68.7.8.3 Sleep Interventions

Sleep is a relatively new target for pediatric obesity interventions. The National Sleep Foundation recommends the following hours of sleep per night by age: one to two-year-olds (11–14 hours), three to five-year-olds (10–13 hours), 6–13-year-olds (9–11 hours), and 14–17-year-olds (8–10 hours).[83] Observational data support that restricted sleep is associated with double the odds of developing obesity in childhood.[84] And each one hour increase in sleep per night has been associated with a 0.05 kg/m^2 reduction in yearly BMI gain.[85] A systematic review and meta-analysis of interventions targeting sleep in children and their effects on health, BMI, diet, and physical activity[86] found only one study that successfully extended sleep duration (and also reduced BMI) through motivational coaching that focused on improved routines.[87] Possible mechanisms to explain the sleep duration-obesity link include increased time awake and related increased opportunity for intake, fatigue leading to decreased physical activity, and dysregulation of hunger and satiety hormones. There is a mixed body of evidence that on the whole supports an association between sleep restriction and unhealthy dietary patterns in children.[88]

68.7.8.4 Anti-Obesity Medications

Combined with ongoing lifestyle efforts, anti-obesity medications can be used as adjunct tools for a subset of youth with obesity.[14,15] While there is no universally accepted guideline for the timing of initiation, pharmacotherapy should be considered if lifestyle intervention for ~6 months has been unsuccessful in curbing weight gain and/or improving obesity comorbidities.[16,89] It is generally accepted that medications should not be used in those <16 years who are overweight, without obesity. Medications should be prescribed and monitored by a clinician experienced in their use and potential adverse effects. A planned assessment of effectiveness and tolerability and a decision to continue should be made within 12 weeks of starting the goal dose. BMI stability (as opposed to reduction) may be a reasonable definition of medication effectiveness in youth.[89] Medication choice should be tailored to the individual and state-specific prescribing regulations should be consulted. For rare monogenic obesities, metreleptin is indicated for leptin deficiency and setmelanotide for mutations in leptin receptor, pro-opiomelanocortin, and pro-protein convertase subtilisin/kexin type 1[90] The most common medications used in US pediatric weight management programs for primary obesity are topiramate, phentermine, metformin, and orlistat.[91] Liraglutide and orlistat are FDA approved for obesity in adolescents 12–17 years old, and phentermine for ≥17 years old. From limited existing adolescent data, placebo-subtracted BMI/weight loss efficacy ranges from no significant change with topiramate[92] to a 5–6% reduction for liraglutide[93] and high-dose phentermine/topiramate[94] Results from phase three clinical trials of phentermine/topiramate and once-weekly injectable semaglutide in youth are expected in 2022. Off-label use of medications for obesity, like for all other conditions, requires sound medical judgment after weighing risks, benefits, and alternatives. The AAP reinforces that the term "off-label" does not suggest "improper, illegal, contraindicated, or investigational use".[95]

68.7.8.5 Metabolic and Bariatric Surgery

In the United States, severe obesity affects 6.1% of youth[96] and is associated with significant cardiometabolic risk including premature death.[15] Given few effective treatment options for severe obesity, metabolic and bariatric surgery (MBS) is increasingly being considered as a tool to achieve significant, sustained weight loss. From the Teen-Longitudinal Assessment of Bariatric Surgery (Teen-LABS) study (the most robust prospective trial of MBS in the United States), at three years postoperatively, mean weight loss was 28% after Roux-en-Y gastric bypass and 26% after sleeve gastrectomy, and remission across comorbidities was 95% (type 2 diabetes), 76% (prediabetes), 74% (elevated blood pressure), 66% (dyslipidemia), and 86% (abnormal kidney function)[33] Comparing five-year outcomes between Teen-LABS and adult LABS participants who underwent bypass, adolescents were 51% and 27% more likely to be in remission from hypertension and type 2 diabetes, respectively, versus adults. However, it is worth noting that weight loss response to MBS at an individual level is heterogeneous.[97] Risks of MBS include possible need for additional surgeries (e.g., leak, cholecystectomy, internal hernia) and micronutrient deficiencies.[98,99] It is recommended that females avoid pregnancy for 12–18 months postoperatively, and a contraception plan should be established prior to surgery. The American Society for Metabolic and Bariatric Surgery's 2018 pediatric guidelines and the AAP's 2019 statement and technical report on pediatric bariatric surgery[100,101] are very closely aligned. The guidelines highlight low access/adoption of MBS in youth with severe obesity despite growing evidence of efficacy and safety. They recommend that MBS candidacy should be driven primarily by medical necessity and that those with younger pubertal stage, intellectual disability, or treated mental illness or disordered eating should *not* be denied evaluation by a qualified multidisciplinary team. Indications for MBS include BMI ≥120% of the 95th percentile or ≥35 kg/m^2 with comorbidities (e.g., obstructive sleep apnea [apnea-hypopnea index >5], type 2 diabetes, hypertension, idiopathic intracranial hypertension, non-alcoholic steatohepatitis, Blount disease, slipped capital femoral epiphysis), or a BMI ≥140% of the 95th percentile or ≥40 kg/m^2 regardless of comorbidity status. A multidisciplinary team, which typically includes at a

TABLE 68.3
Clinical Applications

Application	Description
Evidence-based behavioral targets for obesity prevention and/or treatment	a) Nutrition: Decrease sugar-sweetened beverages, high calorie processed snacks, portion sizes; increase vegetables, fruits, whole grains, home-cooked meals b) Physical activity: 60 minutes (moderate to vigorous)/day c) Sedentary behavior: Decrease screen time d) Sleep: Increase duration to meet age recommendations e) Behavior: Self-monitoring and goal setting, eating behaviors (e.g., appetite/satiety awareness, loss of control eating) f) Intensity: ≥26 hours/year of multidisciplinary intervention
Motivational interviewing techniques	1. *Reflections* (encourage parent to reconsider barriers and convey empathy): "You eat fast food because you are too tired to cook when you come home from work and that is frustrating for you". 2. *Reframing*: "You are able to cook two nights a week. What allows you to succeed in that?" 3. *Open-ended questions*: "Tell me about what makes eating more vegetables hard". 4. *Affirmations*: "You feel that exercising together as a family is important, you value time with your family". 5. *Roll with resistance*: Resist the urge to solve the problem for the family. Avoid saying what they "should" do. 6. *Summaries*: "Preventing diabetes is important to you, so you plan to begin buying more whole grains".
Possible obesity-focused physical exam findings	Vitals: Elevated manual blood pressure (taken with correctly sized cuff); abnormal heart rate; hypoxia Head: Dysmorphic features Eyes: Abnormal visual field testing and papilledema (if concerned clinically for idiopathic intracranial hypertension) Nose and mouth: Nasal turbinate edema; tonsillar hypertrophy Neck: Enlarged or nodular thyroid Cardiopulmonary: Evidence of heart failure which may include murmurs, S3, S4, peripheral edema, or pulmonary rales/rhonchi/wheezing Abdominal: Hepatomegaly; right upper quadrant or epigastric pain Musculoskeletal: Abnormal gait/limp; pain with passive rotation of the hip(s) (SCFE); bowed legs (Blount disease) Skin: Acanthosis nigricans; skin tags; hidradenitis suppurativa; abscesses; cellulitis; hirsutism, alopecia, severe acne Neuro: Developmental delay Psych: Depressed or anxious mood; flat affect

SCFE, slipped capital femoral epiphysis.

minimum a surgeon, pediatric medical provider, psychologist, and dietitian, will assess the patient and family's ability to adhere to pre- and postoperative recommendations. Goal setting, self-monitoring, and positive peer interactions are targeted pre- and postoperatively to help patients reach fluid, protein, and vitamin adherence goals and minimize risks including excess loss of lean muscle mass, micronutrient deficiencies, and weight regain[102,103]

Table 68.3 highlights the key clinical applications of this chapter.

69 Identification and Management of Children with Dyslipidemia

Rachel J. Shustak, MD MSCE, Julie A. Brothers, MD, and Stephen R. Daniels, MD, PhD

KEY POINTS

- Children with dyslipidemia, especially those with elevated low-density lipoprotein cholesterol (LDL-C), are at risk for developing atherosclerotic cardiovascular disease.
- Children should be screened for dyslipidemia with either a fasting lipid profile or a non-fasting, non-high-density lipoprotein (HDL)-cholesterol.
- Heterozygous familial hypercholesterolemia is a common genetic dyslipidemia (1:250 individuals) associated with moderate to severe elevations in LDL-C and premature cardiovascular disease.
- Lifestyle-associated dyslipidemia, often the result of obesity, is associated with elevated triglycerides and low HDL-C.

69.1 BACKGROUND

Cardiovascular disease (CVD) is the leading cause of death in the United States.[1] CVD is not merely an adult phenomenon.[2–5] In children with lipoprotein abnormalities, damage to the arterial endothelium can occur as early as the first decade of life. Over the past decade, screening guidelines to identify children with lipoprotein abnormalities have changed[6] While identifying children with genetically high cholesterol remains a priority, with the increased prevalence of overweight and obesity, identifying children with lifestyle-related abnormalities has also become necessary. In this chapter, we will review the definition of dyslipidemia in childhood, how to screen for dyslipidemia, discuss treatment recommendations regarding diet and lifestyle, and offer guidance for medication initiation. We will present two clinical cases to highlight the management of different dyslipidemias.

69.2 DYSLIPIDEMIA AND LIPID VALUES IN CHILDREN

Dyslipidemia is defined as an abnormality of lipoprotein metabolism resulting in elevated levels of total cholesterol (TC), low-density lipoprotein cholesterol (LDL-C), triglycerides (TGs), and/or low levels of high-density lipoprotein cholesterol (HDL-C). Non-HDL-C, calculated as TC minus HDL-C, is a measure of all the atherogenic apolipoprotein B (apo B)-containing lipoproteins in the circulation and may also be elevated.

Both cholesterol and triglycerides are lipids (or fats) that can be acquired through production in the body or by absorption of food. Cholesterol is necessary for hormone production and is a major component of cell membranes, fat-soluble vitamins, and bile. Triglycerides supply energy to the body. Due to the hydrophobic nature of lipids, they travel in the bloodstream attached to hydrophilic lipoproteins. The polar outer layer of plasma lipoproteins contains apolipoproteins that are important for lipoprotein metabolism.[7]

69.2.1 Progression of Atherosclerosis

The arterial fatty streak is the first lesion in the progression of atherosclerosis visible to the naked eye. This can be seen in children and adolescents with dyslipidemia. While generally reversible, if abnormal lipid levels continue over time, the fatty streaks can progress to irreversible fibrous plaques. These plaques can increase in number and severity as children become adults.[8]

69.2.2 Normal versus Abnormal Lipoprotein Values

Optimal, borderline, and high lipid level classifications are found in Table 69.1.[6] For children and adolescents, the "borderline" or "high" levels correspond to the 75th and 95th percentiles, respectively, and "low" levels to the 10th percentile. Similarly, for young adults ages 20 to 24 years, the "borderline" or "high" level values of TC, LDL-C, and non–HDL-C correspond to the 75th and 95th percentiles. However, for TGs, "borderline" levels correspond to the 75th percentile and high levels to the 90th percentile. For HDL-C, "optimal" levels are greater or equal to the 50th percentile, "borderline" levels are between the 25th and 50th percentile, and "low" levels are below the 25th percentile.[6]

69.3 SCREENING FOR DYSLIPIDEMIA

69.3.1 Universal Screening

In 2011, the Cardiovascular Risk Reduction Guidelines from the National Heart, Lung, and Blood Institute

DOI: 10.1201/9781003227793-81

TABLE 69.1A

Cholesterol Level Classification for Children and Adolescents (in mg/dL)[6]

Lipid Category	Optimal	Borderline-High	High	Low
TC	< 170	170-199	≥200	
LDL-C	< 110	110-129	≥130	
Non-HDL-C	<120	123-144	≥145	
TG				
0-9 yr	<75	75-99	≥100	
10-19 yr	<90	90-129	≥130	
HDL-C	>45	40-44*		<40

*Borderline low

TC=total cholesterol, LDL-C=low density lipoprotein cholesterol, non-HDL-C=non-high density lipoprotein cholesterol, TG=triglycerides, HDL-C=high density lipoprotein cholesterol

TABLE 69.1B

Cholesterol Level Classification for Young Adults (20-24 yrs, in mg/dL)[6]

Lipid Category	Optimal	Borderline-High	High	Low
TC	< 190	190-224	≥225	
LDL-C	< 120	120-159	≥160	
Non-HDL-C	<150	150-189	≥190	
TG	<115	115-149	≥ 150	
HDL-C	>45	40-44*		<40

*Borderline low

TC=total cholesterol, LDL-C=low density lipoprotein cholesterol, non-HDL-C=non-high density lipoprotein cholesterol, TG=triglycerides, HDL-C=high density lipoprotein cholesterol

(NHLBI) Expert Panel were released. The panel recommended that all children be screened for dyslipidemia at least once between the ages of 9 and 11 years and again between the ages of 17 and 21 years.[6] Universal screening recommendations were created to identify patients who may not have been screened for dyslipidemia using the previous guidelines.[9,10] Selective screening can miss up to 30–60% of children with dyslipidemia as parents may be unaware of their own personal or family history of dyslipidemia or too young to have developed early atherosclerosis.[9,11–15] One benefit of universal screening is reverse cascade screening, which can identify affected family members. Relatives of children with hypercholesterolemia are also frequently at increased risk of early CVD.[16,17]

69.3.2 When Should I Screen and What Laboratory Studies Should I Obtain?

The lipid screening guidelines in children and adolescents are shown in Table 69.2. It is recommended that all children

TABLE 69.2

Cholesterol Screening Recommendations by Age[6]

Age	Screening Recommendation	Labs
< 2 years	No screening	
2-8 years	No routine screening	
	Screening if: • Family history of early heart disease** • Parent with TC ≥ 240 mg/dL • High risk condition (see Table 3)	FLP x 2*
9-11 years	Universal Screening	Non-FLP
	If non-HDL-c ≥ 145 or HDL-c < 40	
	Then obtain	FLP x 2*
	If LDL-c ≥ 130 or non-HDL-c ≥145 or HDL-c < 40 or TG > 100 (age < 10yr) or > 130 (age ≥ 10yr)	FLP
	Then obtain	Repeat FLP*
12-16 years	No routine screening	
	Screening if:	
	New knowledge of CVD risk, same as 2-8 yr	FLP x 2*
17-21 years	Universal Screening	
	Ages 17-19:	Non-FLP
	If non-HDL-c ≥ 145 or HDL-c < 40	
	Then obtain	FLP x 2*
	If LDL-c ≥ 130 or non-HDL-c ≥145 or HDL-c < 40 or TG > 100 (age < 10yr) or > 130 (age ≥ 10yr)	FLP
	Then obtain	Repeat FLP*
	Ages 19-21:	Non-FLP
	If non-HDL-c ≥ 190 or HDL-c < 40	
	Then obtain	FLP x 2*
	If LDL-c ≥ 160 or non-HDL-c ≥190 or HDL-c < 40 or TG ≥ 150	FLP
	Then obtain	Repeat FLP*

CVD=cardiovascular disease; FLP=fasting lipid profile; non-FLP=non-fasting lipid profile; LDL-c=low-density lipoprotein cholesterol; HDL-c=high-density lipoprotein cholesterol; non-HDL-c=non-high-density lipoprotein cholesterol (total cholesterol – high density lipoprotein cholesterol); TC=total cholesterol; TG=triglycerides. *2nd lipid profile should be obtained 2 weeks-3 months after the first lipid profile. **Positive family history: a first or second-degree relative with documented CVD (e.g., angina pectoris, peripheral or cerebral vascular disease, myocardial infarction, coronary artery disease, or sudden death) by age < 55 years for a male and < 65 years for females

and adolescents between the ages of 9 and 11 years and 17 and 21 years be screened for dyslipidemia. The Expert Panel selected the initial screening age of approximately 10 years since lipid levels change throughout childhood, most notably during puberty, when there can be up to a 20% decrease in cholesterol levels.[6]

Universal screening can be performed using either a non-fasting lipid panel (non-FLP), where TC and HDL-C are

obtained and the non-HDL-C is calculated, or by obtaining a fasting lipid panel (FLP). The FLP includes the TC, HDL-C, TG, and a calculated LDL-C. The LDL-C is calculated indirectly using the Friedewald formula: LDL-C = TC – (HDL-C – TG/5). If there is significant hypertriglyceridemia (i.e., >400 mg/dL) this formula is not accurate. Instead, one can use the non-HDL-C value to determine if further evaluation is necessary. In 2020, Sampson and colleagues published a new and more accurate LDL-C formula for patients with hypertriglyceridemia (TG ≤800 mg/dL) and/or low LDL-C (LDL-C <70 mg/dL).[18] This may become the predominant formula used to calculate LDL-C in the future.

If there are abnormalities on the non-FLP, then a FLP should be obtained twice, and the average should be used to determine management. If the initial test is a FLP and there are abnormalities, then a repeat FLP should be performed, and the results of the two tests should be averaged. When two FLPs are averaged, the second FLP should be obtained two weeks to three months after the first, once some diet and lifestyle modifications have occurred.

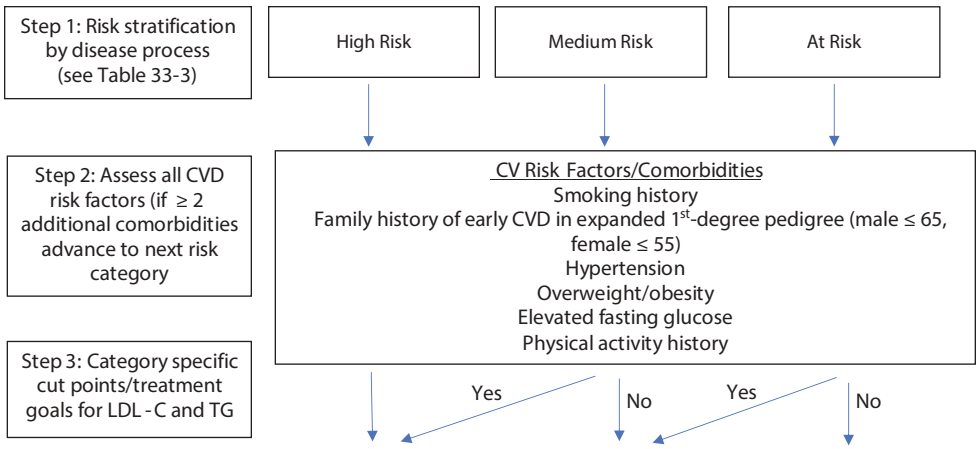
For children 2 to 8 years and 12 to 16 years, selective screening based on personal and family history is recommended[6] Table 69.3 details the conditions for which selective screening should be performed. In 2019, the American Heart Association published a statement on cardiovascular risk reduction in children at high risk for early CVD. This statement proposed a risk stratification schema that accounts for individual risk conditions as well as the compounded effects of multiple conditions (Figure 69.1).[19]

Screening should occur every three to five years in those with a family history of premature CVD (age ≤55 years for males, ≤60 years for females) and annually in those with other risk conditions.[19] Treatment recommendations should be based on the average of two FLPs, with the second FLP ideally two weeks to three months after the first.

69.3.3 Evaluation for Secondary Causes of Dyslipidemia

After a child has been identified with abnormal lipids, the practitioner should perform a thorough evaluation. A complete family history is necessary and should include identifying first- and second-degree relatives with a history of dyslipidemia, premature CVD, diabetes mellitus, and hypertension. For children with severe dyslipidemia, primary genetic causes of dyslipidemia are likely. However, a thorough evaluation for secondary causes should also be performed (Table 69.4).[20] Most secondary causes can be found through a careful medical history and physical exam. Laboratory studies should be obtained to evaluate for diseases that can lead to or are associated with dyslipidemia. These include hepatic function tests for fatty or obstructive liver disease; fasting blood sugar and hemoglobin A1c level for diabetes in the obese; thyroid function tests for hypothyroidism; a urinalysis; blood urea nitrogen; and creatinine level for renal disease.

TABLE 69.3



Risk Factors and Special Risk Conditions for Screening Children for Dyslipidemia, ages 2-8 and 12-16 years[18]

- High risk factor/condition
  - Homozygous familial hypercholesterolemia (HoFH)
  - End-stage renal disease
  - Diabetes (Type I and Type 2)
  - Solid organ transplant vasculopathy
  - Kawasaki disease, with persistent aneurysm
  - Childhood cancer survivor (stem cell transplant)
- Moderate risk factor/condition
  - Severe obesity (BMI ≥120% of the 95th percentile or absolute BMI ≥35 kg/m^2)
  - Heterozygous familial hypercholesterolemia (HeFH)
  - Elevated Lp(a)
  - Chronic kidney disease (pre-dialysis)
  - Aortic stenosis
  - Childhood cancer survivor (chest radiation)
- At risk
  - Obesity (BMI ≥95th percentile)
  - Insulin resistance with comorbidities (dyslipidemia, non-alcoholic fatty liver disease, polycystic ovarian syndrome)
  - White-coat hypertension
  - Hypertrophic cardiomyopathy and other cardiomyopathies
  - Pulmonary hypertension
  - Kawasaki disease with regressed aneurysm (zMax ≥5)
  - Chronic inflammatory disease (JIA, SLE, IBD, HIV)
  - Status post coronary artery translocation for anomalous coronary arteries or transposition of the great arteries
  - Childhood cancer (cardiotoxic chemotherapy only)

BMI=body mass index; JIA = juvenile idiopathic arthritis; SLE = systemic lupus erythematosus; IBD, inflammatory bowel disease; HIV, human immunodeficiency virus.

69.4 CLINICAL CASE 1

A 13-year-old male, A.S., presents to the lipid clinic for evaluation of hypercholesterolemia. A FLP was checked due to his father's history of early heart disease, having undergone a coronary artery bypass graft at the age of 41 years. His paternal grandfather experienced a myocardial infarction at the age of 49 years. His 15-year-old brother has hypercholesterolemia and is on a statin. A.S. plays football and baseball at school. His daily sedentary time is two hours on the weekdays and three hours on the weekends. At home, his family eats a low-saturated fat diet. A.S. buys lunch at school, typically chicken nuggets or pizza. He snacks on pretzels, fruit, or cereal. He drinks juice or water with breakfast and dinner and chocolate milk with lunch. On physical examination, his height and weight are at the 60th and 90th percentile, respectively; his BMI is at the 91st percentile, placing him in the overweight category. His blood pressure is 116/74. The remainder of his exam is

	High risk	Moderate risk	At risk
LDL - C			
• Treatment threshold	LDL - C ≥ 130	LDL - C ≥ 160	LDL - C ≥ 160
• Treatment	Lifestyle change and statin initiation simultaneously	Lifestyle change x 3 months, if remain above goal start statin	Lifestyle change x 6 months, if remain above goal start statin
• Treatment goal	LDL -C < 100	LDL - C < 130	LDL -C < 130
TG			
• Treatment Threshold	TG > 400 or TG 150-400 and non-HDL ≥ 145		
• Treatment	Lifestyle change and pharmacotherapy initiation simultaneously	Lifestyle change x 3 months, if remain above goal start pharmacotherapy	Lifestyle change x 6 months, if remain above goal start pharmacotherapy
• Treatment goal	TG < 150 and non-HDL <145

benign. An average of two FLPs reveal (in mg/dL): TC 444, HDL-C 64, LDL-C 366, TG 69, and non-HDL-C 380. All other labs are within normal limits.

69.5 COMMON GENETIC CAUSES OF HYPERCHOLESTEROLEMIA IN CHILDHOOD

69.5.1 Heterozygous Familial Hypercholesterolemia

Heterozygous familial hypercholesterolemia (HeFH) is an autosomal codominant disorder that occurs in approximately one in 250 people in the general population.[21] HeFH is one of the most common genetic lipid disorders in the pediatric population. It is caused by one or more LDL receptor gene defects that lead to either a defective or a diminished number of LDL receptors. This results in decreased LDL-C clearance from the circulation by the liver and an accumulation of LDL particles in the blood. Children with HeFH may develop subclinical atherosclerosis with evidence of greater carotid intima-media thickness (CIMT) and abnormal brachial artery reactivity, indicating endothelial dysfunction.[22,23] While youth with HeFH generally do not manifest clinically apparent coronary artery disease until adulthood, if left untreated, they have a high risk of developing premature atherosclerosis.[24]

In Clinical Case 1, given the family history and severe LDL-C elevation, A.S. appears to have HeFH. In children and adolescents with HeFH, both TC and LDL-C levels will be well above the 95th percentile for age and sex, starting as young as age two years. Commonly, these children have normal TGs and normal or low HDL-C, unless the patient is overweight or obese; in which case, the child may also have high TGs and low HDL-C. When there is concern for HeFH, it is important to obtain a thorough family history. The patient usually has one parent with significantly elevated TC and LDL-C, and a history of tendon xanthomas

TABLE 69.4

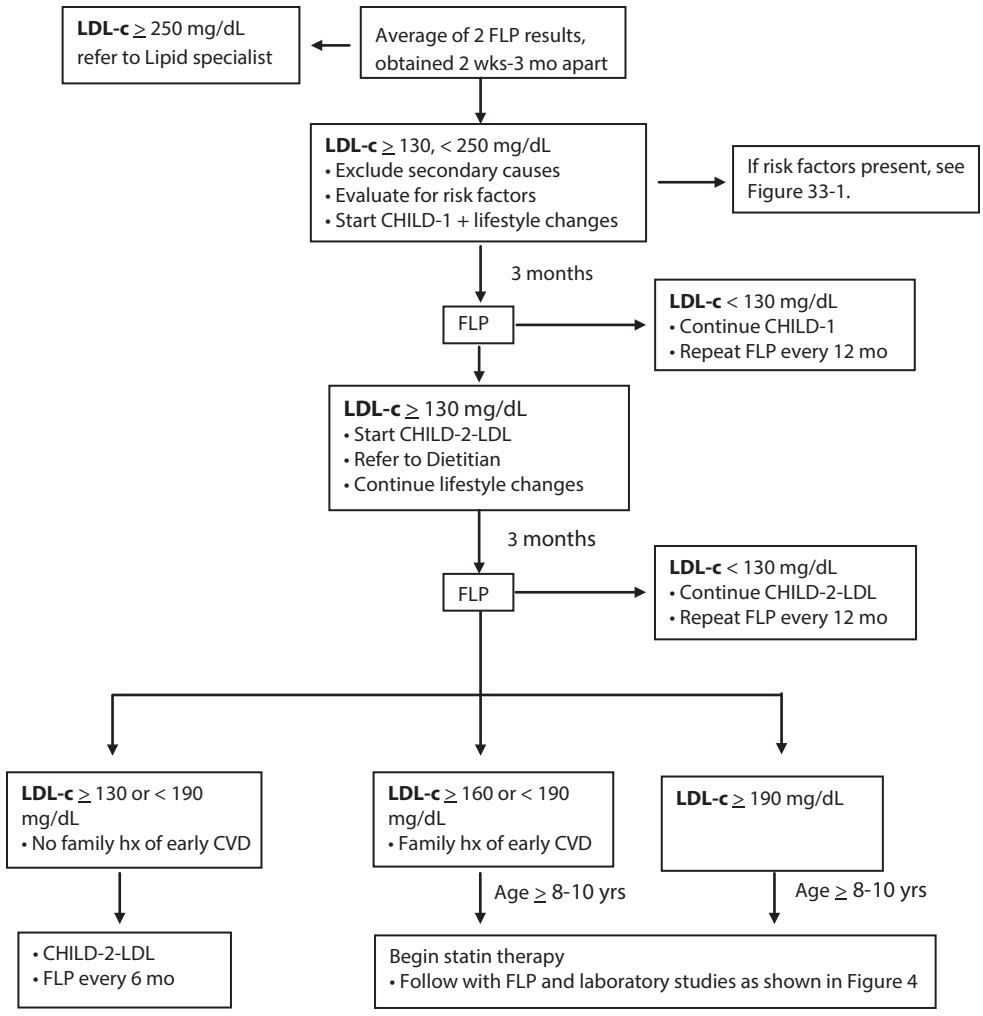
(Figure 69.2) or a family history of premature CVD in first- and/or second-degree relatives. Tendon xanthomas are not generally seen in children and adolescents with HeFH as they normally develop in adulthood. However, they may be palpable on a parent, particularly if they were untreated until adulthood.

FIGURE 69.2 Tendon xanthomas. From: Durrington, P. Dyslipidaemia. *Lancet* 2003; 362:717–731. In Rippe JM (ed): *Lifestyle Medicine* 3rd ed, CRC Press (Boca Raton), 2019. Reproduced by permission of Taylor & Francis Group.

69.5.2 Familial Combined Hyperlipidemia

Another common cause of hypercholesterolemia is familial combined hyperlipidemia (FCHL). This autosomal dominant genetic disorder is the most common genetic lipid disorder in the United States, affecting approximately one in 200 people. There is phenotypic variation among family members with FCHL, with the most common lipid phenotype showing elevated LDL-C and TGs, and low HDL-C. FCHL may also be seen in those with overweight, insulin resistance, or hypertension. FCHL should be suspected when the FLP demonstrates mixed dyslipidemia consisting of elevated TC levels (200–400 mg/dL), elevated TGs (200–800 mg/dL), and low HDL-C (<40 mg/dL), along with a family history of hypercholesterolemia or premature CVD.



69.6 THERAPY FOR PURE HYPERCHOLESTEROLEMIA

69.6.1 Dietary and Lifestyle Intervention

The NHLBI guidelines outline a staged approach to dietary intervention for dyslipidemia in children (Figure 69.3). The first step is called the Cardiovascular Health Integrated Lifestyle Diet (CHILD-1). After a trial of CHILD-1, a more intensive lipid-lowering dietary regimen can be undertaken, if necessary, focusing more on lowering LDL (CHILD-2-LDL) or triglycerides (CHILD-2-TG). Before implementing a CHILD-2 diet, a medical dietitian who is experienced in treating dyslipidemia should be consulted.[6]

69.6.2 Cardiovascular Health Integrated Lifestyle Diet

The CHILD-1 consists of a low saturated fat (<10% of total calories), moderate total fat (≤30% of total calories), low cholesterol (<300 mg/day), and minimal trans-fat diet.[6,25] Sugar-sweetened beverages, high sodium, high sugar, and fried foods should be limited. Other lifestyle changes should be encouraged, including weight

CVD=cardiovascular disease; FLP=fasting lipid profile; hx=history; LDL-c=Low density lipoprotein cholesterol; mo= months; wks= weeks

FIGURE 69.3 The NHLBI guidelines staged approach to dietary intervention for dyslipidemia in children.

management, decreasing sedentary time to no more than two hours daily, and increasing moderate to vigorous physical activity to at least one hour daily. After three months of CHILD-1 and lifestyle changes, a repeat FLP should be obtained. If the LDL-C remains elevated for age, then the family should meet with a dietitian and the CHILD-2-LDL implemented.[6,25] The Child-2-LDL recommends that dietary fat intake be limited to 25% to 30% of total calories, with saturated and monounsaturated fats at no more than 7% and 10% of daily calories, respectively. Trans fats should be avoided. After three months on CHILD-2-LDL, a repeat FLP should be performed (Figure 69.3).[6]

69.6.3 Adjunctive Dietary Therapies

Phytosterols (plant sterols and stanols) are naturally found in plant-based foods and used to lower LDL-C. A meta-analysis found that doses <3 g/day are effective in lowering LDL-C by 5–10% in adults and children with HeFH.[26] Viscous fibers have also been shown to reduce TC, LDL-C, and non-HDL-C. Foods that are high in viscous fibers include oats, barley, legumes, fruits, and vegetables, as well as supplements containing psyllium husk and methylcellulose.[27,28] Recommendations for children include up to 6 g/day of supplemental psyllium fiber for ages <12 years and up to 12 g/day for children ≥12 years. Adjunctive dietary therapies should be considered in children who are unable to lower their LDL-C with dietary and lifestyle management alone and those who are either too young to start a statin or whose LDL-C is nearing the statin therapy threshold.

69.6.4 Pharmacological Intervention for Elevated Low-Density Lipoprotein Cholesterol

Due to the genetic nature of HeFH and FCHL, many children and adolescents are not able to achieve their goal

LDL-C and/or non-HDL-C levels with diet and lifestyle changes alone.

69.6.4.1 When to Start Medication

Medication should be considered in children between 8 and 10 years with LDL-C over goal levels (based on risk factor stratification). The LDL-C cut points for consideration of starting a statin medication are outlined in Figure 69.3 for those with standard risk and Figure 69.1 for those with CVD risk factors (Table 69.3). Some high-risk patients may eventually need more than one lipid-lowering medication and should be referred to a lipid specialist.

69.6.4.2 Hydroxy-3-methylglutaryl-coenzyme A Reductase Inhibitors (Statins)

Hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins) are the first-line medication to reduce LDL-C and non-HDL-C in the pediatric population.[29,30] Statins reduce intracellular cholesterol by inhibiting the rate-limiting enzyme in endogenous cholesterol biosynthesis, HMG-CoA reductase. This leads to the upregulation of LDL receptors in the liver, increasing hepatic clearance of LDL-C from the circulation. Statins also decrease very low-density lipoprotein (VLDL) and intermediate-density remnants, which result in modest TG lowering.

The FDA-approved statins for use in the pediatric population are listed in Table 69.5. These statins are approved for use in children ages ten years or older (≥8 years for pravastatin). The safety and efficacy of statin use throughout childhood and adolescence have been demonstrated in several clinical trials.[31–35] No difference in adverse events has been noted in the pediatric compared with the adult population[36] Studies in children have demonstrated that statins can slow the progression of atherosclerosis and may decrease the future risk of developing atherosclerosis if started at a younger age.[37,38]

69.6.4.3 How to Initiate, Titrate, and Monitor Children on Statin Medication

Figure 69.4 outlines how to initiate, titrate, and monitor children and adolescents on a statin medication. The lowest possible dose should be used when starting. The statin should be taken once a day, ideally at night, although atorvastatin and rosuvastatin can be taken in the morning due to their longer half-lives. After six to eight weeks of consistent use, an FLP, glucose level, and hepatic enzymes, should be obtained. If LDL-C levels are at target, then therapy should continue at the same dose with a repeat FLP in eight weeks, then three months, and then every six months. Hepatic enzyme levels can be measured annually if they have been normal and no dose adjustment has been made in the interim. If LDL-C target levels are not achieved, the statin should be increased by the lowest increment, and a repeat FLP should be obtained in six to eight weeks. If this increased dose does not result in goal LDL-C, ensure that the child is taking the medication as prescribed. If there is adequate adherence, then the physician should refer to a lipid specialist for consideration of a second lipid-lowering medication.[6]

It is important that patients have routine monitoring while on statin therapy (Figure 69.4). Liver and muscle toxicity are the most common concerns for patients and families. Prior to starting a statin, the physician should assess

TABLE 69.5
Medications for Reducing Elevated LDL-c in Children and Adolescents[30]

Medication Class	Medications and Starting Doses	Effect on Lipids	Potential Side Effects
HMG-CoA reductase inhibitors (statins)	Atorvastatin‡: 10 mg QHS or QD Lovastatin‡: 10 mg QHS Pravastatin*: 10 mg QHS Simvastatin‡: 5 mg QHS Rosuvastatin‡: 5 mg QHS or QD	Decrease LDL-C Increase HDL-C Decrease TG	Elevated liver enzymes, CK levels, hemoglobin a1c; muscle cramps and weakness; myopathy; rhabdomyolysis

‡FDA approved for children 10 years and older

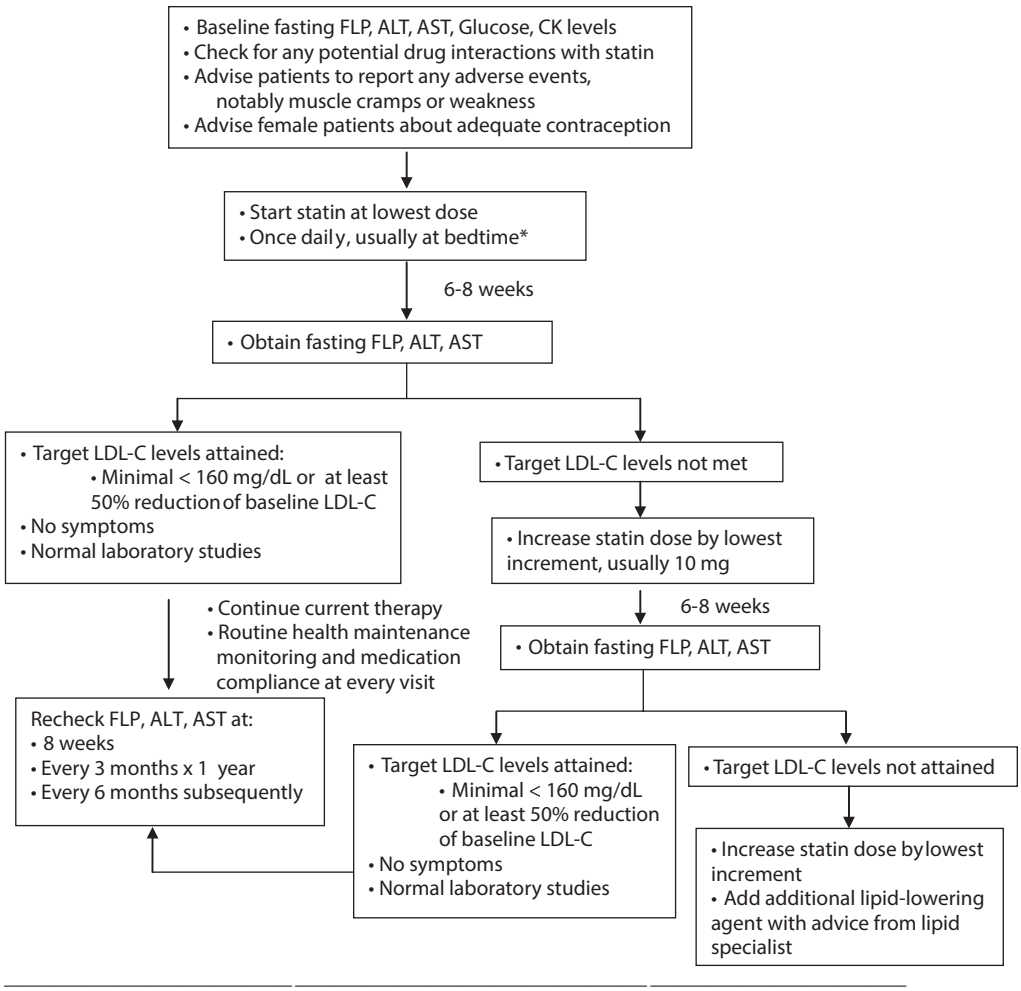

FIGURE 69.4 How to initiate, titrate, and monitor children on statin medication.

for contraindications to use.[30] Once menses have started, girls should be counseled that statins may be teratogenic; physicians should document that female patients are not pregnant and, if sexually active, are using adequate birth control. The patient's medications should be reviewed to assess for potential drug interactions. Patients should limit grapefruit juice if they are taking atorvastatin or simvastatin due to inactivation of the intestinal cytochrome P450 3A4, which increases the blood levels of these statins.[39]

After starting a statin, patients should report any side effects, notably muscle pain, cramps, or weakness. If symptoms are present, they should be evaluated in relation to recent physical activity. If the symptoms seem excessive for the physical activity performed, the medication should be stopped, and a creatinine kinase (CK) level checked. The clinical spectrum of statin-induced myotoxicity includes an asymptomatic rise in CK levels, myalgia (muscle weakness or soreness without CK elevation), myositis (myalgia with CK >10 times upper limit normal), and rhabdomyolysis (widespread destruction of muscle with CK >10 times upper limit normal and decreased renal function). In a meta-analysis of statin use in children, risk of myotoxicity was no greater for those taking a statin versus a placebo.[34] Nevertheless, if myositis is suspected, the statin should be discontinued due to the rare possibility of rhabdomyolysis, which can be life-threatening. After starting a statin, there can be minor elevations of liver transaminase levels (<3 times the upper limit normal). Therapy can continue as these fluctuations are often transient. If the transaminase levels are >3 times the upper limit of normal, the medication should be stopped, and levels should be rechecked in two weeks. Medication can resume, commonly at a lower dose, when symptoms and/or laboratory abnormalities have normalized.[30]

69.6.4.4 Therapy Goals

For those with no risk factors, once a statin is started, the initial therapy goal is LDL-C of ≤160 mg/dL or 50% of

the starting LDL-C. Once that is achieved, then a goal of ≤130 mg/dL can be considered, with an ideal goal of ≤110 mg/dL. For those with CVD risk factors, the initial therapy goal while on a statin is an LDL-C level of <100–≤130 mg/dL depending on risk level (Figure 69.1). As described previously, statin medications should be increased by single dose increments until the goal is met or another agent added.[6,30] There is a balance between achieving the desired LDL-C level and increasing the dose of medication. With increasing doses of statin, there are smaller improvements in LDL-C with the additional risk of side effects.

69.6.4.5 Cholesterol Absorption Inhibitors

Ezetimibe inhibits cholesterol absorption at the level of the intestinal villi, decreasing the absorption of dietary cholesterol, upregulating LDL-C receptors, and improving LDL-C clearance from circulation. Ezetimibe is dosed at 10 mg daily. The addition of ezetimibe can lead to an additional 20% LDL-C lowering when used with a statin, without significantly increasing adverse events in children and adults.[40–42] Ezetimibe should be considered as a second medication for those children who do not meet LDL-C goals while on a statin alone.[6]

69.6.4.6 Bile Acid Sequestrants

Prior to the use of statins, bile acid sequestrants were the medication of choice for children because they were felt to be safer as they were not absorbed.[25] However, between the poor palatability of these agents and the well-documented safety and efficacy of statin medications, bile acid sequestrants are no longer first-line therapy for children.[6]

69.6.4.7 Proprotein Convertase Subtilisin/Kexin Type 9 Inhibitors

Proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors are a newer class of medication for those with persistently elevated LDL-C despite statin and ezetimibe therapy. They are human monoclonal antibodies to PCSK9, an important regulator of LDL-C metabolism. Evolocumab is currently the only PCSK9 inhibitor approved for children (≥10 years) with familial hypercholesterolemia. It is a subcutaneous injection given every two or four weeks. In the phase III trial for evolocumab, those in the treatment arm experienced a 38% greater reduction in LDL-C compared with those randomized to placebo.[43]

69.6.5 Clinical Case 1 Follow-Up

- A.S. returned to the clinic after six months of diet and lifestyle changes. He started packing his lunch for school, going to the gym four days per week, and lost 5 lb. However, his LDL-C did not change significantly. He was started on atorvastatin 10 mg and was up-titrated first to 20 mg and then to 40 mg without any side effects. His most recent laboratory studies showed (in mg/dL): TC 221, HDL-C 73, LDL-C 138, TG 51, and non-HDL-C 148.

69.7 LIFESTYLE-RELATED DYSLIPIDEMIA

69.7.1 Clinical Case 2

A 12-year-old male, N.T., presents to the lipid clinic for evaluation of dyslipidemia. N.T. had a FLP first checked at the age of 10 years as part of universal screening. At that time, his TGs were elevated to 231 mg/dL, and he was instructed to eat healthier. Labs were not rechecked until two years later. Mom reports that N.T. started gaining excess weight around the age of five years but experienced a 60 lb weight gain over the past two years. Family history is negative for early heart disease and dyslipidemia in first- or second-degree relatives. N.T. is not involved in organized sports but does participate in gym class daily. His sedentary time is four hours daily on weekdays and eight hours on weekends. His breakfast consists of high sugar cereal with whole milk and juice. For lunch, he eats a turkey sandwich with cheese on white bread, chips, and an apple. He drinks sweetened iced tea. His after-school snack typically consists of cookies or pudding. Dinners are mainly lean meat, mashed potatoes or pasta, vegetables, and juice; for dessert, he eats ice cream. On physical examination, his height and weight are at the 57th and 97th percentile, respectively. His BMI is at the 98th percentile, placing him in the obese category. His blood pressure is 107/64. A physical exam revealed faint abdominal striae on his abdomen and acanthosis nigricans behind his neck. His FLP reveals (in mg/dL): TC 199, HDL-C 39, LDL-C 82, TG 389, and non-HDL-C 160. His thyroid studies were normal. His ALT was mildly elevated and AST was normal. His glucose and hemoglobin A1c were normal.

69.7.2 Combined Dyslipidemia of Obesity

Nearly half of all overweight and obese children have at least one abnormal lipid value.[44] In this population, the most common dyslipidemia is combined dyslipidemia of obesity (CDO). CDO is characterized by elevated TG, low HDL-C, elevated non-HDL-C, and normal or mildly elevated LDL-C levels. The LDL-C particles tend to be the small, dense subtype.[45] In Clinical Case 2, given N.T.'s BMI and lipid profile, it is highly likely that he has CDO.

Patients with CDO are also frequently found to have elevated insulin levels and central fat deposition. In the Framingham Offspring Study, CDO was found to be one predictor of early clinical cardiovascular events, such as myocardial infarction and death from CVD.[46] Those with elevated TG levels and TG/HDL-C ratios at 12 years of age and similar lipid values in adulthood were also at increased risk for experiencing premature CVD as an adult.[47]

69.8 FAMILIAL HYPERTRIGLYCERIDEMIA

Familial hypertriglyceridemia (FHTG) is an autosomal dominant lipid disorder with a prevalence of approximately one in 500. It is caused by increased VLDL production and/

or decreased VLDL catabolism. In patients with FHTG, certain lifestyle factors or medications can increase VLDL production and worsen hypertriglyceridemia, including a high-carbohydrate diet, obesity, insulin resistance, alcohol use, or estrogen therapy. Patients should be counseled regarding these precipitating factors.

In patients with FHTG, the lipid profile is notable for markedly elevated TGs (250–1000 mg/dL), normal or mildly increased TC (usually <250 mg/dL), and low HDL-C levels. LDL-C levels are generally low or normal. The ratio of TC/TG tends to be lower in FHTG than in FCHL. Eruptive xanthomas (Figure 69.5) may be seen in patients with TG levels >1000 mg/dL and should alert the practitioner to obtain a lipid profile. Patients with severe hypertriglyceridemia (>2000 mg/dL) are at risk for developing pancreatitis.[48]

69.9 THERAPY FOR HYPERTRIGLYCERIDEMIA

69.9.1 Dietary Therapy

Most children and adolescents with hypertriglyceridemia will see normalization or significant improvement in their triglycerides with diet and lifestyle changes. Similar to dietary therapy for pure hypercholesterolemia, a trial of the CHILD-1 diet should be used for patients with CDO, followed by a more intensive dietary regimen CHILD-2-TG if dyslipidemia persists.[6] In a child with CDO, the dietary history should include not just the food the child is eating, but also what and how much the child is drinking. Eliminating sweetened beverages (e.g., soda, iced tea, lemonade, sports drinks) will almost always lead to a reduction in TG levels and weight loss. Additionally, there should be an increase in complex carbohydrates and fiber and consumption of low-mercury fish at least twice weekly. Along with dietary changes, increasing exercise, decreasing sedentary time, and weight loss are very important. After three months of dietary changes, a repeat FLP should be performed. Therapy goals for those without risk factors are outlined in Figure 69.6 and for those with risk factors in Figure 69.1.

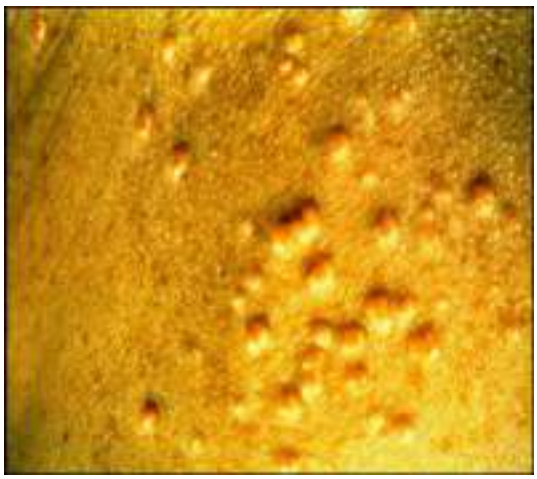

FIGURE 69.5 Eruptive xanthomas (from: Leaf DA. Chylomicronemia and the chylomicronemia syndrome: A practical approach to management. *Am J Med* 2008; 121:10–12. In Rippe JM (ed): *Lifestyle Medicine* 3rd ed, CRC Press [Boca Raton], 2019. Reproduced by permission of Taylor & Francis Group).

69.9.2 Pharmacologic Therapy

Changes to diet and lifestyle, in addition to weight loss, when necessary, are usually sufficient to reduce TG levels. If the child has been adherent to dietary changes, medication can be considered if the TG levels remain greater than target (Figure 69.6). If the average of two fasting TG levels is ≥500 mg/dL or a single fasting TG level is ≥1000 mg/dL, this is likely due to genetic hypertriglyceridemia and the patient should be referred to a lipid specialist.

69.9.3 Omega-3 Fatty Acids

Omega-3 fatty acids (or fish oil) decrease the synthesis of TGs by increasing the degradation of fatty acids. The use of omega-3 fish oil capsules at doses of 2–4 g/day can lower TGs by 30% to 45% and increase HDL-C levels by 6% to 17%. However, it may increase LDL-C levels up to 31%[49] There have been mixed results in the adult literature regarding omega-3 fatty acids and primary CVD reduction.[50] Those with elevated TGs and low HDL-C levels appear to be a subgroup in which CVD risk reduction may be seen.[51] Studies in children have been limited by small sample sizes but have not shown a significant difference in TG levels in those taking omega-3 fatty acids. There have been no significant reports of adverse effects.[49,52] There are a few FDA-approved fish oil capsule preparations as well as several over-the-counter options. Dosing for TG-lowering effect should be 2000 to 4000 mg daily of the eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) components.

69.9.4 Fibric Acid Derivatives

Fibric acid derivatives, or fibrates, work in a complex way to break down VLDL-C and TGs and decrease hepatic synthesis of TG. Fibrates have been shown to lower TGs and increase HDL-C levels without an increase in LDL-C levels. Although not currently FDA-approved for children, a small study in children demonstrated efficacy in lowering TG levels.[53] Prescribing fibrates in the pediatric population should only occur under the guidance of a lipid specialist.

69.9.5 Clinical Case 2 Follow-Up

Three months after the initial visit, N.T. returned to the clinic. He decreased his sugar-sweetened drinks to one serving daily, transitioned to 2% milk, and increased his fruit and vegetable intake. He also joined the soccer team and lost 9 lb, improving his BMI percentile. His lipid panel had significantly improved and showed (in mg/dL): TC 150,

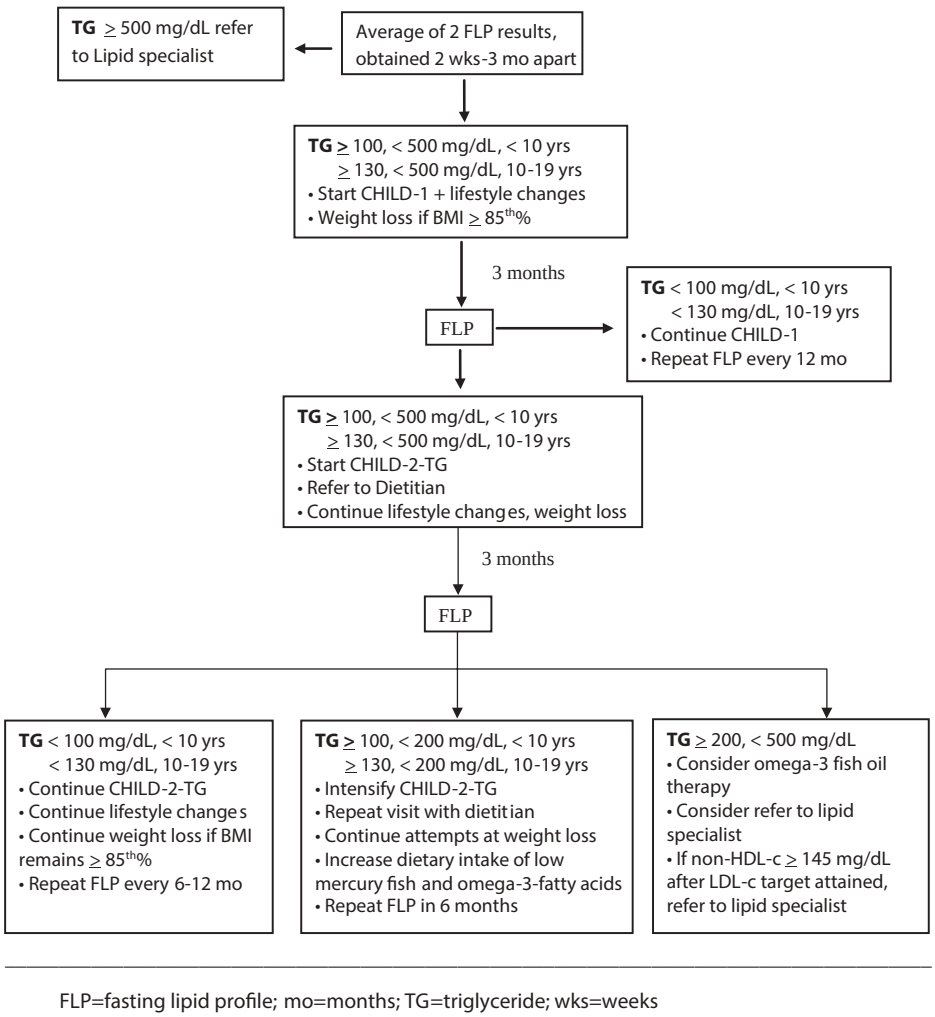

FIGURE 69.6 Therapy goals for those without risk factors.

HDL-C 42, LDL-C 80, TG 139, and non-HDL-C 108. His ALT normalized.

69.10 CONCLUSION

Children with dyslipidemia are at increased risk for premature CVD. Identifying who is at risk has taken on more urgency in the current era due to the increasing prevalence of childhood cardiovascular risk factors, including obesity, hypertension, poor diet, and sedentary behavior. For nearly all children and adolescents with dyslipidemia, the first step in therapy is diet and lifestyle changes. While this can be quite challenging, even small alterations can significantly reduce cardiovascular risk and frequently relieve the need for lipid-lowering medication. However, for children with certain forms of genetic dyslipidemia, as well as those who are unsuccessful in making adequate lifestyle changes, pharmacological therapy may be required. Statin medications are the first-line treatment in the pediatric population for lowering LDL-C levels. Other medications are rarely used and, if necessary, the patient should be referred to a lipid specialist. After a concerted effort on the part of the patient and family with diet modification and increasing physical activity, omega-3 fatty acids may be considered for significantly elevated triglycerides. It is imperative that those who care for children and adolescents identify patients at risk for early CVD and treat or refer them appropriately. Doing so can reduce the lifetime risk of CVD morbidity and mortality, improving the lives of a large number of our youth.

CLINICAL APPLICATIONS

- Increasing numbers of children and adolescents are being diagnosed with dyslipidemia. These children are at risk for developing premature cardiovascular disease.
- Universal screening should occur once from 9–11 years and again between 17 and 21 years using either a non-fasting lipid profile or a fasting lipid profile. If abnormalities are found as detailed in this chapter, then a repeat fasting lipid profile should be repeated in two weeks to three months after dietary and lifestyle changes.

- Before medication is considered, dietary changes and increasing physical activity should be considered in nearly all children and adolescents with dyslipidemia.
- Heterozygous familial hypercholesterolemia is a common genetic dyslipidemia that is characterized by LDL-C levels >95th percentile. It is important to identify as it will lead to premature cardiovascular disease if left untreated. First-line medication treatment is a statin medication at age ten, or age eight years if considered high-risk.
- Combined dyslipidemia of obesity is being seen more frequently and is characterized by elevated triglycerides, mild-moderately elevated LDL-C, and low HDL-C. Treatment is dietary changes, increasing physical activity, and weight stabilization or loss; medication may be needed if lifestyle changes are not made.

70 Diagnosis, Management, and Treatment of Systemic Hypertension in Youth

Carissa M. Baker-Smith, MD, MPH, MS and Samuel Gidding, MD

KEY POINTS

- Elevated blood pressure in children and adolescents is most likely to be primary hypertension and is associated with increased risk for cardiovascular disease.
- Children and adolescents should have blood pressure measured and assessed at each health maintenance visit.
- Children and adolescents with persistent blood pressure elevation should be treated first with increased physical activity and a Dietary Approaches to Stop Hypertension (DASH) type diet along with a reduction in dietary sodium.
- When lifestyle changes are not sufficient to lower blood pressure in children and adolescents with hypertension, pharmacologic agents should be considered. When pharmacologic agents are used, lifestyle interventions should be continued.

70.1 INTRODUCTION

Approximately 2–4% of all children are hypertensive.[1,2] Hypertension (HTN) in youth is an accepted risk factor for HTN in adulthood, while HTN in adulthood is a major cause of heart failure, atherosclerotic heart disease, stroke, and chronic kidney disease (CKD)-related morbidity and mortality.[3] Knowledge of how best to diagnose, manage, and treat systemic HTN in the child and adolescent is essential for the primary care and subspecialist provider.

This chapter is meant to provide a summary of recent proposed changes related to the diagnosis, management, and treatment of high blood pressure (HBP) in youth. Information provided in this text relies upon recommendations made in the 2017 American Academy of Pediatrics "Clinical Practice Guideline for Screening and Management of High Blood Pressure in Children and Adolescents".[4,5] A summary of the 30 key action statements (KAS) and the 27 additional recommendations made in the guideline is provided at the end of the chapter. A case and questions have also been included at the end of the chapter to reinforce the main points.

70.2 DIAGNOSIS AND PREVALENCE OF HYPERTENSION

HTN, defined by an office systolic or diastolic BP greater than the 95th percentile persistent over three or more outpatient visits, or in adolescents ≥130/90 mmHg, is estimated to occur in approximately 2–4% of all children (Table 70.1).[1] Masked hypertension (MH) is defined as normal BP in the office and abnormal BP outside of the office.[4] It is estimated that 10% of children have masked hypertension.[6] However, diagnosing MH typically requires wearing a 24-hour ambulatory blood pressure monitor (ABPM) and finding high out-of-office BPs but measuring normal in office BP.[4] Given the limited availability of ABPM devices, we may underestimate the prevalence of masked hypertension. The prevalence of white coat hypertension (WCH) is also probably underestimated for similar reasons but is currently believed to occur in as many as 13% of children.[7] The prevalence of HTN is highest among children with overweight status and obesity.[8]

The 2017 CPG included several modifications of prior guidelines. These included the replacement of the term pre-hypertension with the term elevated blood pressure (EBP). A simplified blood pressure (BP) table was included to allow for more efficient recognition of abnormal BP (e.g., flagging of high BP values; thresholds in Table 70.2). A role for oscillometric BP measurements was included in the diagnostic algorithm. Updated tables of BP values were developed, removing children with overweight status and obesity from the data set used to derive normative BP values as these children skewed the distribution upward.[9] Simplified diagnostic criteria for HBP once children were 13 years of age and above that aligned with the adult BP classification system were developed (Table 70.1). Finally, recommendations for greater inclusion of ABPM, screening, and data from clinical trials conducted to meet the Food and Drug Administration (FDA) pediatric exclusivity provision were included.

70.3 DIAGNOSIS

Before 1977, BP was not routinely assessed in children. It was not until the mid-1970s and the convening of a dedicated Task Force focused on examining hypertension in youth that the National High Blood Pressure Education Program (NHBPEP) of the National Heart Lung and Blood Institute (NHLBI) began to generate data examining BPs in youth.[4] It was through this process that normative BP ranges were determined. These studies showed that a child's BP was related to age, height, and sex.

TABLE 70.1
Definition of Hypertension[4]

For Children One to <13 Years of Age	For Children ≥13 Years of Age
Normal BP: <90th percentile	Normal BP: <120/<80 mmHg
Elevated BP: ≥90th percentile to 95th percentile; or 120/80 mm Hg to <95th percentile (whichever is lower)	Elevated BP: 120/<80 to 129/<80 mm Hg
Stage 1 HTN: ≥95th percentile, or 130/80 to 139/89 mm Hg (whichever is lower)	Stage 1 HTN: 130/80 to 139/89 mm Hg
Stage 2 HTN: ≥95th percentile + 12 mm Hg or ≥140/90 mm Hg (whichever is lower)	Stage 2 HTN: ≥140/90 mm Hg

TABLE 70.2
Simplified Blood Pressure Table[4]

Age (years)	Blood Pressure (mm Hg)			
	Boys		Girls	
	Systolic	Diastolic	Systolic	Diastolic
1	98	52	98	54
2	100	55	101	58
3	101	58	102	60
4	102	60	103	62
5	103	63	104	64
6	105	66	105	67
7	106	68	106	68
8	107	69	107	69
9	107	70	108	71
10	108	72	109	72
11	110	74	111	74
12	113	75	114	75
≥13	120	80	120	80

Given the paucity of long-term outcome data, it has not been possible to link a level of childhood BP to later cardiovascular disease (CVD), though recently a study that modeled data from longitudinal epidemiologic studies spanning the life course has shown that young adult BP exposure is a significant predictor of adult-onset major cardiovascular events. Therefore, the use of normative BP ranges with cut points based on percentiles to define HTN has remained in place.

For children 1–13 years of age, the diagnosis of HTN is based on age, sex, and height-based BP percentiles. For children greater than or equal to 13 years of age, the diagnosis of HTN was made to align with BP cut-off values consistent with the 2017 ACC/AHA/AAPA/ABC/ACPM/AGS/APhA/ASH/ASPC/NMA/PCNA Guideline for the Prevention, Detection, Evaluation, and Management of High Blood Pressure in Adults.[10] The diagnosis of systemic HTN is based on repeated measurement of systolic and/or diastolic BP that, when averaged over three visits, equals or exceeds the 95th percentile (Figure 70.1).[4] In addition, the terminology was modified to reflect the recognition of BP >90th percentile or greater than 120/80 mmHg as associated with target organ damage (TOD), replacing the term pre-hypertension with "elevated BP".[4]

Given that the use of the full BP tables is cumbersome, a simplified table with a negative predictive value of 99% was created as a way for healthcare staff to more immediately determine which children require reassessment of BP, based on initial oscillometric (or manual) measurements. (Table 70.2) This table reduces the number of BP values from 476 to 52 values. Using the simplified table, healthcare providers need only be aware of a child's sex and age to determine whether the BP requires repeat measurement. The simplified BP is derived from the fifth height percentile and 90th BP value for each age and gender.

Diagnosis of HTN requires multiple measurements of BP (Figure 70.1). The initial BP may be an oscillometric measurement using a validated (www.dableducational.org) and calibrated device or an auscultatory measurement using an aneroid or mercury sphygmomanometer. Appropriate technique, including the use of an appropriately sized BP cuff size, is essential (https://www.youtube.com/watch?v=bYcCkiXJA_Q&t=9s). Once the average of two oscillometric BP readings has been determined to be elevated, then two confirmatory auscultatory measurements should be obtained. These measurements are then averaged. If the average of the auscultatory measurements is greater than the 90th percentile, then a classification of the BP is assigned: either elevated BP, Stage 1 HTN, or Stage 2 HTN.

The frequency with which the BPs are repeated is determined by the stage. Lifestyle counseling should be initiated in all cases—including among children with normal BP. If the BP is elevated, then the BP should be repeated at six months and again at 12 months. If at 12 months the BP is still categorized as elevated, then further diagnostic evaluation should be pursued. If the BP is classified as Stage 1 HTN and the person is asymptomatic (e.g., no reported headache) then it should be repeated in one to two weeks using auscultation (and not oscillometric). If the BP remains in the Stage 1 category, then it should be repeated in three months. If Stage 1 HTN persists at the time of the third visit, despite lifestyle and nutrition counseling, then ABPM (if available) should be ordered for confirmation of diagnosis and for distinguishing systemic Stage 1 HTN from WCH. Diagnostic evaluation, including echocardiography, should also take place at this time and pharmacologic treatment initiated if HBP is confirmed. Finally, if the BP is Stage 2, then upper and lower BP should be checked. Upper and lower extremity BP measurements should include the right arm and either leg and may include an additional measurement in the left leg. This measurement is obtained to assess for coarctation of the aorta (or mid-aortic syndrome). If the BP is higher in the right arm compared with the leg, especially

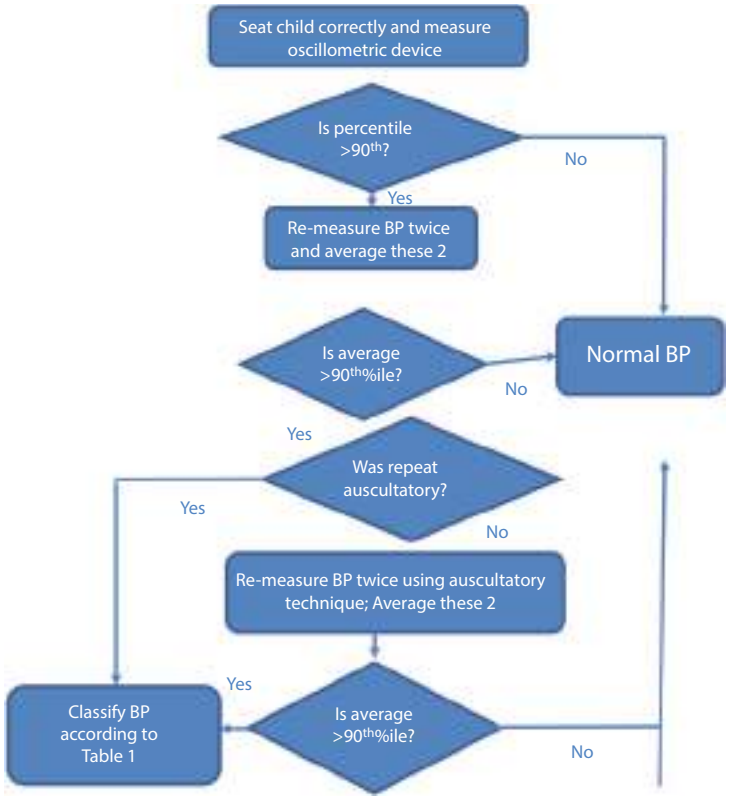

FIGURE 70.1 The 2017 modified BP measure algorithm.

if there is greater than a 20-mmHg gradient between the upper and lower extremities, then evaluation for coarctation of the aorta should be carried out. Next, the BP should be repeated within one week, and referral to subspecialty care considered. If the BP is still elevated in the Stage 2 range at the time of repeat measurement, then diagnostic evaluation for potential secondary causes should commence. The child should have echocardiography to evaluate for left ventricular hypertrophy. The child should be referred to subspecialty care within one week and treatment initiated. A BP measurement in the Stage 2 range and where the child is symptomatic or where the BP is greater than 30 mmHg above the 95th percentile (or >180/120 mmHg) is an indication for immediate evaluation and suggestive of hypertensive urgency. Symptoms of hypertensive urgency may include headache, dizziness, nausea/vomiting, or chest pain.[11]

In all cases, especially with elevated BP and Stage 1 HTN, a high index of suspicion for WCH should be maintained given that initial office measurements are typically higher and repeated measurement often results in a more accurate assessment of the true BP.[12]

Evaluation of BP should begin at three years of age for most children and most children should undergo repeated measurement at each well child visit. Children with risk factors for HBP, including premature birth, a history of congenital heart disease (aortic arch obstruction or coarctation of the aorta), and kidney disease, should undergo BP screening beginning at birth and at each patient encounter.

70.4 AMBULATORY BLOOD PRESSURE MONITORING

The 2017 CPG provides greater detail regarding when to perform ambulatory BP monitoring in children. Indications for ABPM include the following:

1. Confirmation of the diagnosis of HTN in children and adolescents with repeatedly elevated office BP readings; evaluation for WCH.
2. Evaluation for MH in children and adolescents with a history of repaired coarctation of the aorta.
3. Evaluation of BP pattern and risk for hypertensive TOD in children and adolescents with high-risk conditions, such as CKD.
4. Evaluation for possible HTN in children and adolescents with obstructive sleep apnea (OSA) syndrome.
5. Evaluation of BP in pediatric heart and kidney transplant recipients.
6. Assessment of treatment effectiveness in children and adolescents receiving antihypertensive medications.
7. Monitoring of treatment efficacy and possible MH in children and adolescents with CKD.

The use of ABPM has become more common and is now recommended by the US Preventive Services Task Force (USPSTF) to confirm a diagnosis of hypertension among

adults 18 years of age and older.[13] The USPSTF has not yet adopted recommendations for routine use of ABPM in pediatric patients. Current recommendations regarding ABPM use in pediatric patients are based on US guidelines. European guidelines also endorse the use of the ABPM device, but unlike the US guidelines, only when considering antihypertensive medication initiation or for further evaluation of the blood pressure if there has been a hypertensive response during the treadmill test.[14]

ABPM devices are typically no larger in size than a cell phone and record BPs periodically throughout the day and night (e.g., every 20–30 minutes). Limitations of ABPM measurements include a lack of normative data for children below 120 cm in height and the lack of existing outcome data linking ABPM data from childhood with cardiovascular events in adulthood.

The SHIP-AHOY study has addressed several unknowns regarding the value of ABPM including the enhanced sensitivity and specificity of ABPM use for identifying left ventricular target organ injury (e.g., left ventricular hypertrophy [LVH])[15] among persons with systemic hypertension. The presence of an office BP above the 85th percentile has excellent test characteristics for using ABPM most efficiently to diagnose HTN in an outpatient setting.[16] There is now much more population-based data on which to base normal values and definitions for hypertension using ambulatory monitoring.[17,18] Benefits of proposed ABPM use include (1) options for repeated measurement allowing for more data to determine how often and by what degree the BP is elevated both during the day and at night and (2) additional information regarding BP trends (e.g., presence or absence of nocturnal dipping). However, poor tolerability of the ABPM device has been associated with a higher prevalence of ambulatory HTN in adolescents.[16]

70.5 NEONATES AND INFANTS

Information regarding normative BP ranges in neonates and infants is limited. The International Neonatal Consortium recommends that oscillometric BP devices be used to assess BP in newborns and infants but recognizes the potential limitations of such devices in this population when measured BP is either too high or too low.[19] Risk factors for neonatal hypertension include gestational age, birth weight, and maternal factors. Common causes of neonatal hypertension include umbilical catheter associated thrombosis, renal parenchymal disease, and chronic lung disease.[19] The incidence of neonatal HTN is approximately 1%.[20] At present, it is recommended that readers refer to work published by Dionne et al. regarding normative BP values for this population.[20,21]

70.6 WHITE COAT HYPERTENSION

WCH can be found in up to 50% of children with elevated BP. [22] More common than essential hypertension in youth, the diagnosis of WCH relies on the presence of an abnormal in office BP and normal out-of-office BP. ABPM is the preferred method for diagnosing WCH as home measurements and school nurse measurements of home BP may be unreliable.

70.7 MASKED HYPERTENSION

MH occurs when patients have normal office BP but elevated BP on ABPM, and it has been found in 10% of unselected children studied by ABPM.[6] Children at greatest risk for MH may include children with CKD, a history of solid organ transplantation, a history of aortic coarctation, and other secondary forms of systemic HTN.[4] MH has also been associated with the development of TOD.[25,26]

70.8 HYPERTENSION EMERGENCY AND URGENCY

A BP that is greater than 30 mmHg above the 95th percentile (or >180/120 mmHg in an adolescent) requires immediate referral for care in an emergency setting.[4] Patients with such extreme elevations in BP should undergo immediate evaluation for secondary causes.

In such patients, treatment should also be initiated immediately. However, BP should not be reduced by more than 10% during the first eight hours and by no more than 20% during the first 24 hours. Children with extreme elevation in BP are at risk for acute target organ effects, including encephalopathy, acute kidney injury, and congestive heart failure (CHF). Treatment may be initiated with oral antihypertensive agents if the patient is able to tolerate oral therapy and if life-threatening complications have not yet developed. Intravenous agents are indicated when oral therapy is not possible because of the patient's clinical status or when a severe complication has developed (such as CHF) that warrants a more rapid and controlled BP reduction. In such situations, the BP should be reduced by no more than 25% of the planned reduction over the first eight hours, with the remainder of the planned reduction over the next 12 to 24 hours.[27,28] The ultimate short-term BP goal in such patients should generally be around the 95th percentile.

70.9 ASSOCIATED COMORBIDITIES

Excess body weight raises BP.[29] This is most clearly shown by the difference in BP tables between the Fourth Report and the 2017 AAP guideline showing slightly lower BP levels for age, height, and sex in the current tables.[4] The prevalence of hypertension is about three-fold higher in children with overweight/obesity than in normal-weight children. Gaining excess adiposity is associated with incident HTN implying that obesity prevention is the most effective form of HTN prevention. Children with obesity are more likely to sustain the presence of abnormal BP from visit to visit than normal-weight children. Measurement of BP requires attention to proper cuff size so that BP is not over-estimated.[4] Children with obesity are more likely to have MH.[30]

The mechanism of HTN associated with obesity is likely a hyperdynamic state with increased sympathetic tone, increased sodium retention, and higher cardiac index.[31]

70.10 CHRONIC KIDNEY DISEASE

Elevated BP often accompanies CKD.[32] Since HTN chronically injures the kidney, typically by reducing nephron mass, and since HTN is associated with microalbuminuria, controlling HTN is important in CKD management. ABPM is required for the most accurate monitoring. The treatment goal is to achieve BP below the 50th percentile in ambulatory BP tables. Monitoring of proteinuria is important and if present an ACE or ARB agent should be prescribed. Unlike children with essential HTN, children with CKD and other secondary causes of HTN tend to have higher diastolic BPs. Renal disease represents the most common cause of secondary HTN, accounting for 34% of cases.[33]

70.11 DIABETES MELLITUS

The presence of type 1 (T1DM) or type 2 (T2DM) diabetes in association with HTN increases cardiovascular risk.[34] T1DM and T2DM are associated with early vascular injury and microalbuminuria. The threshold for initiation of antihypertensive pharmacologic therapy is lower for those with diabetes; all children with diabetes and elevated blood pressure (>90th percentile or 120/80, whichever is lower) require treatment.[35]

70.12 SLEEP-DISORDERED BREATHING AND OBSTRUCTIVE SLEEP APNEA

Sleep-disordered breathing (SDB) refers to a spectrum of sleep-related abnormalities that include: (1) primary snoring, (2) sleep fragmentation, and (3) OSA.[35] Numerous studies have demonstrated a relationship between SDB and abnormal BP.[36–38] While elevated BP has been reported among adults and children with OSA, a recent study found that, among children with varying degrees of OSA (mild: apnea hypoxia index [AHI] <1; moderate, AHI: 1-4; severe, AHI ≥5), nighttime SBP was highest among those with severe OSA.[39] Findings suggest that nighttime BP most likely correlates with OSA severity. However, OSA is also strongly associated with elevated blood pressure during the day.[40]

70.13 ATTENTION DEFICIT HYPERACTIVITY DISORDER AND COGNITION

Stimulant medication use has been associated with elevations in BP and case reports have suggested that stimulant medication use can be associated with the elevation of blood pressure.[42] However, the presence of HTN has been associated with abnormalities in executive function and working memory among young adults.[43] Recent evidence suggests that the presence of HTN in youth is also associated with cognitive deficiencies, including attention and working memory.[44] Children with HTN may be more likely to have attention deficit hyperactivity disorder (ADHD) and learning deficits (LDs), compared with subjects without HTN.[44] Diagnosing hypertension in the setting of ADHD medication use that increases BP requires careful monitoring and clinical decision-making. ABPM and home BP monitoring are useful as BPs obtained when medication has been cleared by the system can inform diagnosis.[41]

70.14 PRIMARY HYPERTENSION AND EVALUATING FOR SECONDARY CAUSES OF ESSENTIAL HYPERTENSION

70.14.1 Essential Hypertension

The predominant cause of HTN in youth is essential or primary HTN. Genetic and environmental factors may play a key role in the diagnosis. Children with essential HTN tend to be older (i.e., six years of age or older,[46,47] have a family history of HTN[48,49] and have an overweight or obese status).[7,50]

70.14.2 Coarctation and Congenital Abnormalities of the Heart

Coarctation of the aorta is a congenital abnormality with narrowing of the aorta within the juxtaductal region of the aortic arch. Persons with coarctation of the aorta may have evidence of hypoplasia of the aortic arch or other congenital defects of the heart. Coarctation of the aorta is associated with physical examination findings of diminished pulse value in the lower extremities. Patients with coarctation of the aorta may also have an elevated arm-to-leg BP difference with a gradient of at least 20 mmHg. Repair is ideally performed during infancy. However, post-repair, individuals remain at risk for re-coarctation and systemic hypertension. The estimated prevalence of HTN post-repair ranges from 17% to 77%.[51] Routine office-based assessment of BP is often insufficient as the prevalence of MH may be higher than initially appreciated.[52]

70.14.3 Monogenic Hypertension

Monogenic forms of HTN are uncommon, although the exact incidence is unknown. Monogenic forms of HTN should be suspected in hypertensive children with a suppressed plasma renin activity (PRA) or elevated aldosterone to renin ratio (ARR), especially if there is a family history of early-onset HTN. Potential monogenic forms of HTN include familial hyperaldosteronism type I (FH-I), glucocorticoid remediable aldosteronism, Liddle syndrome, pseudohypoaldosteronism type II (Gordon syndrome), apparent mineralocorticoid excess, familial glucocorticoid resistance, mineralocorticoid receptor activating mutation, and congenital adrenal hyperplasia.[52] All manifest as HTN

with suppressed PRA and increased sodium absorption in the distal tubule. Other features may include serum potassium abnormalities, metabolic acid-base disturbances, and abnormal plasma aldosterone concentrations. Clinical presentations of the monogenic forms of HTN can be highly variable.[53]

70.14.4 Endocrine-Related Causes

Endocrinopathies are rare but important secondary causes of HTN.[53-57] Clues to the presence of an endocrinopathy are electrolyte or calcium abnormalities, growth disturbance, and physical examination features related to known syndromes (e.g., Cushingoid appearance). Signs of sympathetic nervous system excess (tachycardia, HTN, flushing) might suggest hyperthyroidism or conditions associated with excess catecholamines such as a pheochromocytoma. Hyperaldosteronism is a common cause of resistant HTN in adults[56,57] and may be associated with more treatment-resistant HTN in youth.

70.14.5 Medications and Environment

A wide array of environmental stimuli and medications can impact BP. HTN should only be diagnosed based on resting BP or ambulatory BP and in the absence of pain or stressful stimuli. In the otherwise healthy patient, stimulant medications increase BP on average 2–3 mmHg but can have exaggerated responses in some individuals. In these settings, the risk of HTN versus the benefit of treatment for ADHD must be evaluated in decision-making.

70.15 TARGET ORGAN DAMAGE AND HYPERTENSION

70.15.1 Left Ventricular Hypertrophy

Defining TOD in the pediatric population can be challenging. Alterations in ventricular geometry can occur among children with systemic hypertension. The best-studied measures of LV target organ injury are measures of LV structure (LV mass and the relationship of LV wall thickness or mass-to-LV cavity volume) and systolic function (LV ejection fraction). LV structure is usually stratified into four groups based on LV mass (normal or hypertrophied) and relative LV wall thickness (normal or increased) (Table 70.3). These four are as follows: (1) normal geometry with normal LV mass and wall thickness; (2) concentric geometry with normal LV mass and increased LV wall thickness; (3) eccentric LVH with increased LV mass and normal LV wall thickness; and (4) concentric LVH with both increased LV mass and increased relative wall thickness.[58,59] Assessments for TOD are recommended at the time of consideration for initiation of antihypertensive therapy. If increased LV mass is present, this indicates that the blood pressure elevation is also having a demonstrable adverse effect on the heart. Treatment of HTN with antihypertensive medication has been shown to reduce left ventricular mass.

TABLE 70.3
Ventricular Geometry and Hypertension

	RWT <0.42	RWT >0.42
Normal mass	Normal geometry	Concentric geometry
Increased mass	Eccentric hypertrophy	Concentric hypertrophy

70.15.2 Ophthalmologic Examination and Hypertensive Retinopathy

The prevalence of hypertensive retinopathy among children with HTN is not well known, however, it has been estimated that approximately 18% of children with severe HTN suffer from retinal changes related to their hypertension diagnosis.[60] Changes thought to occur because of severe HTN include retinal hemorrhages, exudates, and optic disc edema. Proposed risk factors for the development of hypertensive retinopathy in adults include duration of HTN, severity of elevation in SBP, and age.[61] Risk factors for hypertensive retinopathy in youth have not been well studied but are likely similar.

70.16 TREATMENT OF SYSTEMIC HYPERTENSION

70.16.1 Non-Pharmacologic Treatment

Healthy lifestyle decreases the likelihood of a child or adolescent developing systemic HTN. Adoption of a healthy lifestyle is also a critical first step in the treatment of diagnosed systemic HTN in children and adolescents. The American Heart Association defines a healthy diet target as including:

- Reduction in total sodium intake to ≤1500 mg/day
- Intake of four to five cups of fresh (or frozen) vegetables and fruits per day
- Two or more 3.5-ounce servings of fish/shellfish per week (≥200 g/wk)
- ≤36 fl ounces of sugar-sweetened beverage per week
- >4 servings/week (nuts/seeds, 1-ounce legumes, half cup)
- Two or fewer 1.75-ounce servings/week (<100 g/week) processed meats
- <7% energy secondary to saturated fat[61]

The Dietary Approaches to Stop Hypertension (DASH) approach is similar to the AHA healthy diet target but goes beyond to include the consumption of low-fat milk products.[62]

TABLE 70.4
Antihypertensive Agent Class

First and Second Line Antihypertensive Agent Classes	Agent(s)	Mechanism of Action	FDA Approved
Angiotensin-converting enzyme inhibitor	Benazepril, Enalapril, Fosinopril, Lisinopril, Quinapril, Ramipril (Captopril)	Inhibits the conversion of angiotensin I to angiotensin II	Yes (No)
Angiotensin receptor blocker	Candesartan, Irbesartan, Losartan, Olmesartan, Valsartan	Antagonizes the angiotensin II receptor	Yes
Calcium channel blockers	Amlodipine, Felodipine (Nifedipine)	Inhibits calcium influx	Yes (No)
Diuretic	Hydrochlorothiazide	Thiazide diuretic:	No

A diet rich in intake of fruits, vegetables, and legumes has been associated with lower BP in adolescents.[64] Higher sodium intake has been associated with increased arterial stiffness, a pre-clinical measure of CVD.[65] The DASH diet has also been associated with a decrease in obesity, an important step for reducing the burden of hypertension development.[66]

70.16.1.1 Exercise

Physical fitness and increased physical activity are important strategies in the prevention of the development of HTN and in HTN treatment. Increased physical activity over a three-year interval slows age-related rises in BP.[67] Meta-analyses of clinical trials assessing the impact of exercise interventions in healthy children show modest reductions in BP, particularly if interventions last longer than six months.[68,69] There are no clinical trials of exercise intervention specifically for HTN treatment.

70.16.1.2 Sleep

Adequate sleep and high-quality sleep are also critical to maintaining a normal BP in children and adolescents. Inadequate sleep duration of less than five hours per night in children and adolescents has been linked to an increased risk of HTN and is also associated with an increased prevalence of obesity.[40] OSA has been shown to be an independent risk factor for elevated SBP and diastolic blood pressure (DBP), even after adjusting for confounding factors such as increased BMI.[40]

70.16.2 Pharmacologic Treatment

Although, in most cases, treatment using a non-pharmacologic approach is preferred, children who remain hypertensive despite a trial of lifestyle modification or who have symptomatic HTN, Stage 2 HTN without a clearly modifiable cause, chronic kidney disease, or diabetes mellitus with any stage of HTN, should be considered for treatment with pharmacologic therapy. Therapy should begin with a single agent and at a low dose. Recommended classes of antihypertensive therapy for the treatment of systemic HTN include angiotensin-converting enzyme inhibitors (ACEi), calcium channel blockers (CCB), diuretic (e.g., hydrochlorothiazide), and angiotensin receptor blockers (ARBs). There exist unique reported benefits for each agent. A summary of the different classes and agents can be found in Table 70.4.

BP should be assessed on therapy every two to four weeks and the dose adjusted until the BP is initially lower than the 95th percentile and, ultimately, lower than the 90th percentile for age, sex, and height. A maximal dose should be attempted unless side effects develop. If the BP is not controlled with a single agent, then a second agent can be added. Hydrochlorothiazide (HCTZ), while not typically recommended as a first-line therapy, is frequently added to help combat the salt and water retention that typically occurs with the use of other antihypertensive medications. Even if a child is receiving pharmacologic therapy, continued attempts at lifestyle intervention are recommended.

70.17 SUMMARY

The 2017 Clinical Practice Guideline for the Management of High Blood Pressure in Children and Adolescents provides an evidence-based, updated clinical guide. Current guidelines provide (1) updated tables with new normative BP values; (2) an algorithm for diagnosing HTN that includes the use of oscillometric devices as well ambulatory BP monitoring devices; (3) the inclusion of a simplified BP table for screening and for more rapid determination of the need for reassessment of BP; (4) use of adult criteria for the diagnosis of HTN in children over 13 years of age; (5) simplified process for evaluating for secondary causes of HTN; (6) new timing of echocardiography and definitions of LVH (and LV geometry); (7) inclusion of screening for high BP using ambulatory BP monitoring; and (8) inclusion of the data from pediatric clinical trials of antihypertensive agents. Thirty recommendations (key action statements) relevant to the diagnosis, management, and treatment of systemic HTN in children were generated. Recommendation grades that reflect the level of existing

evidence used to support each recommendation are provided in the document.

70.18 CASES

70.18.1 Case 1

J.T. is 13 years old with elevated blood pressure during a recent well child visit one week ago. His BP at that time was 150/80 via oscillometric measurement. J.T. has been asymptomatic and denies headache, chest pain, chest pressure, dizziness, or lightheadedness. He is on no medications. His sister cooks the meals at home. The family has now transitioned to eating at home once concern was raised regarding his BP one week ago. However, total caloric intake remains high.

The family joined the gym and plans to go three days per week for one to two hours. Multiple family members have HTN, including J.T.'s mother, father, and older sister. There is also a family history of multiple family members with obesity, including J.T.'s parents. His maternal grandfather has peripheral vascular disease. His maternal great-grandmother died at 36 years of age from a heart attack. His paternal grandfather had a cardiomyopathy and died suddenly at 70 years of age. There are multiple distant family members with CHF.

In the office:

BP 152/86 (oscillometric) | Pulse 72 | Ht 5' 8.5" (1.74 m) | Wt 278 lb (126.1 kg) | SpO2 98% | BMI 41.65 kg/m^2

Repeat BP at that visit

BP	Pulse	Site	Cuff Size
144/74	–	Right arm	Large
Comment: resting; manual			
138/70	–	Right arm	Large
Comment: resting; manual			

In general, J.T. is in no apparent distress but is an unhealthy weight. He is normocephalic and there are no facial dysmorphic features. He has a normal respiratory effort and clear lung fields bilaterally. His precordium is normal. There is a regular rate and regular rhythm with a normal S1 and a normal S2. There are no murmurs. There is no rub. There is no click. There is no gallop. His abdomen is soft and non-tender. There is no palpable liver edge or spleen edge on his exam. Extremities are warm and well perfused. There are 2+ pulses without brachiofemoral delay. There is no edema. There is no cyanosis or clubbing.

70.18.1.1 LABS

K 3.9. Na 139. Cr 0.72 (normal). Glucose 110 mg/dL UA neg. HgbA1c 5.1%.

J.T. has an average manual BP of 141/72 mmHg. Given that he is 13 years of age, by the 2017 CPG, he has Stage 2 hypertension.

Given this finding, you measure the BP in J.T.'s arm and in his leg. The leg systolic BP is 6 mmHg higher than the arm systolic BP.

Given J.T.'s age and strong family history of hypertension, the most likely cause of his HTN is essential hypertension. Renal causes of hypertension are the most common cause of secondary hypertension but given J.T.'s age and family history, this diagnosis is less likely. While it is possible that J.T. has a monogenic form of HTN, this too is less likely.

Finally, given that the BP in his leg is higher than in his arm, diagnosis of aortic coarctation of mid-aortic syndrome is unlikely.

ABPM will be useful in assessing the BP outside the office setting.

J.T.'s ABPM confirms the diagnosis of HTN.

He undergoes a screening echocardiogram which shows left ventricular hypertrophy and concentric hypertrophy. He is started on a low dose antihypertensive agent.

70.18.1.2 Repeat Visit Four Weeks Later

J.T. remains an unhealthy weight. Competitive sports participation was discouraged until his blood pressure was more normal (e.g., no longer Stage 2 hypertension). Recreational activity was encouraged. He has been playing basketball after school. He denies symptoms of chest pain or pressure.

J.T.'s sister continues to cook the family's meals.

Additional labs were obtained. His total cholesterol is 189 mg/dl, HDL 29 mg/dl, TG 126 mg/dL, and non-HDL 160 mg/dL.

BP 134/88 | Pulse 78 | Ht 5' 8.5" (1.74 m) | Wt 274 lb 0.5 oz (124.3 kg) | SpO2 98% | BMI 41.06 kg/m^2

Repeat BP

BP	Pulse	Site	Cuff Size	Time	Date
130/70	–	Right arm	Large	09:25 AM	11/9/2017
Comment: manual; resting					
130/68	–	Right arm	Large	09:25 AM	11/9/2017
Comment: manual; resting					

J.T. is now in the Stage 1 hypertension range following lifestyle change and an antihypertensive agent with an average manual BP of 130/69 mmHg, and weight loss of ~2kg.

J.T. would like to participate in competitive sports. Based on the 2017 CPG, he can now safely participate in competitive basketball?

J.T.'s goal BP, in the absence of known kidney disease, is ≤130/80mmHg. In the presence of kidney disease, ideally,

the mean arterial pressure by ABPM would be less than the 50th percentile. However, his BP remains elevated.

Ideally, once one antihypertensive agent is started at a low dose, the best option is to increase the dose and then, if needed, add another agent after the dose of the first agent has been maximized. Lifestyle intervention is reinforced regardless. And even though his BP is improved, he should continue his antihypertensive medication.

CLINICAL APPLICATION

- Elevated blood pressure in children and adolescents is most likely to be primary hypertension and is associated with an increased risk for cardiovascular disease.
- Children and adolescents should have blood pressure measured and assessed at each health maintenance visit.
- Children and adolescents with persistent blood pressure elevation should be treated first with increased physical activity and a Dietary Approaches to Stop Hypertension (DASH)-type diet along with a reduction in dietary sodium.
- When lifestyle changes are not sufficient to lower blood pressure in children and adolescents with hypertension, pharmacologic agents should be considered. When pharmacologic agents are used, lifestyle interventions should be continued.

71 Lifestyle Nursing: Lifestyle Medicine and Nursing

Gia Merlo, MD, MBA, MEd and Carolyn Sweetapple, RN, PhD, MBA

KEY POINTS

- Synergies exist between lifestyle medicine and the training and competencies of the nursing profession.
- The current healthcare system is taking a tremendous toll on the well-being of nurses and the healthcare team.
- Innovative clinical models of care that leverage the expertise of nurses as part of the lifestyle medicine team may be part of the solution.
- Lifestyle medicine leadership can play a crucial role in advancing knowledge, adoption, and acceptance of innovative clinical models of care that include a role for lifestyle medicine nurses.

71.1 INTRODUCTION

This chapter, and the four chapters that follow, introduce the exciting potential for nursing professionals to impact the trajectory of lifestyle medicine adoption. This chapter covers how nursing is well positioned to provide and lead lifestyle medicine, the challenges facing nursing today, why it is important to address those challenges, and the benefits to society and nurses by doing so. With a new approach that is bold but familiar, incorporating lifestyle principles into nursing practice professionally and personally will lead to improved outcomes for patients and families and improved health and well-being for nurses.

Nurses play a critical role in the development, provision, and assessment of clinical interventions in various practice settings. As the largest single group of healthcare professionals, nurses are on the frontline of providing sick care as well as providing well care. Within the healthcare team setting, nurses often are the leaders to multiple team members including nursing assistants, patient care associates, and the unit secretary, among others. Nurse managers often serve as the point person on the team to collaborate with pharmacists, physical therapists, environmental service workers, respiratory therapists, and social workers. There are many nuances within the nursing practice that position nurses to drive lifestyle medicine as team leaders.

Much has changed in the education, training, and responsibilities of nurses throughout the years. The incorporation of social determinants of health into the healthcare team process highlights the disparities and inequities of our current healthcare system. To create social, physical, and economic environments that promote well-being, the importance of lifestyle medicine principles is embedded in quality and patient safety. Evolution of lifestyle principles into nursing curricula and practice will further enhance a profession proudly founded in patient education, counseling, and health promotion. Operationalizing that knowledge and practice to provide team leadership will result in a healthier society and better patient outcomes.

Unfortunately, the profession has been faced with some significant challenges. Nursing shortages caused by workforce demands, the retirement of nurses, and the stresses resulting from the COVID-19 pandemic have led to attrition and retention issues. Nurses are not just providers of healthcare, they are consumers in a high-demand, high-stress profession. The need to focus on well-being for nurses is delineated in the 2022 book edited by Gia Merlo and Kathy Berra *Lifestyle Nursing*, which is a part of the Lifestyle Medicine series edited by James Rippe. *Lifestyle Nursing* further emphasizes that healthcare providers are not immune to the stressors of society and the pressures of work. The value of self-care is well documented on an individual and macro level. A healthy nurse results in more nurse engagement, better retention, less compassion fatigue, and protection against burnout. A healthy nurse benefits a healthier society through better patient and family outcomes.

Hope is on the horizon. Lifestyle medicine principles where nurses take a leadership role in promoting the unique contributions of each team member can benefit society and nurses. This chapter will introduce you to the issues and possible solutions. The four chapters following will provide a roadmap to implementation.

71.2 THE NURSING PROFESSION

A reputation for compassion and dedication has earned the registered nurse (RN) profession recognition as the most highly trusted profession for the past 20 years.[1] Nurses complete a rigorous program of didactic and clinical study and work with patients, families, and communities using the core values of the nursing process[2] The nursing process

DOI: 10.1201/9781003227793-84

follows the scientific method and includes assessment, diagnosis, planning, implementation, and evaluation.[2] It is through the critical thinking exemplified in the nursing process that registered nurses synthesize objective and subjective data to provide holistic care to patients.

Nurse practitioners (NP) are registered nurses who have completed a graduate degree at a master's or doctorate level which provides clinical and didactic instruction and training in a designated NP specialization.[3] In addition to instruction and training, a national certification exam must be passed in the specialization area from the American Academy of Nurse Practitioners (AANP), the American Nurse Credentialing Center (ANCC), the Pediatric Nursing Certification Board (PNCB), or the National Certification Corporation (NCC)[3] Finally, the NP must apply for licensure in the state within which they will practice.

According to the American Association of Nurse Practitioners (AANP), the national organization for NPs, the scope of practice for NPs includes the diagnosis, evaluation, and management of acute and chronic health issues. Included in the management of patients is education, counseling, and promotion of health and disease prevention to individuals and families. Nurse practitioners practice in alignment with an ethical code, national certification, and current practice standards using an evidence-based approach to care. While licensing requirements for NPs vary by state and by specialization, all states have a process by which NPs are recognized as advanced practice RNs with advanced training in a clinical specialization.[3]

Despite the licensure of NPs as independent licensed practitioners, currently, 25 states allow NPs full practice authority. Rules and policies of various state agencies still prohibit NPs from practicing to the full scope of their licensure. Research has shown that states with full practice authority are better positioned to improve access to care, grow their workforce, and address healthcare disparities while delivering quality health outcomes for patients.[3]

Full practice authority has not resolved all the barriers to practice independently. Historically, physicians have been cautious about the role of the NP as a licensed independent practitioner. In a brief issued by the Primary Care Coalition from Austin, Texas, reservations include lack of training time, educational requirements that vary from state to state, and less clinical rotation than primary care residents[4] Interestingly, the coalition did recognize the emphasis on NP training in health promotion, patient education, and disease prevention in NP training. In Chapter 75, advanced practice nursing approaches to lifestyle medicine will be reviewed in greater detail.

71.3 NURSING CHALLENGES

In the United States, nearly 70,000 RNs will retire annually from the workforce between 2022 and 2030.[5] The trend is due to the substantial number of baby boomer RNs hitting retirement age who joined the workforce in the 1970s, and the COVID-19 pandemic is anticipated to accelerate this retirement rate. According to a 2020 national survey of registered nurses conducted by the National Council of State Boards of Nursing (NCSBN), the median age of nurses in the workforce was 52 years. Nurses who are aged 65 years or older account for 19% of the RN workforce and comprise the largest age category.[6] In an integrative review study by Falatah, fear of disease, stress, anxiety, and workforce shortages were predictors of a higher intent to leave among nurses, particularly among nurses over 60 years of age.[7]

Recruitment of new nursing entrants is on the rise. According to the Bureau of Labor Statistics in 2022, the RN workforce is expected to grow from 3.0 million in 2020 to 3.3 million in 2030 at a rate of 7% per year[8] The Bureau also projects the outlook for advance practice nurses to grow by 45% between 2020 and 2030. Promisingly, most of the NP entrants will be certified in primary care and 70% will be delivering primary care in the years to come.[3] Unfortunately, attrition and demand are rising greater than the levels of recruitment of new nursing entrants. The Bureau of Labor Statistics also projects 175,900 openings for RNs each year through 2029 when nurse retirements factor into the number of nurses needed in the United States. According to the United States Registered Nurse Workforce Report Card and Shortage Forecast: A Revisit, the shortage of registered nurses is projected to be over 500,000 by 2030[8,9] In this state-by-state analysis, the authors forecast the RN shortage to be most intense in the southern and the western regions of the country.

Additional reasons attributed to the shortage are increasing work demands and problematic relationships with providers. Demand for services has risen due to an aging population, which will require an increased need for geriatric care, including care for individuals with chronic diseases and comorbidities. Finally, problematic relationships with providers have been cited as a reason for intent to leave the nursing profession. In a study by MacKusick and Minick, nurses reported that holistic patient care is emotionally and physically demanding, and these demands increase greatly when a lack of camaraderie exists.[10] For these reasons, the well-being of nurses and the healthcare team is suffering and ought to be addressed.

71.4 TOLL ON NURSES' WELL-BEING

In a 2005 study by Buerhaus et al., more than 75% of RNs believe the nursing shortage presents a major problem for the quality of their work life, the quality of patient care, and the amount of time nurses can spend with patients[11] Additionally, the nurses reported increased stress, lowered patient care quality, and increased intention to leave the profession. Clinicians in all disciplines are experiencing higher rates of burnout, depression, addiction, and suicide.[12]

As a predecessor to burnout, negative outcomes are first seen in the form of compassion fatigue. Compassion fatigue (CF) is defined as "the physical and mental exhaustion and emotional withdrawal experienced by those that care for sick or traumatized people over an extended period

of time"[13] Compassion fatigue occurs when nurses develop decreasing empathetic capacity from repeated exposure to others' suffering[14] Nurses report that CF starts with discomfort and feelings of detachment and distance from their patients progressing to the nurses experiencing physical symptoms such as irritability, trouble sleeping, exhaustion, and forgetfulness[15]

Maslach and Jackson define workplace burnout as a psychological response to job stressors characterized by emotional exhaustion, detachment, and a sense of ineffectiveness.[16] Burnout is a cumulative process marked by long-term exposure to increasing workload and institutional stress. In a study of registered nurses in three hospitals by Kelly et al., more than half the sample experienced moderate burnout and 28% experienced high burnout.[17] Willard-Grace et al. found that physicians and advanced practice providers were 1.5 times more likely to turnover when they had high burnout.[18]

The impact of burnout is wide-ranging. There is a bi-directional relationship between clinician well-being and patient care and safety. According to the NAM, clinician well-being supports improved patient relationships and a high-functioning team.[19] Conversely, there is a negative impact on clinicians' ability to provide quality care when clinicians are not well, including medical errors and unsafe prescribing.[19] The COVID-19 pandemic has created challenges to the well-being of clinicians across the world. One of the solutions may be the protective nature of high-quality teams.

71.5 THE VALUE OF THE TEAM APPROACH

The Institute for Healthcare Improvement (IHI), the international organization committed to improving health and healthcare worldwide, has been a proponent of a team-based care approach as a high-leverage change for over 15 years. Optimizing the care team by having members work to the highest level of their expertise, licensure, and abilities has consistently resulted in greater access, better patient outcomes, and more team member satisfaction.[20]

Lee and Cosgrove suggest a framework that engages other caregivers in multi-disciplinary teams with teamwork done by design.[21] With a shared vision and real collaboration, better care can be achieved by leveraging the skills and talents of all team members. And finally, the systems, processes, and structures, traditionally organized around physicians, should be changed to a team-based approach focused on the patients.[21] With continuing the focus on effective communication and training, team optimization will build team members who have time to do the work they find more challenging and satisfying.[20] Ultimately, an optimized team is a more resilient team.

Why are certain teams and providers more resilient to structural and systems issues? The creation of a culture that rewards and values positive nurse/physician relationships may be part of the answer. Research suggests that strong practice cultures that include teamwork, communication, and psychological safety have increased adaptive reserve to stress and burnout.[22] Magnet hospitals have consistently demonstrated that good relationships between nurses and physicians positively affect patient outcomes[23] St. Luke's Hospital in Florida found that teaching rounds enhanced nurse-physician relationships and promoted nursing education, satisfaction, and retention[24] A study of workplace resilience by Hayes, Chumney, and Buckingham found that survey participants who trusted their teammates, their team leader, and their senior leaders were three times more likely to be fully engaged and highly resilient.[25]

Psychological safety within teams is another factor in building a resilient team. Psychological safety is defined as a team culture that permits team members to take interpersonal risks at work.[26] O'Donovan and McAuliffe performed a systematic review of factors that contributed to psychological safety in healthcare teams.[27] Knowing that your voice is heard, sharing mistakes, asking for direction freely, and trusting your leaders were among the factors identified. These factors are all critical for creating a foundation of team learning and trust.

Lastly, team learning is an important predictor of team performance.[28] Team learning is the process of reflection and action to obtain and process information to detect, understand, and adapt to changes in an environment which, in turn, improves team performance.[26] Ortega's research found that teams that receive training to create a climate of learning perceive a higher degree of psychological safety. The IHI stresses that team learning takes time and positive experience to build trust within a team. With regular practice to fine-tune team skills, shared goals, and clear roles and responsibilities, teams learn to rely on and trust their team members.[20]

The team approach to well-being has resulted in greater access to care and quality outcomes.[29] Each member of the team helps the patient towards wellness through their unique contribution with a shared goal to foster lasting change.[30] There is power in a team to enhance the patient experience and outcomes when nursing takes a larger role. A discussion of the intersection of nursing and lifestyle medicine follows in the next section.

71.6 INTERSECTION OF NURSING AND LIFESTYLE MEDICINE

Nurses are untapped potential partners who believe in and adopt lifestyle medicine quickly. Nursing education and competency have advanced over the years into diverse practice settings, greater scopes of practice, and different specialties[31] Lifestyle medicine principles are being taught in nursing school but may be underappreciated. A body of literature in nursing exists that is siloed and could be leveraged to spread the impact of whole-person lifestyle care. The nursing discipline foundationally focuses on human wholeness, health, healing and well-being, the environment-health relationship, and caring[31] Nurses' knowledge, skills, and academic preparation to counsel and coach patients can

improve health outcomes to advance well-being. In Chapter 73, we will discuss nursing educators' perspectives on the integration of lifestyle medicine into nursing curricula, and, in Chapter 74, a further discussion of clinical nursing approaches to lifestyle medicine will be explored.

As such, nurses play a crucial role in the implementation of lifestyle interventions with patients. Consistent with the tenets of lifestyle medicine, nurses address social disparities, nutrition, stress management, and substance use avoidance.[31] Embedded in the philosophy and training of a nurse is a balanced approach that, when leveraged, complements the lifestyle medicine approach to health. The IHI recognizes the need to better address the needs of patients with chronic illnesses such as diabetes and congestive heart failure. Care coordination and home visits must extend into the community. Nurses through their training and experience can collaborate with patients through the continuum of care, supporting and educating patients on health promotion and wellness. Increased clinician availability and enhanced access to care, with the inclusion of the patient and family in the plan of care, can occur because of enhanced collaboration between multiple team members.[32]

Evidence-based training and mentorship from lifestyle medicine physicians can further refine these competencies. Lifestyle medicine physicians can provide evidence-based education with a focus on health promotion rather than a focus on disease. This education can be incorporated into the curricula of nursing schools, residency programs, medical schools, and NP schools.

71.7 CALL TO ACTION

Charles Darwin said, "It is the long history of humankind that those who learned to collaborate and improvise most effectively have prevailed".[33]

What can we do to survive within a broken healthcare system? We can focus on our role as individual practitioners working within teams while system and structural issues at a macro level are transformed. We can practice our art and our skills in medicine and not focus on what we as individuals cannot change. We can insulate ourselves from the factors that contribute to compassion fatigue and burnout. Here is the call to action and a list of actionable items that can be done today.

First, the team approach is critical to protect against the toll of the workforce shortage. We must leverage our scarce human resources to meet the increasing demand. Good team alignment leads to more reach, more patient contact, and more efficiency. Leveraging and promoting the unique skills of each member allows us to practice at the top of our licenses. Team alignment leads to better patient outcomes, more job satisfaction through meaningful work, and more support through challenging times.

Second, to create a high-functioning team, we need more awareness of what each discipline brings to the team. Through our next four chapters, the contributions nursing and advance practice nurses bring to the table will be discussed. Additionally, there are resources in Section 77.8 to familiarize yourself with the scope of practice and competencies of registered nurses and advance practice nurses. We will introduce you to how nursing education and competencies have changed over the years. Lastly, we will introduce how lifestyle medicine is taught in nursing schools through rigorous curricula.

Next, we are asking you to partner with nursing schools to continue the advancement of curricula and knowledge in lifestyle medicine. We are looking for leaders in the field to promote the team approach and serve as role models. We are looking for leaders to explore the opportunities and potential of a new workforce that leverages the skills and talents of all team members. We are looking for leaders to spark enthusiasm and innovation in a team approach. We are looking for leaders to transfer knowledge to the practice environment. Building trust and competency within a team requires leaders invested in education, training, and reinforcement of the principles of lifestyle medicine.

Lastly, self-care resonates with nurses. As lifestyle medicine practitioners, we must continue to advance approaches to medicine that are vision and value aligned with true health and well-being. Nursing theory is built on a foundation of person, environment, and health, promoting behavior modifications to improve well-being[34] The Nursing Code guides nurses to hold themselves accountable for their own health and safety as they would their patients.[35] Nursing education programs are focusing on the promotion of nurses' health and well-being.[36] A team that is 100% vision aligned for well-being will result in work fulfillment and leave more time to practice the art and skill of medicine.

71.8 SUMMARY/CLINICAL APPLICATIONS

Lifestyle medicine is an evidence-based approach to helping individuals and families adopt and sustain healthy behaviors in preventing, treating, and, oftentimes, reversing chronic diseases. Nurses are often the primary providers providing patient education and counseling and are well-positioned to address lifestyle interventions with patients. By operationalizing lifestyle medicine principles into nursing practice professionally and personally, better patient outcomes and improved nurse well-being can be realized.

As new team-based clinical models in healthcare continue to evolve, the role of nursing can be expanded. The evolution of lifestyle principles into nursing curricula and practice will further enhance a profession proudly founded in patient education, counseling, and health promotion. These tenets of nursing are aligned with lifestyle medicine to create efficient clinical teams that can increase the reach, increase patient contact, and advance the practice of lifestyle medicine for better patient outcomes.

This section of the book has chapters that address/explore nursing contributions to lifestyle medicine. In this overview chapter, a call to action is stated along with resources for further reading on nursing training and education. The nurses' code of ethics, self-care, and the historical changing

roles of nurses are covered in Chapter 72. The nursing educator's perspective on integrating lifestyle medicine into the nursing curriculum is covered in Chapter 73. Staff nurse clinical approaches to lifestyle medicine are addressed in Chapter 74 and advanced practice and specialized nursing approaches to lifestyle medicine are covered in Chapter 75.

72 Code of Ethics, Self-Care, and Historical Changing Roles of Nurses

Deborah Chielli, MSN, APRN, AGNP-C, DipACLM and
Janine Santora MSN, APRN, FNP-C, CNRN, SCRN

KEY POINTS

- From the earliest days of nursing, healing through lifestyle interventions, such as the provision of clean water, fresh air, sanitary conditions, and healthy food, has been fundamental to nurses' healing powers and health promotion.
- The pillars of lifestyle medicine are codified in the Code of Ethics for Nurses and are stated as fundamental to both patient care and nurse duties to self.
- As the largest and one of the most trusted healthcare professions, nurses are uniquely positioned to address the nation's need for accessible, high-quality, person-centered, compassionate care.
- The COVID-19 pandemic and recent landmark government reports identify nurses as well-positioned to bring solutions to social justice and health equity.
- Nurse wellness and self-care are a triple good, first, upholding the duty laid out in the Code for the moral duty of self-care, second, serving as healthy role models for their patients and the public, and third, being empowered with resilience and strength to buffer themselves from illness, injury, and burnout.

72.1 INTRODUCTION: WHAT IS NURSING?

Professional nursing is defined as "the protection, promotion, and optimization of health and abilities, prevention of illness and injury, alleviation of suffering through the diagnosis and treatment of human response, and advocacy in the care of individuals, families, communities, and populations" (p. 1).[4] By definition, the *Scope and Standards of Practice* and the Code are inseparable from nursing's essential contract and relationship with society.[5] A research study using a focus group by Paans et al.[24] examined the essential attributes that define an excellent nurse. According to the study, an excellent nurse should have nine core abilities: to be analytical and apply critical thinking skills; to communicate clearly and effectively; to cooperate within a team and lead and inspire the team; to innovate new, more efficient approaches to problems in the workplace; to be empathic under pressure and use holistic interventions; to disseminate knowledge with patients and members of the team; to use evidence-based research to improve nursing interventions; to coordinate patient care accurately and safely; to be introspective by utilizing constructive criticism to self-reflect and grow professionally.

72.1.1 Evolution of Nursing

The art of caring for the sick began in early civilization, when nurses were innovators, creating and advancing the art of healing the sick.[15] Before the 19th century, religion had a profound impact on the evolution of nursing. Nurses, both women and men, could be found on the front lines treating the injured and sick during the War of Crusades of the 11th, 12th, and 13th centuries. Before formal nursing schools were established, nursing care was passed down through the generations through knowledge sharing and hands-on experience. Nursing eventually became an established profession in the 19th century. Today, nurses comprise the largest group of the American healthcare system with more than 4.1 million registered nurses (RN), 944,000 licensed practical nurses (LPN) and licensed vocational nurses (LVN),[27] and 355,000 nurse practitioners working in diverse roles across the healthcare landscape.[1]

72.1.2 19th-Century Nursing

Nursing evolved into a profession during the 19th century, moving away from a religious order and in the direction of a professional group of individuals.[15] This same century, when it was frowned upon for women to work outside the home, gave rise to nurse pioneers who would change nursing forever.

72.1.3 Florence Nightingale

Florence Nightingale (1820–1910) heard about the plight of soldiers during the Crimean War, and for the first time, professional nursing care was rendered to injured, sick soldiers.[15] Florence Nightingale led a group of professional nurses to Crimea in 1854 to help the wounded and sick.[2] Nightingale's time in Crimea led to her ground-breaking

DOI: 10.1201/9781003227793-85

Nightingale principles.[16] Nightingale's principles were documented in her book, *Notes on Nursing* in 1860, which was used in early nursing schools. The Nightingale principles focus on holistic practices, health promotion, and disease prevention including cleanliness, clean water, fresh air, light, and basic sanitation.

72.1.4 Clara Barton

Clara Barton (1821–1912) was a visionary nurse who helped change the world with her humanitarian spirit. Clara Barton's career began in education, and she opened the first public school in New Jersey (Strickler, 2018).[28] When the Civil War broke out in 1861, she shifted her attention to providing care for wounded soldiers as a self-trained nurse. She went on to found the American Red Cross, recognizing the need to care for people after disasters, not just during wartime. Clara Barton lived a life providing service to others. She was a civil rights activist and an advocate for women's rights.

72.1.5 Linda Richards

Linda Richards (1841–1930) is known as America's first trained nurse.[15] She attended the New England Hospital for Women and Children nurse training program, where nursing students trained up to 16 hours a day. During their training program, nursing students were not allowed to know the names of the medications they were administering to the patients, and exams were not a part of the curriculum. During her career, she established care facilities for the mentally ill.

72.1.6 Mary Eliza Mahoney

Mary Eliza Mahoney (1845–1926) was the first licensed professional nurse of color.[20] She graduated from the New England Hospital for Women and Children Training School for Nurses in 1879, as one of the three graduates from an original class of 40 students. At the time, the school only allowed one person of color per year into the program. As one of the original members of the Nurses Associated Alumnae of the United States and Canada, she was faced with discrimination. She was a pioneer for women of color. As a result, she co-founded the National Association of Colored Graduate Nurses, and in Boston, she was one of the first women to register to vote.

72.1.7 Lillian Wald

Lillian Wald (1867–1940) was inspired to become a nurse after witnessing the care a nurse rendered her sister during the birth of her child.[15] She attended the New York Hospital Training School with additional training at the Women's Medical College in New York City. In 1893, she started a new field of nursing, Public Health Nursing, providing care to the poor and advocating for individuals to take control of their own health. Lillian and Mary Brewster started the Visiting Nurses Service in New York City, while Lillian was additionally a tireless advocate for free school lunches, school nursing, public parks, and racial harmony.

72.1.8 Nursing Education

The Civil War prompted the need for formal nurse training.[2] During the Civil War, approximately 20,000 women and men provided nursing care to the sick and wounded. The Women's Hospital of Pennsylvania and the New England Hospital for Women and Children were two of the earliest hospital nurse training programs. In 1873, three hospital-based professional nurse diploma training programs, known as the Nightingale Schools, were started in the United States. The early nursing programs were associated with hospitals and offered little classroom education. Nursing education moved into college-based training by 1960, and while the baccalaureate-trained nurse was thought to be superior to the hospital-trained diploma nurse by higher institutions, the hospital-based programs held that their students received exceptional bedside nurse training. As the debate continued, the community college nurse training program emerged offering an associate degree program for nurses. The community colleges were able to offer a less expensive route to becoming a nurse when compared with traditional four-year college programs. The debate continued into the late 20th century when research showed the baccalaureate-trained nurse was equated to better patient outcomes. During the 20th century, racial and gender equality in nursing programs and employment transformed the healthcare landscape.

72.1.9 Modern Nursing

Nurses care for patients in a vast array of settings.[10] The nursing profession offers diverse opportunities in many different areas involving healthcare, including the following: hospitals; private homes; rehabilitation centers; research centers; pharmaceutical companies; insurance companies; schools; public health; the armed forces; clinics; and specialized care. The majority of registered nurses can be found working in hospitals. Nursing education has evolved to become multifaceted and diverse. Today, educational pathways include: licensed practical nurses or licensed vocational nurses (12–18 months of training) who work under the supervision of RNs; associate degree RNs and diploma trained RNs (two to three years of training) offered through community colleges or hospitals; bachelor of science (BSN) RNs (four years of training), which includes expanded education in leadership, research, physical and social sciences, and public health; accelerated BSN or master's (MSN/MS) degree in nursing (12–18 months of training) for individuals with a baccalaureate in a different field; MSN or MS degree in nursing (18–24 months of training)

for advanced practice RNs in various fields including nurse practitioner, clinical nurse specialist, clinical nurse leaders, educators, nurse midwives, nurse anesthetists, and administrators; doctor of philosophy in nursing (PhD), which focuses on research; and doctor of nursing practice, which focuses on clinical practice (DNP) (three to five years of training) (Wakefield et al., 2021). What do all nurses have in common? The American public has ranked nurses as number one in ethics in honesty for the last 19 out of 20 years according to the annual Gallop Poll of Professions.[26]

72.2 THE PRINCIPLES OF MEDICAL ETHICS AND NURSING'S CODE OF ETHICS

Ethical tenets are fundamental to the practice of every nurse, physician, and employee in a healthcare setting, as each provides services to patients seeking care for their health. The principles of medical ethics date back to the time of Hippocrates, and these have been further explored and applied in modern times by philosophers Beauchamp and Childress in their book, *Principles of Biomedical Ethics,* now in its eighth edition.[6] The authors synthesized what are today the four primary principles of medical ethics; 1) autonomy or the patient's right to self-determination; 2) non-maleficence or non-harm; 3) justice or fair and equal treatment; and 4) beneficence or to benefit the patient[6,30] Nurses are guided by these four principles and by their own *Code of Ethics for Nurses with Interpretive Statements* (Code). This section offers a brief history of the Code and the evolving principles, practice, ethics, mission, and role of nurses in their social contract with the public and in relation to nurses themselves.

72.2.1 The Code of Ethics Defined

The Code "establishes the ethical standard for the profession and provides a guide for nurses to use in ethical analysis and decision-making" (p. vii); it is a non-negotiable standard[3] As an evolving document, the Code serves to guide nurses as they respond to the present and changing health and nursing needs of patients and populations. It is an expression of nursing's history and social obligations, and provides immutable ethical practice guidelines for every nurse, in every role and setting.[11]

72.2.2 The Code of Ethics History

The creation of the Code began in 1896 when nurses came together to write the Articles of Incorporation for the American Nurses Association (ANA) with the key purpose of creating and maintaining a nursing code of ethics. This culminated in the publication of the first Code in 1950, with revisions in 1956, 1960, 1968, 1976, 1985, 2001, and the current 2015 edition.[12]

From its first publication in 1950 to today, this dynamic text has evolved to be comprised of two components: the nine Provisions which set forth nursing ethical obligations, and the accompanying Interpretive Statements which give detailed guidance for application in today's world. The provisions are broadly organized as: Provisions 1–3 lay out the foundational commitments and values of the nurse; Provisions 4–6 address duties to self and others and associated boundaries; and Provisions 7–9 extend nursing's breadth and depth of responsibilities beyond a single patient.[3]

72.2.3 The Code's Nine Provisions with Interpretive Statements

72.2.3.1 Provision 1

"The nurse practices with compassion and respect for the inherent dignity, worth, and unique attributes of every person" (p. 1)[3] This ethic is further defined as "respect for the inherent dignity, worth, unique attributes, and human rights of all individuals" (p. 1).[3] The right to healthcare is deemed universal, and nurses are to create trusting relationships with patients and value the worth and rights of every person regardless of gender, language, religion, or language.[3]

72.2.3.2 Provision 2

"The nurse's primary commitment is to the patient, whether an individual, family, group, community, or population" (p. 5).[3] Provision 2 elaborates a nurse's chief commitment to the patient and expands the concept of the patient beyond the individual while ensuring that members of the team provide the information necessary for patients to make informed choices.[3]

72.2.3.3 Provision 3

"The nurse promotes, advocates for, and protects the rights, health, and safety of the patient" (p. 9)[3] Privacy and confidentiality are central to the trust between nurse and patient. Provision 3 asserts patients govern access to their personal information, and nurses are vigilant on behalf of vulnerable populations. Nurses are to help promote a "culture of safety" (p. 11)[3] including acting in any situation that puts the interest of the patient at risk.[3]

72.2.3.4 Provision 4

"The nurse has authority, accountability, and responsibility for nursing practice; makes decisions; and takes action consistent with the obligation to promote health and to provide optimal care" (p. 15)[3] Each nurse is responsible and accountable for outcomes of the nursing care delivered or delegated, and with the expanding scope of nursing practice, are to continuously evaluate their own competence.[3]

72.2.3.5 Provision 5

"The nurse owes the same duties to self as to others, including the responsibility to promote health and safety, preserve wholeness of character and integrity, maintain competence, and continue personal and professional growth" (p. 19).[3]

Provision 5 confers moral worth to all human beings and to the nurse herself. "the same duties that we owe to others we owe to ourselves" (p. 19)[3] Furthermore, as "nursing care addresses the whole person as an integrated being, nurses should also apply this principle to themselves"[3]

72.2.3.6 Provision 6

"The nurse, through individual and collective effort, establishes, maintains, and improves the ethical environment of the work setting and conditions of employment that are conducive to safe, quality health care" (p. 23)[3] Nurses are responsible for helping to establish a moral environment of caring and kindness, dignity, and respect.[3]

72.2.3.7 Provision 7

"The nurse in all roles and settings, advances the profession through research and scholarly inquiry, professional standards development, and the generation of both nursing and health policy" (p. 27)[3] Each nurse is responsible for advancing nursing knowledge in the form of research, development, dissemination, evaluation, or application.[3]

72.2.3.8 Provision 8

"The nurse collaborates with other health professionals and the public to protect human rights, promote health diplomacy, and reduce health disparities" (p. 31).[3] "Health is a universal human right" (p. 31)[3] and the Code elevates health diplomacy to be on par with international treaties, while calling on nurses to partner with others to address structural disparities and basic human rights.[3]

72.2.3.9 Provision 9

"The profession of nursing, collectively through its professional organizations, must articulate nursing values, maintain the integrity of the profession, and integrate principles of social justice into nursing and health policy" (p. 35).[3] The Code envisions nursing organizations as powerful forces for advancing health and social justice worldwide.[3] The Code's final statements are far-reaching calls to action, "social justice extends beyond human health and well-being to the health and well-being of the natural world" (p. 37)[3] and "as nursing seeks to promote and restore health, prevent illness and injury, and alleviate pain and suffering, it does so within the holistic context of healing the world" (p. 37).[3]

72.2.4 The Code—Changes Over Time—Significance Today

The Code has evolved and harkens to key national and international documents on health and human rights. It reflects nursing's fundamental ethic of service to others, while articulating nursing advocacy in an increasingly intersectional world, expanding nursing's role in addressing the health of humanity while at the same time calling on nurses to give themselves the same care and concern.[12]

72.2.4.1 Human Dignity

The concept of human dignity was signed into the United Nations Declaration of Human Rights in 1948, and since the Code of 1960, the concept has evolved from patient care to human dignity for all, including the nurse.[12]

72.2.4.2 Patient Rights Include Privacy and Confidentiality

In 1948, the United Nations Universal Declaration of Human Rights declared the right to privacy as a universal human right, yet this concept has been present since Nightingale's pledge and the Code's beginnings.[12]

72.2.4.3 Culture of Safety and Expanding Nurse Responsibility

The "concept of a culture of safety" (p. 50)[3] enters the Code of 2015, which likewise offers the most expansive interpretation for the scope of practice, including nurse authority, accountability, and responsibility for practice.[12]

72.2.4.4 Health as a Human Right

In 1946, the World Health Organization (WHO), defined health as "a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity. The enjoyment of the highest attainable standard of health is one of the fundamental rights of every human being".[8] From the beginnings of modern nursing to today, nursing's role has evolved from addressing the health of the patient and public to promoting health as a universal human right. The Code puts forth an expansive, compelling case for the why and how of nurses' role in addressing these issues.[12]

72.2.5 Nurses as Leaders in Healthcare Transformation and Social Justice

Four landmark reports call for nurses' pivotal role in attaining "the high quality, accessible, and compassionate care that individuals, families, and communities richly deserve", with recommendations for how to support and empower nurses in this role.[23]

- *Nursing, Health, and the Environment: Strengthening the Relationship to Improve the Public's Health*[18] concluded that, "the environment is one of the primary determinants of individual and community health" and "nurses occupy a unique position" as key contributors (p.1).
- *The Future of Nursing: Leading Change, Advancing Health* determined that nurses have distinctive insights and competencies to offer, and should have leadership responsibilities in the redesign of US healthcare.[19]
- *Assessing Progress on the Institute of Medicine Report The Future of Nursing* established there is yet more to do to support nurses' ability to meet the need for high-quality healthcare.[22]

- *The Future of Nursing 2020–2030: Charting a Path to Achieve Health Equity* calls for governments, nurse educators and their institutions, and multiple non-governmental organizations to empower nurses to help bring broad solutions to health equity issues.[23]

72.2.6 The Code, Nurse Self-Care, and Nurse Well-being

- Nursing ethics since the 1800s have asserted the nurse's duty to self, while the Code has evolved to assert, "what I owe to others as moral duties, I likewise owe to myself as a moral duty … self-respect, then, becomes one of the many duties owed oneself" (p. 78).[3] Nurse self-care serves as a triple good—healthy nurses uphold duty to self, model health practices for others, and are less likely to suffer burnout, illness, or injury.[12] The Code calls for nurses to care for themselves as for their patients, specifying nurses are to "eat a healthy diet, exercise, get sufficient rest, maintain family and personal relationships, engage in adequate leisure and recreational activities, and attend to spiritual or religious needs" (p. 19)[3] along with seeking work-life balance.

72.3 Nurse Self-Care, Self-Compassion, and Wellness

The ANA Code includes the ethical duty of nurses to incorporate self-care into their lives to protect their state of wellness.[17] As with the safety instructions on an airplane flight, in an emergency, passengers are to apply their own oxygen mask before assisting others with theirs. The same applies to nurses when it comes to care and compassion, nurses must apply care and compassion to themselves in order to give the best care and compassion to others.[9]

72.3.1 Nursing Health, Burnout, and COVID-19

In every role and setting, nurses can suffer burnout, with baseline rates in US nurses estimated from 35–45%. Nurses are regularly confronted with moral distress caused by constraints or lack of capability to help patients, including lack of time, resources, and other adversities.[23] As a result, nurses suffer health disparities. In the United States, nurses have worse physical health than the general population, particularly regarding physical activity, sleep, and diet. These are compounded by high rates of injury and hazard exposure, which are exacerbated in understaffed or under-resourced workplaces.[23]

Along with poorer physical health, mental health challenges are frequent and widespread among nurses,[23] with the nursing profession experiencing high rates of burnout.[29] Burnout is described as emotional exhaustion, reduced personal accomplishment, and depersonalization. Emotional exhaustion first depletes emotional reserves, which is followed by diminished feelings of personal accomplishment, and eventually, depersonalization results in the development of negative attitudes.

Nurses have been on the frontlines of pandemics throughout history, and the challenges of the recent global pandemic, COVID-19, have led to higher rates of nurse burnout, which can cause higher rates of nurse suicide, depression, anxiety, medical errors, and substance abuse.[31] A systemic review by Galanis et.al.[13] found 34.1% of nurses suffered from emotional exhaustion, another 15.2% from a lack of personal accomplishment, and 12.6% from depersonalization. Nurses are at a significantly elevated risk of mental health consequences, including depression, anxiety, and peritraumatic dissociation as a result of the pandemic.[23]

72.3.1.1 Burnout and Negative Impact on Health

Burnout carries a risk of significant health consequences, including shortening of telomeres—the protective caps at the end of chromosomes.[7] Premature telomere shortening due to burnout is associated with a higher risk of diseases such as heart disease, cancer, pulmonary fibrosis, and aplastic anemia. A cross-sectional study by Wei et al.[31] examined the prevalence of nurse burnout pre-COVID-19 and during COVID-19 on a biological level by measuring telomere length. The study found decreased telomere length in the nurses providing care during COVID-19 when compared with the nurses pre-COVID-19.

72.3.1.2 Presenteeism

Presenteeism, which occurs when an individual comes to work despite feeling cognitively, physically, or emotionally impaired[25] is also more common in the nursing profession and likewise contributes to burnout.[21] Causes include a sense of duty or high level of responsibility, psychological factors impeding the ability to say "no", the inability to find coverage, employment conditions, and relationships with colleagues.[25] Presenteeism can negatively impact productivity, lead to medical errors, increase cost, and burnout, which ultimately negatively impact the nurse, patients, organization, and cost. Perceptions of perfect attendance and organizational commitment need to be changed to increase the well-being of nurses and those under their care.

72.3.2 Barriers to Nurse Self-Care and Self-Compassion

A qualitative study by Egan et al.[9] examined the barriers to self-care and self-compassion among nurses. Poor eating habits and unhealthy food choices were attributed to a lack of time and energy. Additionally, nurses expressed these same factors as barriers to regular exercise. High nurse-to-patient ratios can negatively impact the well-being of the nurse and the patient. The study noted one of the

main concerns expressed by nurses was the inability to take a break. Nurses noted they would work entire shifts without eating, hydrating, or using the bathroom. Many nurses stated they continued to smoke cigarettes to ensure a guaranteed off-site break, and several others in the study expressed the need for a few minutes of solitude during the workday to decompress. Heavy workloads, paperwork, and time constraints leave little to no opportunities to decompress. Not wanting to be perceived as weak or burden other nurses with their workload, nurses hesitate to reach out for help.

Lack of awareness of policies or resources available in the workplace was also noted as a barrier to self-care. According to *The Future of Nursing* report,[23] it is clear that individual solutions are not enough and that systemic factors impacting clinician health and well-being must be addressed.[23]

72.3.3 Stakeholders

Employers play a key role in creating conditions that support the well-being of nurses, notes *The Future of Nursing* report,[22] with multiple areas for meaningful impact including measuring and elevating nurse well-being, improving the culture, system redesign, and support for individuals. Resilience is "the capacity of dynamic systems to withstand or recover from significant disturbances … face adverse situations, remain focused, and continue to be optimistic for the future" (p. 320)[22] Resilience interventions occur at three levels: the primary level offering individual nurses training and support, the secondary level of screening then providing support, and the tertiary level of interventions for nurses whose resilience level was broken, offering healing and support for the eventual return to work (p. 320)[22]

The Institute for Healthcare Improvement (IHI) notes there is growing interest in a model whereby employees would be provided with psychological personal protective equipment (PPE), similar to the concept of physical PPE. The IHI has developed a tool, *Psychological PPE: Promote Health Care Workforce Mental Health and Wellbeing*,[18] and provides steps for leaders at different levels to offer assistance and safeguards for the mental well-being of the staff to be used at the start or end of a work shift.

Nurse leaders and educators can have a significant impact on the well-being of nurses as role models, educators, influencers of organizational practices, and advocates. Nurse education is foundational for the well-being of nurses, with growing evidence for the importance of resilience training and making nursing student well-being an "institutional priority" (p. 329).[22] Importantly, in the New Essentials of the American Association of Colleges of Nursing (AACN), Domain 10 is to "demonstrate a commitment to personal health and well-being", including to "demonstrate healthy self-care behaviors that promote wellness and resiliency" (p. 53).[4]

72.3.4 Nurse Self-Care Resources

There are many varied resources and initiatives from numerous organizations highlighted in the *Future of Nursing*[22] When it comes to the well-being of nurses, the report concludes that "while health care organizations must create the workplace conditions for well-being and integrity to thrive, nurses are also responsible for identifying their own needs and investing in their well-being" (p. 317),[22] responsibility rooted in Provision 5, and the responsibility to eat healthy, sleep, exercise, and participate in leisure and spiritual pursuits (p. 317)[22] The report provides resources for nurses and these include the following.

The Healthy Nurse, Healthy Nation challenge[22] launched in 2017 includes a roadmap for individualizing self-care and well-being assessment and SMART goals. It includes support and annual surveys for nurses to monitor their progress and be role models for others. Whether yoga or tai chi, spinning or hiking, food delivery services or batch cooking at home, a monthly massage or a hot bath, a frolic with a puppy or a play date with the kids, whether hiring someone or asking a friend or family for help, or meditation or movement tracking apps—each nurse must find what works and obtain support. The ANA HNHN provides a nurse-centered launching point to get started.

Mindfulness, including mindfulness-based stress reduction (MBSR) and mindfulness-based cognitive therapy (MBCT), along with cognitive-behavioral therapy (CBT), show promise in helping nurses become aware of emotional reactions and then have the ability to choose their response.[23] MINDBODYSTRONG is an evidence-based intervention taught by nurses to new nurses, while exercises in gratitude and deep breathing are also proving effective. Evidence is demonstrating that brief mindfulness sessions can yield positive results and there is an array of mobile technologies to support nurses' sessions.[23]

72.4 CONCLUSION

From the early days of modern nursing to the Code, to reports by numerous national committees and nursing organizations, nurses have been appreciated as leaders for solving the nation's health crises and social disparities, and likewise are the calls that leadership from across society must rally together to create real-world solutions for the well-being and empowerment of the nation's nurses, who have given and continue to give so much.

CLINICAL APPLICATIONS

- Acknowledge the evolution of nursing history that will empower nurses to face future challenges to the nursing profession and educate the public in regard to the significance of nursing history.

- Discuss the importance of the nursing code of ethics which specifies nurses are to care for their patients and themselves through interventions, including eating a healthy diet, physical activity, stress management, social connections, and rest, and therefore, all nurses are empowered to educate themselves and their patients on the lifestyle choices for optimal health.
- Empower nurses to reduce healthcare disparities, improve healthcare outcomes, and recognize self-care as an ethical duty through the application of the nursing code.
- Help nurses identify burnout, the negative effects of burnout, the barriers to self-care, self-care needs, and self-care resources.
- Educate stakeholders on the importance of creating and supporting healthy resources that will support nursing self-care.

73 Nursing Educators' Perspectives on Integrating Lifestyle Medicine into the Nursing Curriculum

Elizabeth R. Click, DNP, ND, RN, CWP and Gia Merlo, MD, MBA, MEd

KEY POINTS

- Nurses often serve as health role models for their patients.
- Nursing faculty often serve as health role models for their students.
- Academic accreditation and professional nursing organizations have identified the need for curricular content, focused on lifestyle behaviors, within nursing.
- Few schools of nursing currently integrate lifestyle medicine content within their curricula.
- Curricular ideas need to be shared so that greater integration of lifestyle medicine content occurs within nursing curricula.

73.1 OVERVIEW OF LIFESTYLE NURSING

Lifestyle nursing is a specialty within lifestyle medicine, specifically addressing needs from the lens of nurses at the baccalaureate, graduate, and doctorate levels. The first textbook on lifestyle nursing (eds. Gia Merlo and Kathy Berra) was published in August 2022 as part of the Lifestyle Medicine Series (ed. James Rippe).[1] The need to address discipline-specific competencies and educational content in lifestyle medicine is compelling. As the largest healthcare profession in the United States, over four million nurses work to maintain and improve the health of patients. The goal of health improvement for patients is always challenging and recent stressors impacting the healthcare system, exerted by the pandemic, have highlighted the need for and barriers against addressing lifestyle behaviors and health advancement within population health. A disproportionate number of individuals experienced significant health effects of Covid-19.[2] Chronic diseases and conditions exposed large numbers of people to the ill effects of the disease.[3] Routine practices of healthy lifestyle behaviors likely strengthened the health and well-being of others without those diseases.[4] Even before the pandemic, statistics were grim regarding nurses' health.[5] American Nurses Association (ANA) Health Risk Appraisal results revealed that nurses reported poor intake of fruits and vegetables and high levels of stress and the majority of nurses were in the overweight body mass index category. Although positive health practices, such as tobacco avoidance, seven hours of sleep nightly, and low intake of sugar-sweetened beverages were identified, there is still a need for overall health improvement within the nursing profession.

Integrating the six main health behaviors associated with lifestyle medicine (e.g., nutrition, physical activity, stress management, sleep, avoidance of risky substances, and social connection) into each day has been shown to strengthen health and well-being within clinical practice.[6] The need for lifestyle medicine is clear; the healthcare system needs more healthcare professionals with a strong background in lifestyle medicine science and practice. To adequately prepare nurses for supporting patient health within clinical practice, more nurses need to become familiar with key lifestyle medicine concepts. One viable solution includes the integration of this content within nursing curricula. We know that clinician health practices have an influence on their patients.[7] Increasing the number of nurses who are positive, healthy role models will improve nurses' health and positively impact their patients' health.[8] Now is the time to seriously consider how schools of nursing and academic organizations can monitor and direct nursing education and curricula, and integrate this critical content for maximal health benefit in the United States.

A variety of policies and initiatives developed by professional nursing organizations are relevant to, and supportive of, this lifestyle medicine practice suggestion. The Healthy Nurse Healthy Nation effort, from the ANA, is one excellent example that emphasizes the importance of personal well-being in nursing. The critical need for including lifestyle medicine concepts within nursing education is clear. The American Association of Colleges of Nursing Essentials document[9] identifies four future care environments that nurses must be prepared to work within: disease prevention and promotion of health and well-being; chronic disease care; regenerative or restorative care; and hospice/ palliative care. All four types of care are necessary, but advocacy for emphasizing prevention, health promotion, and well-being is critical since the health of the nation

DOI: 10.1201/9781003227793-86

depends on that approach (AACN, 2021). It is easier to keep people with few health risks healthy than it is to improve the health of people with many risks, and there are significant health and cost incentives associated with such care.[6] This approach helps achieve the quintuple aim of improving patient experiences (quality and satisfaction), improving the health of populations, decreasing per capita costs of healthcare, improving care team well-being, and addressing health equity.[10] These initiatives highlight important health parameters for nurses and provide a foundation for the advocacy of lifestyle medicine content integration into nursing education and practice.

73.2 HISTORICAL PERSPECTIVE ON NURSING ROLES

From the beginning, nurses have promoted health for individuals, families, and communities in a variety of care environments such as hospitals, clinics, corporations, schools, and communities. Some of the earliest writings about nursing by Florence Nightingale highlighted the power of self-care practices and lifestyle in strengthening overall well-being.[11] Although there has been less emphasis over time on health promotion and well-being within nursing, a return to full integration of that content is recommended.

73.3 NURSING EDUCATION REVIEW

Many paths exist to become a registered nurse (RN). To achieve the RN license, students might apply to a diploma program (generally affiliated with a healthcare system), a two-year associate degree program, or a four-year undergraduate, baccalaureate degree program (see Table 73.1). The vast majority of nurses enter one of those types of programs (98.1%) versus entering a graduate-level program (1.1%).[12] While all program types provide the educational base required to sit for a state licensure exam to become an RN, significant differences exist in the specific courses taken by students.

Associate degree nursing (ADN) programs generally take two to three years to complete and include nursing-specific and liberal arts courses. On average, 70 course credits are required for graduation and to sit for a state nursing licensure exam. Liberal arts courses, typically considered prerequisites for entry into an ADN program, include psychology, communication, English, biology, anatomy and physiology, chemistry, sociology, and possibly statistics. Nursing coursework focuses on skills and clinical practice within health assessment, nursing practice, medical-surgical nursing, pediatric nursing, maternal-newborn nursing, psychiatric-mental health nursing, community health nursing, microbiology, and immunology. About 700 hours are required within the clinical practice environment as an opportunity to learn and practice key nursing skills. The American Association of Colleges of Nursing (AACN) does support associate degree nursing education despite their description of the baccalaureate degree as the base level required for professional nursing practice.[13]

Bachelor's degree programs in nursing generally provide more comprehensive education than that found in ADN programs. On average, 120 credits are included in these types of programs with an emphasis on physical assessment, nursing theory, statistics, ethics, and leadership. Liberal arts courses such as the humanities, social sciences, and basic sciences are included within the curriculum, generally during the first two years of study. Core nursing courses follow in years three and four. Clinical courses generally offer 700-800 hours of experience in a wide variety of hospital and community settings, although some programs do incorporate more hours (e.g., up to 1300 hours at some schools, such as Case Western Reserve University[14]). As the major educational entry program for nursing, the bachelor's degree prepares graduates to work in complex healthcare settings.[15] Accelerated programs for bachelor's degrees exist within some educational institutions. They offer programs lasting 12–18 months and feature a fast-paced learning environment for students who already have an undergraduate degree in another field (and have completed prerequisite coursework) or those who may already have an ADN. Both accelerated and four-year undergraduate nursing programs have fairly stringent requirements in regard to curricula and offer little room for elective courses, although four-year programs generally offer more opportunities for electives than accelerated programs.

Graduate entry programs have existed within the nursing profession for a number of decades. People who have graduated with a degree in a field other than nursing enter these programs to become an RN. Typically lasting 18 to 24 months, graduate entry programs provide graduate education for students who want to transition into nursing programs from non-nursing degrees. Graduates of these programs may achieve various degrees, including BSN (Bachelor of Science in Nursing) and MN (Master's in Nursing).

Master of Science in Nursing (MSN) programs accept nurses into their programs who are interested in becoming nurse practitioners. Colleges and universities vary in the number and type of programs offered. Master programs that prepare nurse practitioners in acute care, pediatrics, women's health and midwifery, palliative care, gerontology, family care, psychiatric-mental health, nurse anesthesia, nursing informatics, and administration are most common. Clinical nurse specialist master's programs are also offered at some institutions. RNs enrolled in these programs frequently work while taking courses and fit the clinical course requirements around their work schedules. At the end of these two-year programs, graduates are prepared to sit for board exams in their practice specialty and upon passing are able to practice within the scope defined by the state in which they will be working.

Transitional programs exist within nursing to help nurses without a bachelor's degree get an advanced master's degree. For example, RN to MSN programs provide entering students with the ability to take graduate courses to become nurse practitioners. Other such programs, such as a BSN to PhD program, enable BSN-prepared nurses to get a PhD for future academic and research work.

TABLE 73.1
Examples of Nursing Education

Nursing Education Programs	Abbreviation	Example Educational Areas	Length of Program	Number of Course Credits Required	Number of Clinical Hours Required
Associate degree nursing	ADN	Foundations of nursing, clinical nursing	2–3 years	70	700
Bachelor's degree	BSN	Liberal arts, sciences, and nursing specialization courses (e.g., care of patients, families, and communities, and professional issues in nursing),	4 years; the accelerated program is 12–18 months if the undergraduate degree has already been earned	120	700–800; some schools offer up to 1300 hours
Graduate entry	MN	Nursing practice, theory, research, ethics, leadership, and nursing specialization courses	18–24 months; degrees include BSN and MN (Bachelor of Science in Nursing and Master in Nursing)	63–72	500–1000
Master of Science in Nursing	MSN	Adult gerontology, acute care NP, primary care NP, family NP, nurse-midwifery, pediatrics NP, primary care/acute care, psychiatric-mental health NP	2 years	42–49	500–600
Doctor of Nursing Practice	DNP	Practice, practice leadership, education leadership, executive leadership	1–2 years	33–43	500–1000
Other forms of doctoral education (PhD)	PhD	Research areas in health services, adults and aging, and children, youth, and families	3–4 years	48–63	0

Increasing numbers of nurses are completing graduate degree programs in nursing.[12] Doctor of Nursing Practice (DNP) programs are one of those graduate degree programs that have seen exponential growth in the past ten years. The first clinically focused nursing doctorate program was launched at Case Western Reserve University in 1979.[16] The concept of this educational structure is similar to that found within medical and dental schools and provides an alternative for nurses interested in doctoral preparation for clinical work environments.

Doctoral education in nursing also includes PhD programs. Nurses enter these programs with aspirations of becoming researchers and academicians. While most of the students entering PhD programs already have a master's degree in nursing, some direct entry programs move BSN-prepared students through to the PhD. Nurses enrolled in these programs frequently work throughout their programs. It is common for financial support to be available through educational institutions; nurses may also work as faculty to tap into the educational support provided to employees through the educational institution.

The educational options available within the nursing profession are vast. Not only are the standard degree options described here available at many institutions across the United States, but the specific programs of study available to students may also be quite different between those colleges and universities. This educational variability, as well as many clinical, administrative, research, educational, policy, and advocacy jobs and settings available to nurses with different degrees, is part of what makes nursing an attractive profession. Nevertheless, stringent guidelines have been established by academic accreditation organizations (e.g., the Commission on Collegiate Nursing Education [CCNE] and the Accreditation Commission for Education in Nursing [ACEN]) that specify content that must be covered to offer a complete nursing education that fully prepares nurses for their professional work.

73.4 LIFESTYLE NURSING EDUCATION JUSTIFICATION

The need for schools of nursing to increase their focus on wellness and health promotion within curricula is clear.[15]

Increased focus on lifestyle medicine content is needed for future nurses given their poor health practices and the movement within healthcare systems to focus more on population health and wellness.

Nursing faculty are guided in their curricular development efforts by various accreditation institutions. The AACN is particularly relevant, as its "Essentials" document describes the core competencies required for professional nursing practice.[15] Domains and competencies for entry-level professional practice, as well as advanced-level education, focus on knowledge for nursing practice, person-centered care, population health, scholarship for nursing, quality and safety, interprofessional partnerships, systems-based practice, informatics and healthcare technologies, professionalism, and personal/professional/leadership development. The domain especially relevant to lifestyle medicine is population health.[9]

> Domain 3: Population Health Descriptor: Population health spans the healthcare delivery continuum from public health prevention to disease management of populations and describes collaborative activities with both traditional and non-traditional partnerships from affected communities, public health, industry, academia, health care, local government entities, and others for the improvement of equitable population health outcomes.

The emphasis on competency-based education, as described by AACN, is further support for the inclusion of lifestyle medicine and practices within nursing education. It is only by learning this core content and practicing healthy lifestyle behaviors that future nurses will be adequately prepared to attend to their own well-being while also addressing the health promotion and wellness needs of their patients.

Nursing schools have the opportunity to create robust curriculua that meet the quadruple aims of the Agency for Health Care Research and Quality (AHCRQ) goals of improving: population health; experience of care; per capita costs; and health status and resiliency of healthcare providers.[17] This will move the nursing profession in the direction of assuming more responsibility for lifestyle behavior change within their profession and for patients. Modeling curricular paths in nursing after published models from undergraduate and graduate medical curricula is advised.[18] Integration of lifestyle medicine content within nursing education represents one of the best opportunities to positively impact the health of patients.[19]

73.5 CURRENT WORK ENVIRONMENT CHALLENGES FOR NURSING

The rise of burnout and mental health concerns experienced by nurses is associated with the pandemic[20] but existed prior to that time too.[21] Patients are acutely ill when hospitalized which means that care needs are greater. As workload increases, work stress and attrition, as well as patient mortality, are negatively affected.[22] Nurse staffing issues also impact safety and quality of care.[23] Working as a nurse in a hospital environment has become quite challenging. Nurses' health would benefit from the integration of lifestyle medicine within nursing practice.

An increase in interdisciplinary care models, within clinical environments, further highlights the acute challenges for nurses who do not have a solid foundation in lifestyle medicine. As physicians and other healthcare professionals embrace the positive impact of lifestyle in their own lives and that of their patients, nurses will be at a disadvantage when working on care teams if they do not have an educational foundation in lifestyle medicine. Nurses need advanced knowledge of the evidence documenting the numerous positive effects of lifestyle medicine practices as well as practical and personal experience in the benefits associated with lifestyle medicine.

While the emphasis within nursing is on the promotion of health for sick and well individuals, the nursing profession, in general, does not represent or model ideal health. The Nurses' Health Study highlights the impact of unhealthy lifestyle practices on overall well-being.[24] If the Healthy People 2030 goals[25] for the nation are to be achieved, nurses must devote more time and attention to their own health in order to positively impact their patients' overall well-being. Chapter 78 focuses on self-care and provides details on what nurses can do to improve their own health and well-being.

73.6 LIFESTYLE NURSING CLINICAL APPLICATIONS

Poor adherence to lifestyle modifications has negative health ramifications for a variety of conditions including hypertension,[26] diabetes, and cardiovascular disease.[6] Health and well-being will improve for patients when core lifestyle behavior content is incorporated into nursing practice. The need for lifestyle nursing practice within clinical environments is clear and the opportunities for RNs, master's prepared practitioners, and doctoral nurses to integrate lifestyle nursing into their care plans is immense.

73.7 LIFESTYLE NURSING EDUCATION APPLICATIONS

Current curricular efforts in a few US nursing programs may serve as introductory examples for other institutions to consider for their student populations. The whole-person approach espoused by the nursing profession suggests that lifestyle medicine concepts are already an integral component of nursing philosophy. This fact means that it is easy to make the case for the inclusion of lifestyle medicine concepts within nursing. Professional nursing organizations are now advocating for the inclusion of wellness and well-being content for nursing students. The AACN Core Competencies for Professional Nursing Education explicitly state that nursing students must practice wellness and resilience activities to

enhance their own health as well as doing the same for their patients.[9] While there are few, if any, published articles that describe specific curricula in this area, informal reports are available from nursing faculty who describe undergraduate and graduate nursing courses that focus on health promotion and wellness, which include all of the same content comprised by lifestyle medicine.

A handful of schools have integrated specific lifestyle medicine content into nursing courses. These integrated courses are usually a part of a health promotion course that includes concepts of nutrition, wellness, and leadership in the curriculum. Some courses address the vital nature of social connections and health through values identification, culture, relationship building, time management, and communication strategy content.[27] The ANA's Healthy Nurse Healthy Nation[28] Health Risk Assessment and a sleep assessment are utilized within other courses. Self-reflection is often built into the process to encourage consideration of personal progress.[29]

In 2020, New York University's Rory Meyers College of Nursing added a three-credit elective course for graduate and doctoral students that offers 50 contact hours in one semester of instruction, discussions, and group activities titled "Wellness Through the Lens of Lifestyle Medicine". The vision for this course evolved in the spring of 2020 during the COVID-19 pandemic with the faculty-led weekly support wellness meetings with Meyers' doctoral students.

This course is in line with the fundamentals published in 2022 by the American Association of Colleges of Nursing which included a focus on self-care and well-being in Domain 3. The course provides core knowledge; students in this graduate-level course prepare before class by reading assigned literature and then engaging in student-led discussions on the subject and focusing on a discussion-based lecture based on the practical applications of the course material. A similar course has been offered for undergraduate nursing students at NYU since 2021.

New courses need to be developed within other schools of nursing for the full integration of lifestyle medicine content within nursing programs to be realized. More courses are required to provide a solid base of content in this topical area in order to fully impact the lifestyle behavior practices of nurses and nursing students. Adopting this curricular approach is consistent with accreditation organization mandates and is the natural next step to fully embrace our potential for whole-person health and well-being within nursing and across the United States. While a dearth of information is available regarding the incorporation of lifestyle medicine content within nursing curricula, advocacy statements for pre-professional education exist and present strong arguments for the expansion of those efforts.[30]

A curriculum content table (see Table 73.2) is shared with the hope that university curriculum committees across the country find this to be a helpful stimulus for their curriculum development efforts.

73.7.1 Additional Curricular Applications

Additional curricular options include the integration of ACLM-certified programs, as well as the inclusion of ACLM courses within curricula so that evidence-based, best practices are taught, and students graduate having familiarity with established programs that lead to positive health outcomes.[31] Examples include the Complete Health Improvement Program (CHIP), the Chanwuyi Lifestyle Medicine Program, The Life Project, and the 15-Day Whole-Food Plant-Based Jumpstart Program. Including current ACLM courses within nursing lifestyle courses might also be considered. For example, the "Physician and Health Professional Well-being Course" could be offered to graduate students with the "Family Physician's Introduction to Lifestyle Medicine" document serving as required reading.[32]

TABLE 73.2
Curricular Applications

Six Pillars	Foundational Course Content	Advanced Course Content	Course Activity Ideas
Nutrition	X	X	Seven-day dietary recall and review
Exercise	X	X	Exercise is medicine
Stress	X	X	Brief mindfulness activity practice at the beginning of each class with reflections
Substance Abuse	X	X	Case study review(s)
Sleep	X	X	Four-week sleep hygiene tracking and review
Relationships	X	X	Paper assignment to review current evidence on the importance of social connections to health
Behavioral economics	X	X	Guest lecture by business school behavioral economist
Introduction to lifestyle medicine	X		SMART goal creation; self-care plan implementation
Lifestyle medicine in practice		X	SMART goal creation; patient plan implementation

Resources developed for current clinicians would also be helpful references for nursing students. The National Academy of Medicine[33] created an evidence-based resource compendium that includes tools and strategies to enhance healthcare workers' well-being. Schools of Nursing should consider how those resources can foster a culture of well-being for students, faculty, and staff. The American Nurses Association's initiative, titled Healthy Nurse Healthy Nation, includes resources to foster nurses' mental health.[28] It would not be hard to develop new courses on well-being for undergraduate nursing students using the clinician well-being resources previously mentioned. Recently, enhanced attention has been directed to clinician well-being, but redirecting those resources to students is also vital for creating a healthier healthcare workforce.

Advocacy for offering more lifestyle medicine courses within curricula has occurred[34] and should continue so that the full potential of nurses and nursing students to actualize health and well-being within their own lives and that of their patients is realized.

73.8 SUMMARY

The American Nurses Association acknowledged the need for greater attention to healthy lifestyle practices when it created the Healthy Nurse Healthy Nation initiative.[28] The challenges integrated into that program are designed to encourage increases in daily healthy behaviors among nurses. Those efforts are critical for current nurses. The need is great in regard to preparing future nurses to be experts and role models for healthy living. Integration of lifestyle medicine curricula within undergraduate, graduate, and doctoral nursing programs shows promise. Curricular examples are available and greater consideration of this need, with the active creation of new courses within nursing programs, is required to improve nurses' health and that of their patients.

CLINICAL APPLICATIONS

- Personal nursing well-being can be enhanced by following lifestyle principles.
- In contrast with medical education, many nursing degree-granting educational programs can be targeted for lifestyle nursing education.
- While medical education has a rigid curriculum in most institutions, nursing education has flexible elective course options in many degree-granting programs.

74 Staff Nurse Clinical Application of Lifestyle Medicine

Karen Laing, MSN, APRN, AGPCNP-BC, DipACLM, HWNC-BC, CHES

KEY POINTS

- There are four million registered nurses in the United States.
- Nursing is one of the most trusted professions by patients.
- This places nurses in a unique position to share the benefits of lifestyle interventions.

74.1 HISTORY OF LIFESTYLE INTERVENTIONS IN NURSING

In *Notes on Nursing*, Florence Nightingale addressed the need for pure water, uninterrupted sleep, and the mind's impact on the body[1] Modern nursing is rooted in these lifestyle interventions. An interdisciplinary organization, the American College of Lifestyle Medicine (ACLM), has an actively growing member interest group (MIG) made up of hundreds of registered nurses (RNs) and advanced practice registered nurses (APRNs). The RN/APRN MIG mission is "To support RNs and APRNs in the use of evidence-based Lifestyle Medicine principles in nursing practice and to advance the cause of Lifestyle Medicine in the nursing profession through ACLM membership, networking, education, certification, publications, and presentations".[2] Notice the focus on evidence-based therapeutic lifestyle interventions, which nurses may use in their daily practice.

The case for the role lifestyle medicine interventions can play in preventing and potentially reversing chronic diseases is laid out throughout the chapters of this book. This chapter's focus will be on lifestyle interventions available to all nurses, not just those practicing in an APRN role or working within a lifestyle medicine (LM) focused clinic. This chapter intends to offer suggestions and spark personal exploration regarding how lifestyle interventions may be incorporated into the daily practice of the reader, both personally and professionally.

74.2 CRITICAL ROLE OF NURSES IN HEALTHCARE LIFESTYLE INTERVENTIONS

There are currently four million registered nurses in the United States,[3] and nursing is the largest healthcare profession in the United States.[4] Nursing is also recognized as being one of the most trusted professions. With this trust comes the responsibility to provide the best possible care for health.[5] Regular physical activity, daily stress management, a healthy diet, and avoidance of risky substances such as tobacco and alcohol are widely accepted as contributing to optimal health and disease avoidance.[6] Nurses are uniquely positioned to provide examples of these behaviors and patient education regarding modifiable risk factors for chronic diseases. A nurse's own behaviors may influence, positively or negatively, the quality and amount of information shared with the patient. Because they are seen as role models, when nurses engage in behaviors that may be damaging to their own health, they may also be negatively impacting the health of others.[6]

74.3 SCOPE OF PRACTICE FOR THE REGISTERED NURSE

Nurses may be concerned about incorporating lifestyle medicine interventions into their practice. Often, there may be uncertainty about what falls within their scope of practice. Westmoreland et al. describe the unique services nursing offers and define the scope of nursing practice in specific situations. Three major classifications of the scope of practice exist.

- The first classification of nursing services is delegation. They enhance the health of the patient and require a physician's order. Few lifestyle medicine interventions typically fall into this classification.
- The second category of nursing services is interdependent. These services also enhance the health of the patient by assessing, monitoring, detecting, and preventing complications related to a medical diagnosis. They require the nurse to make judgments and have knowledge of signs and symptoms of potential problems and prevent complications. Many lifestyle medicine interventions may fall into this category.[7]
- Last, nursing services may be independent. The nurse may enhance health by assessing, monitoring, and treating with a focus on nursing diagnosis. The connection between the whole patient, body, mind, and spirit is being addressed. Nursing knowledge is required to help the patient and family as they navigate their response to new health

DOI: 10.1201/9781003227793-87

information. While other healthcare professionals are involved in the first two classifications, nursing has the primary responsibility for this third function.[7] Multiple lifestyle interventions can be included here.

74.3.1 Stress Management

Nurses in any practice setting may benefit from practicing personal daily stress management. The Well-being Initiative[8] was developed by the American Nurses Association (ANA) and the American Nurses Foundation (ANF). This initiative offers free resources to foster nurses' mental health and well-being. These factors play a critical role in productivity, personal and professional quality of life, and overall health and wellness.

Nursing staff may also take advantage of workplace wellness programs. These programs vary in their offerings but frequently address physical activity, nutrition, and tobacco cessation, all essential aspects of daily stress management.[9] As identified earlier, the nurse is looked to by the patient as a role model.[6] Modeling these behaviors benefits both the nurse and the patient.

The inpatient hospital setting can be stressful for both nursing staff and patients. Large numbers of people coming and going, noises made by people and machines, and the busyness of frequent activities may contribute to feelings of stress. Regular daily activity routines, food intake, sleep patterns, and socialization are all disrupted for the hospitalized patient. Each patient will perceive the experience differently and respond based on their perceived stress and ability to cope with that stress.

Strategies to assist a patient in coping with these stressors may be as simple as listening to the patient share their experience and feelings or facilitating communication between the patient and family members. The nurse may also teach the patient and family members techniques for and the potential benefits of deep breathing or progressive muscle relaxation exercises to prevent and manage feelings of stress.

Similar interventions may be taught and practiced with adults, teenagers, and children in an outpatient setting. Stress may be experienced in these areas when diseases are newly diagnosed. Or a child may be fearful of healthcare visits due to previous experience with uncomfortable procedures. Patients may also be experiencing stress in their daily work, school, or personal lives.

Nurses working in occupational health or worksite wellness may offer interactive programs or educational workshops regarding ways to minimize the negative impacts of stress. Physical activity programs are an essential component of worksite wellness programs.[10] In addition to physical benefits, physical activity produces both emotional and psychological benefits[11] This is just one example of a specific lifestyle intervention positively impacting another.

74.3.2 Quality Sleep

Interestingly, human beings may deliberately deprive themselves of sleep without any apparent gain. No other species does that.[12] The first standard of nursing practice is assessment.[3] The first sleep intervention the nurse may do for the patient is raising their awareness of how much quality sleep they routinely get, how they feel upon awakening, and whether they feel fatigued throughout the day.

Another critical question is whether the patient has ever been told they snore or have sleep apnea.[13] Obstructive sleep apnea is a common disease, but few patients are diagnosed or treated.[14] Some patients may be concerned about going into a sleep lab for an overnight study. A simple assessment tool, the STOP-Bang questionnaire, available online or as a short paper questionnaire, may be offered to the patient as a self-administered initial screening for predicting the severity of obstructive sleep apnea.[14] Once the patient is aware they have an elevated score, they may more readily enter into a conversation about the possible next step of a home-based sleep study. Although the RN will not be ordering these tests, this nursing interaction may pave the way for appropriate treatment and improved quality of life and health.

Three other vital assessment areas include caffeine, alcohol, and general fluid intake. Worldwide, caffeine is the most commonly used stimulant.[12] The patient may not recognize the potential negative impact on their sleep of those late-evening glasses of iced tea or chocolate bars. Or the patient may be under the false impression that having a drink in the evening will help them fall asleep or sleep more soundly throughout the night.[12] Even more straightforward is the possibility that late-evening fluid intake may be contributing to nocturia. The nurse may take the opportunity of a patient's complaints regarding poor sleep quality to explore whether any of these habits may be contributing to their sleep disturbances.

74.3.3 Quality Food

From the beginning of professional nursing, Florence Nightingale acknowledged the possible effect of food on the patient.[1] Nutrition topics currently included on licensure exams for registered nurses include nutrition assessment and monitoring, diet therapy (including enteral and parenteral nutrition), and patient education and counseling.[15] As knowledge continues to develop regarding best nutrition practices, the nurse with an interest in lifestyle interventions must stay abreast of current research as well as what is being reported in the mainstream media. Members of the public regularly receive poor-quality information about what to eat to promote health, especially regarding obesity.[16]

Many nurses have learned about specific diets to address certain disease states, such as a low-fat diet for patients with heart disease and a low-sugar diet for someone with diabetes. This has led to much confusion for both patients and nurses regarding what to eat after receiving more than

one diagnosis. Part II, Nutritional Aspects of Lifestyle Medicine, will lay out the case for recommending a whole food plant-based diet to reverse and prevent multiple disease states.

A current diet assessment is the place to begin with a patient who has expressed interest in the possibility of making changes. It may be as simple as asking questions regarding what they typically eat and drink during the day. This can be done at the bedside. Or, for the more involved patient or the nurse with time for a more in-depth interaction, a comprehensive nutrition screening tool may be more appropriate. A review of the results with the patient and their support persons can help identify both current positive habits as well as areas of opportunity. While the patient may appear discouraged because their current diet is so "bad", the nurse can offer the encouragement that these are also additional possibilities for achieving their desired goal through lifestyle. A dietitian knowledgeable regarding a whole food plant-based diet is an invaluable resource for both the patient and the nurse.

Optimal nutrition is vital for the prevention and possible reversal of multiple diseases. Exploration in this area may include trying new foods or cooking methods or meeting with other like-minded individuals to share a meal. When armed with evidence-based nutrition practices, nurses can improve their own health as well as educate their patients, leading to improved health outcomes and increased quality and length of life.

Box 74.1 is an example of the use of lifestyle interventions by an RN in a hospital setting. While traditional cardiac rehab intervenes only after the patient receives a cardiac diagnosis, this LM nurse has worked with her team to initiate an opportunity for disease prevention education. The impact is being seen and heard not just by patients but also by their family, friends, and other hospital staff.

BOX 74.1 Nursing Narrative of Lifestyle Interventions for Patients with Coronary Artery Disease

Our "CAD (Coronary Artery Disease) Risk" program is for patients who had a heart catheterization during their current hospitalization, had any CAD greater than 0%, and had no intervention or myocardial infarction. The Inpatient Cardiac Rehab Team takes the opportunity to provide education regarding heart disease and lifestyle factors to these patients and their support people. This education includes an explanation of what the heart does and the result of their catheterization, the relationship between inflammation and coronary artery disease, information about what constitutes a heart attack and angina, and a personalized discussion of heart disease risk factors. Patients and their families and friends express great appreciation for this education and information on potential lifestyle factors. After overhearing these conversations, many hospital staff have changed their language from "clean cath", which was previously used to describe a heart catheterization without intervention even when CAD was found, to "some CAD". This change in language is beginning to shift the message to these patients from "your heart is fine" to "you have some CAD and here's what you can do to prevent its progression".

74.3.4 Physical Activity

Lack of regular physical activity is widespread throughout the United States and significantly raises mortality risk.[17] Overwhelming evidence has repeatedly shown the significant mental and physical health benefits of regular physical activity. In response, the American Medical Association (AMA) and the American College of Sports Medicine (ACSM) developed the "Exercise is Medicine" campaign.[18] Multiple sources have specifically suggested that regular physical activity may delay the development of cardiovascular disease and decrease the incidence of coronary heart disease events.[19] Although nurses are aware of many of the benefits of physical activity, they may not be comfortable making specific exercise recommendations to patients. There may be concern about the risk of harm to the patient.

As with each of the other aspects of lifestyle interventions, nurses can start the process of positively impacting the patient by beginning with an assessment. Exercise is Medicine recommends adding two questions to the patient's health history regarding how many days per week they currently engage in vigorous PA and for how many minutes at each session.[20] Part III, Physical Activity, will guide the nurse regarding recommended physical activity levels and screening recommendations. Armed with this information and the patient's answers to the above questions, the nurse then has the opportunity to discuss with the patient their current PA levels and the potential benefits of working toward the recommended targets. Change cannot happen if the patient is unaware of these guidelines and their possible health advantages.

Patients can sometimes become discouraged if they feel the PA recommendations are too strenuous or time-consuming. The most recent edition of the *Physical Activity Guidelines for Americans* states that any amount of physical activity has some health benefits.[21] These guidelines also include evidence showing that physical activity can have immediate health benefits such as anxiety reduction, lowering blood pressure, and improving sleep quality and insulin sensitivity. This knowledge can encourage the patient with an "all-or-none" mindset. Studies have shown that healthcare practitioners with higher levels of PA are more likely to recommend PA to their patients.[22] And as previously established, nurses can also act as positive or negative health behavior role models for their patients.[6] So, a nurse with a pattern of regular physical activity can

benefit not only herself but the patients she educates and for whom she cares.

74.3.5 Social Connections

Social connections are significant predictors of health, both good and bad. As such, they can be seen as either a risk or a protective factor.[23] Social connections are critical coping mechanisms during times of stress. Unfortunately, some stressful situations, such as the recent COVID-19 outbreak, require many patients to find new ways to connect.[24] Helping patients explore and find the best ways to make and maintain social connections is an area of opportunity for nursing.

Assessment is, once again, the place to start. Does the patient live alone? Do they have regular contact with friends or family members? If adult children live with them, are these positive, supportive relationships? Are they working from home? Are they members of any groups such as a bowling league, book club, or faith community? Are these groups meeting in person or solely virtually? Have there recently been any significant changes in their social connections, such as the death of a spouse or the loss of a job?

These questions do not have to be asked during a lengthy intake interview, although a minimal initial assessment regarding whether the patient lives alone and information about their support person is typically included as part of many initial nursing assessment forms. Further information regarding the patient's social connections may be gathered through conversation during a dressing change or brief office visits for lab work follow-up. Once the nurse has gathered information regarding the patient's current level of social connections, she can educate the patient about the potential benefits of having strong social connections, as outlined in other chapters of this book. Then the nurse can begin to explore possible ways to connect with others that are appropriate for this patient.

The nurse, once again, can benefit both herself and the patient by role-modeling strong social connections.[6] By developing and nurturing these connections, the nurse can personally benefit from the protective effects on the physical and mental health of social connections.[25] The patient may benefit indirectly from the health benefits experienced by the nurse and directly by being encouraged and motivated by their caregiver who can speak to the personal benefits.

74.3.6 Risky Substances

Substance use is common and takes place throughout many cultures and populations. In 2021, the United Nations reported that of the 275 million people who used substances within the past year, more than 36 million had a substance use disorder (SUD).[26] Mortality rates and mental and physical health quality can be directly correlated with substance consumption rates.[27,28] Substances used may be legal or illegal. Features of SUD include loss of control, social or work impairment, risky use, and craving for the substance.[29]

Screening for unhealthy substance use is recommended by the US Preventive Service Task Force for all adults over the age of 18, while the American Academy of Pediatrics recommends substance use screening for all primary care visits for children 12 to 17 years of age.[30,31] Most people experiencing challenges with substance use do not pursue treatment, partly because they do not feel they have a problem.[32] Once again, nurses have an opportunity to assess, raise awareness of the potential for health improvement, and educate on possible interventions.

One practice model used in the healthcare setting is SBIRT—screening, brief intervention, and referral to treatment.[33] The initial screening may be done by nurses working in the emergency department or primary care practices using tools such as the NIDA Quick Screen for Alcohol and Other Substances.[34] Patients with positive prescreens may then receive a full screening tool such as the DAST-10 for further risk stratification.[33] If the additional screening was positive for risky substance use, a ten- to 20-minute intervention session could be offered. This is followed by referral to community resources if the screening score indicates hazardous use or possible SUD.[33]

Although primary care practices and emergency departments are popular SBIRT settings, the reasons for patient visits vary significantly between them. While the reason for an emergency department visit may offer a teachable moment, SBIRT delivery in this setting can be particularly difficult due to time constraints. SBIRT studies have generally shown smaller reductions in substance use in emergency department patients when compared with similar studies carried out in primary care settings.[33]

Motivational interviewing (MI) is one patient-centered intervention with significant support in the literature and can easily be included by the nurse during any screening or brief interaction intervention. MI techniques include eliciting change talk, developing discrepancy, and rolling with resistance to change.[35] Nurses interested in expanding their clinical behavior-change toolbox will want to look in other chapters of this book for further information on these techniques. Other lifestyle intervention tools that nurses may use to assist patients with avoidance of risky substance use include mindfulness,[36] regular physical activity,[37] and a healthy diet.[38]

As a trusted resource, nurses frequently hear concerns from patients regarding substance use that may not be shared with others. The nurse has the potential to raise patient awareness of problematic substance use and make a positive impact through brief interventions. Nurses with a strong knowledge of lifestyle interventions such as mindfulness, regular physical activity, and quality food may also provide support for patients recovering from SUD.

Box 74.2 includes tips for fitting lifestyle interventions into specific brief patient encounters in an outpatient setting. Many nurses are concerned that they do not have time in their already busy schedules to implement LM interventions. This nurse shares examples of quick questions to ask and resources that are easily shared.

BOX 74.2 Tips for Fitting Lifestyle Interventions into a Brief Outpatient Interaction

- After reviewing the patient's medical history and identifying chronic conditions such as hypertension, diabetes mellitus, hyperlipidemia, or cancer, I ask: "Have you made any changes to your diet, exercise, or overall lifestyle since this diagnosis?"
- After administration of the patient health questionnaire (PHQ-9) or generalized anxiety disorder (GAD-7) screening, I ask: "What do you do when you're feeling stressed or overwhelmed? Do you have a trusted friend or supportive community?"
- After reviewing a patient's smoking status, alcohol, and other substance use, I ask: "Have you ever quit before? Is this something you might be interested in pursuing today?"
- During an assessment of a patient's vital signs, I asked: "Are you exercising on a regular basis? If so, how many minutes per day, and days per week?"[38]
- Applicable smart phrases were added to the after-visit paperwork to reiterate the lifestyle changes we had discussed. Examples include: "Please watch Game Changers (on Netflix), Forks Over Knives, or PlantPure Nation (on YouTube) for more information; Recommend removing dairy from your diet—please visit Switch4Good.org to learn more".
- I also kept a binder full of patient education handouts gathered largely from ACLM and Physicians Committee for Responsible Medicine (PCRM) from which I pulled tip sheets—regarding anything from the pillars of lifestyle medicine to condition-specific lifestyle approaches—to share and send home with willing patients.

74.4 NURSE COACHING

Health coaching is one of the latest tools used in healthcare to manage chronic diseases. Other chapters of this book describe the practice of health coaching and lifestyle change. The large number of RNs and the significant amount of time they spend with patients puts the nurse in an excellent position to provide this health coaching. Coaching can be used to decrease the impact of a chronic illness's symptoms and prevent these diseases.[40] The ACLM defines LM as "the use of evidence-based, lifestyle, therapeutic intervention … to prevent, treat, and often reverse disease".[41] Due to the additive power of these intentions paired with the nursing profession's size and the significant amount of nurse-patient interaction time, nurse coaching can be a powerful LM instrument.

While multiple coaching certifications are currently available, only one board certification is offered specifically for nurse coaches by the American Holistic Nurses Credentialing Corporation (AHNCC). These exams are accredited by the Accreditation Board for Specialty Nursing Certification (ABSNC). ABSNC accreditation allows nursing credentialing organizations to obtain and maintain accreditation by demonstrating compliance using a peer-reviewed system. The American Nurses Credentialing Corporation Magnet Recognition Program® recognizes all the AHNCC examinations.[42]

AHNCC is the national certification organization for nurse coaches. According to Margaret Erickson, CEO of the AHNCC, since nurse coaches practice as nurses first, "our examination is based within the context of the Nurse Practice Act". This exam differentiates the nurse from others practicing the role of health and wellness coaching, such as social workers, nutritionists, business professionals, and physical fitness trainers.[43]

Eligibility criteria for the nurse coach exam include specific requirements regarding licensure, practice hours, minimum education level, number of nurse coach-specific CNEs, mentored or supervised coaching experience, and the candidate's agreement at the time of application. Nurses who complete the requirements for nurse coach certification through the AHNCC earn the designation Nurse Coach Board Certified. Any nurse who meets the requirements for this certification and holds one of the holistic nurse certifications offered by the AHNCC earns the designation Health and Wellness Nurse Coach Board Certified.[44]

74.5 CONCLUSION

As the largest healthcare profession in the United States, nurses have the opportunity in a wide variety of settings to make a significant, positive impact on the lives of patients through the use of lifestyle interventions. As one of the most trusted professions, nurses are uniquely positioned to listen to patients and make lifestyle recommendations to potentially reverse or prevent disease. The examples given here encompass just a few of the many possible interventions available to the nurse to positively impact the patient.

CLINICAL APPLICATIONS

- The nursing intervention begins with an accurate assessment and listening to the patient.
- Nursing lifestyle interventions do not have to be of long duration to be powerful.
- Start with interventions that are most pertinent to the current clinical practice setting.
- The potential impact includes the nurse, the patient, the patient's family and friends, and fellow staff members.

75 Advanced Practice and Specialized Nursing Approaches to Lifestyle Medicine

Elizabeth Simkus, DNP, MSN, RN, FNP-C

KEY POINTS

- Advanced practice registered nursing (APRN) dates to the 1800s.
- There are four specialties under the APRN umbrella: certified nurse midwife (CNM), certified registered nurse anesthetist (CRNA), certified nurse practitioner (CNP), and clinical nurse specialist (CNS).
- APRN education aligns with the mission and values of lifestyle medicine.
- RNs and APRNs have demonstrated how they are able to address gaps in care and rise to the changing healthcare landscape.
- APRNs are well suited to be integral members of the lifestyle medicine team.

81.1 A BRIEF HISTORY OF NURSING AND ADVANCED PRACTICE REGISTERED NURSING

Documentation of nursing dates to the Roman Empire era around 300 AD.[1] Historical contributions to science made by nurses demonstrate the depth and breadth of the profession. Florence Nightingale was a nurse who provided care for wounded soldiers in the 1850s. She has been credited for advancing the nursing profession in the 19th century by focusing on decreasing wound infection and improving hygiene in practice[1] The concept of an advanced practice registered nurse (APRN) has its roots back in the mid-1800s. Catherine S. Lawrence was the first nurse to administer anesthetics during the American Civil War in 1861.[2] Today, nearly 44,000 nurse anesthetists are practicing in the United States.[3] Another advanced practice nurse role, the clinical nurse specialist (CNS), was first conceptualized in the 1800s when hospitals educated nurses in specialized psychiatric nursing care. The first official CNS program was established in 1955 at Rutgers University.[2] Today, CNSs are clinician experts defined by areas such as population (pediatrics, adults, women's health); setting (emergency room, critical care, outpatient); disease or specialty (diabetes, oncology, transplant); type of care (psychiatric, inpatient, rehabilitation); or type of problem (pain, wounds, stress).[4]

Nurse-midwifery began in the United States when Mary Breckinridge started the Frontier Nursing Service in 1925.[5] Nurse-midwifery was not nationally recognized until 1954. Up until that point, nurse midwives had a more general practice that also included other pediatric care services[6] The nurse practitioner is a more recently developed APRN role. The first nurse practitioner program was established in 1965 at the University of Colorado School of Nursing. This was in response to physician shortages as well as an opportunity for nurses to grow professionally in public health and to obtain a graduate-level education[2] APRN practice has evolved over the last century to include national associations, certifications, and licensures that ensure quality and cost-effective care is provided by this profession.

81.2 DEFINITION OF AN ADVANCED PRACTICE REGISTERED NURSE

An APRN has a graduate-level degree at the master's, post-master's, or doctorate level. There are four specialties under the APRN umbrella, including certified nurse practitioner (CNP), certified registered nurse anesthetist (CRNA), certified nurse midwife (CNM), and clinical nurse specialist (CNS). They all share the foundational education and experience of the RN, while also having their own role in healthcare. CRNAs are an example of how APRNs can fill gaps in care. Currently, more than 50 million anesthetic procedures are provided by CRNAs each year.[7] In fact, 80% of anesthesia providers in rural counties are CRNAs. A certified nurse midwife specializes in women's healthcare including, health maintenance, prenatal, labor and delivery, and post-partum care.[8] A CNS has a graduate degree and is certified in a specialty. While a CNS typically focuses on education, research, and consulting, they can also apply for authority to prescribe medication.[8] A nurse practitioner (NP) provides comprehensive care including assessment, diagnosis, evaluation, and treatment. RNs and APRNs are educated to provide whole-person care with a focus on primary, secondary, and tertiary prevention. Trained as an RN and an APRN, nurse practitioners are skilled at not only assessing for physical symptoms but also psychosocial and

DOI: 10.1201/9781003227793-88

environmental data[8] Extensive experience in education can also set these providers apart in the arena of lifestyle medicine.

APRNs are regulated through licensure, accreditation, certification, and education (LACE)[9] Although there are national standards in education, accreditation, and certification for APRNs, states have their own specified levels of practice authority.[10] The APRN Consensus Model is an attempt to provide uniform regulations for roles, licensure, accreditation, certification, and education for APRNs in the United States. There has been some progress, but there remain states that have not implemented all elements.[11] For nurse practitioners, 26 states, DC, and two US territories have full practice authority.[12] Thirteen states and three US territories have reduced practice authority and 11 states have restricted practice for nurse practitioners. Full practice authority allows nurse practitioners to practice under the exclusive licensure authority of the state board of nursing. The National Academy of Medicine and the National Council of State Boards of Nursing support this model.[12] The other models either reduce or restrict NPs' ability to engage in one or more areas of practice. These models also have requirements related to collaborative agreements, supervision, delegation, or team management by another health provider.[12]

81.3 APRN EDUCATION AS IT RELATES TO LIFESTYLE MEDICINE

APRNs are trained to view and treat patients in a whole-person manner. There is an understanding of the multidimensional influences on health from family, community, social, political, and economic environments. After establishing a therapeutic relationship, APRNs are skilled at prioritizing health concerns and providing patient-centered, culturally competent care.[13] In addition to nursing-specific coursework, graduates receive liberal education related to cultures and spiritual beliefs. Combining the arts, sciences, and humanities in liberal education prepares the nurse for a unique perspective on healthcare. This includes providing ethical care and acting as an advocate, as well as promoting health equity and social justice with the understanding of structural racism, bias, and social determinants of health[13].

> The study of history, critical race theories, critical theories of nursing, critical digital studies, planetary health and climate science, politics, public policies, policy formation, fine arts, literature, languages, and the behavioral, biological, and natural sciences are key to the understanding of one's self and others, civil readiness, and engagement and forms the basis for clinical reasoning and subsequent clinical judgments.[13]

The American College of Lifestyle Medicine values statement aligns with APRN education, which focuses on using evidenced-based practice, high standards, integrity, healthy equity, and treating the whole person[14] The American Association of Colleges of Nursing has core competencies that are required within APRN education and within these competencies are ten domains.[13]

Domain one is knowledge for nursing practice. This includes translating theories and nursing science into practice. This domain also covers the synthesis of knowledge, ethical decision-making, and socially responsible leadership. APRNs are taught to practice clinical judgment based on the integration of knowledge, evidence, and decision models. Domain two is person-centered care. This begins with fostering and promoting therapeutic relationships. This involves the ability to communicate effectively with patients from a diverse background with preferred methods of learning.

Next, APRNs are trained to provide patient-centered care in the areas of assessment, diagnosis, implementing a plan of care, evaluation, promoting self-care management, and care coordination. Lifestyle medicine asks patients to modify their lifestyle and behavior change is challenging. It would be difficult for a practitioner to guide a patient through lifestyle medicine behavior modifications if they cannot formulate a person-centered plan of care. An example of this is in pediatric weight management programs. Hampton-Anderson and Craighead discuss how African American children benefit less from these traditional programs and how there is a need for programs to consider disparities in eating disorders, psychosocial factors, and cultural factors.[15]

Domain three is population health. APRNs receive education related to assessing the target population and the system's ability to address needs; analyzing population data and comparing benchmark data; using evidenced-based methods to prioritize care for the population; collaborating with stakeholders to implement culturally appropriate intervention and evaluation methods; cultivating effective partnerships to further the pursuit of population health and health equity; socioeconomic landscapes relating to care being provided; health policy; advocacy; and disasters and public health emergencies. Lifestyle medicine implemented at a population health level can address social determinants of health. Health Equity Achieved through Lifestyle Medicine (HEAL) and the ACLM Health Systems Council are two examples of population health initiatives led by ACLM.[16]

The fourth domain is scholarship. There is a breadth of evidence supporting lifestyle medicine in the prevention or management of heart disease and its impact on telomeres, cancer, erectile dysfunction, cognitive function, stroke, diabetes, pain, and weight management.[17] As lifestyle medicine continues to grow as its own discipline, APRNs can play a critical role in the evaluation, translation, implementation, and generation of lifestyle medicine-related scholarship and research. Their education also covers scholarship-related topics such as ethics, IRB guidelines, and methodologies in quality improvement, research, and evaluation.

Domains five and eight relate to quality, safety, and information technology. APRNs receive education on

utilizing data, benchmarks, and outcome metrics to lead quality improvement initiatives. Allowing APRNs to lead quality improvement initiatives can help with reimbursement as well since APRNs are included in the Merit-Based Incentive Payment System (MIPS)[18] In addition, APRNs can utilize quality improvement initiatives, research, and publications as part of their requirements for renewing state licenses and national certification.[2,19]

The sixth and seventh domains pertain to collaborating with other professions and system-based care. Implementing lifestyle medicine on a large scale will need a system-wide, team-based care approach. It would benefit the team to have APRNs who have experience and training in team-based care dynamics that promote inclusion, equity, and diversity. In addition, the ninth domain focuses on professionalism, expanding on concepts of ethics, innovation, communication, leadership skills, accountability, social justice, civility, laws, policies, and regulations.

The tenth domain is centered around the APRN and encourages "participation in activities and self-reflection that foster personal health, resilience, and well-being".[13] Having the concept of self-care within the education of RNs and APRNs will not only reduce the risk of provider burnout but will also be useful in providing optimal lifestyle medicine care. For example, studies have shown that physically active healthcare providers are more likely to counsel their patients on this healthy lifestyle habit.[20] APRN experience and training align well with lifestyle medicine. There is a wealth of opportunities for this profession to offer to the specialty, patients, and population health.

81.4 NURSING: RISING TO THE CHALLENGE AND ADAPTING TO THE CHANGING HEALTHCARE LANDSCAPE

All APRNs have a background as a registered nurse (RN). Registered nurses make up the largest healthcare profession in America, at over four million.[21] In addition, nurses have ranked as the number one profession for honesty and ethics for 20 years in a row.[22] The number of doctorate-prepared nurses tripled between 2010 and 2018 from 10,000 to 33,000[23] Having the foundation of registered nursing prepares APRNs for success when practicing lifestyle medicine. An example of this occurred after the 2020 Surgeon General's Call to Action to Control Hypertension. Nursing leaders from 11 national organizations came together to formulate how nursing could contribute to this call to action.[24] They defined how different sectors of nursing could execute this call to action by utilizing evidenced-based nursing interventions. These included community support to optimize patient care in multiple domains, enumerating roles of registered nurses, advanced practice nurses, QI/population health nurses, schools of nursing, and professional nursing organizations. This example effectively showcases the opportunity that lies within nursing to advance the health of patients and communities. APRNs practicing at the top of their license can interact with the different sectors of nursing and other healthcare disciplines to provide safe, high-quality, equitable care.

The National Academy of Medicine (NAM) (formally National Institute of Medicine) released *The Future of Nursing: Leading Change, Advancing Health* in 2011. Recommendations were made to have nurses included in integral and leadership roles engaged in redesigning healthcare in the United States.[25] In this landmark report, a vision for the future of healthcare in the United States was presented along with the rationale as to why nursing was a key component of realizing this vision. The three areas of necessary change in nursing were practice, education, and leadership. In 2016, a publication was released regarding the progress made on the 2011 report. Areas of opportunity for continued progress included the following: increasing awareness of nurses' capabilities in the areas of practice, education, collaboration, and leadership; the need for diversity in the nursing workforce; and further data collection to continue improvements.[26] To date, the number of nurses with a doctorate has more than doubled since 2011; eight additional states since 2010 have granted APRNs full practice authority; and nurses are holding leadership roles as evidenced by more than 10,000 board seats filled by nurses.[23] As work continues toward the recommendations from the 2011 report, the current Future of Nursing Report for 2020–2030 has been published. This report identifies how nursing ethics, values, and knowledge prepare them to be key stakeholders in addressing social determinants of health (SDOH) and improving health equity.

APRNs are suited to be key stakeholders in expanding access to lifestyle medicine and its pillars to all populations. Bodenheimer and Mason published proceedings of a conference on how nurses, including APRNS, can be partners in transforming primary care and should be able to practice to the full extent of their license.[27] With the projected physician shortages in both primary care and specialties within the next ten years, RNs and APRNs will be asked to fill the gaps in care and improve access to care.[26]

> Allowing APRNs to practice to the full extent of their education and training as recommended in the 2011 The Future of Nursing report would help remediate inequities in access to health care and enable more people to enjoy the benefits of care provided by NPs and other APRNs.[26]

81.5 HOW APRNS CAN ADDRESS THE CURRENT GAPS IN CARE

Building a workforce that is trained in lifestyle medicine can increase accessibility to high-quality care that improves health outcomes. An example could be training CNMs in lifestyle medicine and using their expertise to improve rates of breastfeeding. The American College of Nurse-Midwives (ACNM) Benchmarking Project has been utilizing data from nationally endorsed quality metrics for

quality assurance and quality improvement over the last quarter century.[28] In the 2019 report, they found the average exclusive breastfeeding rate 48 hours after birth among participating midwife practices was 86%. The current reported rate of infants in the United States who are exclusively breastfed at 48 hours after birth is 64.5%[29] This highlights a tremendous opportunity to capitalize on the expertise of CNMs and expand lifestyle medicine across the lifespan.

There is a need for improved data on the cost-effectiveness of both APRN practice and lifestyle medicine. Most data show how APRNs provide high-quality, cost-effective care; however, publications related to evaluating the cost-effectiveness of APRN roles tend to lack quality[30] Abraham et al. conducted a systematic review related to the cost-effectiveness of chronic disease care provided by APRNs compared with physicians.[31] APRNs were cost-effective in the areas of medication management and patient care visits. The findings were not consistent with their cost-effectiveness in laboratory testing and diagnostic procedures. Razavi et al. found that for Medicare beneficiaries, primary care nurse practitioners were more conservative with resource utilization compared with primary care physicians, especially in low-risk populations.[32] A reduction in resource utilization can help with containing costs and additional cost savings in accountable care organizations (ACOs), especially when beneficiaries are not required to see both a physician and an APRN included in the ACO contract. In contrast, Batson, Crosby, and Fitzpatrick found that their 118 advanced practice providers (APPs) within the Hattiesburg Clinic did not perform as well as physician primary care providers in quality metrics, ER utilization, or cost of care provided per member per month (PMPM)[33] The organization concluded that APPs were a critical part of their healthcare delivery and if it were not for the 100-plus APPs employed over 15 years, thousands of patients would have not been able to receive primary care. However, based on the results, APPs were no longer assigned their own patient panels. Veterans Affairs conducted similar studies on patients with diabetes and found lower total healthcare costs for patients with APPs as their primary care provider as compared with physicians.[34] Standardizing the way APRN care is evaluated would be beneficial in determining how to implement their practice into lifestyle medicine. Lopatina et al. recommend utilizing *Guidelines for the Economic Evaluation of Health Technologies: Canada* when evaluating APRN roles.[30] In addition to evaluating APRNs, there are opportunities to expand on the research related to lifestyle medicine interventions and healthcare spending. Livingston et. al expressed the need for lifestyle medicine economic research related to the effects of an intensive therapeutic lifestyle intervention (ITLC), cost savings compared with current disease-related costs, and the impact of lifestyle medicine outcomes on various payment models[35] Training APRNs to practice lifestyle medicine can further improve the cost-effectiveness of the care provided as well as the health of the communities served.

CLINICAL APPLICATIONS

- The foundation of RNs in APRNs prepares them to follow lifestyle medicine practices.
- Strengthening the care team in lifestyle medicine practices can increase high-quality healthcare accessibility and improve health outcomes.
- Increasing the roles of advanced practice providers in lifestyle medicine may lead to cost-effectiveness in healthcare.

http://taylorandfrancis.com

76 Lifestyle Psychiatry: An Overview

Gia Merlo, MD, MBA, MEd, Steven G Sugden, MD, MPH, DipABLM, and Liana Abascal, PhD, MPH, DipACLM

KEY POINTS

- The budding field of lifestyle psychiatry is being acknowledged and growing within lifestyle medicine.
- The interaction of mental health and physical health is bidirectional and is affected by lifestyle medicine's pillars.
- A compelling body of literature shows that lifestyle interventions significantly benefit chronic medical and mental health conditions.
- Addressing the psychological factors contributing to barriers is key to helping patients reach their lifestyle medicine goals.

76.1 THE TIME IS NOW

Since the first publication of this book in 1999, to the forming of the American College of Lifestyle Medicine in 2004, to the now over 2100 diplomats certified in lifestyle medicine, the growing field of lifestyle medicine has come a long way.[1–3] Notable on this occasion is the inclusion of the "Psychiatry and Mental Health" section in this book for the very first time in this fourth edition. This acknowledgment of the importance of mental health as a part of lifestyle medicine is due in part to the understanding of the bidirectionality of mental health and physical health, as well as the impact of lifestyle factors on these areas. The field of lifestyle medicine builds upon the rich existing literature in the fields of behavioral medicine/health psychology, psychosomatic medicine, and psychophysiology. This budding field of lifestyle psychiatry is more thoroughly addressed in the book that is a part of the Dr. James Rippe's Lifestyle Medicine Series with Taylor and Francis titled *Lifestyle Psychiatry: Through the Lens of Behavioral Medicine*, edited by Drs. Gia Merlo and Chris Fagundes.

Even prior to the onset of the COVID-19 pandemic, the impact of mental health in the United States (and the world) has been significant.[4] Subsequently, the incidence of mental health conditions and the prevalence of substance use has grown, attributed to the worsening of the social determinants of health.[5] Although mental health treatment during the pandemic mostly shifted to a telehealth model, Centers for Medicare and Medicaid Services reports that even more individuals are forgoing mental health treatment or have had their access to treatment severely limited.[6,7] These are alarming statistics, as prior to the pandemic more than 57% of people in the United States did not receive the mental health treatment they needed.[8]

Now is the time to leverage the growing and compelling body of literature that shows how lifestyle medicine significantly benefits chronic medical and mental health conditions. Importantly, poor mental health can inhibit the behaviors needed to obtain goals outlined by the lifestyle pillars (nutrition, sleep, exercise, substance use, stress management, and healthy relationships).[9] Addressing the psychological factors contributing to barriers is key to helping patients reach their lifestyle medicine goals.[10] This synthesis of mental health with lifestyle medicine is the crucial step to treating the whole person.

76.2 WELLNESS, MENTAL HEALTH, AND BRAIN HEALTH

As the World Health Organization (WHO) states, "There is no health without mental health".[41] The terms wellness, mental health, and, more recently, brain health, have been used interchangeably by many. Corbin and Pangrazi in 2001 defined wellness as "a multidimensional state of being describing the existence of positive health in an individual as exemplified by quality of life and a sense of well-being".[57] Individual and environmental factors can lead to impaired wellness and impact the person's overall health. However, optimal individual wellness, through the practice of lifestyle medicine and healthy daily habits, cannot be achieved without addressing *all* aspects of health. Mental health, on the other hand, is defined as "a state of mind characterized by emotional well-being, good behavioral adjustment, relative freedom from anxiety and disabling symptoms, and a capacity to establish constructive relationships and cope with the ordinary demands and stresses of life".[58] Mental health also includes freedom from symptoms of mental illness whether they are a diagnosable mental disorder or subsyndromal. Mental health includes wellness, as well as a capacity to experience emotions, thoughts, and feelings, an ability to problem solve and overcome difficulties, make social connections, and connect with the surrounding world.

While mental health is perhaps a term that is well known by both the public and scientific community, it does not capture the importance of the concept of *brain health*. *Brain health* is defined by the WHO as the fostering of optimal brain development, cognitive health, and well-being throughout the entire lifespan.[56] Indeed, brain health

DOI: 10.1201/9781003227793-90

encompasses everything we think, do, say, and feel. For this reason, it can be seen that brain health has an ongoing, fluid course. In this way, the lifespan continuum of brain health is in alignment with current evidence regarding neuroplasticity, the ability of the brain to adapt and escape previous genomic restrictions through the formation and reorganization of synaptic connections. This furthers the role of healthy lifestyle habits and brain health factors in the reduction of risk for brain illness progression and related pathologies, as well as overall health, throughout the aging process.

Of note, all three of these concepts—wellness, mental health, and brain health—have well-being in their definitions. Well-being is defined as "a state of happiness and contentment, with low levels of distress, overall good physical and mental health and outlook, or good quality of life".[59] In 2017, the National Academy of Medicine (NAM) rolled out the Action Collaborative on Clinical Well-Being and Resilience.[61] This collaborative has more than 200 organizations in the network focused on reversing clinician burnout. In 2022, NAM continued to create the National Plan for health workforce well-being.[62] While many definitions have been proposed for these complex constructs, for this chapter, we will focus on the three concepts: wellness, mental health, and brain health since well-being is included in the definitions of these three.[63] See Figure 76.1 for a representation of the relationship between wellness, mental health, and brain health.

76.3 THE GUT MICROBIOTA AND MENTAL HEALTH

The brain-gut-microbiota system (BGM) is implicated in the pathology of various diseases, including those within the scope of brain and mental health. The term microbiota describes microorganisms that live in an established environment, whereas microbiomes are the sites of genetic material of microorganisms within particular environments in the human body.[55]

Many factors influence the composition of the microbiota, including stress, exercise, environment, diet, genetics, medicine, pet ownership, and birth mode. Furthermore, the gut microbiota interacts with the brain via multiple pathways, including the neuroanatomical pathway of the gut-brain axis (vagus nerve), the neuroendocrine hypothalamic-pituitary-adrenal axis, the immune response, the intestinal epithelium and the blood-brain barrier, and the microbial production of neurotransmitters such as serotonin.[13] Emerging data shows that mental health disorders, such as depression, are linked to the compositional states of the gut microbiome in a bidirectional manner.[16]

Dysbiosis, the imbalance of the gut microbiome, is the underlying cause of pathology associated with the BGM. For this reason, the role of lifestyle interventions in the interactions between the brain and gut, as well as the facilitation of optimal overall health, is an emerging area worth further consideration for clinical applications.

76.4 HEALTH NEUROSCIENCE

The human brain remains one of the greatest challenges for modern medicine,[11] yet it is one of the most integral and sometimes overlooked aspects of lifestyle medicine. The human brain consists of roughly 100 billion neurons and 100 trillion neuronal connections and consumes about 25% of the body's energy. Recent scientific discoveries (i.e., sequencing the human genome, technology to map neuronal connections and provide higher-quality resolution of imaging technologies,

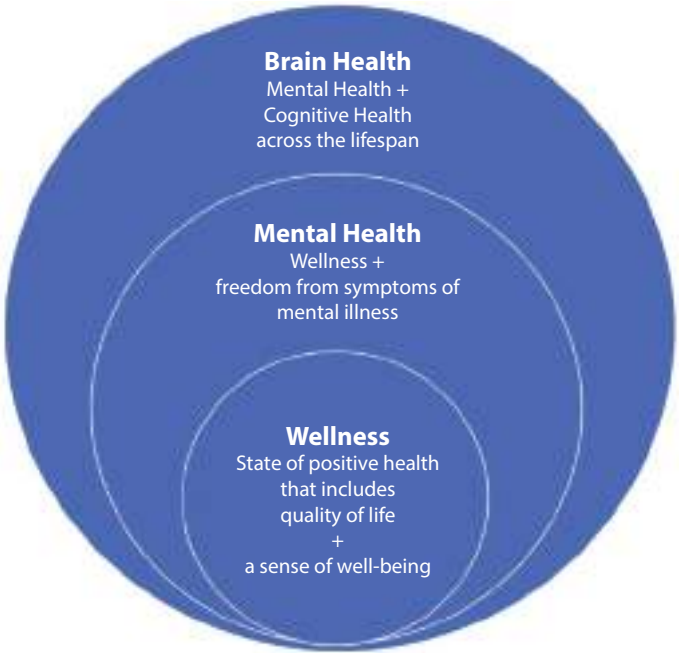

FIGURE 76.1 The relationship between wellness, mental health, and brain health.

and the expanding field of nanoscience) increase the likelihood that the mysteries of the brain will be revealed, particularly as they relate to brain health including neurological and mental and behavioral health disorders. As individuals improve brain health, it will be easier to achieve whole health through implementing lifestyle principles.

To date, these aforementioned technologies have been most successful in diagnosing structural brain deficits, brain tumors, and vascular and inflammatory brain disorders.[12] Currently, there are no established biomarkers for the majority of mental and behavioral health disorders. In their recent review of the current state of imagining and mental and behavioral health diseases, Falkai et al. indicated growing effectiveness in the identification of dementia, particularly Alzheimer's disease (AD), major depressive disorder (MDD), affective psychosis (e.g., bipolar psychosis), and schizophrenia.[12] Specifically, hippocampal volume from structural MRI confirms diagnosis and at-risk populations for AD; for MDD, structural studies are being used to identify potential biomarkers that may help differentiate subcategories of symptoms, like treatment refractory. Individuals with bipolar 1 show a specific pattern of brain anomalies within the temporal lobe, basal ganglia, and ventricular system that can be differentiated from schizophrenia. Finally, for schizophrenia, studies show specific patterns within the hippocampus, amygdala, thalamus, nucleus accumbens, and lateral ventricles that are different from AD, MDD, or bipolar disorder.

Potentially as interesting is the use of functional MRI (fMRI) along with neurofeedback, which shows promise in molding cognition, emotion, thought, and actions as it is able to target specific regions within the brain.[14] In addition to this, there is optimism as new scientific discoveries better explain neurobiological pathways and their correlations with health. For example, in a recent systematic review by Haeger et al, in patients with AD or mild cognitive impairment, aerobic exercise was shown to be the most effective intervention to improve regions prone to neurodegeneration (e.g., hippocampal region, precuneus, anterior cingulate, and the prefrontal cortex). These findings were confirmed by fMRI, diffusor tensor imaging, and cerebral blood flow.[15]

Given the current scientific limitations, Chapman et al. in Chapter 77 propose an assessment tool, the BrainHealth Index. It is a comprehensive survey that combines key aspects of neuroscience and lifestyle medicine, which measures whole brain health: cognition, social functioning, well-being, and real-life functions.[17] This index is not a diagnostic test, however, it is able to detect changes when individuals make adjustments consistent with lifestyle medicine and whole brain health.

76.5 PSYCHIATRIC DISORDERS AND ASSOCIATED MENTAL HEALTH CONDITIONS

Mentions of mental and behavioral health are found throughout early history. Initially, the origins were attributed to supernatural, somatogenic, or psychogenic causes. These varied origins confounded the nature and diagnosis of these mental and behavioral illnesses throughout history. In 1883, German psychiatrist Emil Kraepelin first published a comprehensive collective of psychiatric illnesses around observed symptoms[18] which tried to demystify mental and behavioral health. Unfortunately, unlike other diseases within medicine, there is not a specific laboratory screen test (i.e., checking one-hour post-meal blood glucose), diagnostic test (i.e., cardiac stress test), or radiographic test (i.e., fractured bone) that confirms the diagnosis of mental or behavioral health disease. As such, mental health diagnosis is based on the consensus observations of experts, like in the days of Kraepelin, and their consensus of diagnoses is published in the American Psychiatric Association in the most recent version of the Diagnostic and Statistical Manual of Mental Disorders (DSM). It should be noted that not everyone who shares the same mental or behavioral health illness experiences the same degree of functional impairment or severity of symptoms. The DSM provides modifiers to disorders as *mild*, *moderate*, or *severe*. As such, mental and behavioral health illnesses should be thought of as spectrum disorders, which correlate to the severity of symptoms.

As mentioned earlier, there are an alarming number of individuals who have severe mental and behavioral health diseases, which affect the disease burden among communities, regions, and nations.[4] The disease burden includes growing rates of suicide, substance use, dysfunctional homelife, loss of workplace productivity, and propagated trauma. A meta-analysis by Firth et al. shows how individuals with mental health concerns, even schizophrenia, benefit from routine exercise, which is a key component of lifestyle medicine, yet when one has untreated behavioral and mental health symptoms, it is harder to practice lifestyle-promoting health behaviors and receive these benefits.[19]

As the severity and burden of mental health continue to grow, it is hoped that an early detection system can be developed through neuroscientific advancement. The public and healthcare providers need to be aware of subsyndromal symptoms as these early stages may be the most opportune time to start making lifestyle changes.

76.6 RISK AND PROTECTIVE LIFESTYLE FACTORS FOR MENTAL HEALTH AND PSYCHOLOGICAL WELL-BEING

Across the lifespan, mental health and psychological well-being are influenced by many factors, lifestyle behaviors chief among them. The core lifestyle factors addressed in this chapter (the pillars of lifestyle medicine) include the following: diet and eating behaviors, physical activity, sleep, stress management, substance use, and interpersonal relationships. Each of these lifestyle factors and associated behaviors can serve as risk or protective factors for mental health and specific disorders.

For example, research has accumulated on the positive effects of physical activity on mental health, both as a preventative factor and for the treatment or management

of mental health symptoms. Likewise, sedentary behavior has been linked as a risk factor for depression, anxiety, and sleep disturbances. Of note, physical activity and sedentary behavior are two independent target behaviors, not the flip side of the same coin;[20] one can be active and still engage in significant health-hindering stretches of sedentary behavior.

Robust reviews and meta-analyses have highlighted the link between nutrition and mental health as well. The standard American diet has been associated with an increased risk of depression, while a diet resembling a Mediterranean diet (higher in fruits and vegetables) has been associated with a decreased risk.[21] Randomized controlled trials of mixed dietary interventions have also shown improvement in depression and anxiety symptoms.[22]

The above examples are just the tip of the iceberg when it comes to the evidence of lifestyle medicine benefiting mental health. This profound body of evidence should not be ignored for the fee-for-service, treat-the-disease-once-it-is-diagnosable approach to health and wellness prevalent in the United States. In fact, initial widespread approaches have already been implemented in the recommended guidelines of several large professional organizations (notably not in the United States as of yet). In 2010, the position statement on public mental health from the UK Royal College of Psychiatrists highlighted how lifestyle behaviors, namely tobacco use, infrequent exercise, and poor nutrition, are linked to an increased lifetime risk of mental illness.[23] Based on the preponderance of evidence, the European Psychiatric Association's guidelines recommend exercise as a first-line treatment for moderate depression, and as an adjunctive intervention in severe mental illness.[24] And recently, the updated 2020 guidelines for the treatment of mood disorders from the Royal Australian and New Zealand College of Psychiatrists state that "lifestyle changes and psychological interventions are foundational in the treatment of mood disorders. These are both recommended actions—*essentially non-negotiable and to be discussed with all patients*" (emphasis added).[25] Addressing, preventing, and treating mental health concerns in ways that are accessible and affordable, that help reduce stigma, and that have the convenient side effect of better physical health is a win-win for individuals and the public health of any nation.

76.7 BIOPSYCHOSOCIAL IMPLICATIONS AND THE PREVENTION AND MANAGEMENT OF CHRONIC ILLNESSES

The biopsychosocial model, first discussed by George Engel in 1977, refers to the idea that biological, psychological, and social processes are integrally and interactively involved in illness and health.[26] This model expands far beyond earlier models which were reductionist and purely biomedically based. Key in the biopsychosocial model is the interconnection among the factors: that single-factor explanations are likely to be inadequate and that change in one domain necessarily results in changes in other domains. Additionally, it follows that interventions involving all domains produce better results than those grounded on a single domain.[27]

Examples of the biopsychosocial model in the health realm include the overlap between depression and chronic pain. Chronic pain can lead to depression, and depression is known to worsen the experience of pain; the association is bidirectional. In addition, imaging studies have shown an overlap between pain-induced and depression-induced changes in neuroplasticity and neurobiological mechanisms.[28] Treatment for chronic pain is multifaceted and generally begins with non-invasive and non-medication approaches, like lifestyle changes and psychotherapy.[29]

How psychological and social processes affect biological processes can also be seen in the impacts of chronic inflammation on health. Recent research revisits this evidence of how chronic inflammation contributes to the development of chronic disease.[31] This is particularly noteworthy as non-communicable diseases are the leading causes of death and disability in the United States and around the world.[30] Stress, lack of close relationships, and certain health behaviors are known to promote a pro-inflammatory state which in turn contributes to the development and progression of chronic illnesses. In addition, the risk stemming from certain health behaviors may impact inflammation even more when accompanied by psychological risk factors, creating a synergistic effect. Thus, the application of lifestyle medicine's pillars to the prevention and treatment of chronic inflammation and therefore chronic disease has individual and public health implications that reach far and wide. This crucial relationship is further discussed in Chapter 80.

76.8 A BRIEF OVERVIEW OF MENTAL HEALTH AND THE PILLARS

Below is a brief summary of how the individual lifestyle medicine pillars are affected by, and affect, mental health.

76.8.1 Nutrition

For a vast number of people within high-income countries, diets have become a significant contributor to preventable disease and mortality. As important to the nutritional content of the diet (highly processed food, fatty foods, etc.) are the behaviors surrounding eating (binge eating, eating alone, eating while watching electronic media, eating in the car or bedroom, etc.). Dietary habits have been linked to the development of obesity, type 2 diabetes, hypertension, hyperlipidemia, coronary artery disease, and forms of cancer. Equally important, dietary habits are linked to attention, mood, behavioral, and anxiety disorders.[32] The development of these disorders is largely through the modification of epigenetic factors and the manipulation of the gastrointestinal microbiome.[33] Thus, attention to nutrition quality is a critical aspect of lifestyle medicine. As nutrition

science advances to include mental health outcomes, there will be more opportunities to implement dietary changes to support mental health.

76.8.2 Substance Use

Substance use, at any level, impacts both mental and physical health. Prior to COVID-19, the death rate from substance use was one of the top public health concerns in the United States. In 2017, the US Health and Human Services declared a public emergency.[34] Among the many consequences of COVID-19, substance use has increased.[35] Continued use of substances makes the practice of other lifestyle pillars challenging and contributes to the growing challenges of psychiatric, cancer, cardiac, and endocrine illnesses. The effectiveness of treatment is challenged by the complexity of the neurobiological underpinnings of these disorders. The use of substances and other unhealthy behaviors quickly hijack the brain's reward, stress, contentment, and focus pathways, which reinforce the brain's wanting of these substances or experiences. SBIRT is a national campaign that encourages all providers to universally screen for substance use disorders and refer for treatment. In the United States, providers currently screen for high blood pressure, a condition that affects approximately 75 million people, and costs about $46 billion in direct and indirect costs; by comparison, substance use affects approximately 100 million people and costs nearly $740 billion in direct and indirect costs.[36,37] Recent randomized control studies have shown that improving lifestyle activities and decreasing substance use leads to improved quality of health.[38]

76.8.3 Physical Activity

Engaging in physical activity has wide-reaching benefits—promoting mental well-being, preventing the potential development of mental disorders, and especially providing sustained benefits for depression, anxiety disorders, attention deficit disorders, and substance use disorders.[39] Exercise in depression may promote increased feelings of self-efficacy and self-esteem as well as promotion of prosocial behaviors.[40] To this end, the Royal Australian and New Zealand College of Psychiatrists promote physical activity as the first line of treatment for mild to moderate depression.[41] Yet, despite the growing evidence, many healthcare providers still default to favoring the traditional use of psychotropic medications as first-line treatment without discussing lifestyle interventions.

76.8.4 Stress

The psychiatric and psychological communities have been studying stress for decades and have developed a robust literature. Since 2007, the American Psychological Association (APA) has been conducting annual surveys regarding the impact of negative stress on residents within the United States. Due to the compounding effects of COVID-19, the economy, racial tensions, and multiple forms of scarcity, the APA reports, "We are facing a national mental health crisis that could yield serious health and social consequences for years to come".[42] Fagundes et al. show that heightened chronic stress leads to imbalances of cortisol and other stress hormones and can cause or contribute to immune system suppression and consequent illness, such as increased risk for psychiatric illness, diabetes mellitus, digestive conditions, and cardiovascular disease.[60] It is also associated with an increased risk for self-destructive behavior like substance use, not taking medications, and not engaging in lifestyle interventions.[43,44]

76.8.5 Interpersonal Relationships

In a recent national study, over one-third of Americans reported being "frequently lonely" or "lonely almost all of the time", with the highest concentration among young adults between the ages of 18 and 25 and mothers of young children.[45] Additionally, a recent meta-analysis highlights the negative effects of loneliness on health outcomes (mental health, general health, well-being, physical health, sleep, and cognition).[46] Equally significant, loneliness has been identified as a risk factor for early death, comparable to other lifestyle diseases.[47] Systematic reviews have shown that individuals with partner support have higher adherence with medications and management of chronic illnesses.[48] Interpersonal relationships are critical to mental and physical health and further understanding is needed in the era of COVID-19 about how our increased reliance on technology and extended periods of social isolation affect health.

76.8.6 Sleep

Despite restorative sleep being crucial for physical, mental, and emotional health,[49] more than one-third of Americans sleep less than seven hours a night and report feeling tired.[50] Multiple studies have shown how sleep deficiency is associated with poor immune function and cardiovascular disorders;[51] it is an independent risk factor for mental health and neurologic disorders and is associated with decreased emotion regulation.[52] Sleep insufficiency leads to cognitive impairments such as vigilance, difficulty thinking, and poor decision-making, leading to greater risk for medical errors among healthcare workers, industrial and vehicular accidents, and risky behaviors.[53] A 2021 meta-analysis of 65 randomized controlled trials showed a dose-response effect between sleep quality and depression and anxiety, where the greater the improvement in sleep quality and duration, the greater the improvement in mental health function.[54]

76.9 WHERE DO WE GO FROM HERE?

As we continue to understand the bidirectionality of mental and physical health, the definition of these constructs becomes all the more important. The concept of brain

health is more inclusive than mental health, or wellness in relation to healthcare provisions. The potential for widespread application of brain health is the basis for its gravity in the scope of lifestyle medicine. Healthcare providers in primary care, psychiatry, and others can and should be primed to regard and assess optimal brain development, cognitive health, well-being, and connectedness as important aspects of standard preventative patient care. With this, it is also essential to continue to further our current understanding of the significant and clinical applications of nutrition and the gut microbiota and their effects on brain and mental health.[64] We have reached a vital pivot point where we can provide a future of hope and healing to our society as we advance our understanding of this important function of lifestyle intervention between the gut microbiota, brain health, and overall health.

CLINICAL APPLICATIONS

- Lifestyle interventions have been shown to be effective in mood disorders.
- Because of the bidirectionality of physical and mental health, encouraging patients to address lifestyle interventions has the potential to affect treatment outcomes.
- Environmental, psychological, and physical stress can lead to immune system responses with increased risk for the progression or worsening of psychiatric illnesses.
- Greater adherence to a biodiverse, whole food, plant-based diet has been linked to better cognitive functioning.

77 The Neuroscience of Brain Health

Sandra Bond Chapman, PhD, Ian H Robertson, PhD, Jennifer Zientz, MS, CCC/SLP, Harris Eyre, MD, PhD, Geoff Ling, MD, PhD, and Mark D'Esposito, MD

KEY POINTS

- Improving brain health can provide protective benefits on the range of neurological, neuropsychiatric, and age-related and behavioral problems, comparable to the ways a proactive approach to physical health has led to the decline in heart disease.
- Neuroscientific discoveries about the remarkable plasticity of the brain at all ages make the possibility of harnessing the brain's systems to improve overall health scientifically feasible, even when dealing with brain issues.
- Promoting "brain health" as a continuous process, rather than as a fixed diagnostic disease/injury state, is critical to the adoption of practices that promote brain health and strengthen general healthy habits.
- We manage what we measure; brain health can now be measured, monitored, and improved through training at all life stages.
- By recognizing the interdependency of mental health underneath the concept of brain health, this chapter outlines the science of adopting a holistic approach to build brain capacity whatever the starting level by drawing upon a broad range of mind-brain capabilities.

77.1 INTRODUCTION

Improving the health of the human brain has become a pivotal goal to enhance population health. The brain drives all that we do, think, create, overcome, solve, and feel. A healthy brain is essential for developing other healthy habits, elevating well-being, enhancing social connection, increasing years of productivity, and expanding creativity to deal with challenges across the entire lifespan.[1]

Unlike well-accepted preventive practices for the heart such as exercise and nutrition, the brain is typically only considered after a person begins to manifest noticeable changes in cognitive, psychological, social, or motor functions. Diagnosis and treatment are sought primarily when significant deficits emerge in normal interactions, responsibilities, emotional responses, and mobility. Brain health, however, is much more than the absence of disease and damage.[2] Preventive and restorative approaches to improve brain wellness, akin to those available for physical well-being, are urgently needed. Such a development offers the promise of extending the average level of brain performance well beyond its current peak in the late 20s and early 30s.[3,4]

Brain health has been elusive to clinical practitioners not for lack of interest, but rather due to limited knowledge as to the best practices for translating neuroscience discovery into brain health promotion and care. Reasons for this include:

- Lack of a widely accepted *definition* of brain health.
- Absence of validated multi-dimensional, biopsychosocial *measurements* of brain health.[1]
- Dearth of *access* to brain health-enhancing methods using scalable protocols and technologies.
- Limited medical school *training* about the rapidly emerging discoveries related to neuroplasticity and its application to building brain health.
- Paucity of *reimbursement models* for interventions that prevent deficits and build brain health—in other words, a sort of "preventive neurology", "preventive psychiatry", or "preventive neuroradiology".[5]

This chapter addresses the first three issues and outlines current state-of-the-art research offering the foundations for medical practice guidelines for advancing brain health.

77.2 BACKGROUND

Discoveries in neuroscience over the past two decades have radically revised our understanding of the brain's lifelong ability to change, adapt, and improve its function.[6–10] Longstanding beliefs still prevail in medical practice that the brain's "plasticity" is confined to development (such as within the first few years of life) and recovery (a limited time interval post brain insult, typically three to six months). These beliefs are wrong, yet their persistence means that efforts to improve brain function over extended periods are woefully underexplored.

Emerging evidence shows that comprehensive, multidimensional measures of brain function can reliably assess gains in brain health in response to a number of

DOI: 10.1201/9781003227793-91

interventions—training in strategic thinking and attention, for example—and lifestyle changes such as improved sleep.[11] Healthcare practice has the potential to target brain health (also referred to as brain wellness) rather than focus almost exclusively on detecting problems and charting cumulating age-related losses over time. As with all preventive medicine, intervention before disease onset is much easier to achieve and more effective than after onset. Progress is being made in identifying potential biomarkers, such as gains in neural network synchrony, brain blood flow, and network modularity, which correspond with improved cognitive health.[6,10,12] As these biomarkers become better established and validated in larger populations, the opportunities for effective and individually targeted preventive interventions grow even more urgent.

77.3 DEFINITION OF BRAIN HEALTH

The concept of brain health was introduced in 1999 by scientists at the Center for BrainHealth at The University of Texas at Dallas. The Center for BrainHealth is the first research institute focused almost exclusively on developing and testing measures and protocols to evaluate and enhance brain skills in populations ranging in age from early teens to late life.[13] Since that time, the term "brain health" has become widely used but still with a major bias toward brain injury and disease.

There are many definitions for brain health. It is essential to establish consensus for stakeholders regarding what the concept of "brain health" means. We recommend and adapt the definition set forth by the World Health Organization (WHO). The WHO defines brain health as the promotion of optimal brain development, cognitive health, and well-being across the life course[14] adapted herein to also include the element of *connectedness to people and purpose*.[11] Brain health is viewed as a continuous process rather than a fixed state, which corresponds to the evidence for lifelong neuroplasticity.

One key issue that commonly arises is the relationship of brain health to the term "mental health". The term *brain health* comprises mental health, while not replacing it, whereas the term "mental health" also includes the idea of wellness and is associated with emotional and behavioral deficits such as depression, anxiety, suicidality, and addiction. Unlike brain health, mental health does not usually embrace cognitive and social domains. For example, training cognitive strategies shown to promote brain health, such as strategic attention and innovative thinking, have been shown to reduce symptoms of depression and stress and improve real-life performance.[9]

Brain health may open new horizons to advance more global public health policies that have generalized applications to all patients. This makes brain health highly relevant for lifestyle medicine for several reasons. First and foremost, brain health is more inclusive than mental health across care providers. A multitude of healthcare professionals (e.g., lifestyle medicine, pediatrics, internal medicine, gynecology, family practice, psychiatry, gerontology, and more) can and should be trained to pay more attention to addressing optimal brain development, cognitive health, well-being, and connectedness as routine targets of preventive healthcare.

Second, the term mental health does not typically address cognitive abilities or "cognitive capital", i.e., the summated cognitive capacities of a population. This is important because greater cognitive capital has been shown to predict higher levels of health generally, both physical and mental.[15] The cognitive capital of a community, city, state, or country is also crucial for its economic prosperity because it enables populations to pivot more adaptively in the face of economic shocks, rapid technological change, and environmental challenges.[16,17] An absence or reduction of a flexible mindset contributes to economic and social deterioration that will worsen mental and physical well-being.[18,19]

A third reason that brain health is more policy and lifestyle medicine-ready as a concept than mental health is that it integrates aging-related brain diseases, which are predicted to be one of the greatest health challenges facing the world, one that particularly impacts low- and middle-income countries.[20] In particular, there is a spiraling prevalence of dementia linked to the accelerating proportion of older people in all countries in the world, secondary to the impressive lengthening of life expectancy.[21] Additionally, impaired well-being is a risk factor for dementia but is often overlooked in dementia treatment.[22] Mental health, as a concept, does not afford policy implications for this enormous health challenge that, if unchecked, will overwhelm the resources and finances of health providers and services. Brain health, on the other hand, is ready to be tested, with clear implications for health promotion policy.

Fourth, the concept of brain health has positive connotations centered around capacity-building principles of neuroplasticity that avoid the stigma attached to mental health, as the latter focuses largely on diagnosing deficits rather than considering individual potential. Therefore, it affords considerable opportunities for policymakers to advance population-scale interventions to millions of people and focus on individual empowerment. Brain health offers a positive message that is similar to successful heart-healthy interventions such as those advocating the value of aerobic exercise.[23,24]

77.4 MEASURING BRAIN HEALTH

The lack of a clear index of brain health is a major void for healthcare practice and public policy.[11] Most primary care doctors *rarely* evaluate brain health with any objective measures during regular health exams. Even in cases where brain functions are assessed, the assessment time is minimal and the measures are typically cursory, including very simple tasks such as list memory, naming, or simple figure drawings. These measures were designed to detect significant problems and quantify compromised brain function, not to identify pathways to optimize brain systems.

The National Institutes of Health's definition of brain health is provided by the National Institute on Aging,[25] thus

mistakenly linking brain health solely to advancing age. This age focus ignores the centrality of brain health to well-being, social connection, and physical health in teens and young adults, defining brain health only in the four domains of cognitive health, motor, emotional, and tactile function. Whereas these are important in an aging population, they overlook other crucial dimensions including social interaction (social support, social engagement, compassion), daily life (nutrition, exercise, mindset, sleep, responsibilities), and aspects of well-being (resilience, mood, quality of life).

77.4.1 BrainHealth Index

Brain health is a complex concept demanding an easy-to-understand presentation. A number of groups are developing multi-dimensional measures (e.g., Bassetti et al.[1]), including the Barcelona Brain Health Initiative,[26] the "cognitive clock",[27] and the Human Brain and China Brain Projects.[28,29]

Another significant international effort is the telehealth-delivered BrainHealth Project (https://centerforbrainhealth.org/project/world-class-team), which aggregates multiple dimensions into a BrainHealth Index,[11,30] a composite of 22 gold standard, change-sensitive measures collected with a range of MRI neural markers applied repeatedly over time to a population ranging in age from 18–95. The Project is led by the authors of this chapter and is sponsored by research funding from the Center for BrainHealth. The index assesses *cognition* (e.g., executive functions, memory, innovative thinking, and complex abstraction), *social functioning* (e.g., social support, social engagement, and compassion), *well-being* (e.g., depression, stress, anxiety, quality of life), and *real-life functions* (e.g., exercise, nutrition, sleep, mindset, and responsibilities).[11]

The novel development in the BrainHealth Index was the identification of at least three measurable components, uncovered through factor analysis.[11] These components are the very same factors included in the definition of brain health set out in this chapter. Moreover, longitudinal follow-up of brain health performance in light of these factors reveals dynamic targets for individuals that can contribute to cumulative gains in the holistic Index over time.[30] The Index was not developed to establish a diagnostic label.

These factors are as follows: (a) *clarity* (*cognitive health*), (b) *connectedness*, and (c) *emotional balance* (*well-being*) and are being validated by functional brain imaging measures to chart continued brain change over time (see Figure 77.1).

- *Clarity* measures abstraction, big-picture thinking, memory, sleep, and compassion.
- *Emotional balance* measures mood, stress, and sleep.
- *Connectedness* measures social support, compassion, engagement, happiness, resilience, satisfaction, and meaningful activities.

MRI and other neural correlates of training-related improvements in these factors have revealed increased connectivity in the central executive and the default mode networks, with corresponding gains in brain blood flow.[10,31] Studies are underway to further understand and validate the corresponding dynamic changes over time linking behavioral and neural domains following telehealth-delivered brain health training (https://centerforbrainhealth.org/project). These data will serve to identify the structural and functional brain changes that support the upward potential for building stronger brain health over the life span.

By aggregating brain health measurement across multiple, hitherto disparate, domains, we can evaluate with hopes of eventually predicting how different components interact and influence brain health over time. For example, emotions such as anxiety and depression affect cognitive health,[32–35] whereas strong cognitive functions—particularly executive and attention processes—aid emotional regulation and build social resilience.[36,37] Social isolation has negative effects on emotional well-being and cognitive function[38] Sleep,[39] diet,[40–42] and physical activity[43,44] all mutually interact and affect emotional, cognitive, and social functions. Furthermore, these different processes both depend on and influence the constantly changing structure and function of brain networks and systems.[45,46]

77.5 ACCESS TO INTERVENTIONS PROMOTING BRAIN HEALTH

Achieving optimal brain health demands interventions developed and tested to enhance the multi-faceted aspects of brain health across the age spectrum, rather than a fragmented, siloed approach. To our knowledge, limited consensus exists regarding scalable, evidenced-based interventions delivered either using a face-to-face approach or are capable of being scaled through telehealth. Both approaches are vital. The most prominent and successful attempt at a scalable multi-faceted intervention was directed at older individuals at risk of dementia, known as the Finnish "FINGER" trial. The FINGER trial showed how a multi-modal intervention delivering vascular risk monitoring, cognitive training, and dietary and exercise advice could significantly improve cognition,[47] and has seeded a worldwide network of similar trials (see an overview at https://alz.org/wwfingers/overview.asp).

The FINGER studies are limited in two ways, however. First, the intensive, face-to-face nature of the intervention makes it extremely expensive, labor-intensive, and hence not scalable to millions of people worldwide. Second, it is focused only on older people, yet we know that brain health is a lifelong process with cumulative effects over decades and requiring a whole-life approach.

Our work complements and builds on decades of positive findings for enhancing cognitive and emotional function using verbal and/or procedural protocols ranging from teaching strategies aimed at improving the efficiency of frontal-lobe-based executive networks[48] to enhancing mood and reducing anxiety through methods such as cognitive behavior therapy.[49] The ability to scale such methods

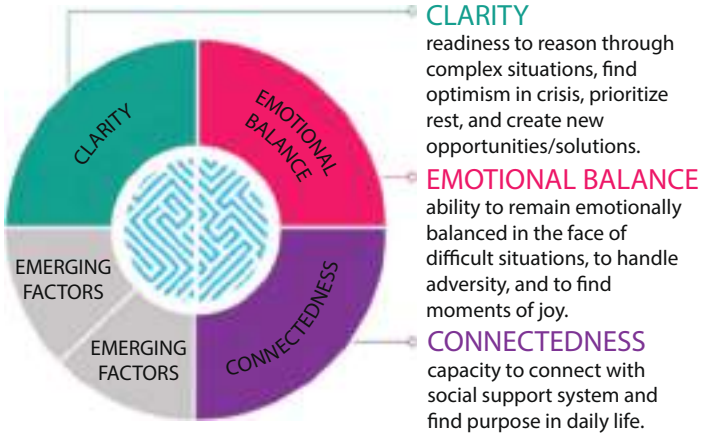

FIGURE 77.1 BrainHealth Index.

using web-based technology enables availability entirely remotely, potentially accessible to millions of users across the globe once language and cultural appropriateness are addressed.

Most online offerings of "brain training" do not have strong published evidence of their efficacy. A review by Owen and colleagues concluded that most online brain training programs improved the specific processes trained but did not generalize to real-life functions.[50] One exception is the BrainHQ (www.brainhq.com) online training programs that have shown positive cognitive effects in a range of populations across many studies.[51,52] One study showed impressive gains in certain cognitive processes of older adults with real-life benefits maintained up to ten years later with just a few booster sessions.[53] Their work has also been shown to be associated with lowering driving accidents in older adults, and improvements in daily life independence.[54,55] Other evidenced-based online training programs include NeuroRacer[56,57] and ACTIVATE,[58,59] both of which have been shown to improve learning and behavior outcomes across populations. Another exception is SMART training, described in the next section. At present, both BrainHQ and SMART are offered through the online BrainHealth Project, which aims to test the extent to which participants can achieve gains on the holistic BrainHealth Index year by year as the study's enrollment is expanded and followed over longer intervals.

Today more than ever, healthcare practitioners need a global brain health strategy translatable and sustainable across the lifespan.[42,60] Heart health lays out a roadmap for how to scale prevention over whole populations based on the Framingham epidemiological study of heart health coupled with lifestyle advice for maintenance.[61] The BrainHealth Project applies and adapts this approach for brain health, helped by advances in e-health, technology, and big data analytics to yield population-scalable interventions.

77.5.1 The BrainHealth Project Intervention

The US National Academy of Sciences published an expert review on the most promising methods for preventing cognitive decline (and by implication improving brain health): blood pressure control, increased physical activity, and cognitive training. The expert panel concluded that the evidence was strongest for cognitive training.[62]

The Center for BrainHealth has developed a method of cognitive training called Strategic Memory Advanced Reasoning Training (SMART). SMART is unique among such methods internationally because of (a) its focus on strategic and tactical control of attention; (b) its use of everyday materials in training; and (c) its proven ability to improve cognitive health, well-being, connectedness, and real-life functions.[10,11,13] SMART improves not only cognition but also emotions, e.g., mood and anxiety,[9,63] making this scientifically supported program unique. Recognizing the range of lifestyle and other factors shown to contribute to brain health such as nutrition, sleep, and exercise, discussed elsewhere, the BrainHealth Project also incorporates interventions and advice aimed at improving these on its web platform by exercising tactical thinking skills as provided by SMART.

The first phase of the larger and longer-term BrainHealth Project study enrolled 180 healthy adults (ages 18–87 years) who took the BrainHealth Index pre and post a 12-week online training period. The training was self-paced and augmented by 30-minute coaching calls with clinicians after the first Index, at six weeks, and again after the second Index at 12 weeks. Seventy-five percent of participants had at least a five-point gain on their BrainHealth Index. The more training modules individuals completed, the higher their gains on the Index. Comparable gains were seen for older and younger adult participants, and across gender and educational levels, with improvements attributable to different combinations across the clarity, emotional balance, and connectedness factors. For example, one participant improved due to increased clarity and decreased stress, while another participant prioritized sleep and social relationships. The effects of the training will be assessed in larger and longer-term follow-up studies for at least ten years.

77.6 GUIDELINES FOR BRAIN HEALTH

The first two principles for brain health in lifestyle medicine include[1] empowering patients to take steps toward building stronger brain skills and[2] inspiring them to get an annual brain health check-up to motivate continued adoption of healthy habits.

77.6.1 General Principles

Empower your patients. By helping patients realize the immense control they have to strengthen their own brain health, lifestyle medicine practitioners are uniquely positioned to promote brain health, particularly when there are no diagnosed brain issues.[64] Despite the fact that many people worry about age-related changes to their brains, or fear future changes, the vast majority do not talk to their physicians about these concerns.[65]

Emphasize the importance of metrics in health. Establish routine methods of objectively assessing and tracking—even in the absence of complaints—patients' brain health, with individuals serving as their own comparison over time. The goal year by year is to achieve "You, but better". The metrics should be framed as dynamic targets, rather than as fixed diagnostic categories, and yield realizable goals for improvement across clarity, emotional balance, and connectedness elements. They also provide practitioners with a compass for when and where to direct patients for specialized medical intervention, as indicated.

Evidenced-based guidance for improving brain health. There is strong evidence to support the effectiveness of certain forms of cognitive training in improving brain wellness with generalization to everyday function such as driving and independent living skills,[53,54] and an expert panel of the National Academies of Sciences and Medicine came to a similar conclusion. There are many different biologically plausible mechanisms by which purely behavioral interventions can modify the brain's physiology and link to improved cognition, hence improving brain health. These can be broadly divided into "bottom-up" and "top-down" interventions.

Bottom-up approaches aim to "force" neural networks to improve the quality and speed of their functioning using adaptive training, where the difficulty of the tasks increases or decreases with performance. The most well-supported of such methods is the suite of programs offered by BrainHQ, mentioned above.[66–68] Many different neural mechanisms likely underpin the observed improvements, such as stimulation-induced white matter changes caused by improved myelination. This benefit to neural systems purportedly is brought about by training-induced oligodendrocyte activity, a type of neuroglia supporting the insulation of axons in the brain. These better-insulated axons increase the fidelity and speed of information passing through neural networks.[69] A second example of these bottom-up effects is the stimulation of norepinephrine activity in the locus coeruleus. Norepinephrine has remarkable neuromodulatory properties, including strengthening of networks needed for the current task in hand while inhibiting neural networks not needed for the current task. Cognitive challenges of the type offered by certain bottom-up cognitive training programs activate this system, strengthening the neural networks that are activated.[70,71]

Top-down approach. The strongest evidence for a "top-down" method is SMART training, described above. This showed significant gains across a wide range of healthy and clinical populations in complex reasoning, innovative thinking, memory, and executive functions as well as generalized benefits such as reduced symptoms of depression and stress[9,10,72] and gains in real-life function such as daily responsibilities, medical decision-making more in line with a personal value system, and improved learning skills[9,13,73] and academic performance.[74,75]

Clinical trials with SMART showed neural benefits, including improved synchrony of pivotal frontoparietal neural networks that act as a "flexible hub". These networks support the ability to rapidly take in and sort the massive amounts of incoming new information and resolve conflicts to guide adaptive behaviors. This complex network supports agility of thinking in conjunction with the ability to focus on tasks to optimize performance.[10,76,77] SMART training trials show significant increases in global and regional cerebral blood flow in healthy adults, as well as those with mild long-term residual brain injury[9] and bipolar disorder.[78] These neural changes were correlated with gains in complex cognition.

77.6.2 Specific Guidelines

Evidence shows global brain health can be enhanced to support an individual's ability to thrive in their context through multiple pathways: clarity, connectedness, and emotional balance.

77.6.2.1 Strengthening Clarity of Thinking

Clarity of thinking represents the readiness to adeptly reason through complex situations and create new solutions/opportunities.[11,79] Brain trainings that teach tactical thinking skills also generalize to making more logical decisions and reasoned health choices.[73,80] Patients can learn to actively orchestrate brain networks in ways that help them escape from habitual, and sometimes toxic, thinking habits such as constant distractions, multi-tasking, and negative ruminations. Such training improves the efficiency of frontal-lobe-based executive networks, which are critical to brain health across the lifespan. Additionally, becoming more critical problem solvers and active decision makers through broader, bigger-picture thinking skills can be practiced and honed. Learning to calm the brain can help reduce information overload, which often leads to poor decision-making. Other contributors to strong clarity are healthy sleep habits and practicing acts of compassion.

Specific tips include:

- Carve out dedicated time of 30 to 45 minutes for your top two tasks, avoiding any distractions and interruptions. Make sure to define tasks that can be completed in this time slot.

- Synthesize key ideas or bottom-line messages from readings, conversations, or meetings to increase deeper-level thinking, as this helps strengthen the brain's frontal networks.[13]
- Innovate and generate a multitude of actionable best next steps when reflecting on failures, challenges, and disappointments. Our brain is uniquely wired and strengthened by innovative thinking across our life span.[72]

77.6.2.2 Maintaining Emotional Balance

Chronic stress has been shown to impair memory function and shrink the hippocampus[81,82] It also impairs prefrontal cortex function because of a variety of mechanisms, including excessive norepinephrine interfering with efficient brain network performance.[83] Reframing challenging situations by evaluating pros and cons, putting forth effort to identify lessons learned, and identifying alternative solutions can all contribute to emotional stability in the face of adversity. Goal setting can serve to help individuals take small steps toward daily success. Achieving even small goals elevates mood and reduces anxiety because perceived success activates the brain's dopamine-fueled reward network. Success can be largely defined by individuals and the goals they set for themselves. SMART training offers systematic methods for structuring brain effort in a way that prevents overloading the brain while promoting mood-enhancing success.

Specific tips are:

- Take regular brain breaks every day of five minutes, five times a day to calm and recalibrate the brain.
- Embrace "Living in the Moment" by savoring the present moment and acknowledging small things for which to be grateful.
- Structure daily life around clearly defined mini goals that are neither too difficult nor too easy. Micro-antidepressant task completions can deliver success-related dopamine-linked activity to increase mood and reduce anxiety.

77.6.2.3 Prioritizing Connectedness

Connectedness (to people and purpose) reflects continually being driven by a bigger purpose and maintaining meaningful relationships and activities. Encouraging individuals to find purpose in their actions and with the people in their lives helps to fortify brain health and is a strong driver of cognitive reserve.[84] Having meaningful interactions, engaging in new activities, meeting new people, mentoring and volunteering, and participating in hobbies are ways to establish a quality social support system and engage in meaningful life activities, as well as provide stimulating cognitive challenges that are critical for resilience across the lifespan.

Specific tips are:

- Contact a friend each day. Initiate outings with others. Be present to focus on quality conversation.
- Volunteer for a cause that is personally motivating and connects with new people.
- Move out of the status quo and participate in activities that are different, out of the ordinary, and/or challenging.
- Seek ways to show compassion (to family and friends, strangers, those with whom you have conflict, other living things) and value yourself by doing simple things you enjoy.

Promote the lifestyle principles and guidelines above combined with other healthy habits that support brain health. These include sleep, physical exercise, nutrition, and controlled heart-healthy factors such as blood pressure and cholesterol, covered elsewhere in this book. Specialized medical interventions are warranted in cases of worsening psychiatric concerns, cognitive slippage, and other social changes so that timely diagnoses and treatments can be provided. Presently, only medical diagnoses and prescription medications have addressed these issues. Greater gains in brain health are shown when these medical interventions are combined with lifestyle interventions and guidance where individuals learn strategies that intentionally shift how they view negative situations to curiosity-seeking solutions. A combined approach may increase efficacy and drive habit change.[85,86]

77.7 CONCLUSION

Our brain is our most valuable resource. Brain health plays a major role in how well individuals embrace opportunities and manage the challenges of life. Improving brain wellness has been shown to help people enhance decision-making, adopt healthier life patterns, find purpose, build grit to overcome adversity, improve learning effectiveness, connect meaningfully with others, and expand emotional balance to better deal with adversity. Unfortunately, brain healthcare and health promotion have not received the attention they deserve, and the dramatic decline of neural health starting in young to middle adulthood is our greatest cost burden.

Boosting individual brain health will do more to help economies around the world flourish than can be captured by GDP.[87] The key source for building better lives and more vibrant communities is building stronger brain health and wellness to support well-being, connectedness, and possibility thinking. We cannot afford to wait another generation to focus a concerted effort on maintaining brain fitness throughout the life cycle.

CLINICAL APPLICATIONS

Some of the clinical applications include:

- Patient education regarding healthy lifestyle habits should include information on brain health, for those with and without brain concerns, as more

can be done to build reserves in health than after brain-related issues are detected.
- Annual assessments of brain health that measure its upward potential can reduce the stigma of brain problems and motivate people to take timely proactive steps toward building brain capacity.
- Clinicians can and should address mental health problems from a higher, more holistic category of brain health since strategies that improve social connectedness and/or cognitive clarity can reduce mental health symptoms, either alone or when combined with appropriate medications.
- Complaints of brain fog (e.g., worsening concentration, memory, speed of processing, innovative thinking, or mental stamina to mention a few) need to be taken seriously and contributing factors addressed with lifestyle changes before difficulties worsen. Brain fog is one of the most common symptoms with a multitude of causes indicating the brain's neural systems are not working at normal capacity and efficiency.
- Empowering a person's role and self-agency in daily tending to their personal brain healthy habits will help people to improve their quality of life at all ages.

78 Diet and Exercise Interventions in the Management of Psychiatric Disorders: Mechanism and Efficacy

Jonathan Burgess, MD, MPH, Patrick Ho, MD, Brigid Riedy, BA, and Douglas L. Noordsy, MD

KEY POINTS

- Diet and exercise are pluripotent interventions that simultaneously sustain cardiometabolic and mental health.
- Diet and exercise are evidence-based treatments for core symptoms of psychiatric disorders, including depression, anxiety, PTSD, ADHD, schizophrenia, and cognitive disorders.
- Mechanisms for diet impacting psychiatric disorders are substrates and cofactors in the production of neurotransmitters, the reduction of oxidative stress and neuroinflammation, the reduction of homocysteine, and the improvement of cerebral blood flow
- Diets that reduce processed foods and increase traditional natural foods with an emphasis on plant polyphenols appear to be most effective (e.g., the Mediterranean diet)
- A mechanism for exercise impacting psychiatric disorders is brain-derived neurotrophic factor restoring brain volume with a reduction of inflammation
- Higher doses of cardiovascular exercise (i.e., frequency × intensity) appear to be most effective

78.1 INTRODUCTION

In a certain sense, it is unimaginable that lifestyle behaviors would not impact mental health. Our nervous system evolved under the same conditions as the rest of our biological system, intimately entrained by the foods we eat and the activities we perform. It becomes an intriguing hypothesis that the same diets, behaviors, and physical activities that sustain cardiovascular and metabolic health would also sustain mental health.

Indeed, the Royal Australian and New Zealand College of Psychiatrists Clinical Practice Guidelines have expanded the bio-psycho-social model to the bio-psycho-social-lifestyle model and now recommend adjuvant diet and exercise interventions as part of the standard of care for people with mood disorders.[1] The European Psychiatric Association has produced a position paper that concluded that cardiovascular exercise is an evidence-based treatment for core symptoms of severe mental illness.[2] The American Psychiatric Association has begun to explore the topic of lifestyle interventions for psychiatric disorders with a recent textbook dedicated to the subject.[3]

Insight into the link between lifestyle behaviors and mental health was initially prompted by epidemiological studies that noticed a co-clustering of cardiometabolic diseases with psychiatric disorders. It was proposed that cardiometabolic diseases and psychiatric disorders might share common etiologies and treatments that are mutually impacted by our choices of foods and our balance of movement and rest.[4] Indeed, a host of epidemiologic, mechanistic, and randomized controlled trials (RCTs) have demonstrated associations, rationale, and efficacy of lifestyle interventions in the management of core symptomology of psychiatric disorders.

78.2 DIET AND PSYCHIATRY

78.2.1 Diet and Psychiatry Mechanisms

Given that diet provides the atomic constituents of our bodies, arguably, there may be no psychiatric mechanism that diet would not impact. Several core mechanisms include nutrients as essential cofactors in the production of neurotransmitters; oxidative stress and neuroinflammation in the CNS[5,6] and the microbiome in the gut-brain axis.[7,8] Thus, diets that contain adequate nutrition provide the substrates necessary to produce sufficient neurotransmitters, and diets that contain significant amounts of antioxidants—or upregulate the production of endogenous antioxidants—reduce oxidative stress and neuroinflammation. Likewise, diets that contain a varied amount of plant ingredients, which may be complemented by fermented foods, produce biodiversity within the microbiome, which subsequently also reduces inflammation.[9,10]

78.2.2 Dietary Depression RCTs

One of the earliest RCTs examining how dietary intervention could impact depression was by Merrill and colleagues

DOI: 10.1201/9781003227793-92

in 2008. Having served over 40,000 participants at the time, the Coronary Health Improvement Project (CHIP) was originally designed as a cardiovascular health intervention. However, CHIP facilitators noticed the improved mood of their participants and formally tested this hypothesis with a six-month 348-person RCT. The initial intervention was a 40-hour health education program, given over four weeks with an emphasis on plant-based, minimally processed foods, such as whole grains, legumes, vegetables, and fresh fruits with lower intakes of fat, sugar, salt, and animal-based protein. At six-week and six-month follow-ups, compared with the waitlist control, the intervention group significantly improved on the Beck Depression Inventory (−2.4 points vs −0.7 points, $p < 0.0001$) and −2.2 points vs −0.8 points, $p < 0.0001$, respectively.[11]

In 2017, Jacka and colleagues published the results of their dietary RCT (n = 67) that was designed for patients with moderate-to-severe major depressive disorder. In addition to receiving standard of care, patients were randomized to receive seven hours with a dietitian recommending a Mediterranean diet vs seven hours with social support as the control group. At 12 weeks, compared with the control group, the intervention group had significantly decreased depression scores with a large effect size (Cohen's d = 1.6) and a between-group difference of seven points on the Montgomery–Åsberg Depression Rating Scale ($p < 0.001$). Additionally, there was a four-fold increased rate of remission from depression in the dietary group compared to the control group ($p = 0.028$).[12]

In 2019, Francis and colleagues completed an RCT (n = 100) evaluating a dietary intervention for college students with depression. Using a 13-minute video, combined with handouts on diet, supplemented by free olive oil and nut butter for the students, the dietary intervention was impressively efficient. At three weeks follow-up, compared with the habitual diet control group, the dietary intervention group significantly decreased depression, as measured by the Center for Epidemiological Studies Depression Scale (CES-D) with a moderate effect size ($p = 0.007$, Cohen's d = 0.65). In fact, when evaluated by the average CES-D score of the group, the dietary intervention group no longer met the criteria for major depressive disorder.[13]

78.2.3 Schizophrenia and Diet

The provocative association between gluten and psychosis was first proposed in 1966 when Dohan evaluated rates of schizophrenia during wartime as countries altered wheat policy to meet martial demands which was mirrored by changes in incidence rates of schizophrenia.[14] As time progressed, DB-RCTs for treating schizophrenia with a gluten-free diet were inconclusive. Some early trials demonstrated significant improvement in psychotic patients,[15–17] whereas other trials demonstrated no improvement.[18] However, ongoing epidemiology, mechanistic understanding, and further case reports[19–21] have evolved to predict which subgroup of patients with schizophrenia might respond to a gluten-free diet. A robust case-control study using subjects from the large Clinical Antipsychotic Trial of Intervention Effectiveness (CATIE) study found six to eight times more antigliadin antibodies in patients with schizophrenia compared with matched controls.[22] These antigliadin antibodies stimulate downstream inflammatory cascades, as well as increase the metabolism of tryptophan into kynurenine which converts to kynurenic acid in the central nervous system, an endogenous NMDA receptor antagonist that is associated with the negative symptoms of schizophrenia.[23] In 2019, the first modern feasibility DB-RCT (n = 16) re-evaluated a gluten-free diet in patients with schizophrenia, specifically those with elevated anti-gliadin antibodies. Kelly and colleagues found significant improvements in the Clinical Global Impression Scale and negative symptoms in the Scale for the Assessment of Negative Symptoms, with large and moderate effect sizes, respectively.[24] A larger follow-up trial is ongoing.[25]

Additional dietary interventions might be inferred from nutrient studies as interventions for people with schizophrenia. Levine and colleagues completed a six-month double-blind, randomized crossover trial (n = 42) utilizing folate, B12, and B6 for patients with co-morbid elevated homocysteine levels.[26] Homocysteine is relevant to schizophrenia, given that it is an inflammatory cytotoxin that readily passes through the blood–brain barrier and degrades the prefrontal cortex and hippocampus,[27] two areas of reduced volume in schizophrenia. Compared with placebo, Levine and colleagues found that reducing homocysteine through folate, B12, and B6 supplementation rendered significant improvements in PANSS total symptoms and trend-level improvements in positive, negative, and general symptoms ($p = 0.02$ to 0.08). It stands to reason that diets that reduce homocysteine would likewise prevent the brain volume loss that elevated homocysteine would otherwise cause.[26]

78.2.4 Diet and ADHD

Successful dietary interventions for ADHD have focused on the few foods diet, consisting of rice, turkey, lamb, vegetables (lettuce, carrots, cauliflower, cabbage, beet), pears, and water, plus potatoes, fruits, corn, and wheat eaten on prescheduled days and doses. In 2011, Pelsser and colleagues published the results of a five-week DB-RCT (n = 100) comparing the few foods diet vs a generally healthy diet control group. Compared with the control group, the intervention group demonstrated remission from ADHD symptoms according to the ADHD Rating Scale and Abbreviated Conners' Scale ($p < 0.0001$). The results were predominantly due to the 64% of patients in the few foods diet that were clinical responders, defined as at least a 40% reduction of symptom burden.[28] These results were largely confirmed in a meta-analysis of the published literature by Sonuga-Barke and colleagues in 2013.[29] One possible mechanism underlying the few foods diet could be the elimination of artificial food additives. As confirmed in a large DB-RCT (n = 297) by McCann and colleagues

in 2007, artificial food additives produced statistically or trend-level significant worsening of attention in children.[30]

78.2.5 Diet and Cognition

Analogous to VO_2 max of the heart, a major factor contributing to acute and chronic cognitive abilities is blood flow to the brain. Acutely, foods that increase the production of nitric oxide increase blood flow to the brain.[31] Chronically, diets that reduce the risk of arterio- and atherosclerosis, such as carotid artery stenosis, increase blood flow to the brain and help to maintain brain volume over a lifetime.[32–34] Although many polyphenol-rich foods, such as green tea, berries, and grapes stimulate the production of nitric oxide, chocolate has demonstrated the most robust results in clinical trials for improving cognition. Desideri and colleagues and Mastroiacovo and colleagues completed two nearly identical eight-week DB-RCTs (n = 180) evaluating the impact of high vs intermediate vs low flavanol chocolate on cognitive performance. In a dose-dependent manner, chocolate flavanols improved cognitive performance on the Mini Mental Status Exam, verbal fluency, and trail making A and B tests ($p \leq 0.005$).[35,36] An impressive three-month DB-RCT (n = 37) by Brickman and colleagues demonstrated that high-flavanol chocolate improved cognitive scores and increased blood flow to the hippocampus, specifically the dentate gyrus of the hippocampus, which is the area of the brain most correlated to age-related cognitive decline and is the only area of the brain capable of producing stem cells in adults ($p \leq 0.005$). With three months of chocolate, cognitive scores improved equal to three decades of age reversal. Of note, to produce double-blinding with chocolate, chocolate processed with alkali, aka Dutch-processed chocolate, was used as the placebo. Alkali binds to the polyphenols of the chocolate, rendering them physiologically inert.[37] Therefore, unprocessed chocolate is essential for beneficial effects.

The efficacy of comprehensive dietary changes in the prevention and attenuation of mild cognitive impairment has been demonstrated in several RCTs. In 2015, Valls-Pedret and colleagues evaluated a subgroup (n = 477) of the very large 7400-person PREDIMED RCT, demonstrating that a Mediterranean diet produced statistically and trend-level significant improvements in memory, executive function, and global cognition over an average of 4.1 years compared with a low-fat control group.[38] In 2015, Ngandu and colleagues completed a large two-year RCT multidomain lifestyle intervention (n = 1260) combining diet, exercise, and cognitive training to prevent cognitive decline in elderly people, as part of the Finnish Geriatric Intervention Study to Prevent Cognitive Impairment and Disability (FINGER). Compared with the healthy advice control group, the intensive lifestyle intervention demonstrated statistically significant improvements in executive function, processing speed, and total neuropsychological test battery score ($p < 0.03$).[39]

A diet that demonstrates promise in the prevention of cognitive impairment is the MIND diet (Mediterranean-DASH Diet Intervention for Neurodegenerative Delay).[41] The MIND diet is a Mediterranean-style diet with particular emphasis on high polyphenol content through leafy greens and choosing berries as the primary source of fruit. Arjmand and colleagues completed an RCT evaluating the MIND diet vs calorie reduction in 40 obese middle-aged women. At three-month follow-up, compared with calorie reduction alone, the MIND diet demonstrated statistically significant improvements in working memory, verbal recognition, and attention.[40] A large 600-person three-year follow-up RCT of the MIND diet is currently underway.[41]

78.3 EXERCISE AND PSYCHIATRY

78.3.1 Exercise and Psychiatry Mechanism

An appreciation of how exercise intervenes with psychiatric disorders requires an understanding of the neurotrophic hypothesis in psychiatry.[42] The neurotrophic hypothesis relates to brain-derived neurotrophic factor (BDNF) and dendritic arborization—arbor as in tree branches. When there is sufficient BDNF and dense dendritic arborization, neurons have extensive branches, interconnecting neurons with other neurons in a rich web. When there is reduced BDNF and dendritic arborization, neurons have limited branches and the neural pathways that exist are restricted. Compared to a rich web of neurons, restricted neural pathways produce rigid patterns of thought and emotion. Rigid patterns in depression produce thoughts and emotions of personal deficiency.[43,44] In anxiety and trauma, rigid inputs produce worry and fear when there is no active objective concern.[45] In cognitive disorders, reduced neural pathways limit access to memories.[46] In psychotic disorders, the reduced brain volume of the prefrontal cortex and hippocampus limits the ability to discriminate reality from aberrant beliefs and perceptions and contributes to negative symptom burden.[47]

In contrast, cardiovascular exercise increases dendritic arborization by increasing BDNF. A partial misnomer, BDNF is produced in the brain but is also a contraction-induced protein generated by vascular smooth muscle, where it works in conjunction with nitric oxide to regulate vasodilatation.[48] As blood vessels expand and contract to accommodate each stroke volume of cardiac output, BDNF is released into systemic circulation, whereupon it passes through the blood–brain barrier and regrows the brain through its neurotrophic action.

78.3.2 Cardiovascular Exercise and Depression

Schuch and colleagues completed a systematic review and meta-analysis of 25 RCTs with a total of 1487 patients evaluating the effects of cardiovascular exercise on depression. After accounting for publication bias, cardiovascular exercise had a statistically significant and large effect size on depression. Moderate and high-intensity exercise produced an even larger effect as did supervised exercise ($p \leq 0.003$).[49]

Exercise appears to be an effective treatment for depression at any age and health status. Wegner and colleagues completed a systematic review and meta-analysis of 30 RCTs with a total of 2110 children and adolescents, demonstrating that cardiovascular exercise has a statistically significant and moderate effect size on depression ($p \leq 0.01$).[50] Herring and colleagues demonstrated the efficacy of cardiovascular exercise as a treatment for depression by evaluating 90 RCTs with 10,534 patients who were older, sedentary, and chronically ill, albeit the effect size was smaller at 0.3 ($p < 0.001$).[51]

Particular attention should be given to an RCT (n = 121) by Murri and colleagues who demonstrated that combining progressive exercise with antidepressants for six months produced an 81% remission from depression, nearly doubling the effect of antidepressant treatment alone ($p < 0.001$).[52]

78.3.3 Cardiovascular Exercise and Schizophrenia

In 2015, Firth and colleagues completed a systematic review and meta-analysis of four RCTs that evaluated moderate-to-vigorous exercise as a treatment for patients with schizophrenia and found significant improvements with moderate-to-large effect sizes for positive, negative, and total symptoms ($p \leq 0.01$).[53] In 2016, Dauwan and colleagues completed a systematic review and meta-analysis of 29 RCTs examining the effects of aerobic exercise and yoga on 1109 patients and found significant improvements in positive, negative, and total symptoms with small to moderate effect sizes ($p \leq 0.05$).[54] In 2017, Firth and colleagues completed a second systematic review and meta-analysis on seven RCTs that evaluated the effect of aerobic exercise on cognitive performance in 385 patients with schizophrenia. Exercise improved global cognition and working memory with small effect sizes, but moderate effect sizes on social cognition and attention ($p \leq 0.24$). Again, greater amounts of exercise produced stronger effects in subgroup analysis.[55]

78.3.4 Cardiovascular Exercise and ADHD

Cardiovascular exercise is known to enhance executive function and working memory,[56] so may have special relevance to patients with ADHD. Liang and colleagues completed a systematic review and meta-analysis of 15 RCTs that evaluated exercise in 493 children and adolescents with ADHD. Exercise had a moderate-to-large effect size on overall executive function (g = 0.611), inhibitory control (g = 0.761), and cognitive flexibility (g = 0.780) ($p < 0.001$). In a subgroup analysis, moderate-intensity exercise was superior to light exercise, and ongoing regular exercise produced nearly double the effect size when compared with acute exercise ($p < 0.05$).[57]

78.3.5 Cardiovascular Exercise and Cognitive Impairment

In 2006 and 2011, Colcombe and colleagues and Erickson and colleagues, respectively, published landmark RCTs demonstrating that cardiovascular exercise could reverse age-related cognitive impairment and brain volume loss. In Colcombe's study (n = 59), after six months, the cardiovascular exercise group increased both gray and white matter brain volume with the largest changes in the frontal lobe, whereas the stretching and toning group continued to lose brain volume ($p < 0.05$).[58] In Erickson's study (n = 120), after 12 months, the cardiovascular exercise group regrew 2% of brain volume in the hippocampi, whereas the stretching control group hippocampi continued to lose 1.4%. The cardiovascular exercise group increased hippocampi volume equal to being three years younger than their stretching group peers in terms of brain volume ($p < 0.001$).[59]

In 2018, Northey and colleagues completed a systematic review and meta-analysis of 39 RCTs with 12,800 older adults and evaluated the efficacy of exercise on cognitive function. Exercise had a small effect size overall (g = 0.29), however, when exercise was completed five to seven days per week, the effect size increased to a moderate-to-large effect (g = 0.69) ($p < 0.01$).[60] Similarly, Liu and colleagues completed a systematic review and meta-analysis of 22 RCTs with 1647 patients with a formal diagnosis of Alzheimer's disease which found that exercise improved scores on the Mini Mental Status Exam ($p < 0.0001$) and the Alzheimer's Disease Assessment Scale-Cognitive ($p = 0.04$) with small and large effect sizes, respectively.[61]

78.3.6 Exercise, Anxiety, and Post-Traumatic Stress Disorder

In 2017, Stubbs and colleagues published a systematic review and meta-analysis of six RCTs with 262 patients evaluating the efficacy of exercise for anxiety, finding a statistically and clinically significant benefit with a moderate effect size ($p = 0.02$).[62] Likewise, in 2021, Björkman and colleagues completed a systematic review and meta-analysis of 11 RCTs with 605 patients with post-traumatic stress disorder (PTSD). Exercise produced statistically significant improvements in core symptoms of PTSD with moderate effect size. In subgroup analysis, symptoms of depression, sleep, substance use, and quality of life all improved ($p \leq 0.05$).[63]

78.4 CLINICAL CONSIDERATIONS

With this formidable evidence base supporting the utilization of diet and exercise interventions in the management of psychiatric disorders, it would be wise to temper expectations with regard to implementation within current healthcare systems. Well-designed clinical trials often provide a level of support and multifaceted interventions that may be untenable for most clinical practices. There are few comprehensive lifestyle interventions covered by insurance,[64] and those usually require a recent acute cardiac event.[65] Therefore, providers generally must

integrate lifestyle interventions within their visits with a range of other agendas. Dietary interventions are possibly the most complicated lifestyle intervention with new skills required for shopping, storing, cooking, and selecting ingredients to create healthy, delicious, and balanced meals. Cardiovascular exercise, as well as other lifestyle interventions, such as meditation and sleep, may be easier to implement given that a single skill is being taught, but even these interventions are more sustainable with guided support. Additionally, in well-designed clinical trials, the number needed to treat is rarely below four.[1,4] Hence, clinicians should reasonably expect that intensive lifestyle interventions may improve psychiatric symptoms in some patients, whereas other patients may not experience benefits. Nevertheless, given the low side effect burden and the global health benefits of improving lifestyle choices, it is reasonable to include lifestyle recommendations as part of a medical and therapeutic treatment plan for most patients.

78.5 CONCLUSION

Although diet and exercise highlight specific mechanisms in psychiatric disorders, there is significant cross-pollination and synergy between lifestyle habits. For instance, BDNF—intervening on the neurotrophic hypothesis of psychiatric disorders—is robustly produced by cardiovascular exercise and is also produced by certain foods high in polyphenols, such as chocolate, tea, and berries.[66,67] Nitric oxide produced by food increases blood flow to the brain and also improves VO_2 max of the heart, exercise intensity, and exercise endurance.[68–71] Although foods rich in antioxidants reduce oxidative stress and inflammation, exercise is likewise anti-inflammatory via cytokines produced by muscular contraction.[72] Other lifestyle interventions, such as sleep, meditation, and yoga, increase BDNF and decrease inflammation[73–75] producing an orchestra of complementary mechanisms building upon each other for optimum effect.

The evidence on lifestyle interventions for psychiatric disorders is considerable with detailed understanding of mechanisms and a consistent demonstration of efficacy in clinical trials. It is reasonable to include lifestyle interventions as a major component of treatment recommendations for fostering optimum mental health in both primary and secondary prevention. Additionally, lifestyle interventions for mental health may be a deft ally in encouraging lifestyle interventions for cardiometabolic diseases. Whereas patient populations may have a conceptual understanding of the long-term risks of heart disease and diabetes, all patients have a palpable understanding of what it is to feel better and have clearer thinking in their day-to-day lives. Hence, the encouragement of lifestyle interventions for improved mental health may be a leverage point for improving global health for individual patients and public health.

CLINICAL APPLICATIONS

Diet and depression	• Mediterranean diets appear to improve depression and increase rates of remission from depression in patients with baseline poor diets.
Diet and schizophrenia	• In a subset of patients with schizophrenia with high gliadin antibodies, gluten-free diets may improve negative and general symptoms. • B vitamins that reduce homocysteine may improve core symptoms of schizophrenia in patients with baseline elevated homocysteine.
Diet and ADHD	• Diets with a complete abstinence from processed foods and artificial ingredients may improve ADHD.
Diet and cognitive disorders	• Foods (chocolate, berries) improve acute cerebral blood flow via the production of nitric oxide, thus improving cognition. • Chocolate processed with alkali aka "Dutch processed" is used as a placebo. Alkali renders active ingredients physiologically inert. • Diets that prevent carotid artery stenosis sustain chronic blood flow and reduce the risk of cognitive impairment and dementia.
Cardiovascular exercise and depression	• CV exercise improves depression in pediatric, adult, and older adult populations. • Combining CV exercise with antidepressants may produce up to 81% remission from depression over a six-month period, double the effect of antidepressants alone.
Cardiovascular exercise and schizophrenia	• CV exercise may improve negative and cognitive symptoms of schizophrenia.
Cardiovascular exercise and ADHD	• CV exercise may improve executive function and working memory in ADHD with moderate-to-large effect.
Cardiovascular exercise and cognitive disorders	• CV exercise restores brain volume in the hippocampus and prefrontal cortex, which may ameliorate, prevent, and/or reverse age-related cognitive decline.

79 Risk and Protective Factors for Mental Health

Alyssa M Vela, PhD, Allison Young, MD, Samuel Kohlenberg, PhD, and April Hirschberg, MD

KEY POINTS

- Lifestyle factors can be protective of, or be detrimental to, mental health.
- Lifestyle interventions can be utilized to prevent and treat mental health conditions and optimize psychological well-being.
- Risk and protective factors can be briefly assessed with brief, validated screening measures to inform lifestyle interventions for mental health.

79.1 INTRODUCTION

Mental health is inextricably tied to lifestyle factors and quality of life across the lifespan. Mental health is defined as "a state of mind characterized by emotional well-being, good behavioral adjustment, relative freedom from anxiety and disabling symptoms, and a capacity to establish constructive relationships and cope with the ordinary demands and stresses of life".[1] In short, mental health includes both an absence of pathology as well as an overall sense of well-being. Lifestyle factors, including diet, physical activity, sleep, stress, interpersonal relationships, and substance use, can each support mental health and serve as a protective factor or be detrimental to mental health.[2,3] Specifically, suboptimal lifestyle behaviors, such as poor nutrition or inadequate sleep, may influence the onset and progression of many health conditions.[4,5] Those who meet clinical criteria for mental illness have higher rates of mortality and morbidity related to a number of direct and indirect factors, such as poor health behaviors and stigma affecting healthcare.[6] Fortunately, several lifestyle factors, such as regular exercise and vegetable-rich diets, are health-promoting and have been shown to improve mental health.[4,5]

A lifestyle medicine approach to addressing risk and protective factors for mental health is especially relevant to primary care practitioners, as most mental health conditions are diagnosed and treated in a primary care setting.[7] Table 79.1 outlines recommendations for brief, validated measures to assess primary lifestyle factors in clinical settings. The current chapter will outline the key areas of lifestyle medicine and address how lifestyle can positively influence mental health or increase risk for poor mental health. While a thorough discussion of sociocultural influences is beyond the scope of this chapter, each of the risk and protective factors outlined below should be considered from a biopsychosocial perspective, including the influence of social determinants of health on lifestyle behaviors, health beliefs, and access to resources.

79.2 RISK AND PROTECTIVE LIFESTYLE FACTORS

79.2.1 Diet and Nutrition

Across the lifespan, diet, gastrointestinal (GI) health, brain health, and mental health have been shown to have a complex and tightly related association.[8,9] Research suggests dietary patterns that prioritize fruits, vegetables, and whole grains are associated with a lower incidence of depression and anxiety disorders when compared with "Western" diets that include large quantities of processed foods, refined grains, and sugar.[10] Another study found that moderate adherence to a plant-rich Mediterranean diet demonstrated a 27% reduction in depression risk, while high adherence was associated with a 32% reduction.[11]

Research is still emerging on the exact ways by which diet impacts mental health, but various mechanistic and clinical data offer potential mechanisms. GI microbiota diversity, which refers to the number of different species of organisms in the gut, has been shown to be important to physical, and now, mental health. Research has found less GI microbiota diversity in individuals with social stress, anxiety, depression, bipolar disorder, and schizophrenia.[12,13] Diet plays an essential factor in determining GI microbiota diversity, with diets high in fiber, polyphenols, and unsaturated fatty acids promoting more diversity, while diets low in fiber and high in refined carbohydrates, sugar, and alcohol result in less diversity.[14,15] A healthy, diverse GI microbiota may contribute to mental health in part through the production of tryptophan, the precursor to serotonin, as well as other neurotransmitters, such as GABA and norepinephrine.[8,14]

Additionally, micronutrient intake may play a role as several nutrients are essential cofactors for neurotransmitter production.[15] Deficiencies of nutrients, such as vitamins C and B, have been linked to the risk of mental health conditions.[12,16–18] Vitamin B12 supplementation has demonstrated benefits for stress and depression.[12,18] Studies

TABLE 79.1
Validated Brief Measures to Assess Risk and Protective Lifestyle Factors for Mental Health

Lifestyle Factor	Validated Assessment Measure	Measure Details
Diet	Short-form Food Frequency Questionnaire (SF-FFQ)	Twenty-five-item measure of diet quality provides a diet quality score.[75]
	Mediterranean Diet Adherence Screener (MEDAS)	Fourteen-item assessment of food consumption of the 12 main aspects of the Mediterranean diet.[76]
Physical activity	International Physical Activity Questionnaire-Short Form (IPAQ-SF)	Seven-item questionnaire assessing time spent doing various levels of physical activity and spent sedentary. Can be self-administered. Available in multiple languages.[77]
Stress	Perceived Stress Scale (PSS)	Ten-item questionnaire assessing the perception of stress, not stress itself.[78] Results and utility are dependent on an individual's ability to identify and report stress.
Substance use	The Tobacco, Alcohol, Prescription Medication, and Other Substance Use Tool (TAPS Tool-I and Tool-II)	TAPS-I is a four-item screen for substance use. For those who screen positive, nine-item TAPS-II can used for additional screening of substance use over the past three months.[79, 80]
Sleep	Insomnia Severity Index (ISI)	Seven-item measure with clinical insomnia cut-off.[81]
	STOP-Bang	Eight-item measure for risk of obstructive sleep apnea.[82]
Social support	Multidimensional Scale of Perceived Social Support (MSPSS)	Twelve-item measure of perceived support across family, friends, and significant other domains.[83]

have also shown that omega-3 deficiency is associated with increased risk for the development of depression, bipolar disorder, substance use disorders, schizophrenia, attention deficit disorder, and neurocognitive disorders, as well as low mood and hostility.[13,19,20]

Diet may also affect mental health through immune-modifying and epigenetic mechanisms.[9,21] Pro-inflammatory Western diets have been shown to cause neuro-oxidative stress and inflammation that can result in neuronal damage,[22] lesser well-being, and greater risk for anxiety and depression symptoms.[23] While research continues to elucidate the ways by which diet impacts mental health, current evidence shows there is an opportunity to address dietary risk factors for mental health and encourage dietary patterns that can protect mental health.

79.2.2 Physical Activity

Many studies have demonstrated a link between physical activity and mental health. Sedentary behavior, defined as activities done in a seated or reclined position requiring low energy expenditure,[24] has been associated with increased depression and stress, as well as poorer self-image and life satisfaction among adolescents and adults.[24,25] Conversely, physical activity requiring high energy expenditure has been associated with improved mental health across the lifespan in a healthy population as well as among adults with a variety of physical health comorbidities, including cancer and autoimmune conditions.[26–30] Physical activity also has a role in the prevention and management of mental illness, as benefits have been demonstrated for mood disorders, anxiety disorders, attention deficit disorders, substance use disorders, and schizophrenia.[10]

The precise mechanisms by which physical activity impacts mental health are unclear, though several hypotheses have been suggested. Exercise has been demonstrated to impact brain structure (e.g., hippocampal volume) and result in neurogenesis, angiogenesis, and synaptogenesis.[10] Additional potential biological mechanisms include neurotransmitter release and mediation of the inflammatory response.[31] Psychologically, exercise may impact mood by increasing self-esteem, self-efficacy, and social connectedness.[32] By incorporating physical activity into a treatment plan, including for those with or at risk for mental illness, there is an opportunity to simultaneously improve mental and physical health.

79.2.3 Sleep

Both quality and quantity of sleep play a key role in overall health, including mental health. Sleep, more specifically insomnia (difficulty initiating or maintaining restful sleep) is an independent risk factor for mental and neurological disorders.[11] Specific sleep disorders, such as obstructive sleep apnea, have also been associated with cognitive impairments, mood dysregulation, and worse immune function.[33] Yet, some of the strongest evidence for the impact of sleep on health points to the relationship between insomnia and depression, with insomnia as a key predictor of the development of depression.[34]

Accordingly, managing sleep issues is an essential part of preventing and treating mental health issues. A 2021 meta-analysis of randomized controlled trials indicated greater improvement in sleep was associated with improvement in overall mental health, depression, anxiety, and rumination.[35] Interventions to address sleep and sleep disorders often include sleep hygiene, which emphasizes behavioral and environmental factors that can influence sleep quality.[36] For those who need more intervention than sleep hygiene, cognitive behavioral therapy for insomnia (CBT-I), is the

gold-standard and first-line treatment for insomnia and is also a promising treatment for comorbid depression and insomnia.[37] CBT-I is an important treatment option as a standalone treatment or combined with other treatments as a common side effect of psychiatric medications is interference in sleep onset and maintenance, thus potentially exacerbating underlying mood and cognitive symptoms.[38] Identifying and treating sleep issues, either in conjunction with mental health treatment or independently, is a critical opportunity for primary and secondary prevention of mental health symptoms and disorders.[39]

79.2.4 Stress

Stress can affect mental health at all stages of life, and successful treatment of stress may reduce symptoms of mental illness.[3] Even before birth, parental stress is thought to lead to epigenetic alterations in offspring which can profoundly influence mental health throughout the lifespan.[40] A preponderance of evidence suggests that stressful early life experiences, sometimes called adverse childhood events, contribute to mental health pathology later in life.[3] Demographic and sociocultural factors, such as race, ethnicity, and social determinants of health, have also been associated with increased risk for chronic stress.[41] It has been posited that the epigenetic inheritance of stress contributes to the racial disparities in cardiovascular disease.[42] Research on social determinants of health also suggests that those who live in unsafe and under-resourced neighborhoods are more likely to experience the physiological effects of stress (i.e., allostatic load), though this relationship is partially mediated by health behaviors (e.g., smoking).[43]

Stress can manifest cognitively, behaviorally, and physiologically, and these different expressions of stress may be independent or interrelated. Recognizing how an individual's stress presents can be the key to effective treatment.[44]

Screening for stress is vitally important and should include attention to physical signs of stress (e.g., GI symptoms), as many individuals struggle to articulate stress when screened.[45] People experiencing stress may have a difficult time making and sustaining changes, including changes to health behaviors that could mitigate stress. For example, research shows those experiencing stress are less likely to change their behaviors than those not experiencing stress,[46] and that stress affects the brain in ways that negatively impact future-oriented planning.[47] While it is impossible to know with certainty which treatment for stress will work best for an individual,[48] screening for stress and identifying manifestations of stress are both critical to effective lifestyle change and health behavior maintenance.

79.2.5 Substance Use

Tobacco, alcohol, marijuana, illicit substance use, and prescription medication misuse are all bidirectionally related to mental health.[3] Many individuals report relying on substances to cope with symptoms of shame, depression, anxiety, and other mental illnesses.[49–52] Rates of alcohol use disorder and other substance use continue to increase, and data continues to emerge regarding the concerning rates at which individuals have relied on substances to cope with the stress of the COVID-19 pandemic.[52–54] Not only does experiencing mental distress increase the likelihood of substance use, but research also shows substance use increases the risk of various mental health issues. For example, research suggests causal links between both alcohol use disorder and illicit substance use and risk for major depression and anxiety disorders.[55,56] Similarly, marijuana use has been shown to predict greater risk for a substance use disorder, while abstinence has been associated with fewer symptoms of anxiety and less alcohol and nicotine use.[52,57]

Cigarette use has a bidirectional relationship with mental health. Smoking has been associated with an increased risk of depression, anxiety, panic disorder, and schizophrenia.[58–60] In a meta-analysis of more than 50,000 adults, smoking significantly increased the prospective risk of depression over six years.[61] Anxiety symptoms have been shown to contribute to the onset of smoking and contribute to smoking behaviors.[60] Though the causal relationship between mental illness and smoking remains unclear, individuals with serious mental illness, such as schizophrenia, smoke at much higher rates than the general population.[62] Tobacco cessation is an important modification to reduce risk for mental disorders, as it has been associated with decreased symptoms of anxiety, depression, self-reported stress, improved mood, and overall quality of life.[63,64] Overall, substance use tends to increase risk for worse mental health, and interventions that support cessation have the opportunity to support mental and physical health and related outcomes.

79.2.6 Relationships and Social Support

Healthy and supportive interpersonal relationships are a protective factor for the prevention of mental health symptoms and disorders and optimal quality of life. Both enacted and perceived social support are important predictors of satisfaction with life.[65] For example, the well-known 75-year longitudinal Grant study found close relationships to be the single most impactful predictor of life satisfaction.[66] Good social support has been associated with better ability to cope with stress, and even less mental decline among older adults.[67] The effects of social support have also been studied across the lifespan, with protection from depression based on parental support for children and adolescents.[68] Research has also indicated the importance of intimate partner relationships, with the quality of a long-term partnership, often in the form of marriage, associated with greater physical and mental health.[67]

Alternatively, there are several relational risk factors for poor mental health, including unhealthy relationships that include harm or abuse, trauma, and social isolation. Intimate partner violence (IPV) is well understood to

adversely impact mental health and has been associated with increased risk for depression, anxiety, and post-traumatic stress disorder (PTSD).[69] Social isolation has been associated with a greater decline in mental health and an increase in symptoms such as loneliness, helplessness, and worse mood.[70] Lack of social connectivity has even been associated with greater degrees of inflammation and worse immune function.[70] Even after controlling for lifestyle and socioeconomic factors, lesser social connection is associated with a higher risk of mortality.[70]

The COVID-19 pandemic exacerbated social isolation and the cascade of mental and physical health implications, such as greater depression and anxiety, and worse sleep quality.[71] Fortunately, social support can be leveraged to positively influence lifestyle interventions and, for example, to improve adherence to lifestyle and pharmacological treatment of type 2 diabetes mellitus.[72] Thus, identifying insufficient social support and providing appropriate referrals to local organizations and social services can reduce risk, protect mental health, and improve the efficacy of lifestyle interventions.[73,74]

79.3 CONCLUSION

The current chapter provided an overview of each of the primary lifestyle factors and their impact on mental health, as well as the utility of associated clinical interventions. As indicated by both well-established and emerging areas of science, health behaviors such as engaging in daily physical activity and managing stress can support mental health, prevent and reduce mental distress, and complement treatment for mental illness. However, other lifestyle behaviors such as insufficient sleep and social isolation are risk factors for worse mental health and increased risk for mental illness. Utilizing brief, accessible, and empirically based screening measures (Table 79.1) within clinical contexts can allow for the assessment of risk factors and lay a foundation for the development of lifestyle medicine interventions to support mental health. While considering social determinants of health, attention to these risk and protective lifestyle factors for mental health can foster opportunities for lifestyle interventions to prevent and treat mental health symptoms and illnesses effectively.

CLINICAL APPLICATIONS

- Lifestyle interventions, including nutrition, physical activity, sleep, social connectedness, substance use, and stress management, impact the risk of developing a mental disorder.
- Lifestyle interventions may complement psychotherapy and medication for the management of mental disorders.
- Evaluations of patients should include a comprehensive lifestyle assessment, which also includes a discussion of the barriers to implementing lifestyle changes (see Table 79.1 for helpful tools).
- Monitor individuals with a diagnosis of mental illness for cardiometabolic risk factors, including side effects of psychotropic medications.

80 Biopsychosocial Implications and the Prevention and Management of Chronic Illnesses

Christopher P. Fagundes, PhD and Jensine Paoletti, PhD

KEY POINTS

- Chronic low-grade systemic inflammation underlies most chronic illnesses.
- Psychological stress, troubled close relationships, and poor health behaviors contribute to an overactive pro-inflammatory state and chronic illness risk.
- Lifestyle interventions that target the "six foundational pillars of lifestyle medicine" can slow and sometimes prevent chronic illnesses; lifestyle interventions also reduce systemic inflammation, indicating a possible mechanism of action.

80.1 INTRODUCTION

Thanks to decreased infant mortality, better nutrition, and extraordinary advances in healthcare, life expectancies have increased dramatically in the United States and globally.[1] People in the United States can expect more than 30 additional years of life than their ancestors born at the dawn of the 20th century. As a result, 16% of the population is older than 65, the age at which people are considered "older adults". Indeed, if someone reaches age 65, they can expect to live another 20 years[1]

Chronic illnesses emerge at a much greater frequency as people age. Accordingly, chronic illness (i.e., noncommunicable diseases) has replaced infectious diseases as the leading cause of death and disability in the United States and globally.[2] More than three-fourths of those over 65 have at least one chronic illness[3] or condition.[4] All six foundational pillars of lifestyle medicine (i.e., diet, exercise, stress management, substance use, sleep, and close relationships) contribute to chronic illness development and progression[5] In this chapter, we consider how stress, close relationships, and health behaviors "get under the skin" to impact the development and progression of chronic illnesses. Toward this end, we take a biopsychosocial approach to understanding the etiology and management of chronic illnesses. We commence by reviewing how molecular processes and cellular alterations associated with aging contribute to the emergence and progression of chronic illnesses. Then, we consider how stress, close relationships, and health behaviors impact the molecular and cellular underpinnings of chronic illness by contributing to age-related changes in chronic low-grade systemic inflammation. Finally, we describe a growing literature showing it is possible to target biological mechanisms through lifestyle interventions.

80.2 INFLAMMATION AS A COMMON PATHOGENIC MECHANISM UNDERLYING CHRONIC ILLNESSES

Age-related alterations in cellular and molecular processes play a critical role in the development and progression of most chronic illnesses.[6,7] Given that the immune system dynamically remodels in older adulthood, gerontologists have become particularly interested in the cellular and molecular processes that promote age-related changes in the immune system (i.e., immunosenescence)[8] As a result of immunosenescence, older adults are less likely to mount an adequate immune response when vaccinated and more susceptible to infection, latent herpes virus reactivation, and an overactive inflammatory network.[9]

Chronic low-grade systemic inflammation is a common pathogenic biological mechanism underlying most chronic illnesses[10] It is necessary and adaptive for the immune system to mount an acute pro-inflammatory response when someone is infected or injured. Yet, chronic low-grade inflammation, revealed by elevated levels of inflammatory biomarkers such as C-reactive protein (CRP), interleukin (IL)-6, and tumor necrosis factor-alpha (TNF-α), is involved in many age-related diseases[10]

Inflammaging is an emerging term characterizing the low-grade, chronic, systemic inflammation in aging that is an important indicator of morbidity and mortality.[7,11] There is a plethora of epidemiological evidence that a mild chronic inflammatory state is predictive of an aging phenotype[11,12] Pro-inflammatory cytokines, such as IL-6 and TNF-α, are predictive of cardiovascular disease, some cancers, type II diabetes, arthritis, osteoporosis, Alzheimer's disease, and periodontal disease[13–16] Chronic inflammation is an essential biological mechanism that promotes waning physical function leading to frailty, disability, and, ultimately, death[17] Inflammation is also associated with

DOI: 10.1201/9781003227793-94

muscle wasting, cognitive decline, and increased disease vulnerability[18]

80.3 MECHANISMS OF LOW-GRADE INFLAMMATION: PATHWAYS TO CHRONIC ILLNESSES

Given the role of chronic low-grade inflammation in the development and progression of chronic illnesses, it is critical to understand the origins and mechanisms that underlie an overactive pro-inflammatory state to create targeted and tailored interventions[12] The origins of a pro-inflammatory phenotype are multifactorial. This chapter focuses on those related to the six pillars of lifestyle medicine[12,19] First, we describe how the stress-response system can promote acute and chronic inflammation. Then, we explain how past and current close relationships can buffer and exacerbate stress's negative impact. Finally, we describe how key health behaviors (i.e., diet, tobacco use, and exercise) promote inflammation while considering how the stress-response system can interact with these health behaviors in additive and possibly synergistic ways.

80.3.1 Stress-Response System

The stress-response system involves alterations in the autonomic nervous system and the hypothalamic-pituitary axis (HPA axis) within the neuroendocrine system in response to stress. When the stress-response system is activated, catecholamines are released as part of the sympathetic nervous system response.[20] Norepinephrine-dependent adrenergic stimulation triggers NF-KB, an intracellular signaling molecule that regulates pro-inflammatory cytokine gene expression.[20] Cortisol, the glucocorticoid produced by the HPA axis in response to stress, also impacts pro-inflammatory activity[21] Although cortisol is anti-inflammatory, chronically elevated cortisol promotes desensitization of the glucocorticoid receptor, thereby promoting glucocorticoid resistance. When the glucocorticoid receptor is desensitized to the anti-inflammatory impact of cortisol, the body cannot regulate the magnitude of inflammatory responses, thus allowing a pro-inflammatory state[22]. There is growing evidence that the parasympathetic branch of the autonomic nervous system is also involved in the regulation of chronic low-grade systemic inflammation[23] Acetylcholine, the principal neurotransmitter of the parasympathetic nervous system, is secreted under conditions of rest and restoration and inhibits systemic inflammation via the "cholinergic anti-inflammatory pathway".[23]

When negative emotions, such as depression, loneliness, and grief, are present over a prolonged period, the stress-response system is "primed" to mount a robust inflammatory stress response[24–28] For example, in 111 recently widowed older adults, my group recently tested the hypothesis that widow(er)s experiencing more profound grief would have a greater pro-inflammatory response to an experimental stressor than those with less grief. After intravenous catheter placement, we took a small amount of blood to obtain levels of IL-6 in serum at baseline. Then, we administered a well-established standardized laboratory stressor designed to elicit a stress response. Blood was taken 45 minutes and two hours after the stressor. Our results indicated that widow(er)s who exceeded the cut-point for grief complications exhibited more significant stress-induced elevations in the pro-inflammatory cytokine, IL-6, than individuals who experienced less grief. Importantly, this finding persisted even after accounting for depressive symptomology.[29] This finding illustrated relational loss's unique impact on the inflammatory stress response. As discussed below, relationships can positively impact pro-inflammatory cytokine production and chronic illness risk[30]

80.3.2 Social Processes

One of the fundamental tenets in lifestyle medicine is that close social relationships impact physical health across the lifespan; elegant theoretical frameworks from the social psychological literature have clearly articulated that human beings have a need to belong. Although this need is universal, not everyone experiences health benefits from social relationships.[31] In fact, social relationships are a source of strain and sorrow, across the lifespan, for a considerable amount of the population.[31] Indeed, those who have stronger social relationships have a 50% greater likelihood of survival than those who report low social support, according to a meta-analysis of 148 studies.[24] Indeed, social integration impacted mortality rates at a level equivalent to smoking and physical activity[24] A meta-analysis of 41 studies revealed that those who reported more social support and social integration had lower systemic inflammation than those who reported less social support and social integration[32]

There has been considerable research to show that objective social isolation and loneliness enhance the risk of poor quality of life and disease.[26,27,33,34] Nevertheless, there is strong evidence that loneliness primarily mediates the link between objective social isolation and mental and physical health outcomes; thus, it is the perception of social isolation (i.e., loneliness), rather than one's objective reality that largely impacts health[28,33] This is important because if one is able to understand when and why people perceive isolation or loneliness, interventions can be designed to alleviate this negative emotion. In an 18-year study of 6729 individuals from the National Health and Nutrition Examination Survey assessing social isolation and multiple markers of chronic inflammation, chronic inflammation explained the link between social isolation and mortality[26] Healthy adults exposed to acute stress exhibited more significant increases in the pro-inflammatory cytokines, TNF-α, and IL-6, than their less lonely counterparts[35] Similarly, lonelier posttreatment breast cancer survivors exposed to acute stress exhibited more significant IL-6 and IL-1β than their counterparts who felt more socially connected[29]

Not only are current interpersonal relationships linked to immune dysregulation, but past relationships are as well. There is considerable evidence that children who were abused have dysregulated immunity.[30,36,37] In a longitudinal prospective study of adults with an average age of 32, more than 10% of adult low-grade inflammation was attributable to child maltreatment. Further, in a study of healthy older adult family dementia caregivers and non-caregivers, children who had experienced emotional, physical, or sexual abuse as children were more likely to have higher IL-6 and TNF-α levels than those who were not abused as children[38] Perceived social status might alter the impact of having troubled relationships with parents. Widow(er)s who reported troubled relationships with their parents, and being of lower social status, produced more robust pro-inflammatory cytokines; however, this was not the case for widow(er)s who reported troubled relationships with their parents as children but high social status.[39]

80.3.3 Health Behaviors: Diet, Exercise, Sleep, and Tobacco Use

Health behaviors are adopted by individuals or groups to prevent illness or injury and maintain health status. Poor diet, lack of exercise and sleep, and tobacco use are modifiable risk factors for morbidity and mortality that impact chronic low-grade inflammation.[40] Ischemic heart disease is the leading cause of death for men and women; scientists estimate that up to 80% of cardiovascular and coronary heart disease events can be attributed to *poor-quality diet*, *excess calorie intake*, physical inactivity, and smoking[41].

Although the risks associated with health behaviors are profound in their own right, recent evidence suggests they may impact inflammation more if accompanied by psychological risk factors (e.g., stress and poor close relationships)[42] Consider how comfort foods high in saturated fat are consumed more frequently during stress. Recent work suggests that these high saturated fat foods may promote greater risk when consumed in times of high stress compared with when they are consumed in times of low stress. For example, triglycerides, which increase after a high saturated fat meal, provoke monocytes to produce pro-inflammatory cytokines;[43] Multiple labs have shown IL-6, TNF-α, and CRP increases following a single meal high in saturated fat.[44–46] Recent work has demonstrated that stress potentiates the adverse repercussions of eating high saturated fat comfort foods because the post-prandial (post-meal) response of lipids and pro-inflammatory cytokines is exaggerated when one experiences frequent stress[47,48] Psychological stress can also promote lipemia (high lipid content in the blood) by enhancing triglyceride responses to a high saturated fat meal and inhibiting clearance[49] For example, in one study, total triacylglycerol and very low-density-lipoprotein-TG areas under the curve were 50% or higher during a stressful condition than in a control condition.[50] This finding was not related to pre-meal levels. Increased post-prandial changes were independent of baseline triacylglycerol levels[50] In another study, acute stress slowed triglyceride clearance.[51] Compared with the non-stress session, clearance of an exogenous fat load took 14% longer on average following a laboratory stressor.[51]

80.4 INTERVENTIONS

Although many health recommendations exist to reduce chronic illness risk, knowing which constructs to prioritize is critical to most effectively and efficiently guide intervention, development, and ultimately reduce risk. For example, if the synergistic impact of diet and psychological stress predicting post-prandial increases in triglycerides and inflammation is robust, this information will guide intervention components above and beyond general dietary recommendations.[42]

Regular physical activity is associated with lower levels of pro-inflammatory cytokines.[51] In addition to its physiological benefits, intervention studies have demonstrated that regular exercise reduces psychological distress and enhances psychological well-being, which may serve as an indirect pathway to reduced inflammation.[52–54] While much of the literature has focused on cardiovascular training, positive effects are also found with a variety of other activity interventions; for example, the flexibility/strength training control group in one study showed a significant decrease in TNF-α,[55] while a tai chi intervention produced positive alterations in varicella-virus specific immunity.[56]

Data from well-controlled randomized clinical trials have demonstrated mindfulness as an important tool to reduce stress, improve sleep, and improve adherence to good health behaviors (e.g., diet, exercise, substance use cessation). Mindfulness reflects an intentional awareness of internal and external stimuli occurring in the present moment.[57] That is, individuals can allow distressing cognitions, emotions, perceptions, and sensations to occupy awareness without necessarily trying to change them and without becoming engaged in their content. These thoughts and feelings are viewed simply as passing mental events that may or may not reflect reality. Mindfulness-based interventions, such as the eight-week Mindfulness-based Stress-Reduction Protocol (MBSR), have been implemented to target various health problems. In a community-based sample of employed adults, MBSR participants reported significantly less anxiety and negative affect after treatment than the control group. In a randomized control trial, those who received a mindfulness-based intervention exhibited a reduced stress response to experimental stress than participants in the control condition.[58] MBSR may be a powerful tool in reversing the physical consequences of a dysregulated stress response.

In addition to interventions that require commitment and behavior change, there is work to suggest a role for supplements and medications. In a clinical trial designed to reduce inflammation in older adults, randomized assigned to receive omega-3 polyunsaturated fatty acid supplementation

showed a modest decrease in the pro-inflammatory cytokine, IL-6, compared with placebo controls.[59] In another trial examining the impact of omega-3 polyunsaturated fatty acid supplementation in medical students, those who received the supplement exhibited a 14% decrease in IL-6 production and a 20% decrease in anxiety symptoms.[59] Medications such as statins, fibrates, and niacin can also be effective, yet these interventions have monetary costs and physical health side effects.[60–65]

80.5 CONCLUSION

Overactivation of the stress-response system is strongly predictive of chronic illness occurrence.[66] A lifetime of elevated levels of low-grade inflammation (sometimes called *inflammaging*) predicts chronic illness incidence, typically occurring in older adulthood.[67] A biopsychosocial approach to systemic inflammation highlights the variety of lifestyle factors that promote chronic illnesses or protect against them. For instance, loneliness, poor social support, childhood maltreatment, high-fat diets, sedentary lifestyles, and tobacco use are all risk factors for chronic illnesses through elevated low-grade inflammation.[66,67] Successful intervention research has demonstrated that systemic inflammation can be reduced by targeting the six pillars of lifestyle medicine.[68] Practitioners and researchers alike may apply these findings to promote healthy aging.

CLINICAL APPLICATIONS

- Behavior change interventions that reduce tobacco use, increase healthy eating, and/or improve exercise may be more helpful when combined with stress-reduction interventions.
- Clinicians should consider assessing patients' social networks, including loneliness and childhood maltreatment.
- Medications such as statins, fibrates, and niacin can be effective for reducing inflammation, but the monetary costs and physical health side effects may make behavior change interventions more appealing to patients.

81 The Influence of Lifestyle on Parkinson's Disease Management

Mohadese Golsorkhi, MD, Ayesha Sherzai, MD, and Khashayar Dashtipour, MD, PhD

KEY POINTS

- Parkinson's disease (PD) is the second-most prevalent neurological condition worldwide and is associated with aging.
- Many low-risk and potentially high-yield recommendations for lifestyle modification could be made to decrease the risk and progression of PD.
- A healthy dietary pattern has been shown to contribute to a lower risk of PD.
- Lack of sleep has a substantial impact on the development of neurodegenerative illnesses and inhibits the body's ability to eliminate neurotoxic substances.
- Physical activity is a key component of rehabilitation programs for patients with PD.
- PD is influenced by both acute and chronic stress.

81.1 INTRODUCTION

Parkinson's disease (PD) is the second-most prevalent neurological condition worldwide and in the United States, almost a million people have PD. By 2030, it is anticipated that this number will reach 1.2 million.

In patients with PD, pathologic processes are already advanced at the time when the clinical diagnosis is made, particularly as the prodromal period may span up to two decades or more. This late timing is likely the reason why it has been challenging to slow the disease progression in patients. There has been increasing evidence from observational studies for the role of several lifestyle factors in modulating the risk for PD at individual and population levels.

In the past decade, additional evidence has been published that enhances our understanding of the complexity of these associations. Despite the caveats of observational studies, a number of low-risk and potentially high-yield recommendations for lifestyle modification could be made to minimize the individual and societal burdens of Parkinson's disease, including dietary modifications, increasing physical activity, and head injury avoidance. The most promising and best-studied factor for disease prevention is exercise. Indeed, studies have shown that regular aerobic exercise is associated with improved preservation of the basal ganglia network, and human studies have corroborated these findings, demonstrating advanced neuroplasticity in the basal ganglia circuitry. Other lifestyle factors such as nutrition, regular consumption of caffeine, reduction of alcohol, prevention of concussions and head trauma, and reduction of environmental exposure to pesticides have been associated with risk reduction. In this chapter, we will explore lifestyle factors that have been linked to the prevention of PD.

81.2 NUTRITION

A healthy dietary pattern has been shown to contribute to a lower risk of PD. Despite the challenges of studying nutrition over a long period of time, many dietary patterns have been studied for their association with PD risk, and the results are a variation of a theme that highlights the importance of improving dietary patterns rather than myopically focusing on specific macro or micronutrients. The dietary pattern most extensively associated with a lower risk of PD is essentially a plant-based dietary pattern with a high intake of fruits, vegetables, legumes, whole grains, nuts, and fish, and a low intake of sources of saturated fat from meat and dairy products, refined carbohydrates, and alcohol. The Mediterranean dietary pattern has been associated with a reduced risk of PD development in multiple cohorts.[1,2] In populations from the Center for Parkinson's Disease at Columbia University, in New York (n = 209), and the Washington Heights–Inwood Columbia Aging Project (n = 48), a higher adherence to a Mediterranean-type diet was associated with 14% reduced odds for PD after adjustment for all covariates (OR, 0.86; 95% CI, 0.77–0.97; P = 0.010). People with lower Mediterranean-type diet scores had a higher risk for earlier PD age at onset (β = 1.09; P = 0.006).[1] In 47,679 participants from the Nurses' Health Study and Health Professional Follow-up Study, adherence to a Mediterranean-style diet, especially among those who scored in the top 20%, were one-third less likely to develop multiple early Parkinson's symptoms over 20 years, compared with people in the bottom 20%. Higher adherence to this dietary pattern was inversely associated with features such as constipation, excessive daytime sleepiness, and depression.[3] In a study from a population-based cohort of older adults (Hellenic Longitudinal Investigation of Aging and Diet) in Greece, high adherence to the Mediterranean

DOI: 10.1201/9781003227793-96

diet was associated with a lower probability for prodromal PD ($P < 0.001$), represented by non-motor markers of prodromal PD, depression, constipation, urinary dysfunction, and daytime somnolence. Each unit increase in Mediterranean diet score was associated with a 2% decreased probability for prodromal PD ($P < 0.001$). Compared with participants in the lowest quartile of Mediterranean diet adherence, those in the highest quartile had approximately 21% lower probability for prodromal PD.[2]

Recently, the MIND Diet (Mediterranean-DASH Intervention for Neurodegenerative Delay) has also been studied with regard to its association with PD, as it has been shown to lower the risk of Alzheimer's dementia and overall dementia. The MIND dietary pattern emphasizes the consumption of leafy greens, berries, vegetables, whole grains, nuts, seeds, and extra virgin olive oil as the main source of cooking oil, and fish as a source of long-chain n-3 polyunsaturated fatty acids (PUFAs) while minimizing the consumption of meat, high-fat dairy, and sources of saturated fats. In a cross-sectional study involving 167 PD patients and 119 controls, adherence to the MIND diet was most strongly related to a later age of onset specifically in the female subgroup, reflecting differences up to 17.4 years ($P < 0.001$). The study found a strong correlation between dietary habits and the age of PD onset, suggesting nutritional habits can play a crucial role in delaying PD progression.[4] In addition, there has also been a link between early changes in gut microbiota and PD.[5]

Gut microbial dysbiosis and alteration of microbial metabolites in PD have been increasingly reported. Alterations in the composition and abundance of gut microbiota can affect both the enteric nervous system and the central nervous system (CNS), indicating the existence of a microbiota-gut-brain axis and thereby contributing to neurodegenerative diseases, including PD. This alteration in the gut microbiota may be related to the cause or effect of motor or non-motor symptoms in PD, but the specific pathogenic mechanisms are unclear. Case-control studies show changes in gut microbiota composition in PD patients compared with healthy individuals, and there are suggestions of a link between microbiota alterations and disease progression. Indeed, in a randomized clinical trial, probiotic products consisting of *Lactobacillus acidophilus*, *Bifidobacterium bifidum*, *Lactobacillus reuteri*, and *Lactobacillus fermentum* were administered to PD patients over a 12-week period, which resulted in beneficial effects on MDS-UPDRS, C-reactive protein, blood glutathione, and insulin metabolism, pointing to a potential association between modification of the gut microbiome and its long-term effect on PD pathophysiology.[6] A recent systematic review of 64 studies showed a strong Mediterranean diet was associated with a lower risk of AD and PD, and due to its high fiber natures, a change in the gut microbiota was observed, where one family, eight genera, and three species had an inverse relationship with the Mediterranean diet and PD. Conversely, weak Mediterranean diet adherence, gut dysbiosis, and PD were suggested to be in a chain of causality.[7] However, the exact mechanism remains to be elucidated, and more studies are needed to investigate the characteristics of microbiota composition with the aim of discovering new biomarkers for the prevention, early diagnosis, or monitoring the disease progression.

There is a strong association between dairy consumption and PD. In a large prospective study of the association between intake of dairy products and risk of PD among 57,689 men and 73,175 women from the American Cancer Society's Cancer Prevention Study II Nutrition Cohort, dairy product consumption was positively associated with risk of PD. Meta-analysis of all prospective studies confirmed a moderately elevated risk of PD among persons with high dairy product consumption. Compared with the lowest quintile of consumption, those with the highest consumption of dairy had a 60% higher risk of developing PD (95% CI: 1.3, 2.0) for both sexes, 80% for men (95% CI: 1.4, 2.4), and 30% for women (95% CI: 0.8, 2.1). These data suggest that dairy consumption may increase the risk of PD, particularly in men.[8] Recently, Mendelian randomization indicated a causal relationship between dairy intake and higher PD risk, not biased by confounding or reverse causation[9]

81.3 SLEEP

One of the most common non-motor symptoms of PD is sleep disturbance, which is experienced regardless of the disease stage and has a major impact on the quality of life of patients.[10] Sleep disturbances can occur in some cases over two decades before the diagnoses of PD such as REM behavioral disorder (RBD).[11] PD affects the control of sleep and wakefulness, which results in the development of disorders such as insomnia and excessive daytime sleepiness (EDS). On the other hand, sleep disturbances can be iatrogenic due to medications.[12]

With the prevalence ranging from 30–80%, insomnia is the most common sleep disorder in such patients. An individual with insomnia finds it difficult to initiate, maintain, or consolidate sleep or to generate a good quality of sleep overall. Patients report sleep interruption and early awakening more than sleep initiation problems. Furthermore, insomnia is associated with nocturnal hypokinesia, dystonia, mood disorder, and pain which can disrupt sleep.[13] Identifying possible causes of insomnia in PD is the first step in managing it, for this, patients should be evaluated for potential nocturnal motor symptoms and mood disorders as well.

EDS is defined by difficulty staying awake and alert during the day, resulting in unintentional episodes of sleep or drowsiness. Its prevalence ranges from 20–75% among PD patients and increases with the disease progression. Dopamine agonists are the most often responsible medications and have been widely connected to EDS and sleep attacks. Physicians should also consider polysomnography to screen or test for comorbid sleep disorders such as obstructive sleep apnea, restless leg syndrome (RLS), and RBD.

RLS is a common sleep disorder found in PD with the prevalence estimated to range from 8–24%. RLS is defined as an urge to move the legs due to sensory discomfort. It may be associated with iron deficiency or exacerbated with medications used to treat motor and non-motor symptoms of PD including antidepressants with serotonergic activity and antihistamines; however, there is not a consensus statement yet.[14] Therefore, it is essential to look for low serum ferritin or medications potentially responsible.

RBD is a parasomnia that arises out of the REM stage, leading to skeletal muscle paralysis which causes patients to act out their dreams. RBD prevalence is estimated to be 2% in the general population[15] and up to 23.6% in PD patients.[16] The underlying pathophysiology for loss of REM atonia is believed to be the accumulation of alpha-synuclein in pontine nuclei. RBD is linked to a worse prognosis for PD and there is a chance of more severe cognitive impairments, hallucinations, and motor dysfunctions in patients with concomitant RBD.[13]

There is no doubt that sleep contributes to the maintenance of physical and neurological health. Neurologic function may be negatively impacted by sleep disturbances, which can range from circadian misalignments to high levels of day-to-day variability in sleep schedule to sleep disorders[17] The discovery that sleep deprivation impairs the elimination of potentially neurotoxic chemicals (such as beta-amyloid and tau) has significance for the etiology of neurodegenerative diseases.[18] In order to improve the neurologic health and function of patients, not only insufficient quantity but also insufficient quality of sleep must be managed.

81.4 EXERCISE

For the first time in 2005, Praag et al. discovered that exercise could boost cognition, spatial learning, and neurogenesis in old mice.[19] Since then, it has now been demonstrated that exercise, even low-commitment exercise programs, has a wide range of positive impacts on the human brain, including memory, mood, cognitive functioning, plasticity, and learning capacities.[20–22]

Physical activity is a key component of rehabilitation programs for patients with PD, currently recommended as a strategy to manage the disability induced by the disease. Exercise is an important therapy technique for managing PD's motor and non-motor symptoms.[23] Various types of exercise-based interventions including aerobic and strength training have been extensively studied through clinical trials. The review of these studies suggests that conventional exercise training positively impacts disease severity, motor disorders, activity performance, and non-motor impairments.[24] In recent studies, novel forms of exercise such as aquatics, tai chi, dance, Nordic walking, and other complementary therapies have shown promising health effects on PD.[25] According to the World Health Organization (WHO), older adults (age >65 years) should complete a minimum of 150 minutes of moderate or 75 minutes of vigorous-intensity aerobic exercise per week. However, a great majority of healthy older adults do not engage in this weekly minimum activity level. As we know, following PD, activity levels abruptly decline and are much lower than those of healthy peers. Patients should consult with their healthcare provider before beginning any exercise plan to be sure they can safely engage in and continue any exercise intervention.

Due to movement disorders attributed to PD, there is a need for an adjusted guideline for the patients. Yet, little is known about the modality, frequency, and intensity required to control symptoms. Guidelines for obtaining the possible disease-modifying effects of exercise have been published by the SPARX2 and Park-in-Shape trials.[26,27] Based on these protocols, PD patients should exercise three times a week; however, it is unknown if exercising more frequently will produce better results. One should consider that after four weeks of inactivity, the short-term exercise-induced improvements in motor symptoms subside. Like anti-parkinsonism drugs, exercise must be included in patients' routines to have long-term effects. Regarding the intensity, patients are recommended to exercise at a level between 70 and 85% of their maximal heart rate. To put that in context, the level of exercise should be raised if a person is able to talk while exercising. In addition, exercise sessions should last 30 to 40 minutes to be sufficient for the primary exercise set. Walking and stationary cycling are the two forms of aerobic exercise that are most frequently mentioned in PD studies. In a setting where most people show gait and balance impairments early in the disease process, stationary cycling could be a safer alternative and lessen the risk of falling.

Since every individual with PD requires specific treatment, it is likely that every patient should have a different prescription for a successful training schedule. Therefore, if exercise is to be used as medication, we need to give each patient a precise "dosage" that may have recognized consequences.

81.5 STRESS MANAGEMENT

Neurodegenerative diseases such as PD are influenced by both acute and chronic stress. Aside from repetitive chronic stressors, single acute stressors can cause structural and functional alterations in neurons. The brain is vulnerable to oxidative stress because it uses chemically varied reactive species to fulfill heterogeneous signaling activities.[28] Acute stress exacerbates motor symptoms such as tremors, freezing, and dyskinesia and reduces the effects of dopaminergic drugs. On the other hand, depression and anxiety disorders are more likely to happen during chronic stress. There is data suggesting an increase in cortisol levels in PD patients, indicating these patients are more vulnerable to stress effects.[29] Recently the COVID-19 pandemic has been a significant stressor worldwide and PD patients with higher COVID-related stress load exhibited more severe motor and non-motor dysfunctions, which is likely due to psychological distress and lack of physical activity. In a recent online

survey performed on a large PD population, stress reduction strategies especially mindfulness have been studied[30] Mindfulness is defined as moment-to-moment non-judgmental awareness. The effects of mindfulness-based interventions (MBI) on psychological distress reduction and symptom improvement in several chronic conditions have been demonstrated. Patients were evaluated in terms of how often they used mindfulness in their daily lives, as well as the self-reported effects that mindfulness had on their symptoms. Mindfulness was practiced by 38% of patients who reported improvement in their motor and non-motor symptoms. They concluded mindfulness may influence PD symptom severity with the greatest effects on depression and anxiety.

A review study consisting of eight articles evaluating the effects of MBI on the clinical symptoms of PD patients was published in 2020. Surprisingly, six out of eight studies reported a decrease in depression and four out of seven showed a reduction in anxiety scores. Only three trials studied motor symptoms and two of those found a substantial improvement following MBI. Two out of eight studies found a significant effect on quality of life in patients.[31]

Impaired self-awareness for motor symptoms in PD is related to lower therapy adherence, higher caregiver burden, and mortality rate. Buchwitz et al. developed a protocol for a newly designed MBI to raise self-awareness in PD. "Insight into Parkinson's Disease Symptoms by Using Mindfulness" or IPSUM is an eight-week program exclusively planned for PD patients. It is expected that this new method can improve self-awareness for both motor and cognitive symptoms. There are a number of criteria necessary for mindfulness training to be a successful method of raising self-awareness in PD patients. For instance, patients' perceptions of their own bodies may change if they are taught how to express their perceptions rather than judge them. As individuals begin to pay more attention to the here and now (during mindfulness exercises), they ought to become more conscious of their bodily movements, posture, and other interior feelings (thoughts and emotions). By being more accepting of oneself and their condition, consistent mindfulness meditation practice, increased management of negative emotions, and attention training, this perceptional shift may be easier to achieve and sustain.[32]

81.6 COGNITIVE-BASED INTERVENTIONS

Compared with the general population, PD patients have an up to six times higher prevalence of cognitive impairment.[33] They may experience a complete spectrum of impairment, from subjective cognitive decline to dementia.[34] Despite increased research over the past two decades, cognitive difficulties in PD remain poorly understood; however, there are interventions designed to improve or maintain patients' cognition commonly called cognition-based interventions (CBI).[35] CBI is divided into three categories: cognitive training, cognitive rehabilitation, and cognitive stimulation. For instance, cognitive stimulation provides a variety of enjoyable activities that stimulate general thinking, concentration, and memory, usually in a small group of people.

A recent systematic review including 11 randomized clinical trials (all with cognition therapy) reported encouraging findings. Nine out of 11 studies showed positive impacts on cognition, particularly on various executive functions and attentional performance.[35]

One of the interesting stimulations investigated is playing chess. Research shows a link between playing chess and reducing the risk of dementia[36] Five cognitive domains are covered by this practice mind sport: math, visual-spatial skills, critical thinking, and short- and long-term memory use. An experiment performed on 500 patients over five years showed those who regularly played board games had a nearly 35% lower risk of dementia compared with individuals who did so sometimes or never. In fact, those over 75 who engaged in brain-stimulating hobbies like chess had a lower risk of developing dementia[37] Chess appears to be a treatment that works to prevent or protect before disease onset; however, there is limited information on chess' advantages once an illness has been recognized and diagnosed.

CLINICAL APPLICATIONS

- The main risk factor for the onset and progression of Parkinson's disease is age and numerous cellular processes predisposed to neurodegeneration are affected by aging.
- A number of low-risk and potentially high-yield recommendations for lifestyle modification could be made to minimize the individual and societal burdens of Parkinson's disease, including dietary modifications, increasing physical activity, and stress management.
- A healthy dietary pattern has been shown to contribute to a lower risk of PD.
    - The dietary pattern most extensively associated with a lower risk of PD is essentially a plant-based pattern with a high intake of fruits, vegetables, legumes, whole grains, nuts, and fish, and a low intake of sources of saturated fat from meat and dairy products, refined carbohydrates, and alcohol.
    - The Mediterranean dietary pattern has been associated with a reduced risk of PD development.
    - Alterations in the composition and abundance of gut microbiota can affect both the enteric nervous system and the central nervous system, indicating the existence of a microbiota-gut-brain axis and thereby contributing to neurodegenerative diseases, including PD.

- Meta-analysis of all prospective studies confirmed a moderately elevated risk of PD among persons with high dairy product consumption.
- One of the most common non-motor symptoms of PD is sleep disturbance, which is experienced regardless of the disease stage and has a major impact on patients' quality of life.
  - Identifying possible causes of insomnia in PD is the first step in managing it, for this, patients should be evaluated for potential nocturnal motor symptoms and mood disorders.
  - The discovery that sleep deprivation impairs the elimination of potentially neurotoxic chemicals (such as beta-amyloid and tau) has significance for the etiology of neurodegenerative diseases.
- Physical activity is a key component of rehabilitation programs for patients with PD, currently recommended as a strategy to manage the disability induced by the disease. Frequency of exercise is three times a week and each session should last 30 to 40 minutes.
  - Novel forms of exercise such as aquatics, tai chi, dance, Nordic walking, and other complementary therapies have shown promising health effects on PD.
  - Walking and stationary cycling are the two forms of aerobic exercise that are most frequently mentioned in PD studies.
  - In a setting where most people show gait and balance impairments early in the disease process, stationary cycling could be a safer alternative and lessen the risk of falling.
- Acute stress exacerbates motor symptoms; however, depression and anxiety disorders are more likely to happen during chronic stress. The effects of mindfulness-based interventions on psychological distress reduction and symptom improvement in PD have been demonstrated.

82 Sleep and Lifestyle Medicine

Param Dedhia, MD, Farah Wahbeh, and Dean Sherzai, MD, PhD, MPH, MAS

KEY POINTS

- Restorative sleep is a cornerstone of lifestyle medicine and contributes to our physical, mental, emotional, and spiritual well-being.
- Sleep disorders are increasingly common, and pharmacological interventions have proven insufficient to treat sleep disorders in the long term.
- Our sleep is significantly influenced by daytime habits like the consumption of caffeine, alcohol, and tobacco, as well as diet, light exposure, and exercise.
- With age, sleep becomes less restorative; hence, it is essential to address unhealthy lifestyle habits to ensure restorative sleep and promote optimal health and healing.
- Sleep disturbances result in mental, emotional, and physical fatigue and are associated with disease and illness ranging from cellular damage to organ malfunction.
- Insufficient sleep increases the risk of obesity and heart disease, especially in patients with diabetes.
- Sleep disturbances accelerate the progression of neurodegenerative disorders, have the potential to trigger seizures, and increase the risk of stroke.
- Bidirectional relationships exist between sleep disorders and psychiatric conditions like depression and anxiety. Sleep is a common comorbidity in patients with ADHD.

82.1 INTRODUCTION

Sleep is critical for maintaining health, especially brain health. As with nutrition and physical activity, sleep is among the cornerstones of lifestyle medicine for optimal physical, mental, and emotional well-being.

There is plenty of data demonstrating the bidirectional relationship between sleep and health; poor sleep increases the risk of disease and illness, and conversely, many diseases disrupt sleep. This can lead to a vicious cycle culminating in worsened morbidity and mortality. Research has demonstrated that a minimum of seven hours of deep restorative sleep is essential for memory consolidation, and much of the cleansing is done through a remarkable system called the glymphatic system.[1] Furthermore, there is significant evidence that individuals who have insufficient depth or quantity (seven to eight hours) of sleep are susceptible to cognitive decline, depression, and anxiety, and are at greater risk of developing dementia.[2–5] Cumulative effects of disordered sleep include early mortality, cardiovascular disease, hypertension, obesity, metabolic syndrome, diabetes and impaired glucose tolerance, immunosuppression, inflammation, cancer, cognitive impairment, and psychiatric disorders, with anxiety and depression being the most common.[6] Despite our greater awareness, it is apparent that the prevalence of sleep disorders is increasing, which may speak to our worsening lifestyles.

To date, we have many tools in our armamentarium to address sleep disorders such as insomnia, restless legs syndrome, sleep apnea, and other conditions. Nevertheless, our approaches, whether pharmaceutical, for insomnia or restless legs syndrome, or appliance-based, for sleep apnea, have been nominal and often fail to reverse the underlying causes of the conditions and do not address the preventive component of these conditions.[7,8]

In this chapter, we hope to provide insight into the tremendous impact of lifestyle on our sleep and its role in avoiding sleep disorders, which are devastating millions worldwide.

82.2 SLEEP DEFINITION AND ITS STAGES

A healthy sleep architecture consists of repeated cycles of around 90 minutes of rapid eye movement (REM) and non-REM stages of sleep through the night. Healthy restorative sleep typically consists of approximately four to six of these cycles. All stages do not need to occur in every sleep cycle; however, optimal sleep needs all stages to occur throughout the night. Each sleep stage in any given sleep cycle contributes to physiological changes that promote brain health. On average, most adults require about seven to eight hours of sleep, although this range varies based on age and genetic predisposition.

Non-REM sleep consists of a continuum of three separate stages (stage 1, stage 2, and stage 3), with each stage progressively "deeper" from a neurophysiological perspective. In non-REM, each "deeper" stage of sleep leads to further reductions in blood pressure and heart rate while rhythmic breathing patterns and heart rate continue. In stage 3 of sleep, there is increased blood supply to muscles, while the energy in the form of adenosine triphosphate (ATP) is restored, and growth hormone is released to promote growth, development, and repair.[9–11]

Sleep patterns change as people age, and sleep disorders become more common as we get older. As many as 57% of older adults have reported complaints of poor sleep.[12–15]

DOI: 10.1201/9781003227793-97

Changes in sleep architecture also occur with aging. In particular, sleep tends to become less restorative as older adults spend an increasing percentage of sleep in stages 1 and 2 and a decreasing percentage of time in deep sleep (stage 3) and dream (REM) sleep.[16–18] Thus, awareness of sleep disorders and lifestyle factors that can potentially disrupt sleep is critical.

Insufficient sleep is often termed sleep deprivation and leads to sleep debt (also called sleep deficit). Sleep debt often results in varying expressions of mental, emotional, and physical fatigue, ultimately leading to difficulties in daily activities, especially those requiring high-level cognitive functions. Similar to ethanol, sleep deprivation leads to impaired judgment and reduced insight. Beyond reduced alertness and insight, symptoms of sleep deprivation include lapses in attention, poor short-term memory, errors by omission, reduced ability to multitask, irritable mood, aggressive behavior, or daytime sleepiness. Physical manifestations of sleep debt include impaired coordination, reaction time, muscle fatigue, hand tremors, lowered body temperature, increased blood pressure, increased stress hormone levels, and increased heart rate variability. Sleep debt tends to accumulate; about two weeks of less than six hours of sleep per night reduces alertness and performance to a level equivalent to 24 hours of sleep deprivation. A week or more of only four hours of sleep each night creates errors in attention-oriented tasks equivalent to two to three days without any sleep.[19] Only sleep reverses the harmful effects of sleep deprivation. Therefore, recovery from sleep loss depends on the consistency of proper restorative sleep.

82.3 COMMON SLEEP DISORDERS

Nearly all of us will experience some sleep disorder during our lifetime. There are over 100 different types of sleep disorders ranging from difficulty sleeping at night to problems with excessive daytime sleepiness. This chapter will focus on the most common lifestyle-responsive sleep disorders.

Sleep apnea is estimated to be prevalent in 15–30% of males and 10–15% of females in North America.[20,21] There are two types of sleep apnea (obstructive and central), with the most common type (>85%) being obstructive sleep apnea (OSA). OSA is characterized by complete or partial collapse of the upper airway for ten seconds or longer repeatedly throughout the night. Although all persons are subject to relative relaxation of the soft tissues in the airway during sleep, in OSA, these tissues create a blockage of the upper airway sufficient to limit airflow and disrupt sleep-related breathing. Moreover, when the airway is blocked, the drop in oxygen levels in the blood leads to arousal and disturbed sleep architecture. Because these awakenings or alterations of sleep state are often brief, there is often no awareness that they occur during sleep. The awakenings repeat during the night, and in severe sleep apnea, 30 or more awakenings occur per hour over one night of sleep. Even though the awakenings are usually very short, the fragmentation and interruption of sleep along with the reduction of oxygenation have a significant and negative impact on health.[22–24] In central sleep apnea (CSA), prolonged breathing pauses lead to hypoventilation and hypoxemia syndromes. These are due to dysregulation and lack of cueing from the central nervous system that would otherwise continue involuntary breathing. As a result, there is no drive to initiate and complete a breath for ten seconds or longer. This process fragments sleep quantity and quality similar to OSA even though the mechanisms are different.[25]

Periodic limb movement disorder (PLMD) is a sleep disorder characterized by the rhythmic movements of the limbs that possibly fragment the quantity but more often disrupt sleep quality. A type of PLMD is *Willis-Ekbom Syndrome* (previously referred to as restless legs syndrome). This sleep disorder is characterized by sensorimotor discord when resting or lying down to sleep, resulting in discomfort, aching, jerking, twitching, tingling, or creeping-crawling sensations, thereby leading to an irresistible urge to move or shift the legs, arms, or torso. Etiologies include iron and vitamin B12 deficiency, third trimester of pregnancy, abnormal blood sugar, thyroid disorders, renal disease, and Parkinson's disease.[26,27]

Insomnia is the most common of all sleep complaints. It is a sleep disorder characterized by difficulty falling asleep, staying asleep, or experiencing restorative sleep for at least one month, ultimately leading to daytime dysfunction or disturbance. Etiologies include poor sleep habits such as late-night eating, stress, medical comorbidities, psychiatric comorbidities including anxiety and depression, medication effects, caffeine, nicotine, or another sleep disorder.[28,29]

82.4 ASSOCIATION OF DISRUPTED OR DISORDERED SLEEP WITH DISEASE AND ILLNESS

Building upon the appreciation of the underlying physiology of sleep and its inherent opportunities, the importance of sleep relates not only to the public's health but also to individuals' health and wellness. Sleep is associated with health and healing, whereas disrupted and disordered sleep is associated with disease and illness. The majority of medical literature has drawn associations between premature all-cause mortality and both shorter (less than seven hours) and longer sleep (more than eight hours).[30,31] Research connects health and sleep by demonstrating the impact of sleep spanning the continuum of cellular health to organ systems. Moreover, sleep impacts health and healing not only on the physical level but also on the mental and emotional levels.

82.4.1 Endocrine System and Sleep

Poor sleep impacts the neurochemistry of hunger[32] as well as hormonal health. Sleep deprivation alters the pattern of growth hormone release, and the timing of cortisol rise can be disrupted by sudden changes in the sleep-wake cycle.[33]

82.4.2 Obesity and Sleep

Adults with shorter sleep durations and sleep loss are at increased risk of becoming obese.[34–36] This association can be explained by the neuroendocrine functions modulated by sleep, which when disrupted, lead to increased levels of ghrelin, decreased levels of leptin, increased appetite, decreased glucose tolerance, and insulin sensitivity, ultimately leading to increased fat accumulation.[35]

82.4.3 Heart Disease and Sleep

Short sleep durations increase the risk of cardiovascular disease, hypertension, and myocardial infarctions. Long sleep durations, on the other hand, are not associated with these risks.[37] Among the common sleep disorders, obstructive sleep apnea is an independent risk factor for hypertension, ischemic heart disease, and even stroke.[38] In patients with type 2 diabetes, disturbances to sleep quality or quantity significantly increase the risk of cardiovascular disease and all-cause mortality.[39]

82.4.4 Autoimmune Disorders and Sleep

Sleep disorders are associated with autoimmune disorders such as systemic lupus erythematosus (SLE), rheumatoid arthritis, and systemic sclerosis.[40]

82.4.5 Neurological Disorders and Sleep

Poor sleep accelerates the progression of major neurodegenerative disorders like Parkinson's disease and Alzheimer's disease, possibly by impairing the clearance of misfolded neurotoxin proteins involved in the pathogenesis of these disorders.[41,42] Epilepsy is another neurological disorder linked to sleep. Sleep deprivation decreases GABA-mediated inhibition, thereby reducing the seizure threshold and triggering epileptic seizures.[43] Importantly, clinically induced sleep deprivation is of high diagnostic utility in epilepsy.[43] In addition to neurodegenerative disorders and epilepsy, stroke is also linked to sleep. Sleep disturbances, including sleep-disordered breathing and disrupted sleep durations, increase the risk of stroke and are also worsened post-stroke.[44] For instance, insomnia patients have a 54% increase in stroke risk, and conversely, half of stroke patients suffer from insomnia. [44,45]

82.4.6 Psychiatric Disorders and Sleep

Many psychiatric conditions are linked to sleep disturbances including depression, anxiety, and ADHD. A bidirectional relationship exists between sleep disturbances and depression. In patients with depression, comorbid insomnia increases the severity and duration of depressive episodes and increases risk of relapse.[46] In patients without depression, having insomnia increases their risk of developing depression.[46]

Similar to depression, sleep disturbances are known to be cardinal symptoms of anxiety disorders. Sleep disruption in the short term increases stress responsivity and anxiety, and has been shown to increase risk of substance abuse.[47,48]

Patients with ADHD commonly have comorbid sleep disorders which lead to significant functional impairments that affect day-to-day functioning.[49] Childhood ADHD that persists into adulthood is significantly associated with poor sleep quality.[50]

82.5 INTERVENTIONS AND TREATMENTS FOR DISRUPTED AND DISORDERED SLEEP

82.5.1 Treatment of Sleep-Related Breathing Disorders

Given the complex nature of sleep apnea, as it pertains to its causes and especially treatments, our approach needs to be detailed and personalized. First, a thorough clinical evaluation with an interdisciplinary team and sleep testing is required so patients are ensured appropriate treatment options. Treatment options can be divided into non-surgical and surgical approaches. By convention, non-surgical approaches are thoroughly reviewed before considering surgical intervention.[51]

Non-surgical approaches for obstructive sleep apnea begin with treating underlying medical conditions, positional therapy, and lifestyle modifications, focusing on nutrition and exercise. Pharmacotherapy directed toward underlying allergic rhinitis or hypothyroidism may be helpful in combination with other therapies.[52, 53] For central sleep apnea, narcotic medications may be a contributor, and thus it is necessary to review medications and propose alternative regimens. Depending on polysomnogram results, positional therapy such as avoiding the supine sleep position can be efficacious.[54–58] Such an approach may improve snoring and resolve or reduce the severity of sleep apnea. A typically helpful lifestyle discussion prioritizes healthy body weight and judicious intake and timing of alcohol.

Nasal dilators and mandibular advancement devices demonstrate promising results for mild and positional sleep apnea. Nasal dilators are particularly helpful for patients suffering from uncomplicated snoring and nasal obstruction. Mandibular advancing devices contract the genioglossus and anteriorly forward the mandible and hyoid bone to increase the oral airway during sleep.[59]

Positive airway pressure (PAP) is the treatment of choice for moderate and severe sleep-related breathing disorders, including obstructive sleep apnea, central sleep apnea, and sleep-related hypoventilation. The most common form—continuous positive airway pressure (CPAP)—maintains a constant level of PAP in a spontaneously breathing patient. Other forms that provide non-invasive positive pressure ventilation include auto-adjusting PAP (autoPAP), bilevel positive airway pressure (Bilevel PAP), adaptive servoventilation (ASV), and volume-assured pressure support (VAPS)[60].

82.5.2 Treatment of Periodic Limb Movements (Willis-Ekbom Disease)

Therapeutic interventions for Willis-Ekbom disease, a neuro-sensorimotor disorder (better known by its previous name, restless legs syndrome), are contingent on the underlying etiology. The challenge lies within the varied causes of genetics and environmental factors. Willis-Ekbom disease is a continuous spectrum with a significant genetic contribution at one end and a major environmental or comorbid disease contribution at the other. Previous research suggests that the involved genes are significantly expressed in the primary form of the disease (idiopathic) and the comorbidities that are the roots of the secondary forms of RLS (Trenkwalder et al., 2016). In up to 42% of cases, genetic factors contribute to the etiology of Willis-Ekbom Disease.[61]

The most common secondary forms are linked to iron deficiency, pregnancy, Parkinson's disease, and end-stage renal disease.[62] Other associations include vitamin and mineral deficiencies, thyroid disorders, cardiovascular disease, arterial hypertension, diabetes, neuropathy, erectile dysfunction, arthritis, rheumatic illnesses, multiple sclerosis, migraine, fibromyalgia, mood disorders, attention-deficit hyperactivity disorder, liver disease, obesity, narcolepsy, and other sleep disorders.[63] Ultimately, most presentations of Willis-Ekbom disease are treated with pharmacology (dopamine agonists, gabapentin, or low-potency opioids).[64] Additional options seek to reduce the excessive periodic limb movement and their arousals by treating an accompanying sleep disorder if present. A newer approach uses a medical device to enhance peripheral circulation with pneumatic compression or introduce counter-stimulation by vibration.[65]

82.5.3 Treatment of Insomnia

Although more than half of primary care patients may experience insomnia, only about one-third report this problem to their physicians,[66] and only 5% seek treatment.[67] As a result, most persons with insomnia remain untreated.[68] Given the fast pace of primary care visits, it is not surprising that two-thirds of patients with insomnia report a poor understanding of treatment options, and many turn to alcohol (28%) or untested over-the-counter remedies (23%) [67]. Given the limited time available for each patient visit in the primary care setting, treatment approaches may rely primarily on pharmacological interventions. This approach takes away the opportunity to help patients live whole lives by discussing underlying issues that contribute to their insomnia. Non-benzodiazepine receptor agonists such as eszopiclone, zolpidem, and orexin antagonist suvorexant may improve short-term global and sleep outcomes for adults with insomnia. However, pharmacotherapies' comparative effectiveness and long-term efficacy for insomnia are unknown. Benzodiazepine hypnotics, melatonin agonists, and antidepressants may be helpful in general populations and for most pharmacologic interventions in older adults in select individuals. However, there is insufficient data about the potential of these medications to be widely helpful. In general, pharmacotherapy is intended for short-term use. Hypnotics may be associated with dementia, fractures, and significant injury. The Food and Drug Administration warns about cognitive and behavioral changes, iatrogenic illness or accidents, including driving impairment, and other harms, and advises lower doses for females and older adults.[8,69]

The therapy paradigm starts with etiology: comorbid insomnia due to another sleep disorder or a medical disorder that requires treatment of the underlying process, or the more common psychophysiological insomnia requiring cognitive and behavioral approaches. Herein set the opportunity for cognitive behavioral therapy for insomnia (CBT-I), which has been well-established and evidence-based as an efficacious treatment for insomnia.[52,70–72] CBT is commonly prescribed for depression, but clinical trials have shown it is the most effective long-term solution for those with insomnia. The positive effects of CBT-I on sleep quality are robust over time.[73] In addition, CBT-I has been found to be efficacious in populations with a variety of comorbid medical conditions, including persons with comorbid insomnia,[74] comorbid psychiatric conditions,[75] and chronic pain.[76–80] CBT-I helps identify the negative attitudes and beliefs that hinder sleep and replaces them with positive thoughts, effectively "unlearning" the negative beliefs.[81] The behavioral aspect of CBT focuses on helpful sleep habits and avoids unhelpful sleep behaviors, as well as managing lifestyle and environmental issues. Behavioral techniques that may be recommended include stimulus control,[82] sleep restriction,[57] systematic desensitization,[83] sleep hygiene, sleep environment improvements, relaxation training,[84] paradoxical intention,[85] hypnosis,[86] and biofeedback.[87] CBT-I throughout six to eight weekly sessions[88–90] for most adults in either individual or group-based administration is effective,[79,91,92] yet vastly underutilized in comparison with pharmacological approaches.

82.6 INTEGRATIVE AND PREVENTIVE APPROACHES

First, the awareness and continued appreciation of the importance of sleep are essential for the best health and critical for preventing sleep disorders. In our ever more complex lives, we seek to expand the hours of the day, and as a result, sleep is treated as a mere luxury when it must be prioritized. Educating the public and our patients about the fundamental need for adequate sleep cannot be overstated. Like nutrition and exercise, restorative sleep is a prerequisite for optimal health and healing. Sleep not only positively impacts the physical body, but also promotes mental and emotional health.

Furthermore, it is essential to note that healthy sleep supports healthy eating and physical activity. Therefore, sleep both directly and indirectly benefits health. Conversely,

disrupted and disordered sleep negatively impacts health and healing opportunities. In this chapter, we have presented sleep and its connection with both public health and personal wellness. Sleep strongly correlates with cardiovascular disease, obesity, metabolic syndrome, diabetes, immune status, cancer, memory, pain control, and mental and emotional health. Although restorative sleep on its own may not be sufficient to prevent the development of these diseases entirely, it plays an essential role in reducing their severity and slowing their progression.

82.6.1 The Link between Nighttime and Daytime

Sleep quality is impacted by time spent in bed and the entire 24 hours of the day; this means that our daytime lives impact our ability to fall asleep, stay asleep, and wake up refreshed for the new day. Many lifestyle interventions can be implemented to achieve a greater quality of sleep; these relate to caffeine, alcohol, tobacco, unhealthy eating patterns, excessive light exposure, and lack of exercise.

82.6.2 Sleep and the Digital Environment

The world as we know it has expanded with artificial light and electronics. Despite the significant advancement, this has been at the cost of sleep quantity and quality. Exposure to light, mainly blue light, acts upon several non-image-forming (NIF) functions of the visual system. They impact sleep by directly acting on the sleep-wake cycle and indirectly by influencing body temperature, hormonal balance, alertness, and cognitive processing—these, in turn, negatively impact sleep.[93] NIF functions are maximally sensitive to blue wavelengths (460–480 nm), which are involved in melatonin suppression, vigilance, and stimulating mental activity.[94,95] Blue light exposure one to two hours before bed reduces sleep onset, REM duration, and overall perception of sleep quality. Sources of blue light include artificial lighting and digital screens (televisions, computers, tablets, and phones). Herein lies the opportunity to honor the benefits that lighting and electronics have added to our lives. However, limiting light exposure to specific times is a new opportunity to ensure healthy sleep.

82.6.3 Sleep and Caffeine

Caffeine is a standard part of many of our lives, as witnessed by morning coffee and tea rituals and the surge in energy drinks among younger adults. Unfortunately, caffeine has a discernible impact on sleep that can significantly affect restorative sleep.[96] Caffeine blocks the adenosine receptor in the central nervous system, which is involved in sleep induction and deep sleep regulation. Caffeine has a half-life of three to seven hours, depending on an individual's cytochrome p450 1A2 genotype expression. Despite the recognized antioxidant benefits of coffee and tea, the timing and quantity of caffeine consumption are essential to consider when it comes to sleep quality. According to the 2001 *Sleep in America* poll by the National Sleep Foundation, 43% of Americans are "very likely" to use caffeinated beverages to combat daytime sleepiness. This, in turn, creates a vicious circle of poor sleep leading to daytime sleepiness, which leads to increased caffeine consumption. The opportunity is to focus on the timing and quantity of caffeine consumption in our daily lives so that it can be a promoter and not a disruptor of our best sleep.

82.6.4 Sleep and Alcohol

Alcohol is commonly used worldwide as a sleep aid.[97] Regrettably, this is neither helpful nor recommended based on its effects on sleep. Whereas in the short term, it helps induce sleep, this effect tapers in a series of days and weeks depending on the individual's hepatic clearance. The impact of ethanol on sleep staging demonstrates a reduction in sleep quality in the second half of the sleep night. Alcohol has physiological effects on sleep, such as airway relaxation and narrowing, negatively impacting sleep-related breathing, such as obstructive sleep apnea. Ethanol demonstrates a dose effect on both its impact on sleep staging and the physiology of breathing during sleep. As with caffeine, the opportunity is to balance the timing and quantity of ethanol in our daily lives so that it does not interfere with healthy sleep.

82.6.5 Sleep and Tobacco

Tobacco has multiple hazards to optimal health. In addition to its addictive potential, tobacco adversely affects the quantity and quality of sleep. Nicotine shifts the circadian rhythm by altering the expression of clock genes.[98] People who smoke tobacco are more than twice as likely to have obstructive sleep apnea. The airflow limitation is partly due to the inflammatory effect on the nasal and oral airways.[99] Tobacco use leads to difficulty initiating sleep due to its stimulant and withdrawal effects.[100] Those who smoke tobacco are more likely to experience restless sleep due to more time spent in the light sleep stages than the deep and REM sleep stages.[101] It is thus critical to universally promote the idea that tobacco cessation is vital for public health and for restorative sleep.

82.6.6 Sleep and Nutrition

Eating patterns and food choices influence overall health as well as sleep health. Individuals consuming an excessive number of calories report short sleep time and quality.[102] Refined carbohydrates such as sugars act as stimulants in the body and influence a wide range of neurotransmitter shifts that make falling asleep and staying asleep more difficult.[103] Individual variance in food tolerance to spicy foods and dairy also impacts the ability to physically be soothed to be able to sleep. Large meals eaten close to bedtime typically disrupt sleep onset and quality. As discussed earlier, poor sleep creates the hormonal and neurochemical basis for food cravings. Again, we see the vicious circle of poor

sleep leading to overconsumption and poor food choices limiting restorative sleep. The opportunity to support healthy nutrition also supports healthy sleep.

82.6.7 Sleep and Exercise

National Sleep Foundation's 2013 Sleep in America poll highlighted the association between exercise and better sleep. A physically robust daytime utilizes our ATP resources such that the cleaving of the phosphate bonds results in a higher amount of adenosine by bedtime. Again, adenosine promotes sleep induction and deep sleep stages. Exercisers, compared with non-exercisers, are more likely to report restorative sleep. Poor sleep makes us less likely to exercise, which in turn leads to relative difficulty falling asleep, falling back asleep in the middle of the sleep night, and waking up too early.[104–107] Thus, there is a vicious circle of reduced physical activity and reduced sleep. Although the timing of exercise has been widely debated, it is likely based on individual experience.

82.6.8 Sleep and Lifestyle Medicine

Lifestyle changes have been relatively easy to state but not always easy to translate into the context of people's lives. Lifestyle interventions go above and beyond by seeing our patients physically, mentally, emotionally, and spiritually. Ultimately, it is understood and appreciated that these dimensions do not reside in different silos of thought or experience but are integrated into our daily lives. With this approach, we can address not only what is helpful but an opportunity to address how and why the current habits are in place. It is this approach that helps people enhance their sleep and their lives. Sleep is a key to health, and lifestyle is an essential path to health and sleep.

82.7 SUMMARY

Restorative sleep is among the cornerstones of lifestyle medicine for optimal health. Lifestyle medicine incorporates the full spectrum of factors that contribute to the quality of sleep relating to all aspects of our daily lives—physical, mental, emotional, and spiritual. The prevalence and incidence of sleep disorders, which adversely affect health in the short and long term, are rising. Although effective in the short term, pharmacological interventions are insufficient on their own for the treatment of sleep disorders. Given that our sleep quality is impacted by the entire 24 hours of the day, it is crucial to address our daytime habits that may reduce our sleep quality. Lifestyle medicine focuses on lifestyle habits while also considering underlying medical conditions to prevent disease and illness.

CLINICAL APPLICATIONS

- Sleep tends to become less restorative as we age; therefore, seeking opportunities to maintain healthy sleep and address lifestyle factors that disrupt sleep is crucial.
- Sleep debt results in mental, emotional, and physical fatigue, causing difficulties in daily activities requiring high-level cognitive functions.
- Our awareness of our cognitive and physical deficits resulting from sleep debt often fades with continued sleep deprivation, leading to reduced alertness and functionality.
- Disordered sleep is associated with disease and illness, and the effects range from cellular damage to organ system malfunction. Sleep impacts health and healing not only on the physical level but also on the mental and emotional levels.
- Insomnia is the most common sleep disorder and is associated with lifestyle factors such as poor sleep hygiene and stress. Other common sleep disorders include sleep apnea (obstructive and central) and periodic limb movement disorder (PLMD) like Willis-Ekbom syndrome (aka restless legs syndrome).
- Given that research has shown that lifestyle interventions are essential to achieve a greater quality of sleep, it is vital to pay special attention to our daytime habits relating to caffeine, alcohol, tobacco, eating patterns, light exposure, and exercise:
  - Frequently consumed to combat daytime sleepiness, caffeine leads to poor nighttime sleep by impairing proper sleep induction and regulation of deep sleep. Poor sleep caused by caffeine consumption ultimately worsens daytime sleepiness, leading to a vicious circle.
  - Alcohol, a common sleep aid, may induce sleep but can significantly affect sleep quality. Alcohol also alters the physiology of breathing, which worsens sleep-related breathing disorders.
  - It is crucial to restrict the quantity and schedule the timing of alcohol and caffeine consumption to prevent these substances from disrupting sleep.
  - Nicotine leads to difficulty initiating sleep and increases time spent in light sleep stages by altering the expression of clock genes that regulate the circadian rhythm.
  - Consumption of spicy foods, sugar and dairy, large meals close to bedtime, or excessive calories leads to stimulant effects, making it difficult to fall asleep and stay asleep. This leads to short sleep time and reduced sleep quality. The resultant poor sleep increases unhealthy food cravings through hormonal and neurochemical mechanisms.
  - Blue light exposure from artificial lighting and digital screens close to bedtime reduces sleep onset, REM duration, and overall perception of sleep quality. Blue light exposure also disrupts

the visual system's non-image-forming functions, resulting in melatonin suppression, vigilance, and stimulating mental activity.
- Physical exercise in the daytime promotes restorative sleep by increasing the amount of adenosine in the body, which induces sleep and prolongs the duration of deep sleep stages. Conversely, poor sleep makes individuals less likely to exercise, leading to difficulty falling asleep, staying asleep, and early wake times.

83 Headache and Lifestyle Medicine

Charn Grewal, MD, Dean Sherzai, MD, PhD, MPH, and Kasra Maasumi, MD, MS

KEY POINTS

- Headaches are one of the most common and disabling conditions experienced globally.
- The most common primary headaches experienced are migraines, tension headaches, and cluster headaches.
- These various types of headaches can often be triggered by environmental and lifestyle factors.
- Increased levels of inflammatory markers in the body disrupt the body's homeostasis and thereby contribute to increased onset, frequency, and severity of headaches.
- Preventive treatment through lifestyle modifications is one of the most powerful tools to improve the quality of life for patients who experience chronic headaches.
- Leading a healthy lifestyle, exercising regularly, and abstaining from smoking can help prevent and reduce headaches.
- Foods with higher levels of omega-3 such as those from a plant-based diet like nuts, seeds, tofu, Brussels sprouts, and avocado help reduce inflammatory levels in the body
- Secondary headaches are rarer in comparison with primary headaches but include conditions such as brain tumors, cervical spine disorders or injuries, concussions, aneurysms, and meningitis.
- Supplements such as magnesium, riboflavin (B2), melatonin, feverfew, and vitamin D have been shown to be helpful for headache management.
- Management of medical conditions such as hypertension, high cholesterol, and insulin resistance/diabetes may help reduce the frequency and severity of headaches.

83.1 BACKGROUND

Despite headache disorders being one of the most common causes of functional

disability experienced by nearly all ages worldwide, headaches continue to be both underdiagnosed and undertreated throughout the world. In the United States, 35 million individuals annually suffer from migraines alone, an often severe and debilitating type of headache. Migraines affect about 18% of American women and 6% of American men. Women, especially those between 18 and 55 years old, are three times as likely as men to have a migraine.[1]

In comparison, nearly 75% of the population worldwide experienced a headache in the past year alone.[2] To date, we have developed several treatments for the various headache types, yet we have not been able to reduce the prevalence of these conditions tremendously. With headache diagnosis and pharmaceutical treatment being difficult and complicated, the focus on lifestyle change and management becomes all the more necessary, as there is growing evidence that lifestyle intervention can have a profound influence on most headaches.

In general, headaches are delineated into primary headaches, which are not caused by another condition, and secondary headaches, which are caused by other conditions such as brain tumors, aneurysms, meningitis, and or brain and neck injuries. The most common primary headaches are migraines, tension headaches, and cluster headaches. Although we currently have many pharmaceutical treatments for many of the headaches, we have also learned that many of the headaches have a significant lifestyle component that is often not addressed. In this chapter, we have reviewed the extant literature related to lifestyle and headaches and how healthcare providers can incorporate the following recommendations into their practice.

83.2 PRIMARY HEADACHES

The most common types of primary headaches include migraine, cluster headaches, and tension-type headaches.

83.2.1 Migraine

Migraines are the fourth leading cause of all emergency room visits reported in the United States.[3] Migraine headaches typically tend to affect women more than men and can be exacerbated by stress, physical exertion, fluctuations in hormone levels (i.e., use of oral contraceptives or during a woman's menstrual cycle), and certain types of food (dairy, cheese, meat, chocolate). For many patients, migraines can occur either episodically or up to several times per month. In 60% of migraine cases, patients report having a unilateral headache described as a moderate to severe pulsating sensation with accompanying symptoms such as nausea, vomiting, or sensation to light or sound.[4]

83.2.2 Tension-Type Headaches

These are the most common types of headaches and are known to affect women more than men. They are typically

DOI: 10.1201/9781003227793-98

described as a bilateral, dull constant "band-like" pain and can be triggered by symptoms of anxiety, stressful situations, depression, poor sleep, physical exertion, and poor posture. Patients typically report feeling a tightness in the back of their neck but do not report symptoms of nausea, vomiting, or aura. These headaches can sometimes accompany symptoms of either increased sensitivity to sound or light but usually do not report both (unlike patients with migraines). Oftentimes, tension-type headaches last anywhere from 30 minutes upwards to seven days, with frequencies varying from occasional to daily, and are usually mild to moderate in intensity.[5]

83.2.3 Cluster Headaches

While migraines and tension-type headaches are known to affect predominantly females, cluster headaches affect mostly adult men aged 20–40 years of age. Patients often report experiencing severe, agonizing pain with unilateral or periorbital headaches. These episodes tend to arise within minutes and are usually short with frequent reoccurrence in a "cyclical" pattern, where the headaches can last weeks to months and then go into remission. In some patients, they can have upwards to eight attacks in 24 hours with pain piercing enough to wake them from sleep. Alcohol may be a trigger for these episodes. Other accompanying symptoms to be aware of include ipsilateral nasal congestion or discharge, lacrimation, ptosis, miosis, or conjunctival injection.[6]

83.3 PROPOSED PATHOPHYSIOLOGICAL MECHANISMS

Despite significant advancement in our knowledge regarding the pathophysiology behind headaches, headaches remain a complex set of disorders to treat. For most of history, headaches, especially migraines, were thought to be a form of a vascular disorder where extracranial vessels become dilated leading to the classical throbbing pain experienced by patients. It is only in the last couple of decades that we have learned about the many different mechanisms that could be propagating the different types of headaches.

83.4 Migraines

Recent evidence has illustrated that a cascade of events occurs during a migraine attack. Multiple potential pathways, including those related to channelopathies, vascular anomalies, and a disorder of sensory processing may occur.[7] Part of the process involves triggers, which can sometimes be instigated by environmental and lifestyle factors.

83.4.1 Lifestyle

Headaches can be both a cause and a consequence of an unhealthy lifestyle. Studies have shown that your lifestyle can directly impact the onset, frequency, and severity of headaches, most notably affecting tension headaches and cluster headaches. Three specific unhealthy behaviors can significantly contribute to having headaches: smoking, being overweight, and exercising less than two times per week. In fact, smoking was associated with an 80% increase in migraines, being overweight with a 60% increase in migraines, and an increase of 50% in those who did not regularly exercise at least three to four times per week.[8] All three of these unhealthy behaviors directly promote inflammation in the body, thereby triggering downstream changes in the brain leading to headaches. It is clear that leading a healthy lifestyle, exercising regularly, and abstaining from smoking can help both prevent and reduce headaches.

83.4.2 Central Nervous System

In biology, homeostasis is defined as the tendency to maintain a steady state despite the influence of external factors. Inflammatory changes caused by living a poor lifestyle can directly affect our body's homeostasis due to changes in the hypothalamus (our brain's control center).[9] The elevated levels of various inflammatory markers mediate a propensity for central sensitization.[10] Studies have shown patients with chronic headaches tend to have more elevated levels of various neurotransmitters and neuropeptides such as interleukins and calcitonin gene-related peptide (CGRP) in comparison with the general population.

83.4.3 Treatments of Migraines

83.4.3.1 OTC Treatments

Some examples of non-pharmacologic treatments for migraines include adequate hydration, resting in the dark, meditation and deep breathing exercises, and physical activity. Common over-the-counter (OTC) therapies include acetaminophen, aspirin, or ibuprofen. However, overusing these medications can result in rebound headaches.

83.4.3.2 Triptans

In patients who experience moderate to severe headaches, triptans are one of the medications initially used for abortive treatment. Triptans work as serotonin agonists. Triptans are contraindicated in patients with vascular disease (i.e., heart attack, stroke, uncontrolled hypertension) because of the medication's effects on vasoconstriction.[13]

83.4.3.3 Ditans

A more recent development in the treatment of migraines includes the class of ditans. Ditans are selective 5-HT1F receptor agonists that act on the trigeminal pathway. The vascular effect of this class of medications is still under investigation.[14]

83.4.3.4 Gepants

The newest classes of migraine treatments are the gepants, CGRP receptor antagonists. This class of migraine treatment blocks the activity of the CGRP molecule to bind to its receptor, which helps both abort and reduce how often

migraines occur. Gepants do not cause vasoconstriction, which makes them safe to use in patients who have underlying cardiovascular conditions.[15]

83.4.3.5 Neuromodulation

An alternative to pharmacologic treatment has been non-invasive neuromodulation devices. These devices are placed directly on the skin and cause electrical impulses. They have limited but noteworthy results in the literature.[16]

83.4.4 Preventive Migraine Treatment

Successful preventive treatment provided to migraine sufferers is one of the most powerful tools available to drastically improve their quality of life. When it comes to migraines and most headaches, there are two types of preventive measures, pharmaceutical and lifestyle modifications.

The pharmaceutical treatment approach has been most effective in reducing the frequency and intensity of headaches;[17] however, despite the benefits of preventive migraine treatment, studies have found that compliance to preventive pharmacological treatment is as low as 25%.[18] It must also be noted that in patients who are compliant with preventive medical treatment, medication needs to be trialed. All medications do not work well for everyone and depending on genetics, compliance, and severity of headaches, there is a phase of trial and error that the patient has to go through to find the right fitting medication.

Although there may be significant trial and error associated with finding individualized pharmaceutical treatments for patients, positive lifestyle changes are often directly correlated with the prevention and reduction of headache episodes.[19] Lifestyle changes can be universally applied with a low risk of associated side effects and are also cost-effective. A healthy lifestyle with adequate hydration, regular exercise, stress reduction, and alcohol and smoking cessation can be an incredibly powerful management strategy alongside pharmaceutical treatments for headache sufferers.

83.4.4.1 Preventive Pharmacologic Drugs

Various classes of drugs have been used as a form of preventive pharmacologic treatment for migraines. Among these include the following: antidepressant drugs such as serotonin norepinephrine reuptake inhibitors (venlafaxine) and tricyclic antidepressants (amitriptyline and nortriptyline); antihypertensive drugs such as beta-blockers (propranolol) and calcium channel blockers (verapamil); and antiepileptic drugs such as valproic acid and topiramate, which have been found to have a great side-effect profile. Recent studies have also shown medications such as lisinopril (angiotensin-converting enzyme inhibitors) and candesartan (angiotensin receptor blockers) to be effective in the prevention of headaches.[20] CGRP monoclonal antibodies have also been found to be effective treatments in reducing monthly headaches and may also have a faster onset compared with other oral preventive treatments.

Overall given the challenges with compliance, the potential for side effects of medications, and the phase of trial error to find the right medication, it is important to institute a combination of pharmacological and non-pharmacological treatments (lifestyle modifications) that may be beneficial to the overall health of the patient.

83.4.4.2 Lifestyle

Headaches can be both a cause and a consequence of an unhealthy lifestyle. Studies have shown that one's lifestyle can directly impact the onset, frequency, and severity of headaches. Common culprits such as smoking and lack of exercise have been shown to contribute to increased headache severity and frequency.[21] It is clear that leading a healthy lifestyle, exercising regularly, and abstaining from smoking can help both prevent and reduce headaches.

83.5 TENSION HEADACHES

As mentioned earlier on in the chapter, tension headaches are the most common headaches to occur in most epidemiological studies. These headaches are typically described as a dull ache occurring in a band-like pain around the head.

The most common pharmaceutical medications used to relieve this common headache include NSAIDs (such as ibuprofen and aspirin) or acetaminophen. In patients who tend to have more frequent tension headaches, a prophylactic medication such as amitriptyline may be considered as well; however, certain medications such as triptans and opioids should be avoided in this headache group.[22]

Non-pharmacological therapy for tension-type headaches is focused on addressing the various exacerbating factors for tension headaches. These include but are not limited to poor sleep and diet, stress, anxiety, depression, and head injury. It is important to implement lifestyle modifications such as proper sleep hygiene, a healthy lifestyle, and exercise. Additionally, patients may also consider cognitive behavioral therapy and relaxation training to address psychiatric root causes.

83.6 Cluster Headaches

One of the most painful types of headaches is the cluster headache. Although these are rarer compared with tension headaches, they are often easier to identify due to the classic one-sided, brief, recurring episodes that occur in a cyclical pattern.

Acute episodes can be treated either with triptans or high-flow oxygen therapy; however, medications such as acetaminophen or ibuprofen are typically not recommended as they can lead to overuse headaches. Verapamil may also be considered for prophylactic treatment.

Various lifestyle changes can help with cluster headache prevention, these include smoking cessation, limiting alcohol, and adhering to a regular sleep routine.[23]

83.7 SECONDARY HEADACHES

Headaches that occur due to an underlying medical condition are known as secondary headaches. These headaches are rarer in comparison to primary headaches but include conditions such as brain tumors, cervical spine disorders or injuries, concussions, aneurysms, and meningitis. Treatment of secondary headaches requires mostly medical management as opposed to lifestyle modification.

83.7.1 Tumors

Any space-occupying lesions in the brain, such as brain tumors, typically present as a dull headache that seems to be side-locked, i.e., the location of the pain tends not to move, unlike primary headache disorders. Over time, patients will experience symptoms of increased pressure that may significantly worsen in weeks to months.[24]

83.7.2 Aneurysms

The clinical presentation of brain aneurysms is highly variable. About one-third of those with aneurysms report having sudden, severe headaches, which present as either dull, sharp, or throbbing.[25] Prevention and minimizing the risk or extension of aneurysms centers around implementing various lifestyle factors. Studies have shown that limiting tobacco products, consuming a healthy diet, regular exercise, and managing blood pressure (low salt diet), cholesterol (reducing saturated fats), and diabetes can play a positive role in prevention. Imaging modalities such as CT scans or MRI can be used to screen for brain aneurysms. Early detection is absolutely imperative in preventing further extension along with utilizing proper lifestyle changes.

83.7.3 Meningitis

Meningitis is a disease due to inflammation of the meninges (fluid and membranes in the brain and the spinal cord). This inflammatory disease can occur as a result of a viral, bacterial, or fungal infection. It typically presents with a triad of symptoms: fever, headache, and neck stiffness/rigidity. Vaccines are widely available to prevent the most common types of meningococcal infections. Proper hygiene, such as regular hand washing, can also help further reduce the risk of meningitis.[26]

83.7.4 Cervical Spine Disorders/Injuries

Cervicogenic headaches are headaches that occur due to problems in the cervical spine. They can be caused by conditions such as disk degeneration or arthritis. Typically, these headaches are accompanied by neck pain and can also appear similarly to migraine headaches. Injuries from sports or motor vehicle accidents can also contribute to these types of headaches. Avoiding injury to the head and neck can help prevent cervicogenic headaches.[27]

83.8 Lifestyle Modifications in General

Although there is evidence that headaches have been present throughout history, there is also evidence that the prevalence and influence of headaches have significantly increased in our modern life. Headaches are not only occurring more frequently but are also occurring in younger patients when compared with the past.[28] This may be due to more stringent epidemiological studies or because we are now looking more for people with headaches. Factors such as increasing stress and anxiety, new physical stressors, lack of physical activity, poor sleep, inadequate nutrition, and increased screen time are all contributing to all types of headaches.[29]

Lifestyle modifications such as improving sleep quality, obtaining proper nutrition, limiting alcohol and caffeine, participating in regular physical activity, and reducing digital technology have been found to be effective in migraine management. Our increased use of technology has significantly contributed to the rise of headache incidence. Studies have shown that more than eight hours of computer use in adults and over four hours of video game play in children have been correlated with headache frequency.[30]

83.8.1 Sleep

Patients with migraines can also modify their triggers through lifestyle modifications. According to the *Cleveland Clinic Journal of Medicine*, SEEDS (sleep, exercise, eat, diary, and stress) is an evidence-based structured approach to help patients manage migraines.[30] In regard to sleep, patients are recommended to optimize both the quality and the amount of sleep they obtain. Most adults require at least eight hours of sleep per night and are recommended to sleep in a dark, cool (around 68°F), and quiet room. Our body produces melatonin (a chemical our brain uses to help us fall asleep), which increases in levels when it starts to become dark. If we regularly keep bright lights on until we sleep, this resets the circadian rhythm of melatonin and inhibits melatonin production. To help maintain an adequate circadian rhythm, dimming the lights in the evening and following good sleep hygiene have been found to be helpful.

Patients with primary headache disorders have been found to experience sleep comorbidities such as obstructive sleep apnea (OSA) or insomnia, which can further exacerbate headaches. Studies have shown that 29% of individuals with OSA experience awakening headaches, 15% experience tension-type headaches, and 8% experience migraines.[31] OSA is treated with the use of continuous positive airway pressure (CPAP) machines, which often results in better sleep quality, thereby resulting in reduced frequency, duration, and pain associated with migraines.[32]

83.8.2 Exercise

In patients with migraines, levels of beta-endorphins were found to be decreased in their cerebrospinal fluid compared

with the general population; however, activities such as exercise can be a way to combat these lower levels. Most patients are recommended to exercise 30–60 minutes at least three to five times per week. Engaging in exercise has been found to be beneficial in patients with headaches due to the natural release of endorphins causing pain relief, thereby resulting in decreased frequency and severity of headaches. On the other hand, a sedentary lifestyle with minimal physical activity has been found to be associated with migraines.[33]

83.8.3 Nutrition

Diet can play a significant role in both the prevention and treatment of headaches. Studies have shown that eating regularly along with maintaining a balanced healthy diet (with plenty of fruits and vegetables) can help reduce headaches. In particular, patients who followed a low-fat diet reported decreased medication use and also had less frequent headache episodes. Additionally, it is important to eat consistently as skipping meals can cause the body to experience stress due to the spikes or sudden drop in glucose levels, which can be a risk factor for headaches. Consuming a high-fiber, plant-based/predominant, low-fat diet was also found to reduce the severity of headaches in women who experience menstrual-related headaches.[34]

It is no surprise that the average American diet promotes an inflammatory state. According to the WHO, approximately 42% of adults in the United States are obese. It has been thought that a hypothetical relationship may exist between obesity and headaches. In patients who suffer from obesity, headaches may be attributed to higher levels of systemic inflammation (i.e., increased levels of CGRP) due to increased body fat percentage or irregular hypothalamic function. In these patients, focusing on dietary changes and weight loss has been found to decrease levels of inflammation, thereby decreasing the frequency and severity of headaches.[35]

Although there is no specific recommendation for a "migraine diet" per se, various studies have shown that certain diets, such as the modified Atkins diet and the ketogenic diet, may play a role in decreasing levels of neuroinflammation, decreasing CGRP levels, improving mitochondrial function, and offering neuroprotection. Also, improving the balance of omega-3 and omega-6 has been found to show a reduction in the levels of inflammatory markers, which may reduce and prevent the onset of headaches in patients.[35] Foods with higher levels of omega-3 include fish, nuts, seeds, tofu, Brussels sprouts, and avocado. In some patients, certain foods can trigger headaches such as chocolate, caffeine, artificial sweeteners, nitrate-containing meats, processed meats, beans, and dairy. Patients are often recommended to keep a headache diary to help monitor which foods, if any, may be triggers for their headaches. Overall, a healthy lifestyle is essential for proper headache management.

83.9 STRESS MANAGEMENT

According to the American Migraine Foundation, stress is a significant inducing factor in approximately 70% of patients who experience migraines. In this patient population, it is vital to implement lifestyle changes for stress reduction. For example, studies have shown that deep breathing exercises, relaxation techniques, and social support can be used to provide stress relief and thereby alleviate headaches. These lifestyle changes can be significantly impactful in improving the quality of life for headache sufferers.[36]

83.9.1 Hydration

A vital component of maintaining a healthy lifestyle is achieving adequate daily hydration. Headaches can be triggered by temperature changes and drinking enough water can help reduce the stress experienced by the body. An average healthy adult requires about eight 8-ounce glasses of water per day, this is often referred to as the "8 × 8" rule.[37]

83.10 MANAGEMENT OF MEDICAL CONDITIONS

Studies have shown that there is a high prevalence of hypertension in patients with both episodic headaches and those with chronic headaches. According to the International Classification of Headache Disorders, headaches are one of the most common symptoms reported in patients with hypertension.[38] Additionally, patients with headaches, especially migraines, are at an increased risk of developing hypertension.[39] Additionally, high cholesterol is another medical condition that has been found to have an association with headaches.[40] In fact, some studies have shown that patients with high low-density lipoprotein (LDL) levels tend to report experiencing more severe migraines in comparison with those with lower LDL levels. Other metabolic conditions such as diabetes have been shown to be associated with more headaches as well, especially during hypoglycemic states. Insulin resistance has also been shown to increase migraine episodes due to increased levels of inflammatory markers like free fatty acids and lipids in the blood (LDL). [41]

83.10.1 Supplements

Herbal and nutritional supplements have also been used for the prevention of migraine. More recent systematic reviews have shown to support the use of magnesium and riboflavin (vitamin B2). The herb feverfew, which is also a commonly used supplement, was found to have more mixed and inconclusive evidence.[42] Magnesium and feverfew have been studied to be helpful in the treatment of the aura phase of the migraine cycle. Currently, the use of melatonin and vitamin D is being studied for migraine prevention. In a randomized controlled trial, the combination of simvastatin and vitamin D was found to reduce the frequency of headaches in patients.[43] Another study was found to show the use

of the synthetic cannabinoid nabilone to be beneficial in the treatment of patients with chronic migraines and rebound headaches due to medication overuse.[44] Another herbal supplement found to be helpful in preventing migraines is butterbur, which is derived from the leaves of *Petasites japonicus*. This herbal supplement was given a level A recommendation by the American Headache Society, but due to its adverse effects resulting in liver toxicity, it was removed from the US market.

83.11 SUMMARY

Headaches are one of the most common reasons for emergency room visits in the United States and one of the ten most common causes of functional disabilities worldwide. Although we now have a better understanding of some of the causes and currently have an armamentarium of treatments for these headaches, unfortunately, there is not as much effort being applied to preventive aspects of these headaches. There is tremendous data that for most of these headaches, preventive measures may have a profound effect on the incidence, prevalence, and burden impact. In order to reduce the burden of those suffering from headaches, it is imperative we close any knowledge gaps by educating others on the influence of lifestyle factors. Nutrition, exercise, stress reduction, sleep optimization, and better medical and lifestyle management of chronic diseases such as diabetes, high blood pressure, and high cholesterol, as well as reduction and better yet elimination of alcohol and cigarette use, can profoundly aid in our fight against onset, maintenance, and reversal of these headaches.

CLINICAL APPLICATIONS

Headaches are underdiagnosed and undertreated throughout the world. Although we have developed several treatments for various headache types, we have not been able to reduce the prevalence of these conditions. In fact, the prevalence and influence of headaches have significantly increased in our modern life. Increasing stress and anxiety, new physical stressors, lack of physical activity, poor sleep, inadequate nutrition, and increased screen time have all significantly contributed to the increased prevalence of headaches worldwide.

Successful preventive headache treatment is one of the most powerful tools available to drastically improve these patients' quality of life. Studies have shown that one's lifestyle can directly impact the onset, frequency, and severity of headaches. Leading a healthy lifestyle, exercising regularly, and abstaining from smoking and alcohol can help both prevent and reduce headaches.

84 Stroke and Vascular Brain Diseases

Vikas Ravi, MD, Dean Sherzai, MD, PhD, MPH, MAS, and Ayesha Sherzai, MD

KEY POINTS

- Stroke is the fourth leading cause of mortality in the United States and the leading cause of disability, however, optimal strategies, including lifestyle factors, can prevent up to 80% of strokes.
- A myriad of modifiable risk factors such as hypertension, hyperlipidemia/atherosclerosis, diabetes, atrial fibrillation (AF), smoking and other drug use, alcohol, diet, and physical activity need to be addressed and optimized to lower the chance of developing strokes.
- Effective strategies, including the use of novel oral anticoagulants for AF, antiplatelet therapy, and intensive lowering of atherosclerosis risk factors, can serve as both primary and secondary prevention of strokes.
- Adherence to DASH, Mediterranean, and prudent dietary patterns reduced the risk of stroke, whereas the Western dietary pattern has been associated with increased stroke risk. Low-fat diets have not been found to have a protective effect.

84.1 INTRODUCTION

Stroke places a tremendous burden on the healthcare system worldwide. In the United States, it is the fourth leading cause of mortality, with an estimated 795,000 incidences of stroke each year. It is one of the leading causes of serious disability.[1,2] According to the Global Burden of Disease, Injuries, and Risk Factors Study (GDB 2019), stroke was ranked as the most common cause of death after ischemic heart disease.[3] The global burden of stroke based on disability-adjusted life years lost and the absolute number of people affected every year is still on the rise, with the highest burden seen in low-income and middle-income countries. As age is one of the main risk factors for stroke, and with the elderly population expected to double to more than 70 million by the year 2030, reducing the incidence of stroke has become a central healthcare policy concern.[4] Treatment costs associated with chronic disease constitute three-fourths of US healthcare expenditures, and of this, $400 billion per year is spent on heart disease and stroke.[5] It is, thus, imperative to identify and implement healthcare policies that can reduce the risk of stroke.

Implementing a national stroke prevention approach can serve as a complementary strategy to reduce the increasing global burden of stroke and subsequent disability.[6] Risk factors associated with stroke have been divided into two main categories: non-modifiable and modifiable. Advanced age, gender, race, and genetic susceptibility are the most prominent non-modifiable risk factors, while lifestyle risk factors such as diet, exercise, and use of tobacco and alcohol are considered modifiable risk factors.[7] By addressing the modifiable risk factors, it is estimated that stroke prevalence can be reduced by as much as 80%.[6] Thus, primary prevention of stroke takes central importance. Substantial research has been done over the past decades to advance the understanding of stroke mechanisms and therapies. Despite a large body of data supporting specific pharmaceutical agents, such as antiplatelets, antithrombotics, and statins, as preventive measures for stroke, diet remains a focus of extensive epidemiological research for stroke prevention. This chapter reviews major advances in stroke prevention in the last few years, pertaining to the modifiable medical and behavioral stroke risk factors.

84.2 PATHOPHYSIOLOGY OF STROKE

The brain microcirculation ensures the proper distribution of oxygen and glucose in tissue while also removing the byproducts of cellular metabolism. The delicate endothelial monolayer of cerebral blood vessels, as part of its normal function, inhibits platelet aggregation and thrombosis to ensure smooth blood flow. Stroke is a devastating process caused by impaired blood flow that results in irreversible damage to the brain by disturbing the cerebral microcirculation. Within seconds after the start of cerebral ischemia, there is a loss of aerobic metabolism causing local acidosis, dysfunction of the ion channels causing accumulation of sodium and calcium within the cell leading to cell swelling, and a release of excitotoxic neurotransmitters, lipase, and proteases, all culminating in neuronal apoptosis.[8]

84.3 MODIFIABLE RISK FACTORS

84.3.1 Hypertension

Hypertension is the most important modifiable risk factor for both cerebral infarction and intracerebral hemorrhage (ICH). Per the most recent guidelines, hypertension is defined as a blood pressure greater than 130/80 mm Hg. Studies have consistently demonstrated a strong, continuous, and independent positive relationship between blood pressure (BP) and stroke, such that the higher the BP, the

DOI: 10.1201/9781003227793-99

greater the risk of stroke throughout the usual range of BP, including the non-hypertensive range.[9–13]

Though the awareness and subsequent treatment of hypertension in the United States has increased over the years, the prevalence of hypertension has remained stable at approximately 29%.[14] Regular medical check-ups and screening are essential in identifying hypertension early and initiating treatment with lifestyle interventions and medications in order to prevent progression and minimize future complications. Other complementary strategies such as population-wide approaches to reduce BP have also been endorsed as more effective than individual approaches for the detection and treatment of high BP, that is, the high-risk approach.[12] There is strong evidence that supports the treatment of hypertension to a goal of less than 150/90 mmHg in those aged ≥60 years and to a goal of diastolic BP less than 90 mmHg in those aged 30–59.[15] Blood pressure control is associated with a lower risk of stroke and cardiovascular events and generally improves health outcomes, especially in older adults, however, in certain high-risk patients, lower BP goals (SBP <120) were associated with hypotension, syncope, increased medication burden, and at times an increase in all-cause mortality.[16–21] Therefore, the management and treatment of hypertension in any individual should be tailored according to their characteristics and the comorbidity burden.

The management of hypertension for secondary stroke prevention is probably the most important intervention and has been studied repeatedly in the past. Studies have shown antihypertensive medication may be initiated or resumed after an acute ischemic stroke within the first 24 hours for patients who have pre-existing hypertension, and who are neurologically stable. For patients who have already experienced a stroke or TIA, treatment to an SBP goal <130 is recommended to decrease risk of recurrent stroke.[22–28] Current guidelines show no definitive evidence supporting specific classes of antihypertensive therapy over others as a means to prevent stroke. Further hypothesis-driven trials are needed to delineate the efficacy of individual agents in specific subpopulations.

84.3.2 Hyperlipidemia and Elevated CRP

Lowering blood cholesterol in patients at elevated cardiovascular risk has been a significant strategy in stroke prevention.[29–31] Several studies have discovered the benefits of statins in reducing stroke risk as both primary and secondary prevention strategies.[32–34] In addition to elevated cholesterol and LDL, high-risk CRP has also been found to predict risk of ischemic stroke, and in patients with a history of stroke, could serve as a potential biomarker to predict risk of recurrent stroke.[35–38] In healthy patients, without a prior history of stroke, there appears to be a benefit in starting statin if hs-CRP levels are found to be elevated despite normal LDL levels.[39] Although high levels of cholesterol and low-density lipoprotein predispose to ischemic stroke (especially of atherosclerotic mechanism), low levels have been associated with an increased risk of intracerebral hemorrhage.[40]

84.3.3 Type 2 Diabetes

Diabetes is a known risk factor for stroke, especially in women and patients younger than 65 with a 74% increased rate if the duration of diagnosis is longer than three years.[41–44] Studies have shown that a hemoglobin A1c goal of less than 7% is optimal for stroke prevention, however, below that does not confer an inverse relationship in terms of stroke prevention.[45]

84.3.4 Atrial Fibrillation

Atrial fibrillation is a common cause of disabling stroke, resulting from embolism of stasis-precipitated thrombi formed in the left atrium, left atrial appendage, or both.[46] There have been advances including the development of new anticoagulants, evidence of the benefits of long-term monitoring, and appreciation of the potential role of atrial disease in cryptogenic stroke, even in the absence of AF. These new anticoagulants can be broadly divided into the direct factor Xa inhibitors, such as rivaroxaban, edoxaban, and apixaban, and the direct thrombin inhibitors, particularly dabigatran, and have demonstrated greater efficacy as well as minimal side effects of bleeding when compared with warfarin.[47–56] One of the challenges in the care of patients with cryptogenic strokes and TIA is the detection of covert paroxysmal AF, which constitutes about 30% of all ischemic strokes.[57,58] Extended cardiac rhythm monitoring of up to 30 days via cardiac telemetry or insertable cardiac monitor in such patients has revealed evidence of AF in a significant proportion of patients, with longer periods of monitoring increasing the yield.[58–60] There is no convincing evidence that anticoagulation protects against recurrent stroke among patients without a definite source of cardiac embolism or in cases of cryptogenic stroke. However, large aortic arch atheroma and complex plaques were associated with a higher risk of stroke over a period of two years.[61] N-terminal pro-B-type natriuretic peptide (NTproBNP) is a serum biomarker associated with cardiac dysfunction that predicts the development of AF and studies have shown that in patients with elevated levels above the 95th percentile who were randomized to warfarin had a reduction in their risk of stroke or death compared with patients allocated to aspirin.[62–64] Further trials of the use of NTproBNP and other biomarkers associated with AF in the risk stratification of patients with cryptogenic stroke are needed.

84.3.5 Chronic Kidney Disease

Chronic kidney disease is an independent risk factor for stroke. A TA analysis of 21 studies has shown that an eGFR<60 ml/min, high albuminuria, and proteinuria are associated with an increased risk of stroke.[65–70] This is especially true in patients requiring dialysis. In a large study in

Taiwan comprising nearly 80,000 dialysis patients, it was found that there was a nearly three-fold increase in ischemic stroke and a six-fold increase in hemorrhagic stroke.[71] Another study titled Choices for Healthy Outcomes in Caring for End-Stage Renal Disease (CHOICE) revealed a nearly ten-fold increase in stroke incidence in dialysis patients when compared with the general population.[72] However, it has also been found that among patients with CKD, there are higher instances of prior strokes, atrophy, and white matter disease when compared with the general population.[73–80] In CKD patients especially, control of blood pressure is one of the most important modifiable risk factors in primary and secondary prevention of strokes.[81]

84.3.6 Obstructive Sleep Apnea

Sleep apnea is becoming an increasingly common condition due to the increased prevalence of obesity and is an established risk factor for stroke.[82–87] It is common among post-stroke patients as well. Managing and treating this condition can serve as both primary and secondary prevention of stroke.[82] Sleep apnea drives a pathological increase in sympathetic activity, which in turn causes the development of or worsens already existing secondary stroke risk factors such as hypertension, dyslipidemia, cardiac dysrhythmias, and glucose tolerance.[83] Therefore, tools such as the Epworth Sleepiness Scale, Berlin Questionnaire, or STOP-Bang can be used to screen patients in the clinical setting to evaluate for possible sleep apnea.[88–90] In patients found to have sleep apnea, weight loss through healthy diet and exercise must be encouraged along with avoidance of provoking factors such as alcohol, smoking, and hypnotic drugs. Treatment of sleep apnea with positive airway pressure ventilation has been shown to improve patient's cognition, neurological function, and disabilities faced post-stroke. Other strategies such as surgical intervention may be employed to reduce the risk of future vascular events.[91–94]

84.4 DIET

There is an increasing interest in the relationship between diet and stroke. However, owing to intrinsic methodological limitations of diet research, there is a trend to study dietary patterns as opposed to single macro- or micronutrients.

84.4.1 Fruits and Vegetables

There is ample evidence that a diet high in fruits and vegetables is associated with reduced stroke risk in a dose-response manner.[95–98] Higher consumption of plant-based foods, namely cruciferous vegetables, green leafy vegetables, citrus fruits, vitamin C-rich fruits, and whole grains reveal an inverse relationship with and incidence of cerebrovascular disease, ischemic stroke, and IH, however, this association was not seen with potatoes and legumes.[95–97,99,100–103] After adjustment for age, sex, BMI, family history of stroke, and other confounding factors intakes of total fat, plant fat, calcium, potassium, vitamin B1, vitamin B2, vitamin B6, niacin, and folate were negatively correlated with the risk of stroke.[103]

84.4.2 Fish

There have been several studies ranging from prospective cohort and case-control studies that have assessed the relationship between fish intake and stroke risk. Overall, the relationship is not entirely clear, however, studies have shown that overall a dose-dependent relationship exists between fish consumption and overall ischemic stroke risk at higher quantities of greater than five times per week, however, in mild quantities of a few servings per month, there appeared to be some protection against first-time stroke, mostly seen in females and the Black population, especially with the intake of fatty fish such as tuna or broiled fish.[104–109] This may be likely due to the atheromatous plaque-stabilizing quality of omega-3 fatty acids and their putative anticoagulant effects.[110,111] However, the anticoagulant effect can only be observed at high levels of fatty fish intake, which may ultimately lead to an increased risk of hemorrhagic stroke but no significant correlation was found between fish consumption and hemorrhagic stroke.[112] The risk of ischemic stroke mainly increased with the consumption of fried and salted fish, with effects seen greater in men.[114]

84.4.3 Meats, Eggs, and Dairy

Animal products, mainly eggs, dairy, and meats, have gathered attention due to concerns that they may increase stroke risk.

The relationship between egg consumption and stroke is of interest due to the presence of both potentially harmful constituents (cholesterol) and healthful nutrients (B vitamins, folate, and monounsaturated fatty acids) in this food. Multiple large prospective studies have examined this relationship and have found no association between stroke at any level of intake, after adjustment for age, gender, BMI, smoking, high blood pressure, diabetes, serum cholesterol, race/ethnicity, and educational status.[115–117]

Milk consumption was not associated with incident stroke mortality. As compared with subjects who consumed milk below the medium intake, those who drank milk at or above the medium intake were at lower risk of ischemic stroke after adjustments were made for age, smoking, total energy, and social class.[118] Although, compared with milk drinkers, non-milk drinkers were more likely to drink alcohol.[119] Whole-milk intake was associated with an increased risk of intracranial hemorrhage and yogurt intake with an increased risk of subarachnoid hemorrhage. The highest quintile of cream intake was associated with a slight decrease in cerebral infarct risk and intracranial hemorrhage, yet no association was found for total dairy intake, ice cream, cheese, low-fat milk, butter, or sour milk and stroke risk[120]

Consumption of meat with a frequency greater than four times per week was positively correlated with risk of all strokes as well as first-incident strokes.[121] However, some preliminary evidence suggests that specific amino acids, such as taurine and arginine, found in animal protein may modulate vasoactivity, resulting in reduced blood pressure.[122] Therefore, low intakes of animal fat and protein may have a stronger association with intracranial hemorrhage as compared with ischemic stroke. Increased risk of intracranial hemorrhage has been observed among women who consume low levels of animal protein and saturated fat, with the latter among hypertensive women only.[123]

84.4.4 Soy

Soy provides an abundance of nutrients including fiber, antioxidants, and phytochemicals and is an especially important food group in the vegetarian food guide pyramid.[124,125] Soy isoflavones can act as antioxidants, reducing the formation of oxidized lipoproteins like low-density lipoproteins. Several studies have examined the relationship between soy and stroke. The highest tertiles of intake of dried soybeans, tofu, soymilk, and total soy foods were each associated with a significantly reduced risk of stroke after adjustment for confounders, as compared with the lowest tertiles of consumption.[126] A protective effect of soy and isoflavone intake against risk of ischemic stroke and myocardial infarction (MI) has also been observed. Evaluation of soy and isoflavone intake revealed a strong inverse association between risk of stroke and MI in women, primarily postmenopausal women, with consumption five times per week, as compared with zero to times per week. However, a weak inverse association was identified between consumption of miso soup, beans, and isoflavones and CVD mortality among men.[127]

84.4.5 Whole Grains

The relationship between grain intake and stroke has been studied. A significant inverse relationship between whole-grain consumption and ischemic stroke risk was observed across all quintiles of intake, which remained unchanged after adjustment for other CVD risk factors.[128] However, no association between total grain intake and incidence of ischemic stroke risk was observed.[129]

84.4.6 DASH Diet

The DASH diet, which emphasizes a high intake of fruits, vegetables, grains, low-fat dairy products, nuts, chicken, and fish and a low intake of red meat, sweets, and refined carbohydrates, has demonstrated great efficacy in reducing blood pressure and low-density lipoproteins, which are known risk factors for CVD.[130] Higher adherence to the DASH diet was significantly associated with reduced risk of stroke.[131]

84.4.7 Mediterranean Diet

The Mediterranean diet has been touted for its health benefits and has been found to decrease risk of vascular deaths, myocardial infarction, and stroke in a dose-dependent manner.[131–134] The Mediterranean diet has also been shown to be effective in reducing risk and mortality for a number of chronic diseases including CVD, cancer, and neurodegenerative disease.[135] It is consistent with the American Heart Association's dietary guidelines, as it is high in fruits, vegetables, monounsaturated fat, fish, whole grains, legumes, and nuts, and recommends moderate alcohol consumption and a low intake of red meat, saturated fat, and refined grains.

84.4.8 Other Dietary Patterns

Research on low-fat diets, particularly low trans fats and cholesterol, and replacing saturated fats with polyunsaturated and monounsaturated fats, have demonstrated reduced risk of cardiovascular disease, however, there was no statistical association with specific types of fat (total, animal, vegetable, saturated, monounsaturated, polyunsaturated, and trans fat) and stroke risk.[134–137]

84.5 EXERCISE

Physical inactivity has been proven as a risk factor for stroke and it has been demonstrated that moderate to vigorous intensity aerobic exercise for at least 30 minutes, three to four times a week can cut the incidence of stroke.[138–140] Multiple trials have been able to demonstrate the protective effects of physical activity for both men and women. In the Northern Manhattan Study, individuals in the upper quartile of increased level of physical activity had lower risk of silent brain infarcts, compared with those who did not exercise.[141] A preliminary study of the California Teachers Study Cohort, postmenopausal women on hormone therapy who exercised moderately to strenuously in the three years before enrollment had a 20% reduced risk of stroke; physical activity appeared to counteract the high risk of stroke associated with hormone therapy.[142]

84.6 SMOKING

Smoking has been strongly associated with a two to four times increased incidence of stroke, worse outcomes post-stroke, and increased risk of recurrent strokes.[143,144] This relationship has not been established for ICH, perhaps owing to the small sample size of patients in that group.[144] Exposure to environmental tobacco smoke (passive cigarette smoke, or "secondhand" tobacco smoke) is an established risk factor for heart disease.[145] One way to reduce the risk of stroke is by a combination of counseling and medication, including medications such as nicotine patches, bupropion, and varenicline.[143] Recent observational studies provide evidence that smoking bans in communities can

reduce the risk of stroke. After Arizona enacted a statewide ban on smoking, for example, there was a 14% reduction in strokes in counties that had not previously had a ban in place.[146]

84.7 ALCOHOL USE

Studies showing the relationship between alcohol and stroke risk have revealed somewhat of a protective effect with low intake of alcohol (one drink per day for women, two or fewer drinks per day for men), however, it is not recommended to start drinking alcohol for stroke prevention if previously abstinent.[147] There is also a dose-dependent relationship between alcohol consumption and risk for hemorrhagic stroke.[148,149]

84.8 SUMMARY

Stroke is a devastating condition that is one of the leading causes of disability in the United States and abroad. Although this condition can be managed with acute treatments and secondary prevention, an increasing amount of evidence through recent research shows that there is potential to drastically decrease the incidence of stroke by over 80% with lifestyle factors alone. In addition to managing traditional stroke risk factors such as hypertension, diabetes, hyperlipidemia, chronic kidney disease, and sleep apnea, research has shown tremendous benefit in lifestyle changes through healthy diets such as DASH, the Mediterranean diet, and plant-based diets which have been shown to decrease stroke risk. Regular exercise, abstinence from smoking, and limited quantities of alcohol have also been strategies for stroke prevention. Moving forward, it is imperative that health policy and public health facilities put a larger amount of focus on the prevention of stroke through lifestyle management.

CLINICAL APPLICATIONS

Modifiable Risk Factor	Summary of Findings
Hypertension	• There is a strong, continuous, and independent positive relationship between blood pressure (BP) and stroke.[9-13] • Regular medical check-ups and screening are essential in identifying hypertension early and initiating treatment with lifestyle interventions and medications in order to prevent progression and minimize future complications. • After a patient suffers from a stroke or TIA, treatment to a SBP goal <130 is recommended to decrease risk of recurrent stroke.[22–28] • Current guidelines show no definitive evidence supporting specific classes of antihypertensive therapy over others as a means to prevent stroke.
`Hyperlipidemia	• Lowering blood cholesterol in patients at elevated cardiovascular risk has been a significant strategy in stroke prevention.[29–31] • Several studies have discovered the benefits of statins in reducing stroke risk as both a primary and secondary prevention strategy.[32–34] • In addition to elevated cholesterol and LDL, high-risk CRP has also been found to predict risk of ischemic stroke, and in patients with a history of stroke, could serve as a potential biomarker to predict risk of recurrent stroke.[35–38] • In healthy patients, without a prior history of stroke, there appears to be a benefit in starting statins if hs-CRP levels are found to be elevated despite normal LDL levels.[39] • Although high levels of cholesterol and low-density lipoprotein predispose to ischemic stroke (especially of atherosclerotic mechanism), low levels have been associated with an increased risk of intracerebral hemorrhage.[40]
Type 2 diabetes mellitus	• Studies have shown that a hemoglobin A1c goal of less than 7% is optimal for stroke prevention, however, below that does not confer an inverse relationship in terms of stroke prevention.[45]
Atrial fibrillation	• Factor Xa inhibitors and direct thrombin inhibitors have demonstrated greater efficacy and decreased risk of bleeding when compared with warfarin.[47–56] • [56]Extended cardiac rhythm monitoring of up to 30 days via cardiac telemetry or insertable cardiac monitor has revealed evidence of AF in a significant proportion of patients, with longer periods of monitoring increasing the yield.[58–60] • There is no convincing evidence that anticoagulation protects against recurrent stroke among patients without a definite source of cardiac embolism or in cases of cryptogenic stroke. • Large aortic arch atheroma and complex plaques were associated with a higher risk of stroke over a period of two years.[61] • N-terminal pro-B-type natriuretic peptide (NTproBNP) levels predict the development of atrial fibrillation and studies have shown that patients with elevated levels above the 95th percentile who were randomized to warfarin had a reduction in their risk of stroke or death compared with patients allocated to aspirin.[62–64]
Chronic kidney disease	• Chronic kidney disease is an independent risk factor for stroke, especially in patients dependent on dialysis.[71] • An eGFR<60 ml/min, high albuminuria, and proteinuria are associated with an increased risk of stroke.[65–70] • Control of blood pressure is one of the most important modifiable risk factors in primary and secondary prevention of strokes in patients with CKD.[81]

Obstructive sleep apnea	• Management and treatment of sleep apnea can serve as both primary and secondary prevention of stroke.[82] • Tools such as the Epworth Sleepiness Scale, Berlin Questionnaire, or STOP-Bang can be used to screen patients in the clinical setting to evaluate for possible sleep apnea.[88–90] • In patients found to have sleep apnea, weight loss through healthy diet and exercise must be encouraged along with the avoidance of provoking factors such as alcohol, smoking, and hypnotic drugs. • Treatment of sleep apnea with positive airway pressure ventilation has been shown to improve patient's cognition, neurological function, and disabilities faced post-stroke.[82] • Other strategies such as surgical intervention may be employed to reduce the risk of future vascular events.[91–94]
Diet	• Higher consumption of plant-based foods, namely cruciferous vegetables, green leafy vegetables, citrus fruits, vitamin C-rich fruits, and whole grains reveal an inverse relationship with and incidence of cerebrovascular disease, ischemic stroke, and IH, however, this association was not seen with potatoes and legumes.[95–97,99,100–103] • Intakes of total fat, plant fat, calcium, potassium, vitamin B1, vitamin B2, vitamin B6, niacin, and folate were negatively correlated with the risk of stroke.[103] • The relationship between fish consumption and stroke risk is unclear. A dose-dependent relationship has been shown to exist at higher quantities of greater than five servings per week, however, in mild quantities of a few servings per month, there appeared to be some protection against first-time stroke mostly seen in females and the Black population, especially with the intake of fatty fish such as tuna or broiled fish.[104–109] The risk of ischemic stroke mainly increased with consumption of fried and salted fish, with effects seen greater in men.[114] • Studies have found no association between stroke at any level of egg consumption after adjustment for age, gender, BMI, smoking, high blood pressure, diabetes, serum cholesterol, race/ethnicity, and educational status.[115–117] • Milk consumption was not associated with incident stroke mortality. Whole-milk intake was associated with increased risk of intracranial hemorrhage and yogurt intake with an increased risk of subarachnoid hemorrhage.[120] • The highest quintile of cream intake was associated with a slight decrease in cerebral infarct risk and intracranial hemorrhage, yet no association was found between total dairy intake, ice cream, cheese, low-fat milk, butter, or sour milk and stroke risk.[120] • Consumption of meat with a frequency greater than four times per week was positively correlated with risk of all strokes as well as first-incident strokes.[121] • Some preliminary evidence suggests that specific amino acids, such as taurine and arginine, found in animal protein, may modulate vasoactivity, resulting in reduced blood pressure.[122] Therefore, low intakes of animal fat and protein may have a stronger association with intracranial hemorrhage as compared with ischemic stroke. • Increased risk of intracranial hemorrhage has been observed among women who consume low levels of animal protein and saturated fat, with the latter among hypertensive women only.[123] • The highest tertiles of intake of dried soybeans, tofu, soymilk, and total soy foods were each associated with a significantly reduced risk of stroke after adjustment for confounders, as compared with the lowest tertiles of consumption.[126] • A protective effect of soy and isoflavone intake against risk of ischemic stroke and myocardial infarction (MI) has also been observed in women, primarily in postmenopausal women.[127] • A significant inverse relationship between whole-grain consumption and ischemic stroke risk has been observed but the same was not seen with total grain intake.[128,129] • Higher adherence to the DASH diet was significantly associated with reduced risk of stroke.[131] • The Mediterranean diet has been found to decrease risk of vascular deaths, myocardial infarction, and stroke in a dose-dependent manner.[131–134] • There was no statistical association between specific types of fat (total, animal, vegetable, saturated, monounsaturated, polyunsaturated, and trans fat) and stroke risk.[134–137]
Exercise	• Physical inactivity has been proven as a risk factor for stroke and it has been demonstrated that moderate to vigorous intensity aerobic exercise for at least 30 minutes, three to four times a week can cut the incidence of stroke.[138–140]
Smoking	• Smoking has been strongly associated with a two to four times increased incidence of stroke, worse outcomes post-stroke, and increased risk of recurrent strokes.[143,144] • A combination of counseling and medication, including medications such as nicotine patches, bupropion, and varenicline, is a strategy to decrease stroke risk.[143]
Alcohol	• There is somewhat of a protective effect against stroke with low intake of alcohol (one drink per day for women, two or fewer drinks per day for men), however, it is not recommended to start drinking alcohol for stroke prevention if previously abstinent.[147] • There is also a dose-dependent relationship between alcohol consumption and risk for hemorrhagic stroke.[148,149]

85 Alzheimer's Disease
Pathophysiology and Prevention

Selene Jamall, DO, Sharanya Thiagarajan, MS-IV, and Dean Sherzai, MD, PhD, MPH, MAS

KEY POINTS

- Alzheimer's disease affects people of all ethnicities, all over the world. It is the fourth leading cause of morbidity and mortality globally and creates a huge social and financial burden on worldwide healthcare systems.
- To date, pharmaceutical therapies directed at targeting early-onset Alzheimer's disease pathologies have been largely unsuccessful, further emphasizing the role of preventive measures through lifestyle change.
- The amyloid and tau theories are the prevalent disease models for Alzheimer's dementia and are driven by inflammation. This inflammation is caused by systemic problems such as diabetes, hyperlipidemia, oxidative stress, head trauma, and tobacco and alcohol use.
- The conventional Western diet promotes neuroinflammation through the consumption of excess fat, cholesterol, and sugar/fructose. Furthermore, this diet pattern negatively affects beneficial intestinal bacterial populations. Diets with more anti-inflammatory effects include the DASH diet, the Mediterranean diet, the MIND diet, and in some cases, the ketogenic diet.
- In addition to diet, key influencers in preventing dementia include exercise, stress reduction, sleep optimization, and addressing hearing loss.
- Strategies for reducing the incidence of dementia largely involve early lifestyle interventions at a population level. More comprehensive models that aim to improve the quality of life for people with dementia involve patient care teams as well as interventional training at the clinic level.

85.1 BACKGROUND

One of the most devastating and fastest-growing epidemics affecting the world is dementia, currently affecting approximately 57 million people and potentially 152.8 million by 2050.[1] Dementia disproportionally affects certain subsets of the population including women, African Americans, and Hispanics, especially those living in low to middle-income communities.[2] Many people are led to believe that the disease is part of normal aging, or are diagnosed when it is too late for any preventive interventions. According to the World Health Organization, dementia is currently the fourth leading cause of mortality and morbidity globally, and the top leading cause of morbidity in the United States; one American is diagnosed every 64 seconds.[3]

There are several types of dementia, including Parkinson's dementia, vascular dementia, frontotemporal dementia, dementia with Lewy bodies, Huntington's dementia, mixed dementia, and dementia secondary to underlying conditions such as traumatic brain injury (TBI). The most common type is Alzheimer's dementia (AD), representing 60–80% of all dementias. While many public health interventions and medical treatments have been successful in reducing mortality in people living with diabetes, HIV, cancer, and heart disease, AD-related mortality has risen by a staggering 145.2% in the last 20 years. Though the human cost is immeasurable, the direct cost to the healthcare system of AD is estimated to be $321 billion. The indirect cost to families as a result of time lost from work and the cost of out-of-pocket support is more than $271.6 billion per year.[1] Heart disease, the highest leading cause of mortality globally, comparatively averages $378 billion annually.[4] The yearly cost of AD is expected to rise to $1.1 trillion solely in the United States and $20 trillion worldwide by 2050.[5]

AD research has been targeting two early-onset pathologies that play an important role in the onset of disease: amyloid-beta (Aβ) peptide and hyperphosphorylated tau (p-tau).[6] However, despite high trial expenditure, the US Food and Drug Administration (USFDA) has approved only six drugs, including three cholinesterase inhibitors (donepezil, rivastigmine, galantamine) and one N-methyl-d-aspartate (NMDA) receptor antagonist (memantine). Though heavily used in the AD population, their effectiveness can be questioned as they are not disease-modifying therapies and are expensive. One of the previously mentioned drugs per patient can cost $1800 annually or $5 per day.[7] These drugs improve symptoms at a certain snapshot of time but neglect the progression of this deadly disease.

Aduhelm (aducanumab-awa) is the most recent drug, approved by the FDA in 2021, and is designed to alter disease progression by removing amyloid-beta (Aβ) peptide which accumulates and forms plaques.[6] Two studies have shown that intravenous infusion of Aduhelm in patients decreased the amount of "amyloid fibril", confirmed with positive emission tomography (PET) scans. However, the same two clinical

DOI: 10.1201/9781003227793-100

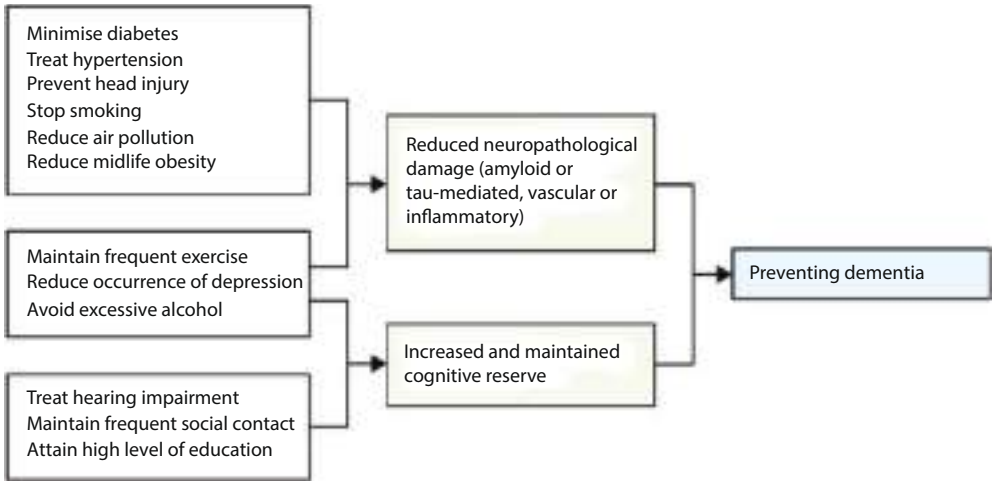

FIGURE 85.1 Preventing dementia.

studies did not reproduce these clinical benefits and could not confirm a positive relationship between reduction in amyloid burden and improved clinical outcome.[7] Though the drug was approved on the basis of its significant therapeutic benefit in certain situations, it has not produced any clinically substantial results in subsequent AD trials.

Although risk factors such as insulin resistance, high cholesterol, elevated blood pressure, and high body mass indexes increase with age, many normal functioning processes such as inflammation, oxidation, glucose and insulin regulation, and lipid dysregulation become less efficient with age. These can accelerate various disease processes in individuals.[8] However, there has been significant research that "successful cognitive aging" involves strategies at both the individual and community levels[9] Early diagnosis of risk factors and comprehensive lifestyle change is the most powerful approach in reducing mortality and incidence of dementia. Higher adherence to a healthy lifestyle score, characterized by nutrition, exercise, stress management, restorative sleep, and mental and social optimization is related to decreased risk of AD incidence.[10]

85.2 PROPOSED PATHOPHYSIOLOGICAL MECHANISMS

85.2.1 Amyloid Theory

Amyloid precursor protein (APP) is a cell surface receptor most densely found in neuronal synapses, regulates neuronal plasticity and nutrient transport, and supports the development of new synapses. APP is cleaved by an enzyme called alpha-secretase, producing neuronal transmembrane peptides that reduce intracellular calcium in neurons, preventing apoptosis. When APP is instead cleaved by beta- or gamma-secretase, this produces dysfunctional transmembrane proteins that allow more intracellular calcium (leading to apoptosis). These cleaved fragments also "clump" together and oligomerize.[11]

The amyloid theory was proposed 25 years ago when it was discovered that mutations in APP, presenilin 1, and/or presenilin 2 genes (PSN1/PSN2) were associated with increased amyloid-beta protein production. It was first found to aggregate in key processing areas of the brain, reducing synaptic transmission, forming "plaques", and activating local microglial inflammatory responses. Although beta-amyloid is normally found in the aging brain, disruption in neuronal metabolism was found to lead to increased phosphorylation of amyloid-beta, further stabilizing these plaques which interfere with neurotransmission,[11] triggering inflammation, leading to synaptic dysfunction, and eventually, cause gradual apoptosis leading to dementia. However, with the failure of several anti-amyloid medications, more recent hypotheses now posit that beta-amyloid may instead be a trigger for the hyperphosphorylation of tau protein, which may be the active cause of Alzheimer's disease. In essence, beta-amyloid may be thought of as laying the groundwork for tau protein to cause pathology.[12]

85.2.2 Tau Theory

The tau theory suggests that aggregations of tau protein strings form neurofibrillary tangles inside of cells, leading to inflammation and cell death. Deposition of tau protein is often seen ten or more years prior to the deposition of beta-amyloid protein and has been a more consistent predictor of AD later in the disease.[12] Tau protein stabilizes microtubules in cells. When it undergoes phosphorylation, this destabilizes the microtubule which can develop into neurofibrillary tangles. This becomes pathologic as neuronal cells with impaired microtubule formation have impaired axonal transport and are unable to undergo normal reparative and supportive processes.[13] Several anti-tau therapeutics have been proposed, however, these have not yet shown clinical benefit.[14]

85.2.3 Diabetes and Insulin Resistance

The brain is an extremely glucose-sensitive and by extension an insulin-dependent organ. Among other brain

structures, both insulin receptors and insulin-like growth receptors are expressed in the hypothalamus, hippocampus, and cortex, structures that are primarily involved in metabolic regulation, memory, and executive function. Unsurprisingly, insulin plays a large role in synaptic plasticity, and insulin signaling is often impaired in the brains of patients with diabetes and Alzheimer's disease[15] due to hyperinsulinemia as a response to hyperglycemia. For this reason, Alzheimer's disease is sometimes referred to as "type III diabetes"[16] Specifically, as glucose crosses the blood–brain barrier, peripheral hyperglycemia causes glial-mediated inflammation, leading to increased neuronal insulin resistance. Over time, this results in synaptic failure and degradation as the blood–brain barrier also becomes more permeable through insulin resistance

85.2.4 High Cholesterol

Since the identification of the ApoE4 gene (which encodes the ApoE4 protein, responsible for lipid transport) and its correlation with a predisposition for Alzheimer's disease in 1993, elevated cholesterol has been a target in the prevention of dementia. Increased low-density lipoprotein leads to increased production of the cholesterol metabolite, 24-hydroxycholesterol exclusively generated in neurons. Although not pathologic by itself, increased production was observed in patients with early development of Alzheimer's disease. Furthermore, increased glial-mediated inflammation, as also seen in diabetes, was also noted with increased cholesterol levels.[17]

85.2.5 Inflammation

The brain's macrophage, microglia, have several critical roles including synapse organization, debris removal via phagocytosis, cellular protection and repair, control of neuronal signaling and excitability, and turnover of myelin. They produce inflammatory signals as a part of the brain's innate immune response. Sustained activation of this inflammatory response has been shown to exacerbate the role of both beta-amyloid accumulations and neurofibrillary tangles, which in turn enhance microglial activation.[18] ApoE4 expression is increased in activated microglia, as is the expression of NLRP3. NLRP3 acts as a sensor of neuronal environment irritants, a critical component of immune homeostasis. When activated, it creates what is known as the NLRP3 "inflammasome", which releases a cascade of pro-inflammatory cytokines.[19] Another genetic marker of interest is triggering receptor expressed on myeloid cells 2 (TREM2).[20] It was discovered that mutations in this gene have also been associated with a higher likelihood of developing Alzheimer's disease. Normal TREM2 maintains the metabolic function of microglia, especially during stress, however, its mutated form inhibits this protective ability.[21] Therefore, continually sustained activation of these components creates an environment of perpetuated inflammation in the brain.

85.2.6 Oxidation

Oxidative stress refers to an imbalance between the production of reactive oxygen species and antioxidant production. This results from increased protein oxidation, lipid peroxidation, and end-glycosylation products, all of which are molecular processes that produce byproducts that increase oxidation at the cellular level. The antioxidant defense mechanism primarily includes the production of intracellular low molecular weight glutathione, which decreases with age.[22] Furthermore, reactive oxygen species (peroxyl radicals) and reactive nitrogen species directly damage proteins and DNA bases, leading to aldehyde byproducts that deplete glutathione.[23] Therefore, the cumulative effect of increased oxidation production overwhelms the already reduced potential from antioxidant production.

85.2.7 Head Trauma

Although the exact mechanism supporting the relationship between the development of dementia and the incidence of traumatic brain injury is not well described, many studies have found a positive correlation between head injury with or without loss of consciousness and the later development of dementia. A single head injury (regardless of loss of consciousness) is associated with a 1.25 increase in risk of developing dementia over the next 25 years. In the case of two or more head injuries, that risk increases to 2.14.[24]

85.2.8 Alcohol

Alcohol consumption has long been associated with major impacts on health and is a significant contributor to global disease burden. This has previously been discussed in relation to "heavy" alcohol use (an average of four standard drinks daily) and its effects on cognition, cardiovascular disease, nutrition, and cancer. The effects on cognition are assessed by measuring global brain volume, and both gray and white matter volume. While studies in the early 2000s touted that small quantities of alcohol, specifically containing resveratrol (a compound found in red wine) conferred health benefits,[25,26] recent research does not support this practice. In several large population studies, one standard drink daily was enough to result in overall damage to the frontal lobes, hippocampus, and cerebellum. These subjects were found to have decreased gray matter volume in critical structures of the prefrontal cortex, insula, superior temporal gyrus, striatum, thalamus, and hippocampus when compared with healthy, alcohol-abstinent controls.[27] Regular consumption of alcohol also downregulates structural proteins necessary to maintain the integrity of the blood–brain barrier (zona occludins-1, VE-cadherin, and occludin), which leads to damage by neurotoxic agents.[28] Increased iron deposition in the brain has also been noted with moderate alcohol intake, leading to both Alzheimer's and Parkinson's disease.[29] Therefore, it is no longer accurate to suggest that any level of alcohol consumption is beneficial for health.

85.2.9 Smoking

Smoking is associated with increased production of reactive oxygen species, therefore, leading to increased oxidative stress. As previously discussed, damage caused by free radical species incites a systemic inflammatory response that has profoundly damaging effects on neuronal tissue through increased production of superoxide radicals and hydrogen peroxide.[30] A large body of epidemiological research has demonstrated a dose-dependent but increased risk for Alzheimer's disease and dementia in association with cigarette smokers,[31] a risk that persists even years after tobacco cessation.

85.3 NUTRITION AND ITS EFFECT ON RISK

Several studies have aimed to assess the relationship between dietary composition and Alzheimer's disease. A 2002 study in Finland suggested that elevated total cholesterol and high blood pressure contributed to a greater risk of Alzheimer's disease than the ApoE4 gene mutation or any familial risk.[32] A 2.2–2.4 times increase in risk was seen in patients with a high intake of saturated and trans-unsaturated fats.[33] More recent associations with all components of a typical "Western diet", consisting of refined sugars, simple carbohydrates, salt, saturated fatty acids, and cholesterol (and poor in grain, fiber, and mono- and polyunsaturated fatty acids), have been made with impaired cognition, learning, and memory specifically through changes in gut microbiota.[34] Changes to the population of gut microbiota, referred to as "dysbiosis", have been linked to a propensity toward developing obesity and diabetes among other metabolic disorders.

85.3.1 The Effect of the Western Diet

The Western diet pattern has demonstrated an association with decreased overall hippocampal volume, and more concerning, may also be transmitted from mother to child through epigenetic mechanisms. Increased accumulation of amyloid-beta protein, increased levels of neuroinflammatory markers (such as TNF-alpha, IL-6, IL-1 beta), and increased blood–brain barrier permeability has been demonstrated in consumers of high fat, cholesterol, and sugar/fructose diets.[34] However, just as the Western diet has been studied in connection with inducing all of these neurodegenerative changes, several diets have also been shown to modify intestinal bacteria populations in ways that prevent the development of type 2 diabetes and other known neuroinflammatory disorders.[35]

85.3.2 Risk Reduction through Diet

Popular dietary models that have been associated with overall Alzheimer's dementia risk reduction include the DASH (Dietary Approaches to Stop Hypertension) diet, Mediterranean diet, and ketogenic diet. Perhaps the most well-known of these is the Mediterranean diet. The Mediterranean diet is rich in olive oil, vegetables, fruit, nuts, cereals, legumes, fish, and seafood. Overall, it consists of a high ratio of monounsaturated to saturated lipids. A four-year trial found that a sustained Mediterranean diet led to a reduction in inflammatory markers, such as VCAM-1, ICAM-1, IL-6, and CRP. Lowering inflammation reduces all-cause mortality including cancer, cardiovascular, and cerebrovascular causes.[36]

The DASH diet consists of mostly whole grains, with protein coming from lean meats, fish, poultry, nuts, and beans. It is rich in fruit and vegetables, and low-fat dairy products, resulting in a high fiber to low/moderate fat ratio. The diet overall proposes reduced sodium intake for the control and reduction of high blood pressure (daily sodium intake is typically <2400 mg). It excludes or proposes reducing saturated fats, total fat, cholesterol, refined grains, and sweets. More recently, a hybrid of the DASH and Mediterranean diets has been proposed, called the MIND diet, alluding to its clear benefit with regard to neurological health.[36,37] It promotes a plant-based diet, limiting meat, salt, and dairy products. In the Rush University Memory and Aging Project, strict adherence to the MIND diet resulted in a 53% risk reduction in the development of Alzheimer's disease for subjects aged 58–98 years old. Importantly, even moderate adherence to the diet resulted in a 35% risk reduction.[37]

Finally, the ketogenic diet proposes a high fat, moderate protein, and low carbohydrate intake. Ketogenic diets have been shown to improve neuroinflammatory markers and amyloid/tau deposition, resulting in short-term cognitive improvements in humans.[38] It should be noted, however, that there exists very little evidence that this diet plan can be sustained by most patients for longer than three months.[39]

85.4 OTHER LIFESTYLE INFLUENCES

85.4.1 Exercise

For decades, physical exercise has been shown to have a positive correlation with health as a whole. Exercise can be broken down into four categories: aerobic, anaerobic, agility training, and stretching and flexibility.[40] However, not all exercise provides equal benefits in improving vascular health and growth, psychological processes, and the development of new neuronal connections. Extended periods of regular, high-intense aerobic exercise dramatically reduce rates of AD. LADIS, a European multicenter study, revealed that in three years, physical activity reduced the risk of cognitive impairment and dementia by 40%.[41] Another study revealed that when comparing intensive aerobic exercise with stretching on those diagnosed with mild cognitive impairment (MCI), the participants who engaged in the intensive aerobic exercise exhibited better executive function due to greater blood flow to the frontal lobe and an increase in brain size, regardless of their genetic disposition to AD.[42]

Anaerobic exercise such as strength training also resulted in an inverse relationship with cognitive decline. A 2010 meta-analysis consisting of 15 studies with 34,000 participants further demonstrated that strenuous exercise resulted in a 38% reduction in cognitive decline.[43] Another type of anaerobic exercise, resistance training, improved cognition to normal in 47% of subjects with MCI; greater leg strength as a result of this exercise also proved contributory to better brain quality.[44] Therefore, any exercise, but especially regular aerobic exercise to one's daily regimen, is crucial for maintaining brain functioning and improving brain health.

85.4.2 Stress

Environmental threats and adversity increase systemic cortisol production, which in turn upregulates the production of pro-inflammatory cytokines. Via the limbic-hypothalamic-pituitary-adrenal axis (HPA axis),[45,46] the brain regulates and processes emotional responses to stimuli. If perceived as a negative stressor, it induces the hypothalamus to release corticotropin-releasing factor (CRF). This causes a release of multiple pituitary hormones, including ACTH, which then act on the adrenal glands to secrete both mineralocorticoids and glucocorticoids such as aldosterone and cortisol.[47] This flood of steroid hormones results in the dampening of higher cognitive processing. Under evolutionary circumstances, this is useful for making quick responses focused on an immediate threat. However, similar threat responses are generated over increasingly "smaller" matters today and occur much more often. This creates elevated baseline levels of circulating cortisol and other pro-inflammatory cytokines, leading to neuronal atrophy and cell loss in the limbic system and prefrontal cortex.[48] This atrophy occurs through glucocorticoid suppression of brain-derived neurotrophic factor (BDNF), which typically promotes the growth and maturation of neuronal cells.[49]

The sympathetic pathway also activates a similar response, together with the HPA, resulting in increased glucocorticoid release. Microglia, which compromise the main component of the brain's immune system, are inhibited by glucocorticoids and noradrenaline, which is released through the activation of the sympathetic nervous system. Curiously, both glucocorticoids and noradrenaline can also enhance the activity of microglia under acute stress conditions but have deleterious effects under severe, continued stress conditions.[50] The sympathetic nervous system also perpetuates systemic vasoconstriction under stressful conditions. Acutely, this decreases the involvement of the medial prefrontal cortex, which can lead to neuronal loss in this area as well as the insula and parietal cortex under chronic stress conditions.[51]

One such proposal for stress reduction that has been shown to result in meaningful structural change is meditation. Several studies have linked regular meditation practice with reduced brain atrophy, increased neuroplasticity, and improved cognition. Specifically, MRI findings demonstrated increased thickness of the outer (cortical) layer used in higher cognitive processes, and this effect was most pronounced in older subjects.[52]

85.4.3 Sleep

The amount and, more importantly, the depth of sleep are associated with corresponding changes in memory consolidation, cognition, and appetite. Sleep is an anti-inflammatory process. Similar to a stress state, sleep deprivation results in dysfunction of the hypothalamic-pituitary-adrenal axis, and excessive daytime sleepiness from inadequate sleep is associated with a decreased response to chronically elevated baseline cortisol.[53] This results in attenuation of microglial activity by pro-inflammatory cytokines, adenosine, and interferons.[54] Microglia are responsible for the normal maintenance and "pruning" of neurons during sleep. A structure located in the area of the rostral pons, known as the locus coeruleus, is a key part of the reticular activation system and mediates wakefulness through the secretion of norepinephrine. It continually secretes norepinephrine throughout the brain except during REM (rapid eye movement) sleep and just before NREM (non-rapid eye movement) sleep.[55] These pauses allow for the incorporation of new information via synaptic plasticity into memory circuits.

The "dual process hypothesis" of sleep has suggested that non-REM or NREM sleep, which takes place typically during the first half of the sleep cycle, is necessary for the consolidation of declarative memory, while REM sleep in the second part of the sleep cycle is for implicit (procedural) memory[55] It therefore follows that a dysfunctional HPA axis, leading to elevated cortisol and therefore a pro-inflammatory chronic state, creates an environment for the development of chronic disease. Furthermore, chronic stimulation of the brain by norepinephrine in the absence of the deeper sleep phases creates a chronically sleep-deprived state.

Addressing sleep deprivation requires a multidisciplinary approach that takes many of the above factors into account: lowering baseline stress levels, optimizing an exercise routine, and making dietary changes to maintain a healthy weight. Obstructive sleep apnea, most often caused by obesity, leads to periodic hypoventilation throughout the night, which, over time, leads to increased neuronal stress and inflammation.[56] Other behavioral interventions for optimizing sleep include decreased intake of caffeine, as well as establishing sleep hygiene routines.

85.4.4 Diminished Hearing

Age-related hearing loss is another modifiable risk factor that is linked to cognitive decline and dementia. According to the 2018 meta-analysis by Loughrey et al.,[57] hearing loss can affect the clinical outcomes of dementia. Though easily amenable with hearing aids, only one in five Americans with hearing loss acquire these devices;[58] some reasons

include lack of access to a primary care provider, unsupportable insurance, or high costs. However, further clinical trials are needed to determine the causal relationship between hearing loss and cognitive decline.

85.5 IMPLEMENTING RISK REDUCTION GUIDELINES

Community involvement is a key sector to be utilized to tackle this and other public health concerns. A study published by the Flemish Ministry of Welfare[59] reported that a mass media public health campaign involving social media and an interactive online assessment increased 80.5% of the participants' motive to engage in healthier activities by exercising and eating healthier meals. The feedback from post-campaign also revealed that more than half of the subjects were unaware of the strategies to reduce dementia risk, followed by a lack of motivation, financial constraints, and a shortage of time. With strong efforts in public awareness, people may feel empowered to take control of disease, rather than be fearful, improving their quality of life.[60] Another study conducted in Saudi Arabia reported positive attitudes toward people with AD but lacked the required knowledge to understand the disease.[61] This further echoes a similar conclusion that more educational programs via video clips or in-person presentations at a community level such as churches, dance centers, gyms, and movie theaters are needed.

85.5.1 Early Diagnosis and Prevention

Healthy lifestyle changes have been the gold standard in controlling hypertension, type 2 diabetes, and their effects on systemic disease. However, the effect of disease on brain health has not been emphasized. Most neuroimaging with MRI and EEG occurs when individuals present with abnormal cognitive functioning that significantly affects their daily life, and often are left with limited options in the further prevention of progression of the disease.[62]

The importance of primary care in early and ongoing cognitive testing has been studied. A study conducted in China explored the importance of using several tests due to the varying sensitivity and specificity. The Clinical Dementia Rating (CDR) has 74% accuracy in screening patients for dementia—more significant than the Brief Elderly Cognitive Screening Inventory (BECSI), the Quick Cognitive Screening Scale for Elderly (QCSS-E), the Mini-Mental State Examination (MMSE), and the Core Neurocognitive Test (CNT).[63] Another study conducted in Hong Kong compared the efficacy of using a digital cognitive test to screen for MCI and dementia with the conventional Montreal Cognitive Assessment. The EC-Screen uses a platform that reads the test instructions for the various tasks, which can be completed in approximately five minutes. Unlike the MOCA, which is dependent on education level, the EC-Screen has made an alternative version adapted for individuals with a lower education level.[64] It can be administered by any staff, family member, or personally, which can improve efficiency in primary health and community areas.

In addressing brain health, recognizing the disease is equally important as maintaining a management plan with a collaborative team of providers including nurses, pharmacists, nursing home staff, and caregivers.[62,64]

85.5.2 Comprehensive Intervention Models

Several studies have been conducted where intervention models were designed to help dementia patients both maintain and improve their daily living ability.[65] One study conducted in 2019 in China involved a five-part model that incorporated self-care training (dressing, preparing food), exercise, cognitive training (matching games, concentration), social interest (calligraphy, painting, reading), and nursing (directed toward caregivers' understanding of health knowledge and behavior processing).[66] Compared with standard medication management (control), the intervention group improved in self-care ability, housework, communication, and leisure activity domains. Although this did improve patient quality of life, this study as well as a similar study in 2016 (focused solely on caregiver education and interventions), did not lead to slowed disease progression nor improvements in their memory or directivity.[67]

This highlights the importance of multimodal interventions that not only improve the quality of life in existing dementia but also in the prevention of the multiple risk factors that have been shown to slow disease progression. This is best demonstrated by the Finnish Geriatric Intervention Study to Prevent Cognitive Impairment and Disability (FINGER) model.[68] Patients in this randomized control trial were assigned to either a control group or an intervention group that received dietary counseling, physical exercise, cognitive training, and the monitoring of metabolic and vascular risk factors. This model resulted in an average of 25% improvement in global cognition, executive function, processing speed, and complex memory tasks even at several years follow-up post-study compared with the control group.

85.5.3 Clinic-Based Intervention Protocols

Since 2001, at least seven studies lasting anywhere between one to four years have been conducted to examine the outcomes of collaborative, outpatient primary care models. They are listed below with their respective outcomes:

- Healthy Aging Brain Center (HABC, 2004): Reduced ER usage and need for acute hospitalization.
- Aging Brain Care Medical Home (ABC, 2012–2014): Decreased severity of cognitive, functional, and psychological impairment.
- Alzheimer's and Dementia Care (ADC, 2012–2014): Patients passed 92% of specific "dementia care quality" indicators such as degree of mental

status changes and usage of acetylcholinesterase inhibitor medications.
- Alzheimer's Disease Coordinated Care for San Diego Seniors (ACCESS, 2001–2002): Of several findings, there was more support group engagement, more usage of acetylcholinesterase inhibitor medications, and more adherence to dementia care guidelines.
- Centre for Family Medicine Health Team (2008–2011): Decreased wait time to access psychoeducation and greater satisfaction with education received.
- Dementia Life- and Person-Centered Help in Mecklenburg-Western Pomerania (DeLPHi, 2012–2016): Increased chance of receiving antidementia drug treatments.
- DementiaNet (2015–2017): Earlier dementia diagnosis and better coordination of care.

All of the above studies noted improvements across multiple surveys assessing the severity of dementia symptoms and quality of life. Benefits to patient caregivers and financial burden were also noted for certain studies.[69]

85.5.4 Population-Based Intervention Protocols

At a population level, the focus on minimizing the risk of dementia is based on prevention. Specifically, addressing many of the aforementioned risk factors at all stages of life—avoiding head injury, decreasing alcohol intake, cessation of both active and passive smoking, a sustained exercise routine, social life, and the maintenance of systolic blood pressure throughout the midlife years ≤130 mmHg.[68]

85.6 SUMMARY

The development of Alzheimer's disease is attributable to a culmination of different risk factors, often both lifestyle- and environmentally based, most of which are modifiable. In summary, the prevention of chronic vascular disease (through cessation of smoking, cholesterol control, blood glucose control, etc.) aids in reducing cumulative systemic inflammation, which overall lowers the risk of developing dementia. Addressing environmental and external risk factors, such as sleep hygiene, stress levels, and head trauma are also key factors in preventing Alzheimer's disease. Just as the approach to reducing the incidence and burden of dementia is multifactorial, interventions at the clinic and population level must also be multi-pronged, with the ultimate goal focused on disease prevention in the early years through midlife.

CLINICAL APPLICATIONS

- *Prevention through early life and midlife*
  - Control of hypertension, diabetes (type II), and hyperlipidemia.
  - Avoidance of head trauma.
  - Avoiding tobacco use and alcohol use, or early cessation.
  - Implementing anti-inflammatory dietary changes.
  - Development and maintenance of regular varied exercise.
  - Addressing sleep hygiene
- *Diagnosis*
  - Early and ongoing cognitive testing has been found to screen patients with dementia with high efficacy.
  - Early neuroimaging may be considered depending on cognitive screening.
- *Intervention*
  - Different models exist that address dementia at both the clinical level and the multidisciplinary level (involving physical therapists, dietitians, nursing staff, and caregivers). All of these emphasize a multi-pronged approach to delaying the progression of dementia and improving symptom management through exercise, dietary changes, social enrichment, caregiver involvement, and cognitive challenges.

86 Definition of Lifestyle Medicine*

George Guthrie, MD, MPH, CDCES, CNS, FAAFP, FACN

KEY POINTS

- Lifestyle medicine is a relatively new medical specialty being defined as the prevention and treatment of appropriate disease states by changing the personal habits and behavioral choices of individuals in such a way as to address the underlying cause
- Practitioners of lifestyle medicine see it as part of allopathic medicine and neither complementary nor alternative but foundational to treating chronic lifestyle-caused disease.
- Lifestyle medicine can be effective in the treatment and, in some cases, the complete reversal of the manifestations and possibly even the cure of many chronic non-infectious diseases.

86.1 LIFESTYLE MEDICINE: THE HISTORY OF A DEFINITION

The phrase "lifestyle medicine" appears to have been first used by the epidemiologist Ernst Wynder in a discussion of the effects of smoking on lung cancer risk around 1988.[1] Wynder used the phrase in a symposium title in 1989.[2] Hans Diehl reports hearing Wynder use the term, being enamored with the phrase, and seeking to copyright it in the United States in 1988.[3] The request was denied by the authorities because the individual words were of widespread common use and the combination was not distinct. James Rippe published the first text entitled "Lifestyle Medicine" in 1999.[4] Gary Egger, A. Binns, and S. Rossner published "An Introduction to Lifestyle Medicine" in 2007.[5] PubMed references to the phrase rose from 208 in January 2018[6] to 859 in November 2022[7] and reflect continued interest (see Figure 86.1).

Within the medical community, the phrase "lifestyle medicine" has variations in implications/meanings. Those early users of the paired-word phrase seemed to be focusing on how the personal behaviors of individuals affect their health and well-being. As noted above, the first documented use was referring primarily to the effect of smoking on the risk of emphysema/COPD pathology. Hans Diehl was the founder of the Coronary Health Improvement Project (CHIP) program, and his efforts for lifestyle change in the treatment of coronary heart disease focused on nutrition, exercise, and other modifiable risk factors to help reverse atherosclerotic pathology. The CHIP program promoted the newly added credibility proffered when Dean Ornish published his randomized controlled trial (RCT) demonstrating the reversibility of the disease.[8] Early implications center on personal behavior change and have invoked significant reference to behavioral change techniques.

Rippe's initial 1999 text defined lifestyle medicine as, "The integration of lifestyle practices into conventional medicine to lower the risk for chronic disease and, if disease is already present, to serve as an adjunct to therapy".

In 2008, the leadership of the American College of Preventive Medicine, Mark Johnson and Mike Barry, defined lifestyle medicine as, "A defined scientific approach to decreasing disease risk and illness burden by utilizing lifestyle interventions such as nutrition, physical activity, stress reduction, smoking cessation, avoidance of alcohol abuse, and rest."

In his 2008 textbook, Eggers addressed the definition in this way: "The therapeutic use of lifestyle interventions in the management of disease at all levels to help manage the growing number of cases presenting to doctors now with a lifestyle-based cause of disease such as obesity and type 2 diabetes". He then added a sentence that lessens the personal "guilt" for an individual disease sufferer and admits to important societal forces (now popularly referred to as "Social Determinates of Health) active in deciding individual behavioral choices. "The application of environmental, behavioral, medical and motivational principles to the management of lifestyle related health problems in a clinical setting".

The American College of Lifestyle Medicine and American College of Preventive Medicine prepared an overview of lifestyle medicine in 2009 that sought to gather into one place the current thinking on the area from a medical perspective. Unfortunately, it is no longer posted online.

Lifestyle medicine core competencies were published in *JAMA* (2010) to help define the discipline within medicine.[9] These were organized into six Accreditation Council for Graduate Medical Education and American Board of Medical Specialties (ACGME/ABMS) categories. The final list consisted of 34 competencies in the six ACGME/ABMS categories. A recent update[10] expands the list to 88 and is available at https://journals.sagepub.com/doi/epub/10.1177/15598276221121580.

In the fall of 2012, ACLM convened a task force to draft the official standards for ACLM and the field of lifestyle medicine that focused primarily on the clinician-patient relationship.

DOI: 10.1201/9781003227793-102

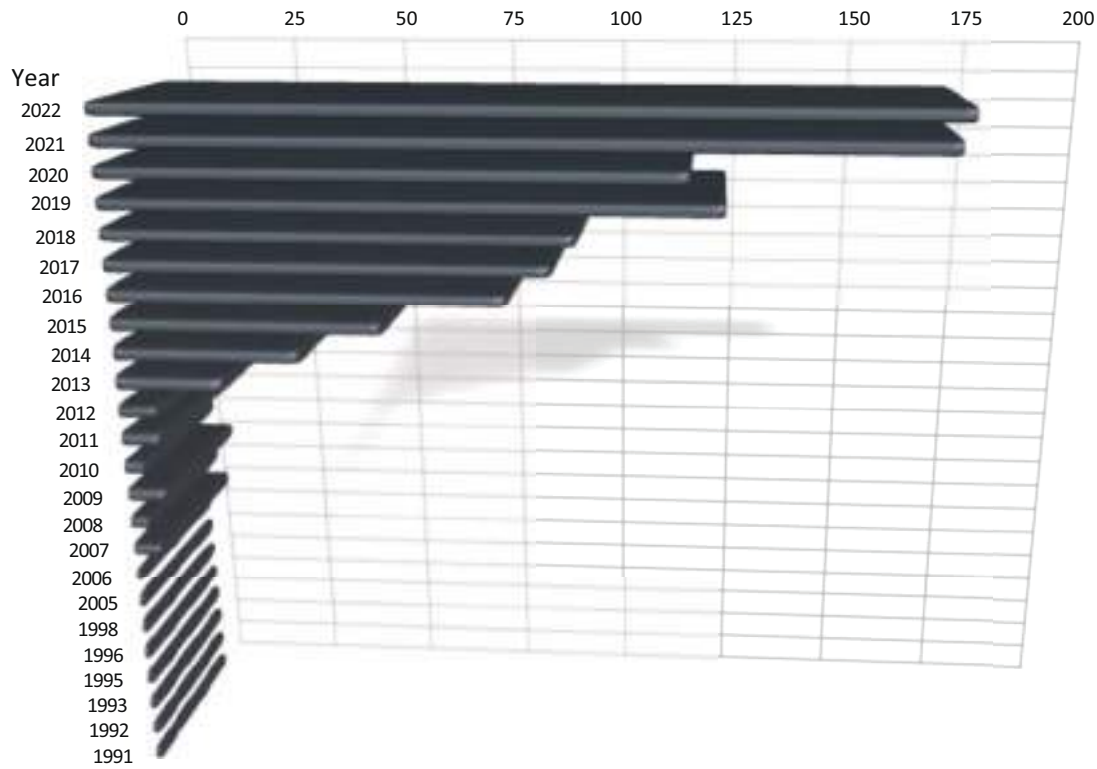

FIGURE 86.1 PubMed references to "lifestyle medicine" by year (https://pubmed.ncbi.nlm.nih.gov/?term=%22Lifestyle%20medicine%22&timeline=expanded).

> Lifestyle Medicine is the therapeutic use of evidence-based lifestyle interventions to treat and prevent lifestyle related diseases in a clinical setting. It empowers individuals with the knowledge and life skills to make effective behavior changes that address the underlying causes of disease.[11]

A similar definition appeared in late 2014 in the *International Journal of Clinical Practice* that included a community focus.

> Lifestyle Medicine is the evidence-based practice of helping individuals and communities with comprehensive lifestyle changes (including nutrition, physical activity, stress management, social support, and environmental exposures) to help prevent, treat, and even reverse the progression of chronic diseases by addressing the underlying cause.[12]

In their 2016 book, *Lifestyle Medicine: A Manual for Clinical Practice*, Mechanick and Kushner hinted at the concept of a specialty within medicine when they defined lifestyle medicine as

> a branch of medicine focused on preventive healthcare and self-care dealing with research, prevention, and treatment of disorders caused by lifestyle factors and preventable causes of death such as nutrition, physical inactivity, chronic stress, and self-destructive behaviors including the consumption of tobacco products and drug or alcohol abuse.[13]

The website of the American College of Lifestyle Medicine continues to provide a definition that has now morphed to include an allopathic specialty status. It is an expansion of previous definitions that focused primarily on modalities and evidence-based science as well as the prevention and reversal of disease.

> Lifestyle medicine is a medical specialty that uses therapeutic lifestyle interventions as a primary modality to treat chronic conditions including, but not limited to, cardiovascular diseases, type 2 diabetes, and obesity. Lifestyle medicine certified clinicians are trained to apply evidence-based, whole-person, prescriptive lifestyle change to treat and, when used intensively, often reverse such conditions. Applying the six pillars of lifestyle medicine—a whole-food, plant-predominant eating pattern, physical activity, restorative sleep, stress management, avoidance of risky substances and positive social connections—also provides effective prevention for these conditions.[14]

In Egger's 2017 edition, the definition expanded to include, "The application of environmental, behavioural (sic), medical and motivational principles to the management (including self care and self-management) of lifestyle-related health problems in a clinical and/or public health setting."[15] As it did in its earlier rendition, the current Australasian Society for Lifestyle Medicine (ASLM) webpage definition

goes on to endorse the social and policy dimensions of the basic six pillars earlier defined by the American College of Lifestyle Medicine.[16]

86.2 THE AMERICAN BOARD OF LIFESTYLE MEDICINE

In early 2016, the American Board of Lifestyle Medicine[17] (ABLM) was formed as an independent not-for-profit company (501c6) to identify lifestyle medicine clearly within the "house of medicine". This was shortly followed by the formation of the International Board of Lifestyle Medicine (IBLM). Because of the desire to eventually be accepted as a subspecialty by the American Board of Medical Specialties, the focus was on evidence-based medicine. Established pathways were followed.[18] As of June 2022, there are over 2009 ABLM physicians and 3234 worldwide physician diplomats in 72 countries.[19] The test questions and board review materials have gone a long way toward collecting, categorizing, and developing standards from the peer-reviewed evidence while creating a foundation on which the practical "definition" of lifestyle medicine will continue to expand (Figure 86.2).

To facilitate the teaching of lifestyle medicine, the American College of Lifestyle Medicine has created curricula for colleges, medical schools, and graduate medical education. The Lifestyle Medicine Residency Curriculum (LMRC) is to be available as a standardized curriculum virtual learning tool that is updated continually on a three-year cycle. When completed and verified by participating residency leadership, the virtual presentations and corresponding required activities make the resident board eligible. Its adoption has primarily been in preventive medicine, internal medicine, and family medicine residencies around the United States.

86.3 THE UNIQUE ROLE OF LIFESTYLE MEDICINE WITHIN ALLOPATHIC MEDICINE

There is a growing interest from the political realm influencing various professional organizations to address environmental and social determinants of health, society, and agribusiness disease-modifying factors. While lifestyle medicine has focused more on health professionals working to modify the behaviors of individuals to prevent disease, improve health, and even reverse disease, there is a recognition that these larger factors are important. Effectiveness in creating change in society is often perceived as in the realm of public health. Additionally, many lifestyle medicine practitioners are also schooled and even boarded in this specialty. Lifestyle medicine and public health in many ways share the task of engendering positive change in the slightly different but overlapping responsibilities.

In recent years, various professional organizations have begun to emphasize the importance of lifestyle medicine and have taken steps to increase the visibility of lifestyle interventions within the various specialties. This reflects a practical response to the growing body of evidence for the effectiveness of lifestyle interventions. An example of this includes a 2021 consensus report acknowledging

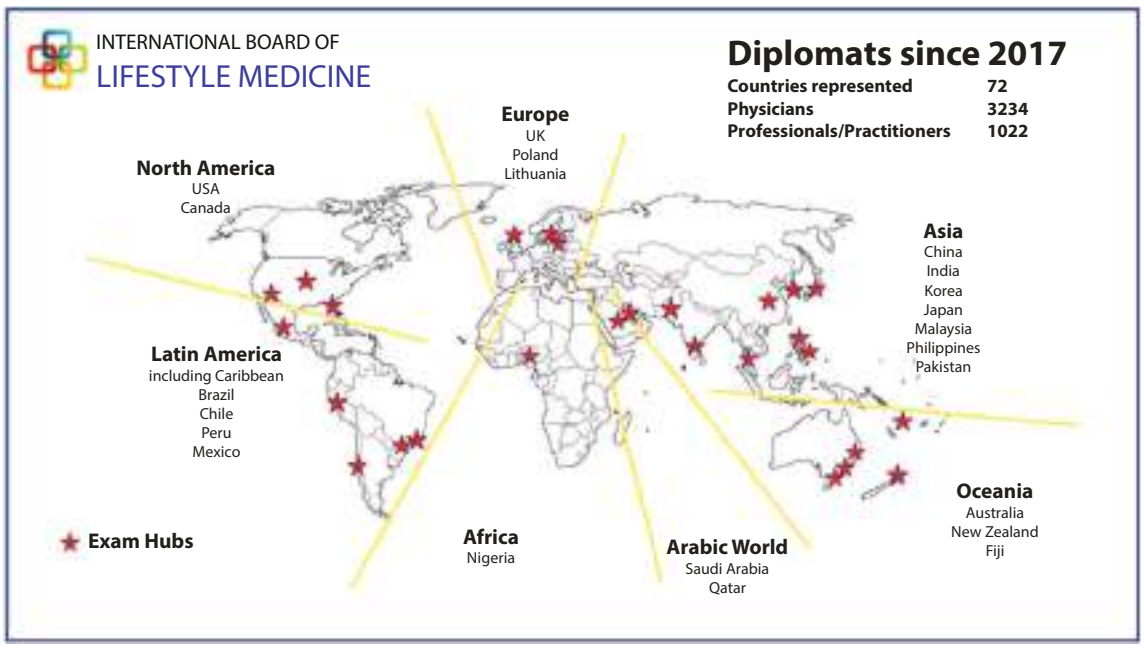

FIGURE 86.2 Report of total number of diplomats between when the first board was offered and June 2022. Received as PowerPoint slide from Stephan Hertzog, Executive Director, American Board of Lifestyle Medicine, International Board of Lifestyle Medicine (received June 12, 2022.) Used with permission.

the possibility of the potential remission of type 2 diabetes through lifestyle changes prepared by the American Endocrine Society, the European Association for the Study of Diabetes, Diabetes UK, and the American Diabetes Association and published in *Diabetologia*,[20] *Diabetes Care*,[21] *The Journal of Endocrinology and Metabolism*,[22] and *Diabetes Medicine*.[23]

Lifestyle medicine plays an important role within standard allopathic medicine. Its focus is primarily on individual lifestyle behaviors. Its success depends more on patient motivation and coaching than on physician prescription. The inclusion of cognitive behavioral therapies in lifestyle change and motivational counseling coaches patients to become more involved and responsible for their own outcomes. By nature, "coaching" applies to every lifestyle medicine practice and patient interaction within the context of a collaborative care model and may make significant use of allied healthcare professionals to provide much of the direct counseling. Prescriptive lifestyle interventions for specific diseases are best done with a multidisciplinary healthcare team. The evidence for the effectiveness of these prescriptions is strong and growing and is being included in many national guidelines for use in both prevention and treatment.[24]

There are a growing number of clinicians who wish to practice lifestyle medicine as the key driver of their medical practice. One might well identify these as lifestyle medicine specialists. There are efforts underway for the introduction of standards as well as additional board certification for the advanced lifestyle medicine specialist.

This should create three levels on which practitioners include lifestyle medicine in their practice. For those practicing more traditional allopathic medicine, lifestyle medicine remains central to practice as evidenced by its presence in the national guidelines for virtually every metabolic disease. Second, some desire to include a special lifestyle focus into their primary care practices, the lifestyle medicine specialist who, while not ignoring effective techno-therapies, gives primary, real, and effective attention to the behavioral, environmental, and societal factors of chronic disease prevention and management. Third, there remains a conceptual need for the advanced lifestyle medicine specialist with the skill to coordinate the clinical teams addressing resistant cases to instruct and manage intensive lifestyle care programs (both inpatient and outpatient) and guide communities, healthcare institutions, and government policy in the appropriate application of lifestyle medicine within their appropriate cultural spheres.

86.4 DIMENSIONS OF THE DEFINITION

A definition of a field of study must, of necessity, lay out in broad strokes the meaning. In applying the definition to practice, the dimensions and application are more fluid, reflecting the expansion and application of medical knowledge and experience in how lifestyle practices affect health and well-being. These are key concepts of lifestyle medicine:

- Primary prevention, secondary prevention, and tertiary prevention are included. This means that lifestyle change may be effective for the full spectrum of chronic disease treatment and even remission or cure.[25] It appears from the evidence that lifestyle medicine can often be more effective than tertiary techno-therapies such as cardiac bypass surgery or stenting for heart disease[26–30] and pharmaco-therapies for diabetes.[31]
- Lifestyle medicine is an essential component of the treatment of most chronic diseases and is incorporated into many national disease management guidelines. These should be a part of every practicing physician's thinking and practice. Unfortunately, when the guidelines are applied in "usual" clinical practice, the recommendations are given a modicum of lip service but lack an adequate application of the necessary evidence-based changes to the individual patient's present behavioral practices.[32] Recognizing the importance of dealing with the underlying cause, lifestyle medicine practitioners apply the principles and techniques of behavior change to effectively address the lifestyle determinants of chronic diseases.
- As a practical clinical discipline, lifestyle medicine incorporates clinicians working with a team of other healthcare professionals to develop patient-specific interventions. Nutritionists, behaviorists, coaches, exercise physiologists, nurses, and others should be included. A range of health professionals working as a team is needed to prevent, manage, and treat the estimated 70% of modern health problems that have a lifestyle-based etiology.
- The process of medical education should both introduce and expand the student's awareness of the ability of lifestyle change to positively affect outcomes as well as teach the skills of behavior change. Movement in this area is reflected by the 2020 American Heart Association's revision and update of its 2016 statement emphasizing the importance of medical education to achieve competency in lifestyle counseling.[33]
- Lifestyle medicine bridges the gap between health promotion, behavior change, and conventional medicine. The scientific disciplines come together to create effective behavior change. One might view lifestyle medicine as inhabiting a space somewhere between behavioral psychology and primary care. This perspective calls for the lifestyle medicine physician and the caregiver team to rely more on modern coaching techniques and less on expert- or dictatorial-toned interactions.
- While allopathic medicine requires overt treatment directives (and even demands) in critical

care, trauma, and other acute situations, the lifestyle medicine approach recognizes that the patient is ultimately in control of the journey away from disease and into well-being. The lifestyle medicine clinician, of necessity, must provide direction, education, and motivation rather than simply being a coach encouraging the individual to set his/her own goals.

- One must recognize that it is not possible to solve health problems by "doing the wrong thing better". The "right thing" (best or evidence-based way) must be identified and made plain even if the individual can only see himself or herself making small steps in that direction.
- The lifestyle medicine clinician will also find cognitive behavioral therapy practices of benefit in helping the individual overcome barriers to improving behaviors. Helping to identify cognitive distortions and reframe behavioral decisions from the vantage point of "truth" can lead to more efficient and long-lasting behavioral health changes.
- Sound scientific evidence from diverse health-related fields coalesce to assist clinicians in the process of treating disease and promoting good health. In practice, lifestyle medicine is most effective when a well-informed primary care provider coordinates a team-based application. While medical sub-specialists should be knowledgeable in the lifestyle dimensions of their system specialty, they are often lacking in the practical application of the evidence as well as the skills needed for successful application.
- Many healthcare workers do not practice in their own lives what they know to be the healthiest lifestyle practices and often have a difficult time instructing their patients to do something they "do not think anyone will actually do" (see Chapter 91). When there is a cognitive dissonance between personal practice and the best scientific evidence, the clinician's personal biases interfere with the proffering or even the acknowledgment of the best evidence. This problem is not unique to lifestyle medicine but is common to any application of the scientific process.
- Measuring a biometric more consistently (lipids or A1C) or prescribing appropriate drugs may prolong life but do not adequately address the behavioral and complex biochemical interactions that cause and/or accelerate the lifestyle-caused disease process. In order to deal with the root cause of chronic non-infectious diseases, patients are required to change high-risk health behaviors to behaviors that will help to reverse the pathology and/or reduce the likelihood of disease progression. Even as effective evidence-based health technologies are applied, lifestyle behavioral changes are usually required to stop or reverse the underlying pathophysiology.
- As the medical profession has developed over time, physicians have often functioned as experts in diagnosis and treatment. As holders of the knowledge and skills, they prescribe the appropriate technology to the recognized disease pattern and expect the patient to comply. The evidence is that compliance with pharmaco-technology is rather low (for example, around 50% at one year for hypertension medications[34]) and the cause is multi-factorial.[35] A patient's calculation of the risks and benefits is often different than that of the clinician. A study of cardioprotective drug interventions suggests that informing patients of the actual percentage chance (not relative risk) of the benefit from preventive drug strategies will substantially reduce the actual use of such drugs. For the individual, this is unlikely to be detrimental. However, there is concern for the population at large as reduced uptake of the drug will lead to an increased prevalence of the target event and clinicians are used to managing treatments at this level.[36] The same compliance issues are present with the lifestyle medicine approach. Directly addressing the patient's fears and perceptions and shifting the "control" to the patient is required, as it is the patient who must make the behavior change. Indeed, taking the necessary steps to place the patient in control of their disease is likely to significantly increase behavioral compliance. Certainly, just the perception that the physician has understood the patient and that the patient understood what the clinician was communicating, termed "concordance" in the literature, has been reported as one of the strongest determinants of compliance.[37] Societal, legal, and public health interventions will also need to focus on making it easier for the public to make the right personal choice. Lifestyle medicine changes the emphasis to an approach in which the patient becomes increasingly involved in his or her care and moves the physician toward being a coach-educator and less of a dictator.
- Lifestyle medicine is not simply about prolonging life, it is about ensuring people can enjoy their later years with less pain and disease. As David Katz, one of the more prolific lifestyle medicine communicators of recent years, is often heard to say, lifestyle medicine is about "adding years to life and life to years".
- Lifestyle medicine relies heavily on the scientific process but also embraces evidence-based creative thinking as the first step of the scientific process. While recognizing the importance of blinded and randomized controlled trials for minimizing bias, it is clear that these studies are not easily applied universally to the diversity of individual human

experience. Due to a focus on limited hypotheses and relatively larger expense, RCTs have a significant and inherent inefficiency. Well-designed and run prospective epidemiological trials have the capacity to bring larger volumes of high-quality evidence while more effectively addressing the complexities and nuances of biological diversity and individual behaviors, and should be accepted as actionable evidence on an equal, but separate, basis with the RCT.

- The scientific process focuses on probabilities in populations but each patient as an individual has unique characteristics of physiology and perspective that require adaption to the best evidence of the individual. Reductionism is incompetent to address this diversity and uniqueness. While there are certainly exceptions, researching and applying healthy lifestyle patterns are usually of more practical use than focusing on one particular nutrient or behavior.[38]
- There is much to be learned from the scientific process despite its inherent weaknesses and slowness. Humility and the desire to discover more are keys to progress. The lifestyle medicine clinician will welcome honest scrutiny and seek to broaden both understanding and practical application. This concern has been addressed in a review of research tools that builds on several approaches to suggest a strength of evidence approach entitled Hierarchies of Evidence Applied to Lifestyle Medicine (HEALM).[39] It provides a framework through which to identify actionable recommendations where evidence has not or cannot reach the level of a randomized control trial.
- Changing individual behaviors is a challenging task in the best of circumstances but it is made even harder by a culture and subculture that encourages unhealthy behaviors. From the ubiquitous advertising of unhealthy value-added dietary and drink choices to a work and commuting environment that discourages physical activity, hundreds of cultural practices and environmental pressures undermine the health of individuals and communities. These may include structural interventions such as:
  - Increasing bike commuting, green space, and walking trails
  - Making it easier to take the stairs in buildings
  - Subsidizing whole plant food to make it more easily available in "food deserts"
  - Establishing farmer markets for the sale of local produce
  - Implementing a system in grocery stores for rating food healthfulness and quality to assist those seeking to make healthier choices
  - Limiting food stamps use to healthier foods
  - Cigarette taxes and banning advertising

  Those things that improve the context in which people are making choices will promote sustainability and may be included within the realm of lifestyle medicine. There is a tendency to place blame on individuals for their unhealthy practices, but commonly, at least a portion of the guilt belongs to unintended consequences or even the profit-driven actions or intent of capitalists within Western society. An expanded understanding of lifestyle medicine will necessarily expand the focus to include the improvement of society, culture, environment, and even government in ways that make it easier for everyone to make healthier choices. The real win in lifestyle medicine is a cultural win that makes the best lifestyle choices easy.
- Lifestyle medicine practitioners should be reimbursed for outcomes. The current payment system rewards procedures, putting the lifestyle physician at a disadvantage.[40] While the system is moving in that direction, its focus is more on screening and prevention rather than decreasing the per-member-per-month cost or quality of life.

86.5 DEFINITION CONSTRUCTS

Over the years, those active in the field have developed constructs with which to communicate and operationalize lifestyle medicine. They become the structure for patient education and programming. There are a variety of emphases ranging from nutrition and exercise to interpersonal relationships, stress management, and optimizing social relationships. While a complete listing is not possible here, a selected chronological listing may be helpful in understanding the dimensional complexity of lifestyle medicine as it has been developing through the years (Table 86.1).

86.6 SUMMARY

Lifestyle medicine is a relatively new term that has been adopted widely by the allopathic medical community. Its definition has expanded from beginnings that focused on health behaviors to include a clinical team, a branch of medicine, a medical specialty, and the social determinants of health within a society. The American College of Lifestyle Medicine defines lifestyle medicine as the following:

> Lifestyle medicine is a medical specialty that uses therapeutic lifestyle interventions as a primary modality to treat chronic conditions including, but not limited to, cardiovascular diseases, type 2 diabetes, and obesity. Lifestyle medicine certified clinicians are trained to apply evidence-based, whole-person, prescriptive lifestyle change to treat and, when used intensively, often reverse such conditions. Applying the six pillars of lifestyle medicine—a whole-food, plant-predominant eating pattern, physical activity, restorative sleep, stress management, avoidance of risky

substances and positive social connections—also provides effective prevention for these conditions.

CLINICAL APPLICATIONS

- Lifestyle medicine involves significant evidenced-based changes in behaviors that affect health by a multidisciplinary team whose members have adopted healthy lifestyles.
- Ideally, every physician should offer lifestyle therapies to their patients with amenable disease states.
- There is a place for lifestyle medicine specialists to manage more challenging cases.
- The intent of lifestyle medicine is to increase both the quality and quantity of life with lower personal and societal costs.
- Interventions are based on the best quality evidence available from randomized controlled trials and well run epidemiologic observational trials.
- Lifestyle medicine seeks to change the cultural environment by working with businesses, communities, and governments to bring effective structural and social changes that encourage healthy behavior choices.

Those in lifestyle medicine see themselves as within the house of medicine, practicing evidence-based allopathic medicine that focuses on improving individual and societal behaviors that address the underlying cause of disease with the intent to both prevent and reverse disease.

87 Health Provider Core Competencies in Lifestyle Medicine

Liana Lianov, MD, MPH, FACPM, FACLM

KEY POINTS

- In 2009, a national panel of health professionals convened by the American College of Lifestyle Medicine (ACLM) and the American College of Preventive Medicine (ACPM) recommended 15 core competencies for providers to practice high-quality lifestyle medicine.
- The original competency domains covered leadership, knowledge, assessment skills, management skills, and use of office and community support.
- The refined and updated domains include the topics of practitioner's personal health, community advocacy, nutrition science, physical activity, sleep health, treating tobacco use disorder and managing other toxic exposures, key clinical processes, health behavior change fundamentals, emotional and mental health, and connectedness and positive psychology.
- The fundamentals of lifestyle medicine emphasize maximal use of science-based interventions, minimal use of medications and/or supplements, clinical approaches that leverage shared medical appointments, team-based care, behavioral science, and clinical patient and family/caregiver support enhanced with community resources.
- Key application areas of lifestyle medicine include nutrition and physical activity prescriptions, sleep hygiene guidance, facilitating health behavior change, assisting tobacco cessation and avoidance of risky substance use, stress management, promoting emotional well-being, and weight management.
- Provider self-care is an essential competency area that is shown to enhance providers' lifestyle counseling.
- The competencies have been refined during the development of national training programs of the ACLM and ACPM and the certification requirements and examination questions set forth by the American Board of Lifestyle Medicine.
- A dedicated committee of international lifestyle medicine experts will continue to update the competencies regularly to reflect the latest science and the advancing practice of the field.

87.1 INTRODUCTION: BACKGROUND AND DRIVING FORCES FOR CORE COMPETENCIES

The term "lifestyle medicine" has been used by a small group of practitioners and frontrunners in the field since 1988. However, it has not been used broadly across medical settings. Healthcare practitioners have been either unaware of the term or have used it to refer to different practices. No standard definition existed, leading to a lack of effective communication about the key elements of the field and what constitutes high-quality lifestyle medicine clinical practice and training.

By 2009, leaders of the *American Journal of Lifestyle Medicine*, the American College of Lifestyle Medicine (ACLM), and the American College of Preventive Medicine (ACPM) had developed their own definitions, overlapping, but slightly different. These definitions are reviewed in Chapter 86. Clearly, in order to advance the field with effective communication, research, training, and practice, consistency in terminology was necessary. Therefore, in 2009, the ACLM and the ACPM, with assistance from a special grant, convened a panel of representatives from an array of medical specialty societies that would develop a standard definition. The panel was also tasked with identifying the knowledge and skill competencies that physicians need in order to offer high-quality lifestyle medicine services.

87.2 NATIONAL CONSENSUS PANEL: BREAKTHROUGH FOR THE FIELD OF LIFESTYLE MEDICINE

The consensus panel gathered for a one-day meeting in 2009 led by Mark Johnson, representing ACPM, and Liana Lianov, representing ACLM, and facilitated by Mike Parkinson, a former ACPM president. The remainder of the panel consisted of representatives from the American Academy of Family Physicians, the American Medical Association, the American College of Physicians, the American Osteopathic Association, the American Academy of Pediatrics, and the American College of Sports Medicine. The panelists continued their discussion electronically for the ensuing year until they agreed on a definition for lifestyle medicine and 15 core lifestyle medicine competencies for primary care physicians. The panel also

DOI: 10.1201/9781003227793-103

agreed that the initial focus should be on physicians, with the alignment that competencies for other health professionals and healthcare team members were necessary and would be developed subsequently.

The definition of lifestyle medicine that the panel developed is, "The evidence-based practice of helping individuals and families adopt and sustain healthy behaviors that affect health and quality of life". As reflected in this definition, the panelists clearly resonated with the fact that the role of supporting patients with behavior change is at the root of the practice to secure improved health outcomes. Much discussion was ignited about the types of behaviors a lifestyle medicine practitioner should aim to support. In the end, the panel decided to keep it open-ended with: "Examples of target patient behaviors include but are not limited to eliminating tobacco use, improving diet, and increasing physical activity".

The panel aligned around the basic constructs for a competent lifestyle medicine practitioner. These constructs require the ability to 1) perform comprehensive lifestyle assessments including risk factors and patient's readiness to change modifiable risk factors, 2) use national guidelines in lifestyle prescriptions, 3) use a team approach and establish effective patient and caregiver relationships, 4) make referrals when appropriate, 5) use information technology to maximize continuity of care, 6) personally practice a healthy lifestyle, and 7) promote healthy behaviors as the foundation for clinical care and lifestyle medicine. One can easily recognize how all of the outlined competencies can apply to primary care and other medical specialty practitioners. The key difference is in the focus area of using lifestyle change to, not only prevent but also treat diseases. Table 87.1 provides the complete list of the competencies, as worded by the consensus panel.

Unlike many other competency topics, which required discussion, the recommendation that physician personal health be a competency received immediate unanimous agreement by the panel. Physicians must aim to practice healthy lifestyles to maintain their own health and more effectively work with patients.

These recommendations of the national consensus panel were immediately seen as a breakthrough for the field of lifestyle medicine. The new set of core competencies that were developed in alignment with representatives from diverse physician and health organizations signaled the birth of a new field to the modern medical community, the knowledge and skills of which are relevant to any physician aiming to offer standard, quality services that leverage lifestyle change to achieve health outcomes. The statement of the consensus panel was published as a commentary in the *Journal of the American Medical Association* on July 14, 2010.[1,2] This article was the first circumstance in which the term "lifestyle medicine" was mentioned in the journal, outside of book reviews. The commentary aimed to nudge the general medical community to adopt these competencies.

87.3 REFINING THE ORIGINAL LIFESTYLE MEDICINE CORE COMPETENCIES

As seen in Table 87.1, the competencies developed in 2010 are worded succinctly and have led to much discussion about

TABLE 87.1
Original Lifestyle Medicine Core Competencies Identified by National Consensus Panel

Competency Domain	Core Competencies
Leadership	Promote healthy behaviors as foundational to medical care, disease prevention, and health promotion.
	Seek to practice healthy behaviors and create school, work, and home environments that support healthy behaviors.
Knowledge	Demonstrate knowledge of the evidence that specific lifestyle changes can have a positive effect on patients' health outcomes.
	Describe ways that physician engagement with patients and families can have a positive effect on patients' health behaviors.
Assessment skills	Assess the social, psychological, and biological predispositions of patients' behaviors and the resulting health outcomes.
	Assess patient and family readiness, willingness, and ability to make health behavior changes.
	Perform a history and physical examination specific to lifestyle-related health status, including lifestyle "vital signs" such as tobacco use, alcohol consumption, diet, physical activity, body mass index, stress level, sleep, and emotional well-being.
	Based on this assessment, obtain and interpret appropriate tests to screen, diagnose, and monitor lifestyle-related diseases.
Management skills	Use nationally recognized practice guidelines (such as those for hypertension and smoking cessation) to assist patients in self-managing their health behaviors and lifestyles.
	Establish effective relationships with patients and their families to effect and sustain behavioral change using evidence-based counseling methods and tools and follow-up.
	Collaborate with patients and their families to develop evidence-based, achievable, specific, written action plans such as lifestyle prescriptions.
	Help patients manage and sustain healthy lifestyle practices and refer patients to other healthcare professionals as needed for lifestyle-related conditions.
Use of office and community support	Have the ability to practice as an interdisciplinary team of healthcare professionals and support a team approach.
	Develop and apply office systems and practices to support lifestyle medical care including decision support technology.
	Measure processes and outcomes to improve quality of lifestyle interventions in individuals and groups of patients.
	Use appropriate community referral resources that support the implementation of healthy lifestyles.

their detailed interpretation. For example, some lifestyle medicine leaders expressed concern over the competency that discusses the use of national guidelines. In Chapter 86, lifestyle medicine was described as using treatments that have a basis in science. Yet some experts expressed concern that national guidelines can be influenced by commercial sectors, not always abiding by science.

Most hotly debated has been the issue of whether a whole food, plant-based diet should be the standard diet in lifestyle medicine interventions. To address some of these concerns, ACLM brought together the Lifestyle Medicine Standards Task Force, chaired by Jennifer Rooke, to review the literature and develop standards for the field. The Task Force's final standards released in 2013 confirm the National Blue Ribbon Panel's core competencies and enhance them with details. The Task Force concluded that the current scientific evidence favors a whole food, unprocessed, plant diet. The Task Force added two modality domains to the three in the consensus panel definition: stress management and "interpersonal-community-group relationships". They acknowledged that lifestyle medicine core competencies are essential to all physicians as a basic approach to managing chronic diseases. They also noted that a deeper set of knowledge and skills is required to offer lifestyle medicine as a specialized service.

87.4 LIFESTYLE MEDICINE CORE COMPETENCIES TRAINING

After the publication of the lifestyle medicine core competencies in *JAMA* in 2010, practitioners began to request training in these competencies. ACLM and ACPM successfully secured funding and in 2013 began the development of an online training program that was tested as a webinar series in 2014 and released in 2015. In the process of developing the training with learning objectives, the faculty further refined the core competencies. In addition, key modalities were covered, including nutrition, physical activity, sleep, avoiding risky substance use, stress management, and emotional well-being.

Principles highlighted in this training included maximal use of science-based interventions, minimal use of medications and/or supplements, clinical approaches that leverage shared medical appointments, team-based care, behavioral science, and clinical patient and family/caregiver support enhanced with community resources. Settings in which lifestyle medicine services can be integrated include primary care, specialty care, solo practitioner and team-based care, and virtual/telemedicine practices.

Additional organizations and partners, such as the Institute of Lifestyle Medicine, have contributed to training physicians in the core competencies through live and online training. Incorporating training early in a medical career is essential, as medicine builds a healthcare community of the future that fully integrates lifestyle medicine principles. An initiative, LMed, is offering online access to a variety of lifestyle medicine training modules geared for medical students and residents.[3,4]

87.5 REFINING THE COMPETENCIES FOR LIFESTYLE MEDICINE CERTIFICATION

As practitioners began training in lifestyle medicine, interest grew in establishing a certification process. In 2016, the field took another leap forward with the establishment of the American Board of Lifestyle Medicine for which Wayne Dysinger is the founding chair and Liana Lianov is the founding vice-chair. The founding board further refined the list of competencies upon which a certification exam is based.

87.6 UPDATING THE COMPETENCIES

In 2022, an update of the refined competencies list that was developed by a committee of lifestyle medicine experts from several different nationalities was released. The committee members met virtually over several months and made changes based on a consensus process. These updated competencies will serve as the foundation for lifestyle medicine training and education and board certification examinations. A committee with oversight by the Lifestyle Medicine Global Alliance will continue the updating process on a regular basis.

The updated competencies were reorganized, condensed where there was overlap, and reworded for clarity, and a few new competencies were added. Otherwise, the overall intent and content remained the same (Table 87.2). One new competency related to the prevalence and cost burden of lifestyle-related diseases was added. Several competencies on the therapeutic alliance and competency regarding the comparison of lifestyle medicine with medication treatment were added. Also, the role of lifestyle medicine in promoting personal practitioner resiliency and reducing burnout was specifically called out. The topic of sleep hygiene assessment became a separate competency and a competency was added to activities that increase physical, mental, and emotional flourishing.

Applicants for certification need to define lifestyle medicine, understand the difference between this field and related fields, and describe its unique role. They must understand the importance of lifestyle interventions in treating lifestyle-related diseases, describe the role of behavioral determinants in achieving positive health outcomes, and cite the scientific evidence for behaviors and lifestyle changes that impact health outcomes and disease pathophysiology.

The core of successful lifestyle medicine interventions is enabling patients to achieve health-appropriate behavior change. Hence, practitioners need to skillfully assess each patient's change-readiness stage and offer stage-matched responses. Empathetic interactions with patients and their families and caregivers are required to build effective

TABLE 87.2

2022 Updated Core Competencies[5]

A. Introduction to Lifestyle Medicine	1. Discuss lifestyle medicine and its unique role in healthcare practice 2. Describe the lifestyle medicine core competencies as identified by a national consensus panel 3. Compare and contrast lifestyle medicine with other fields of health and medicine 4. Summarize the scientific evidence that shows health behaviors are associated with key health outcomes 5. Describe the evidence showing that lifestyle interventions effectively impact disease pathophysiology 6. Describe the priority of lifestyle medicine in the spectrum of treatment algorithms for chronic, lifestyle-related diseases across the lifespan 7. Discuss the prevalence and associated cost burden of lifestyle-related diseases, such as hyperlipidemia, cardiovascular disease, prediabetes, diabetes, hypertension, obesity, and cancer 8. Explain the impact of lifestyle choices on planetary health and sustainable living
B. The Role of the Practitioner's Personal Health and Community Advocacy	1. Examine scientific evidence that suggests practitioners who practice healthy lifestyles are more likely to offer counseling, serve as role models, and improve patient outcomes 2. Develop a culture of leadership by modeling personal health behaviors 3. Describe strategies for incorporating personal wellness for practitioners into clinics, medical offices, or other healthcare settings, including wellness programs 4. Examine essential practitioner characteristics and practices that increase the capacity and impact of the therapeutic alliance 5. Integrate personal readiness assessments and lifestyle action plans into sustainable life patterns for practitioners 6. Explore the role of lifestyle medicine in promoting personal practitioner resiliency and reducing burnout 7. Advocate for lifestyle medicine directly with patients and their families, as well as policy and decision-makers within the community
C. Nutrition Science, Assessment, and Prescription	1. Assess food intake patterns and nutrients of deficit and excess 2. Analyze food labels for the health impacts of ingredients 3. Discuss commonalities and key messages of global dietary guidelines. 4. Summarize the health impact of prominent dietary patterns, including plant predominant and non–plant predominant patterns 5. Describe how the level of processing in a food affects health and discuss the evidence base for these effects 6. Describe the practice of culinary medicine and its role in sustainable healthy eating behavior 7. Summarize the major studies of nutrition in the prevention, treatment, and reversal of hyperlipidemia, cardiovascular disease, prediabetes, diabetes, hypertension, obesity, and cancer 8. Apply nutrition prescriptions based on science that shows how nutrition can address the pathophysiology of most chronic diseases, including inflammation, oxidation, glycosylation, epigenetic expression, and the microbiome* 9. Demonstrate the ability to write evidence-based nutrition prescriptions* 10. Describe indications for referral to a lifestyle medicine trained registered dietician to translate and further personalize nutrition prescriptions
D. Physical Activity Science, Assessment, and Prescription	1. Discuss the aerobic, strength, flexibility, and balance components of physical activity 2. Examine the evidence and pathophysiology between physical activity components and health outcomes 3. Describe the benefits of physical activity in preventing or treating disease in special populations, such as healthy older adults, pregnant women, children and adolescents, persons with obesity or disability, cardiovascular disease, diabetes, cancer, disability, and stroke 4. Summarize the role of physical activity guidelines 5. Integrate key physical activity assessment tools into clinical practice 6. Define fitness terminology relevant to writing exercise prescriptions 7. Integrate evidence from relevant physical activity literature into treatment protocols for management, remission, or reversal in patients with diabetes, cancer, cardiovascular, and cerebrovascular disease* 8. Describe indications for referral to health fitness professionals 9. Develop physical activity prescriptions appropriately modified for special populations, such as healthy older adults, pregnant women, children and adolescents, persons with obesity or disability, cardiovascular disease, diabetes, cancer, disability, and stroke*
E. Sleep Health Science and Interventions	1. Describe sleep's role in health and chronic disease pathophysiology 2. Perform sleep assessments to identify patients with insufficient or poor-quality sleep 3. Summarize lifestyle-based interventions that can improve sleep health 4. Assess the risk for common sleep disturbances, such as obstructive sleep apnea, chronic insomnia, and restless legs syndrome, and refer to sleep specialists when applicable 5. Describe the indications for referral to a sleep specialist or for a sleep study to assess for sleep apnea 6. Describe indications for referral to a program or specialist in cognitive behavior therapy for insomnia

(*Continued*)

TABLE 87.2 (CONTINUED)

2022 Updated Core Competencies[5]

F. Treating Tobacco Use Disorder and Managing Other Toxic Exposures (Including Vaping, Alcohol Use, and Other Illicit Substances)	1. Describe the health effects of tobacco, alcohol, and other frequently used substances and the benefits of cessation 2. Apply patient screening tools for substance use 3. Create patient-centered substance use treatment plans using practice guidelines and behavioral interventions* 4. Summarize the diagnostic criteria for common substance use disorders 5. Integrate behavior therapy with pharmacotherapy for tobacco and other substance use disorder plans, and refer to a substance use disorder specialist when indicated* 6. Apply the United States Preventive Services Task Force guidelines for patients with tobacco use disorder
G. Key Clinical Processes in Lifestyle Medicine	1. Integrate lifestyle vital signs into components of the patient history and physical exam 2. Analyze and implement evidence-based clinical practice guidelines relevant to lifestyle medicine for prevention, treatment, and reversal of chronic diseases* 3. Describe the treatment of disease with the lifestyle medicine pillars as compared with medication 4. Demonstrate how to screen, diagnose, treat, and monitor a lifestyle-related disease and provide lifestyle medicine–focused anticipatory guidance* 5. Discuss strategies for a clinical practice to access and implement use of local, national, and global resources 6. Describe the key strategies for leveraging inter-professional teams to enhance health behavior change interventions 7. Examine how group visits and telehealth can optimize lifestyle medicine treatment encounters 8. Create and utilize data from office systems, such as electronic health records with lifestyle medicine guidance, in clinical decisions and care, including tracking screening frequency, test results, referrals, and recommended follow-up 9. Analyze the evidence for collaborative and chronic care models on improved lifestyle outcomes 10. Discuss successful primary care and office-based models for lifestyle modification 11. Design a quality improvement project for lifestyle medicine clinical practice, using tools, such as Plan-Do-Study-Act (PDSA) cycles 12. Explain principles of evidence-based medicine and their application to lifestyle medicine 13. Describe methods of assessing effectiveness of interventions, such as patient activation measures and therapeutic alliance measures
H. Fundamentals of Health Behavior Change	1. Summarize health behavior change theories, such as the health belief model, the social learning theory, and the transtheoretical model (TTM), and their application to lifestyle medicine practice 2. Demonstrate key elements of conducting a patient assessment within the TTM and collaborate to develop stage-matched responses 3. Apply the process of building effective and therapeutic alliances with patients that foster their personal growth 4. Explain how to collaborate with your patients to promote health behavior changes 5. Apply motivational interviewing, cognitive behavioral, health coaching, and positive psychology techniques 6. Summarize the evidence to support the use of behavior change techniques in clinical practice 7. Use the skills of open inquiry, reflections, and empathy to develop and maintain a therapeutic alliance 8. Describe the impact of positive emotions on the success of health behavior change 9. Develop patient-centered, written action plans based on the appropriate stage of change of the TTM 10. Summarize the process of follow-up for ongoing lifestyle change progress, including building patient self-efficacy and relapse prevention 11. Describe the factors that support sustained behavior change 12. Explain the role of family and other support to initiate and maintain health behavior change 13. Manage disruptions to the therapeutic alliance 14. Identify patient resources for sustainable behavior change in relation to the pillars of lifestyle medicine
I. Emotional and Mental Health Assessment and Interventions	1. Apply screening tools for stress, depression, and anxiety in clinical practice 2. Explain the relationship and pathophysiology between emotional and physical health 3. Summarize the nature of stress, the role of stressors, such as adverse child experiences, and identify manageable elements of pathogenic stress reactions 4. Describe and utilize evidence-based and patient-centered mental and emotional health, including self-management and resilience-building techniques 5. Analyze the clinical relevance and evidence base for mindfulness-based stress reduction (MBSR) and related stress management strategies 6. Manage treatment plans for lifestyle-related mental health diseases, such as depression and anxiety* 7. Describe indications for referral to mental health professionals (versus when clinically indicated) 8. Apply mindfulness skills to enable presence, clarity, and curiosity in the clinical encounter
J. The Role of Connectedness and Positive Psychology	1. Apply positive psychology in health behavior change counseling 2. Describe how positive psychology strategies support achieving and sustaining healthy behaviors 3. Compare and contrast eudaimonia and hedonia, and explain their effect on physical health, including longevity 4. Describe how social connectedness and social networks influence emotional well-being, physical health, and longevity 5. Summarize the deleterious and positive effects social media has on emotional well-being and flourishing 6. Explain the relationship among the lifestyle pillars, positive emotions, and flourishing 7. Describe positive psychology activities that can boost emotional well-being and flourishing

*Indicates competencies that might be beyond the scope of practice for some health professional groups. The lifestyle medicine board examination includes additional questions for physicians/health care providers.

relationships that support successful outcomes. Skills in motivational interviewing and cognitive behavioral and (see also Chapter 22 on Motivational Interviewing and Lifestyle Change) positive psychology techniques (see also Chapter 24 on The Impact of Positive Psychology on Behavioral Change and Healthy Lifestyle Choices) also enhance relationships with patients that support behavior change.

Practitioners must not only be able to make lifestyle treatment prescriptions but also assist patients who are in the action stage to develop written feasible, individualized action plans.

For patients who achieve action plans, providers must be able to help patients maintain those healthy behaviors. Effective use of motivation and confidence scales is essential. Also, an understanding of health behavior change theories (see also Chapter 21 on Applying Psychological Theories to Promote Healthy Lifestyles by Gholami et al.), including the key construct of self-efficacy and frameworks, such as the five As (ask, advise, assess, agree, assist) model[6] how to incorporate these techniques into the office visit and how to apply the elements of sustainable self-management is essential. Skills to support behavior change include coaching skills appropriate to patient readiness, culture, and personality, offering follow-up strategies for ongoing lifestyle change progress, and relapse prevention planning.

- Describe the process of building effective relationships with patients.
- Apply motivational interviewing, cognitive behavioral, and positive psychology techniques.
- Develop a written action plan based on the treatment prescription adjusted for the appropriate stage of change.
- Describe strategies for helping patients maintain healthy behaviors.
- Cite at least three health behavior change theories and their potential application to practice.
- Understand the five As and how to incorporate them into the office visit.
- Identify two key constructs for effective, sustainable self-management.
- Describe the process of follow-up for ongoing lifestyle change progress, including building patient self-efficacy.
- Demonstrate the use of readiness, importance, and confidence scales.
- List components of relapse prevention planning.
- Cite the evidence base for effective coaching that promotes health behavior change and improves health outcomes.
- Describe how to create relationships with patients that foster their personal growth.
- Describe the role of self-motivation and self-confidence in effective coaching for health behavior change.
- Describe the main stages of the coaching process.
- List the coaching questions for each stage of change.

The ability to conduct key clinical processes of a successful lifestyle medicine practice includes taking a patient history and conducting a physical examination with emphasis on lifestyle risk factors, ordering appropriate screening and diagnostic tests relevant to lifestyle-related diseases, interpreting the tests using scientifically based criteria, and referring to local community resources. Additional crucial lifestyle medicine practice skills involve collaborating with other health professionals, such as dieticians, health educators, fitness trainers, and psychologists outside of the practice, as well as leveraging an interdisciplinary team in the practice (where available) to enhance health behavior change interventions.

In fact, the refined competencies were adapted for an array of health professionals beyond the initial target groups of physicians. Hence, a number of the competencies are distinguished with an asterisk as ones that may be outside of the scope of practice for some health professional groups.

A clinical practice that optimally supports lifestyle modification must work with office systems and tools that track screening frequency and test results and proactively prompt follow-up, incorporate planned and group visits, maintain information about local community resources, and design office flow to assure consistent and up-to-date referrals. The provider should be able to cite the evidence for successful collaborative chronic care and primary care office-based models for lifestyle modification.[7] As with any healthcare practice, lifestyle medicine providers should be able to apply healthcare service quality improvement processes, including the Plan-Do-Study-Act (PDSA) cycles.[8] But these processes should focus on how best to implement lifestyle interventions.

As noted in a prior section, one area on which the national consensus panel for the core competencies unanimously agreed is the physician's personal health practices. Providers eligible for certification should be able to cite scientific studies demonstrating that physicians who practice healthy lifestyles are more likely to offer counseling and improve patient outcomes. (see also Chapter 24 on The Impact of Positive Psychology on Behavioral Change and Healthy Lifestyle Choices). Lifestyle medicine clinicians should be able to implement strategies for incorporating healthcare team wellness activities into clinics, medical offices, or other healthcare settings. Moreover, since a healthy lifestyle is more likely to be achieved and maintained in supportive environments, lifestyle medicine practitioners should conduct effective advocacy and lend their expertise in healthy lifestyles to policy-makers and decision-makers within the community.

The single modality area with the greatest attention and focus in a healthy lifestyle, due to its spectrum of approaches and controversy across health professionals, is nutrition. A foundation for nutrition prescriptions is to first understand the Dietary Guidelines for Americans and why they are important. But the field of lifestyle medicine also requires going beyond the guidelines to the latest science, with the acknowledgment that dietary guidelines can have

limitations. Criteria to determine which foods are healthiest and which are least health-promoting should be based on this science. Providers need to be able to list the food components most Americans get too much of and in which foods they are found, as well as the

shortfall of nutrients that Americans are failing to sufficiently consume and in which foods they are found.

Lifestyle medicine practitioners should be able to summarize the major nutrition studies and the evidence base for nutrition prescriptions. They need to demonstrate the ability to perform a basic nutrition assessment and make nutrition prescriptions to address basic disease processes such as inflammation, and prevent and treat the most common chronic diseases including hyperlipidemia, diabetes, hypertension, cardiovascular disease, and cancer. An understanding of macronutrients in various dietary patterns, food types that contain important micronutrients, and the oxidative impact of food preparation methods are key knowledge areas. Providers must also be knowledgeable in effective community programs and digital applications, such as the Complete Health Improvement Program,[9] and refer patients to them appropriately. An understanding of the avoidance of medication side effects through appropriate intensive nutritional interventions, and the role of epigenetics in healthy nutrition, are additional core knowledge areas. The ability to manage medications during the transition to a healthy lifestyle in diabetes and other chronic diseases is an essential skill.

Knowledge of the science supporting physical activity and skill in prescribing physical activity constitute the second major lifestyle medicine modality. Practitioners need to define physical activity and exercise, list the most recent Physical Activity Guidelines for Americans (PAGA) (see also Chapter 16 on Exercise Prescription for Apparently Healthy Individuals and for Special Populations) and the recommendations for healthy adults, children, pregnant individuals, and individuals with various chronic illnesses. (See Chapter 16). They must be able to describe the key scientific evidence that links physical activity and health that supports the physical activity components (aerobic, strength, flexibility, and balance) and the use of physical activity in contrast to medication to treat chronic disease and manage weight.[10,11] They also must identify the minimum and maximum levels of exercise, list key physical activity assessment tools, have the ability to use METS in assessing fitness, and be proficient at developing exercise prescriptions, including the basic components of the prescription (frequency, intensity, type, and time) (see Chapter 15 on Physical Fitness Evaluation). As with other modalities, effective practitioners must understand the role of personal behavior and role modeling.

MDs/DOs

- Thirty hours of online CME
- Ten hours of in-person CME
- A case study outlining your personal experience with lifestyle medicine

PhD/master's Level

- Thirty hours of online CME
- Ten hours of in-person CME

While the ABLM sets the certification competencies and lifestyle medicine standards, it is left up to the participants to acquire the necessary knowledge, skills, and experience from reputable sources. The ABLM accepts CMEs of the following programs/providers:

Online content:

- ACLM/ACPM Lifestyle Medicine Core Competencies (LMCC)
- Institute of Lifestyle Medicine (Harvard) online courses
- Cornell certificate in plant-based nutrition

In-person learning:

- ACLM conferences and workshops (CME)
- Institute of Lifestyle Medicine (Harvard) conferences (CME)
- Food as Medicine conferences (CME)
- International Plant Based Nutrition Healthcare Conferences (CME)
- ACPM conference, lifestyle medicine stream (CME)

Rules:

- CMEs must be no older than 36 months at the time of registration
- Proof of CMEs, credentials, and case study must be submitted at least 30 days prior to the certification exam
- To certify as a Lifestyle Medicine physician
  - You must be an ABMS board-certified MD or DO
  - Your certification will be issued by the ABLM
- To certify as a Lifestyle Medicine professional
  - You must hold a PhD or master's degree in a health or allied health discipline, or
  - You must be a Doctor of Nursing Practice, or
  - You must be a certified and licensed physician assistant, or
  - You must be a Doctor of Optometry, or
  - You must be a Doctor of Podiatry, or
  - You must be a Doctor of Chiropractic, or
  - You must be a Doctor of Psychotherapy, or
  - You must be a Doctor of Exercise Physiology, or
  - You must be a Doctor of Occupational Therapy, or

- You must be a Doctor of Pharmacy, or
- You must be a Doctor of Physiotherapy, or
- You must be a Doctor of Psychology, or
- You must be a Doctor of Dentistry
- Your certification will be issued by the ACLM

Demonstrate key elements of conducting patient readiness assessment and stage-matched responses

Describe the relationship between physical activity (PA) and health:

- Develop an exercise prescription
- Describe the major evidence for the physical activity components (aerobic, strength, flexibility, and balance)
- Define physical activity and exercise
- List the components of exercise
- Describe the US Physical Activity Guidelines for Americans (PAGA)
- Understand the role of personal behavior and role modeling
- Understand the use of METS in assessing fitness
- Describe the impact of exercise on weight
- Identify the minimum and maximum levels of exercise
- Describe the major evidence for the physical activity components (aerobic, strength, flexibility, and balance)
- List key physical activity assessment tools
- Describe how to collaborate with your patients to promote physical activity change
- Identify resources for sustainable behavior change
- List the components of writing the exercise prescription
- Describe the treatment of disease with exercise as compared with medication
- List evidence-based PA recommendations for healthy older adults, pregnancy, obesity, heart disease, diabetes, cancer, disability, and stroke

Emotional and mental well-being is at the heart of a person's ability to achieve and maintain healthy lifestyles. Emotional distress and mood disorders are frequent comorbidities of common chronic illnesses, such as diabetes and cardiovascular diseases, and have direct physiologic effects, which impact health outcomes directly in addition to lowering attention to and capacity for health behaviors. Lifestyle medicine providers must maintain knowledge of these associations and the latest science, including the role of stress and the physiologic impact and effectiveness of interventions, such as mindfulness-based stress reduction. They need to be able to conduct assessments, offer appropriate interventions, manage depression and anxiety as comorbidities, and refer to mental health professionals when indicated. They must be skilled at applying screening tools for stress, depression, and anxiety, assisting patients with self-management, implementing principles of positive psychology, and referring to emotional well-being programs. Providers who engage in effective patient relationships are able to identify the benefits of physician empathy, attunement, and resonance in the clinical encounter, and practice it consistently.

Sleep is another fundamental component of a healthy lifestyle (see Chapter 82). Lifestyle medicine practitioners must understand sleep's role in health and chronic disease and be able to recommend physical activity, dietary, environmental (such as light exposure), and coping behaviors that can improve sleep health. Also essential to the lifestyle medicine practice is knowing how to assess for key factors that differentiate patients with insufficient or poor-quality sleep and the ability to recommend lifestyle adjustments related to light exposure and meal composition and timing to support improved sleep.

Understanding sleep's role in health and chronic disease:

- Identify lifestyle-based activity, dietary, environmental, and coping behaviors that can improve sleep health
- Identify at least two lifestyle adjustments related to light exposure and meal composition and timing that support improved sleep
- Identify key factors that differentiate patient subpopulations with insufficient or poor-quality sleep
- Understand the role of light exposure and endogenous melatonin in sleep health
- Identify two to three lifestyle adjustments related to light exposure that support improved sleep
- Identify one to two lifestyle adjustments related to meal composition and timing that support improved sleep

Assisting patients with tobacco cessation (see Chapter 97) and managing risky alcohol (see Chapter 98) are additional skills critical to a high-quality practice. The practitioner needs to describe the evidence-based literature on the health effects of tobacco, the role of avoiding excessive alcohol intake in preventing and treating chronic disease, and effective tobacco cessation and alcohol misuse interventions. He must demonstrate the ability to screen for tobacco use and alcohol misuse and assist patients to develop and implement plans for tobacco cessation plans and avoiding risky alcohol use.

Weight management is an important focus area for lifestyle medicine due to the current obesity epidemic. The practitioner must understand the medical risks associated with overweight and obesity and the complex etiology of obesity (see Chapter 42). He needs to use evidence-based weight management guidelines, such as those released by national organizations, including the Endocrine Society, the American Heart Association, the American Gastrological Association, and the Obesity Society[12] to design successful intervention plans and programs. He also needs to be able to implement the four main components of weight management skills within clinical practice: behavior change, nutrition, physical activity, and psychosocial support.

87.7 THE ONGOING EVOLUTION OF LIFESTYLE MEDICINE COMPETENCIES

As described in this chapter, the knowledge and skill competencies of practitioners in the field of lifestyle medicine have been identified, expanded, and refined in the years since the term was first used. Innovators in the field began defining the practice in the 1980s. The field came into its own with the release of a definition and core competencies by the National Consensus Panel in 2010. Training programs for continuing education, as well as for students and residents, and the development of a certification program have further defined and refined these knowledge and skills areas required for competent lifestyle medicine practitioners. The application of the competencies was expanded for use by a variety of health practitioners beyond the initial target group of physicians and certain competencies may be relevant only for physician or other health provider groups. The competencies were updated in 2022 and will need ongoing updates. With the growing interest of physicians in focusing on lifestyle medicine as an area of specialization, competencies for physicians specializing in lifestyle medicine have been developed.[13] A set of competencies for lifestyle medicine intensivists whose practices are dedicated to intensive lifestyle medicine interventions are soon to be released.

The field is continuing to evolve, as the science and evidence that supports it expands.

Opportunities to study and implement new clinical applications will influence the competency requirements (Table 87.3). However, the core basis of the field will remain focused on lifestyle interventions for treating disease based on scientific evidence.

American College of Lifestyle Medicine: https://lifestylemedicine.org/certification

TABLE 87.3
Clinical Applications

Competency Area	Key Clinical Applications
Personal Health/Self-Care	Model healthy behaviors for patients
	Discuss with patients behavior change challenges and solutions from personal experience, as appropriate
Health behavior change	Assess patients' readiness to change
	Engage in empathetic interactions with patients/families
	Apply evidence-based coaching techniques, such as motivational interviewing, cognitive behavioral and positive psychology techniques
	Help patients develop relapse prevention planning
Effective clinical processes	Take a patient history, conduct a physical examination, and order and interpret appropriate screening and diagnostic tests relevant to lifestyle-related diseases
	Refer to local community resources and collaborate with other health professionals,
	Work in an interdisciplinary team
	Incorporate planned and group visits
Healthy nutrition	Perform a basic nutrition assessment
	Make nutrition prescriptions to prevent and treat the most common chronic diseases
	Manage medications during the transition to a healthy diet and lifestyle
Physical activity	Use physical activity in contrast to medication in treating chronic disease and managing weight
	Use METS to assess fitness
	Develop exercise prescriptions, including the basic components of the prescription (frequency, intensity, type, and time)
Mental and emotional well-being	Apply screening tools and assess for stress, depression and anxiety, and general emotional well-being
	Manage mood disorders and refer to mental health professionals when indicated
	Assist patients with self-management and refer to emotional well-being programs
	Consistently practice physician empathy, attunement, and resonance in the clinical encounter
	Recommend positive psychology-based activities
Sleep Health	Recommend physical activity, dietary, and coping behaviors that can improve sleep health.
	Assess for key factors that differentiate patients with insufficient or poor quality sleep
	Recommend lifestyle adjustments related to light exposure and meal composition and timing to support improved sleep
	Understand sleep's role in health and chronic disease
Tobacco cessation and managing risky alcohol use	Screen for tobacco use and alcohol misuse
	Assist patients in developing and implementing plans for tobacco cessation plans and avoiding risky alcohol use
Weight management	Use evidence-based weight management guidelines
	Design successful intervention plans and programs
	Implement the four main components of weight management: behavior change, nutrition, physical activity, and psychosocial support

88 Lifestyle Medicine Clinical Processes

Jeni Shull Clayton, MD, MPH, DipABLM, FACLM
and Ingrid Edshteyn, DO, MPH

88.1 INTRODUCTION

What sets a traditional clinical practice apart from one that has a foundation in lifestyle medicine? Practicing lifestyle medicine (LM) in the clinic first entails placing the patient at the center of the encounter. Patients are the experts of their own lives, necessary to every aspect of care, and treatment depends on their consent. Second, the patient's lifestyle is assessed, and positive change is supported throughout the encounter. The treatments and follow-ups are prescribed according to the patient's engagement level in lifestyle change. Education, referrals, and community resources are provided with respect and in line with the patient's goals, values, and need for further care.

In this chapter, we explore four perspectives of clinical processes:[1] the clinical encounter,[2] interdisciplinary team-based care,[3] office systems and processes, and quality improvement,[4] and how each is essential to forming and sustaining a lifestyle medicine practice.

88.2 LIFESTYLE MEDICINE IN THE CLINIC

The clinical practice of LM necessitates a comprehensive approach that identifies underlying lifestyle-related risk factors through vital signs, history, physical examination, and screening and diagnostic tests (Figure 88.1). Once lifestyle risk factors are identified, lifestyle medicine treatments can be prescribed at a high enough intensity to affect health outcomes, while systematically tracking and documenting patient outcomes. As lifestyle-related diseases improve, some medications may need to be reduced or discontinued, making LM one of the few fields of medicine where deprescribing is a routine part of practice.

88.2.1 Lifestyle-Focused History

The process of taking an LM history includes an assessment of behavioral risk factors, such as physical activity level, nutrition, stress and well-being, social relationships, sleep, and substance use, as well as environmental and occupational factors, that predispose one to developing preventable lifestyle-related diseases. The 2010 foundational JAMA article, *Physician competencies for prescribing lifestyle medicine*,[1] labeled these brief assessments done at the point of care lifestyle "vital signs". Implementing lifestyle vital signs is considered a key proficiency for the LM practitioner.

88.2.1.1 Lifestyle Medicine Vital Signs

Traditional vital signs, like temperature and heart rate, are measurements of the body's most basic functions. They must be within a certain range to sustain life. Following a similar logic, lifestyle medicine vital signs assess a range of behaviors at which a "healthy" life is sustainable.

The Physical Activity Vital Sign described by Coleman et al was the prototype that other LM vital signs followed.[2] This simple two-question screening could quickly let clinicians know if a patient was inactive, insufficiently active, or appropriately active. Physical fitness is now recognized as both a current measure of health and a surrogate marker of future disease.

The ongoing challenge has been clearly identifying the fundamental behavioral pillars of health and how best to assess them. Useful lifestyle medicine vital signs may differ between practices and locations around the world. The goal remains for providers and patients to efficiently identify the presence of helpful or harmful lifestyle behaviors.

As seen in Figure 88.2, the American College of Lifestyle Medicine has produced a Lifestyle Assessment Short Form to assist clinicians in delivering a brief assessment to evaluate several of these key components with a brief series of questions.

Given the expanse of potential questions and responses in an LM-focused history, it is valuable to have both brief and expanded measures for LM risk factors, creating a more efficient delivery mechanism and the ability to target counseling to those areas in which the individual is receptive to change or has greater need. A more in-depth version of the Lifestyle Assessment Form[3] has been developed for a detailed analysis of these components and can be found in Figure 88.3.

Some providers chose to use a long form at an initial patient assessment as an exhaustive evaluation of all potential lifestyle-related health behaviors. Others chose to evaluate behaviors briefly, identify the key areas of interest, and then provide appropriate longer assessments at the subsequent visits or for the patient to complete on their own time. Below, brief and in-depth methods are discussed to evaluate individual pillars of health.

88.2.1.2 Physical Activity Assessment

The relationship between physical activity and health outcomes is generally curvilinear so marked health benefits can be seen with relatively minor increased amounts of physical activity. Exercise is safe for most people and has many associated health and fitness benefits (Table 88.1).[4]

DOI: 10.1201/9781003227793-104

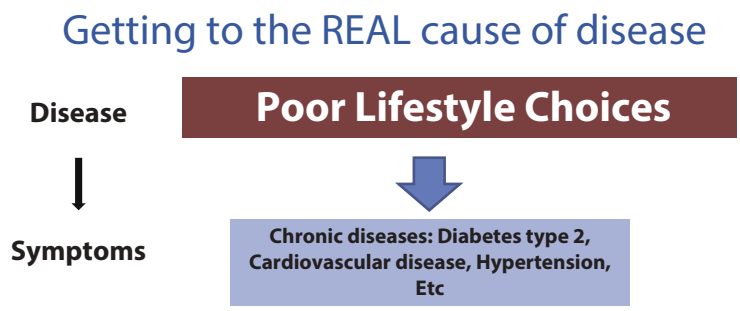

FIGURE 88.1 Real cause.

A helpful tool to assess who is safe to begin exercise and who is not is the Physical Activity Readiness Questionnaire (PARQ).[12]

88.2.1.3 Nutrition Assessment

Nutrition assessments and interventions very often demand the most attention but may also yield the highest benefit. An unhealthy diet can be closely correlated with an increased risk of chronic conditions, including overweight, obesity, diabetes, hypertension, and hyperlipidemia (Table 88.2).[13,14]

When measuring dietary habits, appropriately train your team and prepare educational materials that clarify terms like serving size, food groups, complex versus simple carbohydrates, and "processed" meat. Heavy attention has been given to the macronutrients (carbohydrates, protein, and fat), however, it may be more meaningful to assess for dietary patterns, looking for things such as 1) the presence of whole foods rather than select nutrients (e.g., whole grains rather than selenium), 2) foods associated with health and disease resistance (e.g., vegetables, fruits, whole grains, legumes, nuts and seeds), and 3) foods associated with disease (e.g., processed meats, red meats, fried foods, added sugars, refined grains).

Encourage self-monitoring, for example, measurement of nutrition and caloric intake has shown a consistent association with successful weight loss.[30] Advanced smartphone apps may also encourage weight loss.[31]

88.2.1.4 Stress Assessment

A national study on stress estimated that 60 to 80% of primary care visits were associated with stress-related complaints (headache, back pain, migraines), therefore, making it crucial to assess stress (Table 88.3).[32]

88.2.1.5 Well-Being Assessment

Well-being measures include the presence of positive emotions and moods (e.g., contentment, happiness), the absence of negative emotions (e.g., depression, anxiety), satisfaction with life, fulfillment, and positive functioning.[37] Well-being can be challenging to assess in the clinic as it addresses the sensitive areas of mental and emotional health.

If possible, allow the patient to answer this type of question in a more private setting such as surveys administered on paper, mobile phone, or tablet at the time of visit rather than directly asking the questions. Paper screening and e-screening both appear to have similar benefits and risks from disclosure.[38]

As in nutrition, digital tools may offer utility not only in the evaluation and monitoring phases but also in planning and implementing the interventions. Apps for emotional and mental self-help were found to increase motivation and the desire to set goals, confidence, control, and intentions to be mentally and emotionally healthy, with association with perceived change in behavior.[48] These mobile health technologies have the potential utility of incorporation into the electronic record for an efficient clinical practice.

88.2.1.6 Social Support Assessment

A 75-year cohort study on adult development that compared male Harvard students to similar men from inner-city Boston concluded that the single most important predictor of happiness and longevity is social connectedness.[49] Social support and optimism can help negate the typical health effects of a disadvantaged childhood.[50] Gaining an understanding of a person's social support system may be essential to behavior change.

88.2.1.7 Sleep Assessment

Sleep is one of the least appreciated pillars of lifestyle medicine. It is considered almost heroic by some in American culture if one can function continuously on a small amount of sleep. However, evidence seems to indicate that no one really functions well in a sleep-deprived state. Chronic sleep deprivation increases the risk of cardiovascular disease, obesity, and type 2 diabetes.[53] Sleeping less than six hours a night increases a driver's risk of crashing by 33%. [54]

88.2.1.8 Substance Use

Substance use is already a part of the social history asked in most medical clinics. The harms of tobacco, alcohol, and illicit drug use are well known. We continue to learn more about the health impacts of recreational marijuana. Prescription drug misuse and overprescribing continue to rise. Getting an idea of how often and how much your patients use these substances can help gauge their health risks.

88.2.1.9 Risk Factors

National and international guidelines and risk factor assessments may also be used to evaluate disease risk.

Lifestyle Assessment Short Form

OVERALL HEALTH

1. Please circle your overall LEVEL of HEALTH

0 Very poor health 1 2 3 4 5 6 7 8 9 10 Excellent health

SLEEP

2. OVER THE LAST TWO WEEKS, how many hours of sleep did you average in a 24-hour period?

a. Less than 4 hours
b. 4-5 hours
c. 6 hours
d. 7-8 hours
e. 9 or more hours

3. OVER THE LAST TWO WEEKS, how often did you feel tired or have difficulty staying awake during routine tasks in the day?

a. Not at all
b. Several days
c. More than half the days
d. Nearly every day

NUTRITION

5. OVER THE LAST TWO WEEKS, how often have you eaten fast food, sugary drinks (e.g., soda, sports drinks, juice) or packaged foods (e.g., chips, candy, crackers, cookies)?

a. Not at all
b. Several days
c. More than half the days
d. Nearly every day

6. ON AN AVERAGE DAY, how many servings of whole fruits and vegetables do you eat (1 serving is about a handful and does not include fruit juice)?

a. Less than 2 servings
b. 2-3 servings
c. 4-5 servings
d. More than 5 servings

WEIGHT MANAGEMENT

4. What do you think about your current weight?

a. I want to gain a lot of weight
b. I want to gain a little weight
c. I am happy with my weight
d. I want to lose a little weight
e. I want to lose a lot weight

EXERCISE

7. OVER THE LAST TWO WEEKS, how many days did you exercise at a moderate to strenuous intensity (e.g., brisk walking or enough movement to break a light sweat)?

a. Less than 1 time per week
b. 1-2 times per week
c. 3-4 times per week
d. 5 or more times per week

8. DURING AN AVERAGE SESSION, how many minutes do you exercise at a moderate to strenuous intensity (e.g., brisk walking or enough movement to break a light sweat)?

a. Less than 10 minutes
b. 10-29 minutes
c. 30-49 minutes
d. 50 minutes or more

FIGURE 88.3 (CONTINUED) American College of Lifestyle Medicine long form.

dyslipidemia, hypertension, and personal history of diabetes and smoking. The estimates apply to African American and non-Hispanic white men and women 40 through 79 years of age and are available online and through an application.[69] Lifetime risk can be estimated for adults 20 to 59 years of age. The goal is to facilitate physician-patient discussion and support decision-making to optimize care and lower the risk for ASCVD. These tools can help create quantitatively driven discussions that compare normal and optimal risk levels and identify those factors contributing to the elevated ten-year and lifetime risk.

88.2.1.11.2 Metabolic Syndrome Assessment

Metabolic syndrome is a combination of multiple risk factors that arises from insulin resistance accompanying abnormal adipose deposition and function. The metabolic syndrome is accompanied by a two-fold increase in the risk of cardiovascular disease and a five-fold increase in the risk of type 2 diabetes. A clinical diagnosis of the metabolic syndrome is useful because it affects therapeutic strategy in patients at higher risk, whether to single out and treat each risk separately or to implement therapies that will reduce all of the risk factors simultaneously with an LM

NUTRITION

EATING PATTERNS
Please answer based on your typical eating habits

a.	On average, how many cups (8 oz.) of caffeinated beverages do you drink **per day** (tea, soda, coffee, or energy drinks)?	0	1	2	3	4+
b.	On average, how many servings of alcohol do you drink **per day**?	0	1	2	3	4+
c.	On average, how many cups (8 oz.) of sugary drinks (soda, sports drinks, juice) do you drink **per day**?	0	1	2	3	4+
d.	On average, how often do you snack on convenience or "junk" food **per day**? (i.e. chips, candy, granola bars, crackers, cookies, etc.)	0	1	2	3	4+
e.	On average, how many meals do you buy from a restaurant or fast food **per week**?	0	1	2	3	4+
f.	On average, do you drink at least 8 glasses of water **per day**?		No		Yes	
g.	On average, do you eat at least 5 handfuls of nuts **per week**?		No		Yes	
h.	Do you use natural or artificial sweeteners? (i.e. Equal, Stevia, Splenda, Sweet & Low, honey, agave, etc.)		No		Yes	
i.	Do you add salt to most of your meals?		No		Yes	
j.	Do you eat processed meats (i.e. sausage, hot dogs, salami, bacon)?		No		Yes	

k. Do you have any bad reactions (sensitivities or allergies) to food? If yes, please list here: _____

l. Do you avoid any particular foods? If yes, please list here: _____

m. Do you have foods that you crave? If yes, please list here: _____

n. Are you currently following a particular diet or nutrition plan? If yes, please list here: _____

o. During the last 3 months, did you have any episodes of excessive overeating? If yes please explain here: _____

p. Are you concerned about making the wrong food choices? If yes, please explain here: _____

q. Have you ever had an eating disorder? If yes, please list here: _____

Do you use any of the following VITAMINS or SUPPLEMENTS? *Check all that apply*

❑ Vitamin D ❑ Calcium ❑ Vitamin B12
❑ Probiotics ❑ Omega 3 ❑ Multivitamin
Other: _____

Do you use any of the following OILS with your meals or cooking? *Check all that apply*

❑ Olive Oil ❑ Canola Oil ❑ Vegetable Oil
❑ Coconut Oil ❑ Butter ❑ Lard
Other: _____

FOOD RECALL: *Please record below what AND how much you ate and drank yesterday (or the last typical day)*

Breakfast: _____ Time: _____
Lunch: _____ Time: _____
Dinner: _____ Time: _____
Snacks: _____ Time: _____
Drinks/Beverages: _____ Time: _____

approach focused on weight reduction, increased exercise, and improved nutrition. [70]

According to guidelines from the National Heart, Lung, and Blood Institute (NHLBI) and the American Heart Association (AHA), metabolic syndrome is diagnosed when a patient has at least three of the following five conditions:[71]

- Glucose ≥100 mg/dL (or receiving drug therapy for hyperglycemia)
- Blood pressure ≥130/85 mm Hg (or receiving drug therapy for hypertension)
- Triglycerides ≥150 mg/dL (or receiving drug therapy for hypertriglyceridemia)
- HDL-C <40 mg/dL in men or <50 mg/dL in women (or receiving drug therapy for reduced HDL-C)
- Waist circumference ≥102 cm (40 in) in men or ≥88 cm (35 in) in women; if Asian American, ≥90 cm (35 in) in men or ≥80 cm (32 in) in women

WEIGHT MANAGEMENT

BEHAVIOR PATTERNS	Never	Seldom	Sometimes	Often	Always
a. How often do you skip meals?	1	2	3	4	5
b. How often do you snack in between meals?	1	2	3	4	5
c. How often do you eat while watching TV?	1	2	3	4	5
d. How often do you eat while in bed?	1	2	3	4	5
e. How often do you have difficulty sleeping?	1	2	3	4	5
f. How often do you lack physical activity or exercise?	1	2	3	4	5
g. How often do you feel a lack of purpose or meaning in your life?	1	2	3	4	5

Which of the following factors apply to your eating habits and current lifestyle? ***Check all that apply***

❑ Like healthy food	❑ Don't like healthy food	❑ Know how to cook healthy foods
❑ Fast eater	❑ Eat slowly	❑ Read nutrition labels
❑ Rely on packaged or fast foods	❑ Dislike cooking	❑ Prepare meals at home
❑ Do not plan meals	❑ Eat a variety of foods	❑ Always hungry
❑ Late night eater	❑ Negative relationship to food	❑ Erratic eater
❑ No time to prepare healthy food choices	❑ Don't know how to cook	❑ Live alone or eat alone often

Do any of the following situations or emotions cause you to eat? ***Check all that apply***

❑ Sadness	❑ Pain	❑ Insomnia	❑ Anxiety
❑ Fatigue	❑ Social or Family Situations	❑ Boredom	❑ Stress

88.2.1.11.3 Diabetes Risk Assessment

The American Diabetes Association has developed a risk assessment tool to assist in screening for diabetes. Using age, gender, medical history, family history, activity level, and weight category, the algorithm can be used to identify those who score five or higher and are at increased risk for having diabetes.[72] Other resources include the International Diabetes Federation online type 2 diabetes risk assessment, which is designed for people without a current diagnosis of diabetes and is intended to highlight a person's risk of developing type 2 diabetes in the next ten years.[73]

WEIGHT MANAGEMENT (continued)

WEIGHT HISTORY

a.	Have you ever been overweight or obese? If yes, answer below:	No	Yes
	Were you overweight as a child?	No	Yes
	Were you overweight as a teenager?	No	Yes
	Were you overweight between the ages of 20-29?	No	Yes
	Were you overweight between the ages of 30-39?	No	Yes
	Were you overweight above the age of 40?	No	Yes
b.	Are you currently trying to lose or gain weight?	No	Yes
	If yes, please circle your goal: Lose weight Gain weight		
c.	Have you ever intentionally lost or reduced your weight by more than 5 lbs.?	No	Yes
	If yes, did you regain weight within 1 year?	No	Yes
d.	Have you had weight loss surgery?	No	Yes
	If yes, please list the type of surgery you had: _____		

Have you ever used weight loss medications? *If yes, circle which ones you have used? If other, please list.*

❑ Acutrim ❑ Alli ❑ Amphetamines ❑ Anorex ❑ Belviq ❑ Byetta ❑ Contrave
❑ Desatrim ❑ Didrex ❑ Fastin ❑ Fenfluramine ❑ Mazanor ❑ Meridia ❑ Obalan
❑ Phendiet ❑ Fen-Phen ❑ Phentermine ❑ Plegine ❑ Plegine ❑ Prozac ❑ Pondimin
❑ Qsymia ❑ Redux ❑ Sanorex ❑ Tenuate ❑ Tepanil ❑ Vyvanse ❑ Wechlesa
❑ Wellbutrin ❑ Xenical ❑ I don't remember the name of the medication
❑ Other _____

WEIGHT LOSS STRATEGIES

Have you tried any of the following alternative therapies or programs? *Check all that apply. If other, please list.*

❑ Acupuncture	❑ Acupressure	❑ Nutritionist/Registered Dietitian
❑ Residential Programs	❑ Hypnosis	❑ Physical Activity/Exercises

❑ Other _____

Which commercial or fad diets have you tried in the past? *Check all that apply. If other, please list.*

❑ Atkins Diet	❑ Low Fat	❑ Calorie Counting	❑ Paleo
❑ CHIP	❑ South Beach	❑ DASH	❑ Vegan
❑ Mediterranean Diet	❑ Elimination Diet (Allergy)	❑ Gluten Free	❑ Vegetarian
❑ Jenny Craig	❑ Weight Watchers	❑ Low Carb	❑ Slim Fast/Meal Replacement

❑ Other _____

Patient Name: _____ DOB: _____

88.2.2 Lifestyle-Focused Physical

88.2.2.1 Biometric data, Physical exam, Fitness, and Laboratory Testing

88.2.2.1.1 Overweight and Obesity Identification

In addition to measuring weight and height for body mass index (BMI), the addition of the waist circumference is of value to help screen for possible health risks associated with increased abdominal adiposity. This is a component of the screen for metabolic syndrome, as increased waist circumference increases the risk of developing heart disease and type 2 diabetes.[74,75] The combination of weight and waist circumference data provides simple and accessible markers for measurement in ongoing clinical evaluations and helps individuals recognize their health risk categories, ranging from normal to extremely high.

EXERCISE

EXERCISE HABITS: AEROBIC/CARDIO TRAINING

a. During the average week, how many **days** do you exercise at a moderate to strenuous intensity (i.e. brisk walking or enough to break a light sweat)? _____days

b. During an average session, how many **minutes** do you exercise at a moderate to strenuous intensity (i.e. brisk walking or enough movement to break a light sweat)? _____min

_____ total min/week (days x min)

c. List types of aerobic activities you do (i.e. walking, jogging, swimming, bicycling, dancing, etc.): _____

_____

EXERCISE HABITS: STRENGTH/RESISTANCE TRAINING

a. During the average week, how many **days** do you do strength/resistance training? _____days

b. How many **minutes** do you exercise with strength/resistance training? _____min

_____ total min/week (days x min)

c. List types of activities you do (i.e. weightlifting, Pilates, kettle ball, resistance machines, exercise bands, etc.):____

_____

What MOTIVATES you or would motivate you to exercise? *Check top three*

❑ Nothing would motivate me ❑ Family or partner ❑ Improve mood ❑ Weight reduction
❑ Control Blood glucose ❑ Body Image ❑ Increase Energy ❑ Reduce blood pressure
❑ Decrease stress ❑ Prevent heart disease ❑ Prevent Bone loss ❑ Improve sleep
❑ Increase self-esteem ❑ Other:_____

Are there any BARRIERS or PROBLEMS that limit exercise? *Check all that apply*

❑ No barriers ❑ Depression ❑ Work Responsibility ❑ Cost
❑ Life Transition Period ❑ Time ❑ Fear ❑ Other
❑ Family Responsibility ❑ Apparel ❑ Energy

EXERCISE SAFETY

a. Do you have any injuries that would make it difficult to exercise? No Yes
If yes, please explain: _____

b. Do you have any joint, muscle, or bone problems that might get worse with exercise? No Yes
If yes, please explain: _____

c. Do you have any breathing problems while exercising? No Yes
If yes, please explain: _____

d. Do you have any balance problems or have had a fall in the last 6 months? No Yes
If yes, please explain: _____

e. Do you have any difficulty completing your activities of daily living (i.e. showering, dressing, toileting)? No Yes
If yes, please explain: _____

Do you have any of the following health problems? *Check all that apply*

❑ Arrhythmia or irregular heartbeat ❑ Uncontrolled diabetes ❑ Recent heart attack
❑ Arthritis or significant joint pain ❑ Severe or uncontrolled heart failure ❑ Chronic or unusual fatigue/tiredness
❑ Chest pain/angina ❑ Uncontrolled asthma ❑ Difficulty breathing with activity
❑ Other

FIGURE 88.3 (CONTINUED) American College of Lifestyle Medicine long form.

88.2.2.1.2 Blood Pressure

The 2017 American College of Cardiology and American Heart Association (AHA) guidelines updated the definition of high blood pressure to account for complications that can occur at lower numbers and to allow for earlier intervention.[76]

For an adult 45 years of age without hypertension, the 40-year risk for developing hypertension is 93% for African Americans, 92% for Hispanics, 86% for whites, and 84% for Chinese adults. A 20 mm Hg higher SBP and 10 mm Hg higher DBP are each associated with a doubling in the risk of death from stroke, heart disease, or other vascular disease. In persons ≥30 years of age, higher SBP and DBP are associated with increased risk for CVD, angina, myocardial infarction (MI), heart failure (HF), stroke, peripheral arterial disease, and abdominal aortic aneurysm.[77]

Use of BP-lowering medications is recommended for secondary prevention of recurrent CVD events in patients

MENTAL HEALTH

PERCEIVED STRESS

	Never	Seldom	Sometimes	Often	Always
a. How often have you felt that you were unable to control the important things in your life?	1	2	3	4	5
b. How often have you felt **lack of** confidence about your ability to handle your personal problems?	1	2	3	4	5
c. How often have you felt that things were **not** going your way?	1	2	3	4	5
d. Have often have you found it hard to let go of things that upset you?	1	2	3	4	5

How do you COPE with stress? *Check all that apply*

❑ Meditation	❑ Food (too much, too little)	❑ Gambling	❑ Distraction
❑ Exercise/Physical Activity	❑ Spirituality/Faith	❑ Journaling	❑ Hurting yourself (i.e. cutting, etc.)
❑ Counseling/Psychotherapy	❑ Sex	❑ Massage/Body work	❑ Pet therapy
❑ Socializing with friends or family	❑ Recreational drugs (i.e. marijuana, cocaine, etc.)	❑ Prayer	❑ Other
❑ Art	❑ Television and/or video games	❑ Substance (tobacco, alcohol)	

RESILIENCE

When I am under extreme stress	Never	Seldom	Sometimes	Often	Always
a. I find a way to learn from my experience.	1	2	3	4	5
b. I find a way to take action.	1	2	3	4	5
c. I find it easy to prioritize what is important in my life.	1	2	3	4	5
d. I look at a stressful situation as an opportunity to grow.	1	2	3	4	5
e. I meet the goals I set for myself.	1	2	3	4	5
f. I believe that there are a lot of ways around a problem.	1	2	3	4	5
g. I feel motivated to pursue my goals.	1	2	3	4	5
h. I know I can get through it.	1	2	3	4	5

Patient Name:_____ DOB: _____

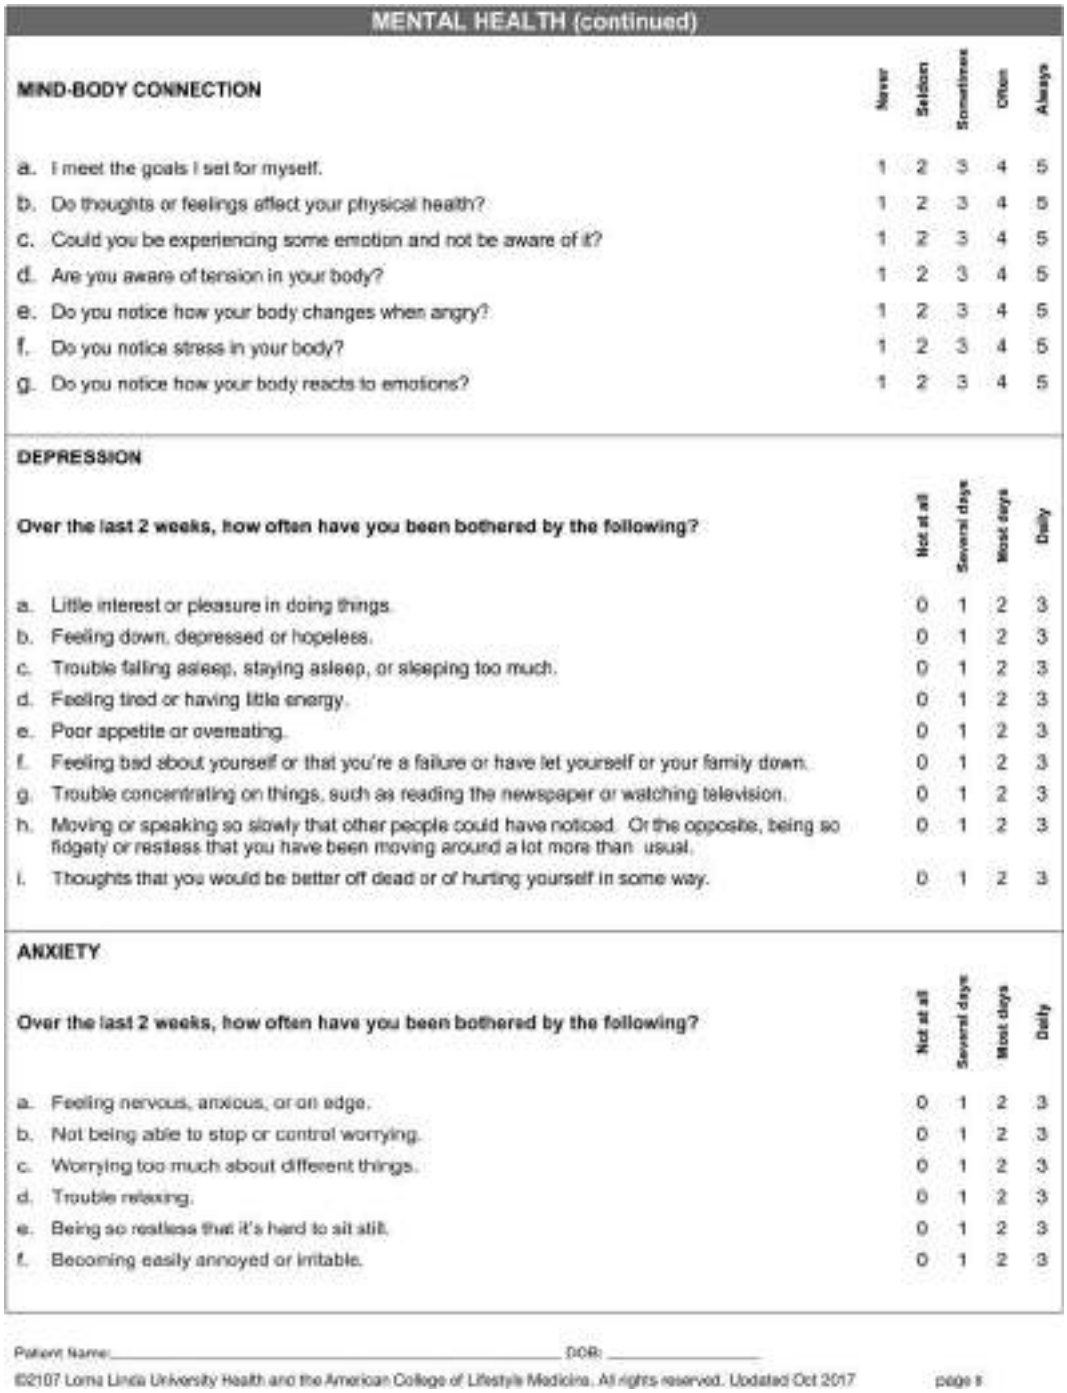

FIGURE 88.3 (CONTINUED) American College of Lifestyle Medicine long form.

with clinical CVD and an average SBP ≥130 mm Hg or a DBP ≥80 mm Hg, or for primary prevention in adults with no history of CVD but with an estimated ten-year ASCVD risk of ≥10% and SBP ≥130 mm Hg or DBP ≥80 mm Hg. Use of BP-lowering medication is also recommended for primary prevention of CVD in adults with no history of CVD and with an estimated ten-year ASCVD risk <10% and an SBP ≥140 mm Hg or a DBP ≥90 mm Hg.[77]

The goal of the new guidelines is to increase hypertension awareness, encourage lifestyle modification, and focus antihypertensive medication initiation and intensification on US adults with high CVD risk. [77]

88.2.2.1.3 Fitness Measures

Multiple options are available for body composition assessments, including skinfold measurements, bioelectric impedance analysis (BIA), and dual-energy x-ray absorptiometry (DXA). Although not always paid for by insurance, these measurements help differentiate whether weight is due to either fat mass or lean tissue, which is of value when

MENTAL HEALTH (continued)

MIND-BODY CONNECTION	Never	Seldom	Sometimes	Often	Always
a. I meet the goals I set for myself.	1	2	3	4	5
b. Do thoughts or feelings affect your physical health?	1	2	3	4	5
c. Could you be experiencing some emotion and not be aware of it?	1	2	3	4	5
d. Are you aware of tension in your body?	1	2	3	4	5
e. Do you notice how your body changes when angry?	1	2	3	4	5
f. Do you notice stress in your body?	1	2	3	4	5
g. Do you notice how your body reacts to emotions?	1	2	3	4	5

DEPRESSION Over the last 2 weeks, how often have you been bothered by the following?	Not at all	Several days	Most days	Daily
a. Little interest or pleasure in doing things.	0	1	2	3
b. Feeling down, depressed or hopeless.	0	1	2	3
c. Trouble falling asleep, staying asleep, or sleeping too much.	0	1	2	3
d. Feeling tired or having little energy.	0	1	2	3
e. Poor appetite or overeating.	0	1	2	3
f. Feeling bad about yourself or that you're a failure or have let yourself or your family down.	0	1	2	3
g. Trouble concentrating on things, such as reading the newspaper or watching television.	0	1	2	3
h. Moving or speaking so slowly that other people could have noticed. Or the opposite, being so fidgety or restless that you have been moving around a lot more than usual.	0	1	2	3
i. Thoughts that you would be better off dead or of hurting yourself in some way.	0	1	2	3

ANXIETY Over the last 2 weeks, how often have you been bothered by the following?	Not at all	Several days	Most days	Daily
a. Feeling nervous, anxious, or on edge.	0	1	2	3
b. Not being able to stop or control worrying.	0	1	2	3
c. Worrying too much about different things.	0	1	2	3
d. Trouble relaxing.	0	1	2	3
e. Being so restless that it's hard to sit still.	0	1	2	3
f. Becoming easily annoyed or irritable.	0	1	2	3

FIGURE 88.3 (CONTINUED) American College of Lifestyle Medicine long form.

combined with the basic measurements of weight, BMI, and waist circumference.[78]

88.2.2.1.4 Cardiorespiratory Fitness Testing

Fitness testing options are numerous and need to be adapted to the LM practice setting based on the availability of clinical staff members, resources, and timing constraints. Cardiorespiratory fitness testing defines how well the body can perform dynamic activity using large muscles at a moderate to high intensity for a period of time, which is valuable in evaluating overall fitness and determining functional capacity as well as any underlying cardiorespiratory abnormalities that are due to cardiovascular disease. The maximum volume of oxygen (VO_2 max) consumed during exercise, also known as aerobic power, is an indirect marker of cardiorespiratory fitness.

PURPOSE AND CONNECTION

How often do you agree with the following:	Never	Seldom	Sometimes	Often	Always
a. I live a purposeful and meaningful life	1	2	3	4	5
b. I have a spiritual community that I can turn to in times of need	1	2	3	4	5
c. I have a source of inner strength and meaning	1	2	3	4	5
d. I am satisfied with my current belief system	1	2	3	4	5
e. I have people who care about what happens to me	1	2	3	4	5
f. I have people who accept me at my worst and best	1	2	3	4	5
g. I have people I trust at home or work who I can talk to about my problems	1	2	3	4	5
h. I get help when I'm sick	1	2	3	4	5

SMOKING AND SUBSTANCE HISTORY

NICOTINE/TOBACCO (i.e. cigarettes, e-cigarettes, e-cigarettes/vaping, cigars, chew, snuff)

a. Do you use any of the nicotine products listed above? No Yes
If yes, do you want to quit using the nicotine/tobacco products? No Yes
If yes, answer the questions below:

b. How soon after you wake up do you use nicotine/tobacco?
❑ After 60 minutes ❑ 31-60 minutes ❑ 6-30 minutes ❑ Within 5 minutes

c. How many cigarettes do you smoke per day?
❑ 10 or less ❑ 11-20 ❑ 21-30 ❑ 31+

d. What age did you start smoking? _____
e. What is the longest time period you have stayed quit? _____
f. What made you start smoking again? _____
g. Which of the following people smoke around you? *Check all that apply*
❑ Friends ❑ Family ❑ Partner
❑ Co-Workers ❑ Other: _____

h. How many times have you seriously tried to quit? ___
i. For your most recent quit attempt, how long did it last? _____
j. Who is supporting you to quit smoking? _____
k. What is your most important reason to quit smoking? _____

l. Are you currently using or have used any medications to help you quit smoking? No Yes
If yes, check with of the following medications you have used:
❑ Nicotine Patch ❑ Nicotine Gum ❑ Nicotine Lozenge
❑ Wellbutrin/Bupropion Pill ❑ Chantix/ Varenicline Pill ❑ Other: _____

m. If you used any of the medication listed above, did they help? No Yes
If yes, list which ones helped: _____

FIGURE 88.3 (CONTINUED) American College of Lifestyle Medicine long form.

88.2.2.1.5 Muscular Fitness Testing

Muscular fitness testing includes both muscular strength and muscular endurance. Muscular strength is difficult to test in a clinic unless the clinic has the hardware to measure an applied load to certain movements (e.g., a bench press or leg press). Muscular endurance testing measures the ability of a muscle group to perform repeated or sustained contractions to sufficiently evoke muscular fatigue, thus providing an evaluation of the ability to perform activities of daily living. Muscular endurance tests include push-ups, curl-ups, and body weight squat tests. The total number of correctly performed repetitions is then evaluated based on established age and sex norms. These tests may be best performed by a fitness professional as part of an

SMOKING AND SUBSTANCE (continued)

n. Have you used any methods in the past other than medications to try to quit? No Yes

If yes, check which of the following methods you have used:

❑ Self-help ❑ Gradual reduction ❑ Cold turkey ❑ Hypnosis

❑ Acupuncture ❑ Special filters ❑ Vaping/e-cigarettes ❑ Other: _____

ALCOHOL

a. Do you drink alcohol? No Yes

If yes, please answer the questions below:

b. What type of alcohol do you prefer? _____

c. On average, how many servings do you drink per day/week/month/year on average? _____

If yes, please answer the questions below:

d. Have you ever felt you should "**Cut** down" on your drinking? No Yes

e. Have people **Annoyed** you by criticizing your drinking? No Yes

f. Have you ever felt **Guilty** about your drinking? No Yes

g. Have you ever had a drink in the morning to steady your nerves or to get rid of a handover (**eye opener**)? No Yes

h. Do you binge drink (more than 5 drinks for men or 4 drinks for women within 2 hours)? No Yes

Have you used any of the following substances in the past year?

Recreational drugs (cocaine, heroin, meth, etc.) No Yes

If yes, what level of concern do you have regarding use of the substances? No Concern 0 1 2 3 4 5 High Concern

If yes, how much substance do you usually use? _____

Marijuana No Yes

If yes, what level of concern do you have regarding use of the substances? No Concern 0 1 2 3 4 5 High Concern

If yes, how much substance do you usually use? _____

TREATMENT HISTORY

Have you ever received treatment for a mental health problem? No Yes

Have you ever received treatment for drug or alcohol use? No Yes

Patient Name: _____ DOB: _____

©2107 Loma Linda University Health and the American College of Lifestyle Medicine. All rights reserved. Updated Oct 2017 page 1o

FIGURE 88.3 (CONTINUED) American College of Lifestyle Medicine long form.

interdisciplinary LM clinical team, as the proper technique is paramount in evaluations of muscular endurance and strength to avoid injury.

Some basic movement patterns assessing activities of daily living, hip hinge evaluations, air squats, and push-pull-press motions with the upper body, can be incorporated into the clinical musculoskeletal exam and addressed through prescribed fitness programs. Patients can be encouraged to track their own fitness level over time through simple tracking. If they are unable to complete certain activities, help patients with modifications to make fitness safe. As an example, if unable to do a push-up on the floor because of knee pain, have the patient start with wall push-ups.

MEDICAL SYMPTOM QUESTIONNAIRE (MSQ)

This questionnaire identifies symptoms that help to identify the underlying causes of illness, and helps you track your progress over time. Rate each of the following symptoms based upon your health profile for the **PAST 30 DAYS**. If you are taking after the first time, record your symptoms for the LAST 48 HOURS ONLY.

Point Scale

0 = Never or almost never have the symptom
1 = Occasionally have it; effect is not severe
2 = Occasionally have, effect is severe
3 = Frequently have it, effect is not severe
4 = Frequently have it; effect is severe

88.2.2.2 Resources

Exercise is Medicine (EIM) was started through a Global Health Initiative and is overseen by the American College of Sports Medicine.[85] Their goal is to make physical activity assessment and promotion a standard part of clinical care. EIM has created several helpful resources such as individual exercise prescriptions based on one's diagnosis (i.e., diabetes, hypertension, fibromyalgia). These resources can be found on the website (www.exerciseismedicine.org) under "Rx for Health Series".[86]

PREVENTIVE SERVICES

a. Have you had a physical exam and/or "Wellness" Visit in the past 12 months? No Yes I don't know
If yes, list date and outcome: _____

b. Have you had a dental exam and teeth cleaning in the past 12 months? No Yes I don't know
If yes, list date and outcome: _____

c. Have you been screened for diabetes with blood work? No Yes I don't know
If yes, list date and outcome: _____

d. Have you had your cholesterol, lipids or triglycerides measured? No Yes I don't know
If yes, list date and outcome: _____

e. Have you ever had a bone density test to check for osteoporosis? No Yes I don't know
If yes, list date and outcome: _____

f. Do you have any balance problems or have had a fall in the last 6 months? No Yes I don't know
If yes, list date and outcome: _____

g. Do you have any difficulty completing your activities of daily living (i.e. showering, dressing, toileting)? No Yes I don't know
If yes, list date and outcome: _____

h. Do you have any concerns about your ability to drive safely or have you had any car accidents in the past 12 months? No Yes I don't know
If yes, list date and outcome: _____

i. Do you have any concerns about your memory? No Yes I don't know
If yes, list date and outcome: _____

j. Do you have any trouble with your hearing? No Yes I don't know
If yes, list date and outcome: _____

k. Have you had your eyes checked for vision problems? No Yes I don't know
If yes, list date and outcome: _____

l. Have you ever had your metabolism or thyroid checked? No Yes I don't know
If yes, list date and outcome: _____

m. Have you ever been told that you have a sexually transmitted disease/infection? No Yes I don't know
If yes, list date and outcome: _____

n. If you smoke, have you ever had an abdominal ultrasound to check for possible aneurysms? No Yes I don't know
If yes, list date and outcome: _____

o. Have you ever received counseling behavioral therapy for any of the following problems?

❑ Weight management or obesity ❑ Nutrition ❑ Smoking or use of other nicotine products ❑ Alcohol use

p. Which of the following screenings have you completed

❑ Colon cancer screen (stool test or colonoscopy ❑ Breast cancer screen (mammogram) ❑ Cervical cancer screen (PAP smear)

❑ HIV/AIDS blood work screen ❑ Hepatitis C blood work screen ❑ Depression or sadness screen

q. Have you had the following vaccines?

❑ Flu ❑ Hepatitis B ❑ Pneumococcal or Pneumonia

Patient Name: _____ DOB: _____

FIGURE 88.3 (CONTINUED) American College of Lifestyle Medicine long form.

TABLE 88.1
Physical Activity Assessment Tools

	Question(s)	Interpretation
Brief	**Physical Activity Vital Sign (v)**[2,5,6]	Physical Activity Vital Sign
	1. How many days per week do you engage in moderate to strenuous exercise?	Inactive: median <1 min/kw
	2. On average, how many minutes per day do you exercise at this level?	Insufficiently active: 1–149 min/wk
		Sufficiently active: ≥150 min/wk
	Strength and Resistance Exercise[7]	Insufficient: 0–1x/wk
	How many days a week do you engage in strength training or resistance exercises?	Sufficient: ≥2 times/wk
	International Physical Activity Questionnaire Short Form (v):[8] Seven-question survey for the past seven days of physical activity level in adults 15–64 years old.	Low, moderate, or high physical activity
In-depth	**Sedentary Time and Activity Reporting Questionnaire (STAR-Q)** (v)[9,10]	Estimates activity expenditure
	Past month activity and sedentary behavior questionnaire for adults	
	International Physical Activity Questionnaire Long Form (v)[11]	Low/inactive, moderate, or high. Can estimate MET-min/wk of physical activity
	Assesses all types of physical activity in the past seven days.	
Technology	Pedometer	Concrete number of steps or minutes of activity that can be monitored over time
	Smartphones/devices	
	Applications	

v, validated.

88.2.2.3 Laboratory Testing

Basic laboratory evaluation that would be of value in identifying and tracking baseline chronic illness include the following:

Laboratory Test	Reasoning
Complete blood count	Assess for anemia and platelet levels
Comprehensive metabolic panel*	Fasting blood glucose, electrolytes, baseline kidney function, baseline liver function, and albumin level.
Lipid panel*	Assess cholesterol and other lipids.
TSH, Free T4	Thyroid function.
Glycosylated hemoglobin	Blood sugar control over the last three months to monitor for insulin resistance, prediabetes, or diabetes.
hs C-reactive protein	Measure of inflammation associated with CVD.[87]
Vitamin D	Assess for vitamin D deficiency. Deficiency can lead to poor bone development (Rickett's, osteoporosis) and is associated w/some cancers, CVD, DM, autoimmune disease, and depression.[88]
Vitamin B12	Assess for Vit B12 deficiency. Deficiency is associated with hematologic and neurologic symptoms.[89]

*Fasting. IR, insulin resistance; PDM, prediabetes; DM, diabetes mellitus; CVD, cardiovascular disease.

88.2.3 Lifestyle-Focused Assessment and Plan

Once the LM vital signs, physical exam, and appropriate laboratory work have been completed, the next step is to focus on the assessment and plan. It is not possible to discuss all the treatment modalities for lifestyle medicine-related conditions here. We will focus on principles within the encounter to enable patient success in behavior change.

88.2.3.1 Touch Points

The provider should begin the visit by reviewing the patient's chief concern (Figure 88.4). Acutely ill patients or patients with medical emergencies should be rapidly assessed without delay or unnecessary questioning. In this case, only the physical vital signs and pertinent medical history are collected. Once the patient is stable or improving, follow-up visits can be used to address the lifestyle risk factors that may have led to the illness or emergency. It may still be appropriate for the provider to share some pertinent information on lifestyle risk factors during the visit for acute illness. For example, patients with COPD should be made aware during their visit for acute COPD exacerbation that cigarette use is a direct cause and should be discontinued. Chronic care visits and annual physicals are appropriate times to collect physical and LM vital signs.

After a review of the physical and LM vital signs, the highest risk areas should be briefly discussed with the patient to assess for urgency and patient safety. For example, a patient sleeping four hours a night during shift work who reports briefly falling asleep behind the wheel should have an urgent intervention. In-depth LM assessments can be done with further screening after the visit, at a follow-up appointment, or by ancillary staff.

The physical vital signs, blood pressure, heart rate, weight, and so on provide information on whether the unhealthy lifestyle patterns have progressed to the extent of disease formation. Laboratory work and imaging are also helpful as they provide concrete information about the state of one's health or disease. Next, risk calculators as mentioned above, such as the American College of Cardiology

TABLE 88.2
Nutrition Assessment Tools

	Question(s)	Interpretation
Brief	**Rapid 3 Question Assessment**[15] Over the last two weeks, how often have you eaten fast food, sugary drinks (e.g., soda, sports drinks, juice), or packaged foods (e.g., chips, candy, crackers, cookies)? a. Not at all b. Several days c. More than half the days d. Nearly every day On an average day, how many servings of whole fruits and vegetables do you eat (one serving is about a handful and does not include fruit juice)? a. Less than 2 servings b. 2–3 servings c. 4–5 servings d. More than 5 servings How many servings of processed or red meat do you eat in a week?[16] a. Less than 2 servings b. 2–3 servings c. 4–5 servings d. More than 5 servings	The less intake of fast food, sugary drinks (e.g., soda, sports drinks, juice), packaged foods (e.g., chips, candy, crackers, cookies), or processed or red meat, the better it is for one's health. The more whole fruits and vegetables the better for health.
	24 -hour verbal or written dietary recall Include portions, timing, and frequency of foods consumed and any associated symptoms (acid reflux following fatty meal). Asking patients to log an average day of eating, a healthy day, and an unhealthy day can provide a very informative range	As described in Rapid 3 question assessment Associated symptoms should help guide clinical interventions.
	Starting the Conversation (v)[17] An eight-item simplified food frequency instrument designed for use in primary care and health-promotion settings	The final score will be a range from 0 to 16. The lower the score, the healthier the diet.
In-depth	**The SOS-Free (salt/oil/sugar-free) Diet Screener**[18] from T. Colin Campbell Center for Nutrition Studies	Assess for the presence of vegetables and fruits, whole grains, legumes, nuts, and seeds.
	Mediterranean Diet Adherence Screener (MEDAS)(v)[19,20] Rapid assessment of Mediterranean Diet (MD) adherence via 14 questions regarding the main groups of food consumed as part of the MD	The higher the score, the more adherence and positive association with HDL and negative association with BMI, WC, TG, FBG, and TC/HDL ratio.
	Automated Self-Administered 24-hour Dietary Assessment Tool ASA24® (v)[21, 22] Free online tool for completing a 24-hour food recall.	A "Respondent Nutrition Report" is generated after completion, and provides feedback on the reported diet compared to the participant's country-specific dietary guidelines (calories, food groups, and nutrients)
	Dietary Screener Questionnaire (DSQ) (v)[23–25] Nineteen-item questionnaire assessing for the presence of fruits and vegetables, whole grains, added sugars, dairy, fiber, and calcium.	Provides estimates[24] of mean intake of fruits and vegetables (cups/day), added sugars (tsp/day), sugars from sweetened beverages(tsp/day), dairy (cups/day), whole grains (ounces/day), calcium (mg), fiber (gm), red meat (times/day), and processed meat (times/day). Results consistent with 24-hour food recalls.
Technology	Photographs of recent meals[26–28]	Plates of food should resemble ACLM's healthy plate:[29] 50% fruits and vegetables, 25% plant proteins, 25% whole grains, and water to drink.
	Applications	Efficient tracking process that can simultaneously provide nutritional content information (grams of fiber, milligrams of vitamin D).

HDL, high-density lipoprotein cholesterol; BMI, body mass index; WC, waist circumference; THG, triglycerides; FBG, fasting glucose; TC/HDL ratio, total cholesterol/HDL ratio;
v, validated.

TABLE 88.3
Stress Assessment Tools

	Question(s)	Interpretation
Brief	**Single Question Stress Scale** How stressful is your life on a scale of one to ten? One means little to no stress and ten means a great deal of stress[33]	Low stress 1–3 Moderate stress 4–7 High stress 8–10 American average 5.4/10 Perceived "healthy" stress 3.7/10
	Perceived Stress Scale-4 (PSS-4) (v)[34] Four-question survey on perceived stress	Scoring is from 0–16. The higher the score, the more perceived stress one is under.
In-depth	**Perceived Stress Scale 10-item (PSS) (v)**[34–36] Ten-question survey on perceived stress	Scoring is from 0–40 with higher scores indicating higher perceived stress. Low stress 0–13 Moderate stress 14–26 High stress 27–40
Technology	Wearable devices Applications	Could allow physiologic tracking of heart rate, blood pressure, and sleep with subjective stress levels. Other applications allow for stress symptom monitoring or journaling alone.

v, validated.

ASCVD Risk Estimator, and guidelines for disease diagnosis, such as those for metabolic syndrome, should be applied to the patient's data. The provider should discuss the patient's unique risk factor profile and any diagnosed medical conditions which may include traditional diagnoses such as diabetes and hypertension, or diagnoses based on lifestyle medicine vital signs such as insufficient sleep, acute or chronic stress, or physical inactivity.

Shared decision-making is essential in a lifestyle medicine visit. Treatment plans should be developed based on the potential detriment of the risk factor and the patient's willingness to change. While obtaining traditional vital signs, the nurse or medical assistant can ask if the patient is ready or willing to make any lifestyle changes. Additionally, if the Lifestyle Medicine Short Form assessment is used, the patient is asked to identify the "Top Three" areas they are most motivated to change. The nurse can potentially provide brief coaching and/or educational information to assist the change before the provider enters the room.

The provider should describe the treatment options: 1) traditional allopathic medicine—treatments are based on evidence-based guidelines, treatment is generally medications or surgical interventions; 2) a combination of traditional allopathic medicine and therapeutic lifestyle change; or 3) intensive therapeutic lifestyle changes. When treatment based on therapeutic lifestyle change alone is chosen, it must be clear that the required intensity must be to the level where lifestyle-related diseases are expected to improve or potentially achieve remission. This concept of required intensity is comparable to antibiotics or seizure medications at which a therapeutic level drug level must be reached for effective therapy.

During treatment discussions, lifestyle medicine providers should be prepared to discuss the following:

- Lifestyle is the foundation of health and often the primary modality of healing while medications are best considered adjuncts
- Compare and contrast lifestyle treatment outcomes to traditional medical care
- Pathophysiology of common lifestyle-related illnesses such as diabetes, high cholesterol, hypertension, and cardiovascular disease
- The emotional, social, and financial cost of therapeutic lifestyle changes such as eating a predominantly whole food, plant-based diet

Once a treatment plan has been decided, the provider should use a coach approach and motivational interviewing to help the patient create action steps toward their treatment goal. Keeping in mind, it may not include any lifestyle change if that is what the patient chooses. Provide engaging educational and motivational materials when warranted.

Motivational materials may also help patients move from contemplation to planning or action. Examples: films like PlantWise™, Eating You Alive™, Forks Over Knives™, or The Game Changers™, or books like The China Study© and Preventing and Reversing Heart Disease©, or programs like Diabetes Undone™[90] or PIVIO™[91] Whenever possible, these resources should not denigrate the medical profession. These may be introduced to the patient as a prescription, flyer, or even a photocopied picture of the cover or web page. The office may prepare preprinted prescription pads for such purpose, or the links may be sent via electronic means to the patient portal.

Establish appropriate follow-up. Refer, if needed, to interdisciplinary team members, specialists, an intensive therapeutic lifestyle change (ITLC) program, or other online or community resources.

The American College of Lifestyle Medicine has created a helpful resource for providers called the "ACLM Reimbursement Roadmap" to appropriately bill for lifestyle medicine visits that is available on their website.[92]

Providers should effectively use their electronic medical records to record and track lifestyle medicine activities,

TABLE 88.4
Well-being Assessment Tools

	Question(s)	Interpretation
Brief	**Patient Health Questionnaire 2 item (PHQ2)** (v)[39,40] Over the last two weeks, how often have you been bothered by the following problems? 0 (Not at all) to 3 (Nearly every day) – Little interest or pleasure in doing things? – Feeling down, depressed, or hopeless?	Total score ≥3 suggests depression. A more in-depth assessment like the PHQ9 or a clinical interview should then be completed.
	Generalized Anxiety Disorder 2 (GAD-2) (v)[41] Over the last two weeks, how often have you been bothered by the following problems? 0 (Not at all) to 3 (Nearly every day) – Feeling nervous, anxious, or on edge? – Not being able to stop or control worrying?	Total score ≥3 suggests anxiety. A more in-depth assessment like the GAD-7 or a clinical interview should then be completed.
	Patient Health Questionnaire 2 item (PHQ4) (v)[42] Combination of the above two screenings PHQ2 and GAD2	Total score is determined by adding together the scores of each of the four items. Scores are rated as normal (0–2), mild (3–5), moderate (6–8), and severe (9–12).
	Abbreviated version of the Satisfaction with Life Scale (SWLS) (v) [43] On a scale of one (lowest) to seven (highest): – In most ways, my life is close to my ideal. – I am satisfied with my life.	Higher scores are associated with higher satisfaction in this area.
In-depth	**Patient Health Questionnaire 9 item (PHQ9)** (v)[40,44,45] A nine-item measure of depression	Scores range from 0–27: 0–4 no or minimal depression 5–9 mild depression 10–14 moderate depression 15–19 moderately severe 20–27 severe depression
	General Anxiety Disorder-7 (GAD-7) (v)[41,46] A seven-item measure of anxiety	Scores range from 0–21: 0–4 no or minimal anxiety 5–9 mild anxiety 10–14 moderate anxiety 15–21 severe anxiety
	Satisfaction with Life Scale (v)[43,47] Five-item questionnaire assessing satisfaction with life: one (strongly disagree) to seven (strongly agree)	30–35 very high score, highly satisfied 25–29 high score 20–24 average 15–19 slightly below average 10–14 dissatisfied 5–9 extremely dissatisfied
Technology	Applications	Allow frequent tracking of subjective well-being, PHQ9 assessment, GAD7 assessment, or depression and anxiety symptoms.

v, validated.

treatment plans, and results. Electronic medical records may also be useful in creating patient registries, tracking routine preventive care and need for screenings, and risk stratification based on data in the system (blood pressure, LM health risk assessment score, or A1c).

Another responsibility of the lifestyle medicine provider is to assess if medications will need deprescribed prior to or during a lifestyle medicine treatment. Generally, the more intense the intervention, the higher the need for medication reduction and monitoring, especially in the case of medications with the potential to lead to acute hypoglycemia or hypotension. If any obstacles to the treatment regimen are present (side effects, complicated administration regimens, daily pill burden, or medication expense), this should be taken into consideration as to which medications should be discontinued first.

Polypharmacy is the prescribing of multiple medications, especially those that are inappropriate, unnecessary, or harmful.[93,94] Deprescribing has been most studied in the elderly, targeting drug classes like anti-psychotics,

TABLE 88.5
Social Relationships Assessment Tools

	Question(s)	Interpretation
Brief	**Loma Linda Social Relationship Questionnaire**[51] Four questions survey, patients rank their answers from one (never) to five (always). 1) I have people who care about what happens to me 2) I have people who accept me at my worst and best 3) I have people I trust at home or work who I can talk to about my problems 4) I get help when I'm sick	Answering "Never" or "Seldom" would be worrisome.
In-Depth	**A Brief Measure of Social Support** also known as **Social Support Questionnaire Short-Form 6 (SSQ6)** (v)[52] Survey inquiring who a patient can count on in six specific areas of life and how satisfied they are with the support.	If "no one" is marked by the patient or if satisfaction is low, this is an area of concern and should be further assessed

v, validated.

TABLE 88.6
Sleep Assessment Tools

	Question(s)	Interpretation
Brief	**Single-Item Sleep Quality Scale** (v)[55] Overall sleep quality in the past seven days is rated on a scale from one (terrible) to ten (excellent).	Sleep quality is a subjective measure. 0 Terrible 1–3 Poor 4–6 Fair 7–9 good 10 Excellent. If a patient answers fair, poor, or terrible, further assessment should be completed
In-depth	**Global Sleep Assessment Questionnaire** (v)[56,57] Eleven questions with four possible responses (never, sometimes, usually, or always) based on the past four weeks. Screens for insomnia, OSA, shift workers disease, RLS, PLMS, parasomnia, and secondary causes.	There is no total score, and any answer besides "never" should be further evaluated.
	STOP-BANG Questionnaire (v)[58, 59] This acronym stands for Snoring, Tiredness, Observed apnea, blood Pressure, Body mass index, Age, Neck circumference, and Gender, and helps screen for obstructive sleep apnea. Each of the eight items is answered as yes[1] or no[0].	Risk for moderate to severe OSA: 0–2 Low risk 3–4 Further assess 5–8 High risk Sensitivity to detect OSA with a score ≥3 for moderate 93% and severe OSA is 100%.
	Pittsburgh Sleep Quality Index (PSQI) long form (v)[60,61] Assesses seven areas that impact the quality of sleep over the past month via 19 questions with the goal of assessing sleep quality and distinguishing between "good" and "poor" sleepers.	Each of the following areas is scored from 0–3: sleep quality, sleep latency, sleep duration, habitual sleep efficiency, sleep disturbances, use of sleeping medications, and daytime dysfunction. The sum of these creates a global score. Global scores ≥5 are consistent with "good" sleepers.
Technology	Wearable devices Applications	Sleep quantity and quality can be monitored through wearable devices and results reviewed on compatible applications.

v, validated.

benzodiazepines, antihypertensives, statins, and non-steroidal anti-inflammatory drugs/COX-2 inhibitors/acetylsalicylic acid.[95–97] Proton pump inhibitors are also frequently targeted for deprescribing.[98–100] Recent lifestyle medicine studies have described their deprescribing protocols during lifestyle interventions.[101]

88.2.3.1.1 Resources for Deprescribing

- Deprescribing.org
- Medstopper.com

If available, consider involving a clinical pharmacist for additional support as they have specific knowledge and training regarding best deprescribing practices.

TABLE 88.7
Substance Use Assessment Tools

	Question(s)	Interpretation
Brief	**NIDA Quick Screen** (v)[62]	If the answer to all the questions above is "Never", screening is complete. Encourage the patient to maintain abstinence.
	Asks about the frequency of use in the past year of alcohol, tobacco products, prescription drugs for non-medical reasons, and illegal drugs (Never, Once or Twice, Monthly, Weekly, Daily, or Almost Daily)	If a patient answers yes to any of the above, further assessment should then be completed.
	Tobacco, Alcohol, Prescription Medication, and Other Substance Use (TAPS) Tool. Part One (v)[63]	Any response other than "never" is a positive screen and should be assessed with TAPS-2
	Screens for substance abuse	
	Alcohol Use Disorders Identification Test—Concise AUDIT-C (v)[64,65]	Scored on a scale of 0–12.
		Men score of ≥4 positive
	Three questions, rated 0 (never, low number of occurrences) to 4 (daily, high number of occurrences)	Women score of ≥3 positive
		The higher the score, the higher the likelihood that drinking is affecting the patient's safety.
	(1) How often do you have a drink containing alcohol?	
	(2) How many drinks containing alcohol do you have on a typical day when you are drinking?	Positive scores should be assessed with the ten-team AUDIT.
	(3) How often do you have six or more drinks on one occasion?	
	NIDA Modified Assist (v)[62]	Substance involvement score ranges for risk of illicit or non-medical prescription drug use:
	Appropriate to conduct if Yes to any questions on the NIDA Quick Screen	0–3 Lower risk
		4–26 Moderate risk
		27+ High risk
	Tobacco, Alcohol, Prescription Medication, and Other Substance Use (TAPS) Tool. Part Two (v)[63]	Scores have a potential range of 0–3 for tobacco and other drugs, and 0–4 for alcohol.
	Appropriate to conduct if Yes to any questions on TAPS Tool Part One	For tobacco, alcohol, THC:
		≥1 further assess for problem use
		≥2 further assess for substance use disorder
		For all other drugs:
		≥1 further assess for substance use disorder
	AUDIT 10 Item (v)[66, 67]	Score of ≥8 likely harmful or hazardous drinking.
	Appropriate to conduct if AUDIT-C screen is positive	Score of ≥13 for women or ≥15 for men likely alcohol dependence.
Technology	Carbon Monoxide Breath Sensor System (CMBSS)	Monitor the amount of carbon monoxide in one's lungs due to inhaled tobacco use. CMBSS are available over the counter and link with smart devices.[68]
	Smart devices	
	Applications	Applications are available to monitor sobriety for alcohol, narcotics, and some illicit drugs. These are dependent on patient input.

(v) = validated

88.3 LIFESTYLE MEDICINE INTERDISCIPLINARY CLINICAL MODEL

A core competency for the LM clinician is being adept in the development, support, and practice of an interdisciplinary team of healthcare professionals.[1] This "team" may also include appropriate referrals to other independent health professionals to leverage their expertise in enhancing health behavior change interventions.

88.3.1 Chronic Care Model

The Chronic Care Model identifies six fundamental areas that form a system encouraging high-quality chronic disease management which are then applied to a variety of chronic illnesses, healthcare settings, and target populations. This model is valuable when applied in LM as it highlights the components needed for interdisciplinary collaboration as well as a proactive model of healthcare (see Figure 88.5).[102–105]

88.3.1.1 Components of the Chronic Care Model[102, 106]

88.3.1.1.1 Self-Management Support

Patients with chronic illness need support and information to effectively manage their health. This includes information about their disease pathophysiology and behavioral determinants, assistance with self-management skill building, and ongoing support from members of the practice team.

88.3.1.1.2 Delivery System Design

The delivery of care to people with chronic conditions requires not only determining what interventions are needed, but also clarifying team member roles and tasks

TABLE 88.8
Anthropometric Measurement and Body Composition[78]

Test	Measurement	Results
Skinfold thickness testing with calipers	Subcutaneous fat is proportional to the total amount of body fat.	With proper technique, measurements for the percent total body fat can be within 2–3.5% of the gold standard, of hydrostatic weighing. If the evaluator is inexperienced or using poor technique, measurements may only be within 8% (% total body fat)
Bioelectric impedance analysis (BIA)	Measures electrical signals as they pass through fat, lean mass, and water in the body to assess leanness.	Accuracy is based primarily on the machine and the validity of the prediction algorithms.
Dual-energy X-ray absorptiometry (DXA)	Body fat percentage is estimated using the ratio of body mass to body volume.	The most accurate and precise method and can identify regional body fat distribution.

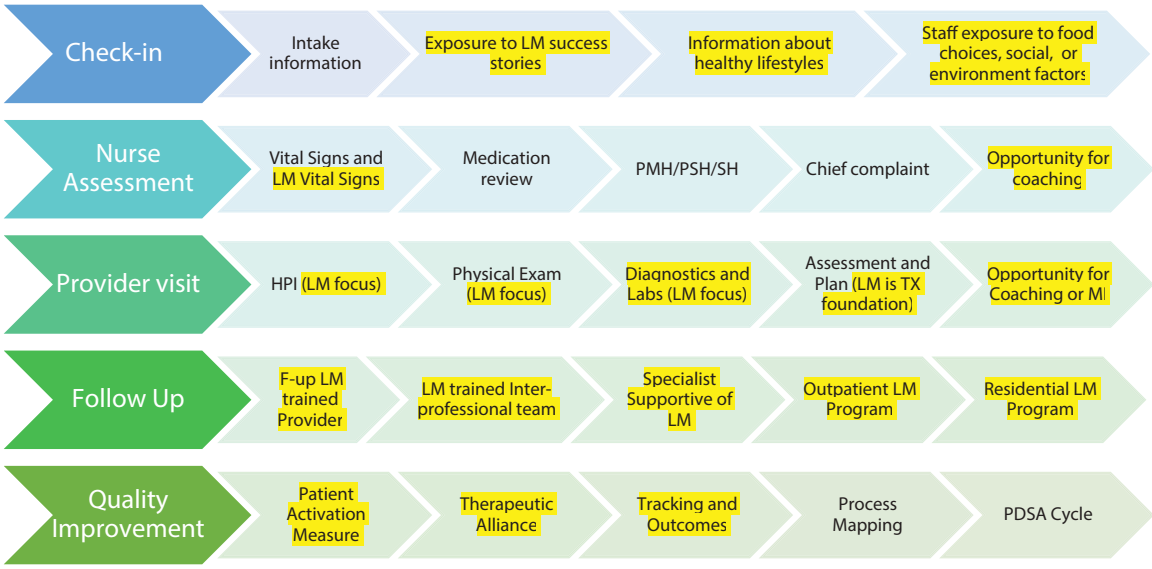

TABLE 88.9
Cardiorespiratory Fitness Testing[79]

Rockport Fitness Walking Test (one mile)[80]	Estimates aerobic power, VO_2 max, after completion of a one-mile walking course as fast as possible using immediate post-exercise heart rate and the one-mile walk time. No heart monitor or equipment is necessary.	Results are then placed into an equation that predicts VO_2 max in $mL \times kg^{-1} \times min^{-1}$. For most individuals, the predicted VO_2 max ranges within 0.335 L/min of the actual VO_2 max.
Six-Minute Walk Test[81,82]	Measures the distance a patient can walk quickly on a hard, flat surface in a period of six minutes. Upon completion distance covered, Borg fatigue and dyspnea levels, SpO_2, and pulse are documented.	Evaluates functional exercise capacity and is particularly useful for measuring response to medical interventions in those with moderate to severe heart or lung disease.
Step Tests[83,84]	Submaximal assessment of VO_2 max that can be implemented in a variety of situations within the general adult population	Heart rate is auscultated or palpated for one minute immediately after the three-minute step test and provides a measure of fitness rating based on calculated norms for age and gender.

TABLE 88.10
Tracking Personal Fitness

Component of Fitness		Starting Date	Follow-up
Cardiorespiratory fitness			
Step test	HR after 3 min stepping and 1 min rest		
Mile test	HR upon completing 1 mile, time		
Muscle strength			
Bench press	Amt of weight, # of reps		
Squat press	Amt of weight, # of reps		
Muscle Endurance			
Push-ups	# in 1 min		
Arm curls	# in 1 min		
Squats	# in 1 min		
Sit-ups	# in 1 min		
Core strength			
Plank test	Time		
Flexibility			
Sit and reach test	Inches or cm reached beyond feet		
Balance			
Standing on single leg	Time		

HR, heart rate.

FIGURE 88.4 Touch points for lifestyle medicine in a lifestyle medicine clinic.

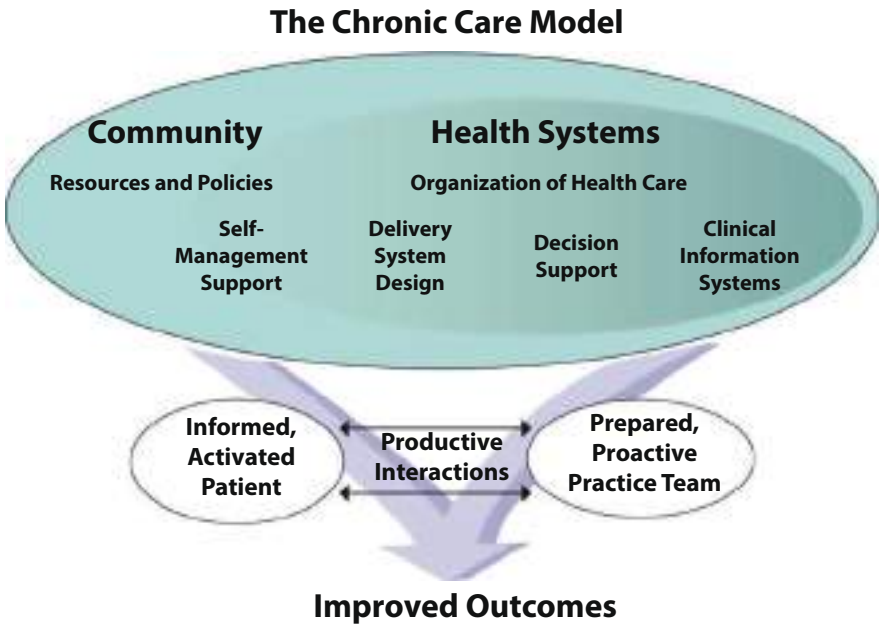

FIGURE 88.5 Chronic Care Model (developed by The MacColl Institute, ©ACP-ASIM Journals and Books, reprinted with permission from ACP-ASIM Journals and Books. Source: Wagner EH. Chronic disease management: What will it take to improve care for chronic illness? *Effective Clinical Practice* 1998;1(1):2–4).

to ensure the patient receives the care they need. This requires making sure that all involved clinicians have centralized, up-to-date information about the patient's status, and implementing follow-up as a standard procedure that is closely tied to the Clinical Information System.

88.3.1.1.3 Decision Support

Where possible, treatment decisions should be based on explicit, proven guidelines. Ideally with integration into the day-to-day clinical practice in an accessible and easy-to-use manner.

88.3.1.1.4 Community Support

Community programs and organizations can support or expand a health system's care for chronically ill patients and can assist in making prevention strategies more actively utilized. Many of the changes required in lifestyle medicine are for a long duration and frequently impact a patient's

social sphere; involving the community can help garner the social support needed to sustain change. Identifying state programs, local agencies, schools, faith organizations, businesses, and clubs that offer programs synergistic with the goals of LM distributes the responsibility and collectively enhances the potential for long-term successful outcomes.

88.3.1.1.5 Health System or a Health Organization

The health system or health organization is composed of leaders, staff, operations, values, and goals. The organization may range from a small primary care clinic to an extensive multisite integrated health system.

88.3.1.1.6 Clinical Information Systems

The purpose of this element is to have a disease-specific database of patients promptly available. This database should alert the healthcare professional about needed healthcare maintenance screenings and tests, and it should provide tracking of the results. In addition, clinical information systems (CIS) should help expedite the exchange of information between different healthcare professionals and patients.

According to the Robert Wood Johnson Foundation:

> Research has long shown that collaboration across healthcare professions improves coordination, communication, and ultimately, the quality and safety of patient care. It utilizes both the individual and collective skills and experience of team members, allowing them to function more effectively and deliver a higher level of services than each would work alone.[107]

Chronic care is part of lifestyle medicine practice. Following a model for chronic care can be an efficient and effective way to implement and maintain an effective LM program.

88.3.1.2 The Interdisciplinary Team

According to the World Health Organization, "Collaborative practice happens when multiple health workers from different professional backgrounds work together with patients, families, careers, and communities to deliver the highest quality of care across settings".[108]

This collaboration also includes the interactions between healthcare professionals to execute quality and safety checks, share information, and help patients comprehend and comply with treatment plans.

The developed interdisciplinary care team is a reinforcing interface that advocates for lifestyle modification in the treatment of chronic disease while supporting high levels of self-efficacy and self-management, both of which are associated with higher levels of treatment compliance.

The steps to building an interdisciplinary team include 1) identifying and/or hiring the right team members, 2) training the team well, 3) setting appropriate expectations, and 4) assessing competency and providing feedback for growth.

Identifying/ hiring	Need to have an authentic interest in lifestyle medicine and be on the health journey, not necessarily being an expert or perfect at it.
Training	Consider enrolling all team members into an intensive therapeutic lifestyle change (ITLC)* program so they can experience the difference in themselves before working with patients. Long-term training may include LM clinical pearls, grand rounds, lifestyle challenges, becoming certified in LM,** and an LM journal club.
Setting expectations	Lifestyle medicine should be looked upon as the foundation of medical treatment. Patient communications should be standardized so patients receive congruent advice on topics such as diet and exercise. Team members should model health behavior with a "do as I do" mindset.
Assessing competency	Patient charts and cases should be reviewed, and meaningful feedback provided to improve patient care and the team's performance.

*Some options for ITLC programs available online include the 21 Day Vegan Kick Start program (free) through the Physicians' Committee for Responsible Medicine PCRM[109] Pivio, formerly the Complete Health Improvement Program (at cost) through the Lifestyle Medicine Institute (LMI);[91] or PlantPure Rx (at cost).[110]

**Several training courses and certifications are now available for staff through the American College of Lifestyle Medicine, Wellness Coaches, and the American College of Preventive Medicine.

A true collaboration from all members of the team requires confidence, commitment, and competency. An interprofessional team includes an internal team and an external team.

The internal team (within the clinic) may include nurses, medical assistants, receptionists, support staff (billing and operations), advanced practice providers, condition management clinicians, health coaches, physical therapists, and fitness experts.

External teams (outside of the clinic) may include other primary care providers, specialists, chiropractors, massage therapists, naturopathic doctors, midwives, hospitals, and payers.

88.3.2 Sample Effective Programs

In a report on the effectiveness of strategies to change the behavior of health professionals and the organization of care to promote weight reduction in those who are overweight or obese, when compared with standard care, educational interventions by general practitioners could reduce

the average weight of patients after one year by 1.2 kg. However, patients may lose more weight (6 kg) after one year if the care is provided by a doctor-dietitian team.[111]

In an Australian general practice, a lifestyle intervention that included a health check with brief lifestyle counseling and referral of high-risk patients to a program consisting of one to two individual visits with an exercise physiologist or dietitian and six group sessions showed that those in the intervention group had increased their physical activity levels and lost more weight if attending the minimum number of group program sessions. Practice nurse involvement was important to sustaining implementation. This integrated model showed that counseling with the physician provided some benefit, but more long-term changes were possible via a group-based approach.[112]

In a study that examined the outcomes and costs of an LHE-delivered translation of the Diabetes Prevention Program (DPP) evidence-based lifestyle intervention for older adults in Arkansas senior centers, participant weight loss averaged 3.7 kg at four months, providing an effective tool for LM system design that occurs in partnership outside the usual clinical settings.[113]

88.4 LIFESTYLE MEDICINE OFFICE SYSTEMS

88.4.1 Information Systems

Information systems are likely present within an existing electronic medical record for tracking HEDIS and other value-based care imperatives and can be used simultaneously with other resources to track lifestyle behaviors, proactively identify high-risk patients, and facilitate LM intervention decision support. Designing an office system that can assimilate this LM data and make it available for routine use by team members is a critical component of a next-generation model for LM care.

88.4.2 Care Settings

88.4.2.1 Group Visits

The value of group visits is that they appropriately allow clinicians to see more patients more frequently for follow-up chronic disease management visits and allow more availability of proactive and coordinated interactions with the clinical team, leading to higher patient and provider satisfaction. Patients receive the benefit of prompt access to care, extra time with the physician and clinical team, and answers to questions they might not have thought to ask (because others in the group ask). In addition, patients may be motivated by the stories and experiences of other patients, gain greater education, and receive more assistance for psychosocial issues.[114]

88.4.2.2 Community and Digital Connection

A referral network to community-based resources is an important element of a comprehensive LM clinical system design, as a number of programs may be offered locally that would provide care that may not be feasible to include within a clinical practice. An example of such is the Diabetes Prevention Program[115] with multiple delivery sites regionally as well as through online delivery systems.

The online community has also expanded access to many LM interventions and can become a readily available resource for patients in helping to provide health education and the social relationships that encourage lifestyle change outside of a clinical setting. In a relevant study, with clear advantages for reach, social media and mHealth technologies offer the ability to scale and engage entire populations at low cost, while developing supportive social networks, connecting patients and providers, encouraging adherence with cancer care, and collecting vast quantities of data for advancing cancer research. Best practices have yet to be developed amid the rapid and numerous development efforts.[116]

88.4.2.3 Lifestyle Medicine and Telehealth

Since the SARS-COV-2 outbreak and the "lockdown", most electronic medical records (EMRs) have incorporated Telehealth systems and these have found broad acceptance by both payers and the public. While telehealth often involves the use of new or sophisticated technology, it is helpful to remember the foundational emphasis of lifestyle medicine on social connection. It is well established that the physician-patient relationship is a therapeutic modality in and of itself[117–119] A lifestyle medicine use of telehealth will seek to utilize it in a way that enhances relationships. It is important to have a shared discussion with patients about how they like to communicate and be communicated with; e-mail/secure message, phone, or video. Clear expectations and setting appropriate boundaries with patients for virtual visits may be important.[120]

88.4.3 Collaboration and Resources

Another core competency from the 2010 JAMA article addresses the measurement of processes and outcomes with the intent of improving the quality of lifestyle interventions in individuals and groups of patients. Data collection and analysis allow the assessment of a patient's current status and movement toward health behavior changes. Following the progress of multiple patients allows for analysis of the system's effectiveness as well as the identification of weak areas. A key element of LM quality improvement is to routinely plan, conduct, and evaluate interventions to improve processes and outcomes. Identifying a team member or committee to collect medical record data and/or perform chart audits facilitates this process, fostering accountability within the system.

88.5 LIFESTYLE MEDICINE QUALITY IMPROVEMENT

88.5.1 Principles of Evidence-Based Medicine

Quality improvement is foundational not only to personal practice, but to population management and health behavior change for patients. While its elements are simple, it is not always intuitive, and expertise only comes with practice. The American Academy of Family Physicians sums up the basic principles of quality improvement as follows: 1) establish a culture of quality in your practice; 2) determine and prioritize potential areas for improvement; 3) collect and analyze data; 4) communicate your results; 5) commit to ongoing evaluation; and 6) spread your successes.[121]

Many of the process and quality improvement principles can be traced back to W. Edwards Deming. His work, most famously adopted by Japanese manufacturing, includes the Plan-Do-Study-Act (PDSA) cycle, and spawned Toyota's LEAN, and Six Sigma.[122] Many of the quality improvement principles from auto manufacturing apply to healthcare, and in today's pay for performance and ACO healthcare environment, strategic use of quality improvement is essential.

The Institute for Healthcare Improvement (IHI) has excellent resources on quality improvement. Much of their "Open School" curriculum has been free for medical students and residents, and it is well worth reviewing. In addition to the basic quality improvement curriculum, they have a curriculum on patient safety/medical mistakes, leadership, and a variety of other topics.[122]

88.5.2 Quality Improvement

88.5.2.1 Process Mapping

Clinical LM practice is unique in that multiple providers may be involved in ongoing care that includes multiple interventions, such as nutrition, fitness, and stress management. Understanding the process flow can offer great value to becoming an efficient system that reduces unnecessary clinical components while providing an effective and efficient LM solution using workflow diagrams (Figure 88.6).[123]

The symbols are important in a process flow map. Ovals show input to start the process or output at the end of the process. Boxes or rectangles show the task or activity performed in the process. Arrows show the process direction flow. Diamonds show points in the process where a yes/no question is asked or a decision is required. Usually, there is only one arrow out of an activity box. If there is more than one arrow, a decision diamond may need to be used. If there are feedback arrows, the feedback loop should be closed, i.e., it should return to the input box.

The process map should have a specific start and end point. Each step should be listed and placed in sequence. Each team member should review it. Analyze the map by asking: What steps are essential and add value? What steps do not add value (and can be removed)? What steps do not add value, but are not avoidable (and might require longer-term solutions)?

The following questions may add even further value: Are the steps done in a standardized way or differently depending on which team member does that step? Consider which way is truly the most effective way. Are steps repeated unnecessarily or out of sequence? Are there process steps where errors occur frequently? Process Mapping fits well with the next step of quality improvement, which identifies and evaluates necessary changes.

88.5.3 Plan-Do-Study-Act

A commonly used construct for quality improvement in healthcare is the PDSA method.[124] This tool enables small-scale improvements over short periods of time. In the Plan

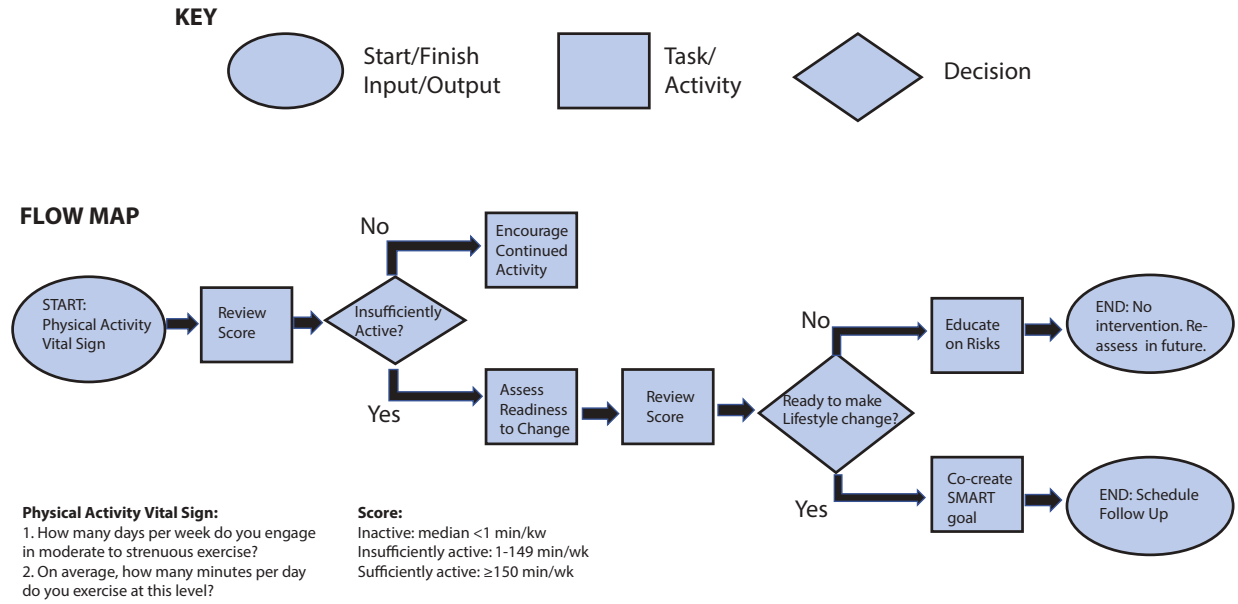

FIGURE 88.6 Process flow map.

phase, the objective is to identify a goal and develop a plan, clearly identifying the who, what, when, and where of the desired "intervention". It is helpful to have a clearly defined cause-effect hypothesis to guide the cycle in making predictions. This allows for refinement of the underlying hypothesis with each cycle of improvement. In the Do phase, the plan is carried out, documented, and the initial data can be analyzed for modifications that may be necessary immediately. In the Study phase, the complete data is analyzed and compared to predictions to create an evaluation and summary of the lessons learned from the process. In the subsequent Act phase, the intervention is either instituted, dropped, or modified based on reflective and constructive evaluation. Resulting refinements may then be added to the selected workflow. (See Figure 88.7.)

The PDSA cycle requires quick planning, small tests of change, and time to evaluate the results for further refinements in an iterative process over several cycles. The optimal end point rarely occurs after one implementation; being nimble and adaptive is at the core of this technique for enhancing the LM clinical process.

88.5.4 Root Cause Analysis

Another tool in quality improvement for understanding the underlying reasons we are producing certain outcomes is through root cause analysis.[125] The fishbone diagram is useful in identifying the causes leading to an effect and can be drawn visually. The participation of the care team is important in gathering comprehensive perspectives as to root causes and to drill down to discover what is occurring. The problem needs to be defined specifically, followed by a quick brainstorm of all possible causes, without the solutions being offered at this stage. Then all these causes are written down or typed into an electronic program. The problem is placed at the head of the "fish". The categories point toward the central line of the fish's "body" as individual branches, representing things such as equipment, process, people, materials, environment, management, communications, policies, and patients.

The team then discusses and analyzes the resulting diagram: Are there repeated causes? Are most causes under one category? A few priority causes are identified to concentrate on, and the possible solutions are reviewed by the team. The chosen solution(s) are then applied using PDSA cycles.

These resources reflect the important conceptualization that LM clinical processes are ongoing and iterative built on the culture of quality improvement. Retaining flexibility in adjusting roles and procedures based on measurement results and openness to innovation is key to shaping next-generation models of care. These processes are key to the successful improvement in lifestyle medicine practices where the variables are so numerous that best practices are virtually impossible to define prospectively.

88.6 Clinical Process Conclusions

A lifestyle medicine clinical practice is defined by its systematic integration of key lifestyle behavior assessments and counseling into a comprehensive patient-centered process addressing the actual cause of illness. The four key components to consider for LM integration include making

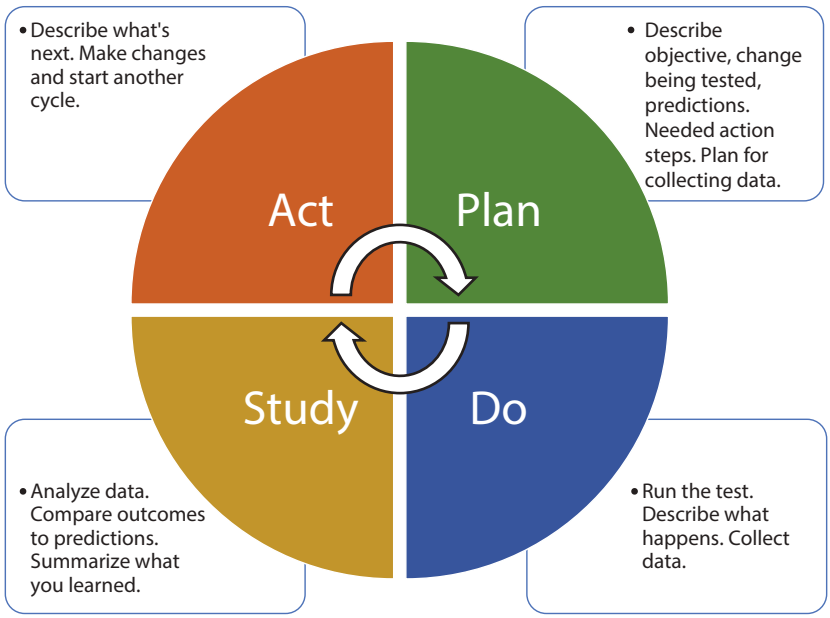

FIGURE 88.7 PDSA cycle.

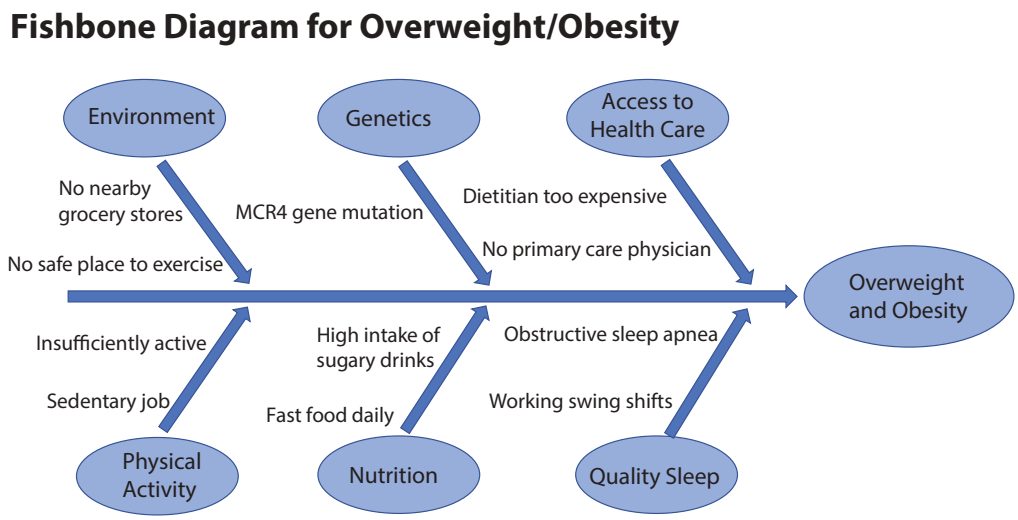

FIGURE 88.8 Fishbone diagram.

lifestyle medicine the foundation of the clinical encounter, using an interdisciplinary clinical care model, creating efficient and effective office systems, and engaging in ongoing quality improvement.

LM treatment addresses reversible unhealthy or risky lifestyle factors and follows evidence-based practice guidelines. Current reactive care models have generally not done well at fostering collaboration between providers or adequately engaging patients in this positive behavior change. An effective proactive system recognizes that tracking LM vital signs, follow-up (possibly through group visits), and a variety of systems for motivating and documenting behavior change are key to the lifestyle practice. This entails fully leveraging partners in the system, such as other health professionals in the office or experts in the community, to provide a consistent message and the required social and educational resources needed to support a lifelong process of making healthful lifestyle choices. At the same time, the LM practice must continually strive for the improvement of office systems, intervention practices, and the ability to motivate patients to change and maintain the healthiest lifestyle choices.

Only a small fraction of an individual's lifetime is spent interacting with a healthcare team. Lifestyle medicine clinical processes need to be designed in such a way as to facilitate real and beneficial change in the habits of a patient's daily life. With intention and design, these encounters can reduce chronic disease and healthcare spending, promote health, and save lives.

CLINICAL APPLICATIONS

- Depending on the time availability of the patient and medical staff, brief or more in-depth assessments of LM risk factors can be incorporated into the clinical visit. Based on the patient's motivation and confidence level for change, evidence-based treatment plans can then be implemented to address unhealthy or risky lifestyle factors.
- The identification of key metrics in clinical practice, such as blood pressure, adiposity, and metabolic syndrome, engenders targeted discussion of lifestyle risk factors and identifies areas for improvement.
- For a successful implementation of an LM intervention and patient lifestyle empowerment, the following should be in place: easily available educational information, a team approach for delivery, and connection with community resources.
- Group visits offer an alternative process in which individual patient concerns are addressed while leveraging the benefits of the dynamics of the group and the potential integration with behavioral health services.
- Telehealth services are now widely available. They may be more convenient and improve access to care for patients.
- Continuous quality improvement is foundational to growing an LM practice. It can be started small, identifying a single process that needs improving. Successful implementation builds the strength of the clinical team and encourages active participation in clinical care and system improvement.

89 Emotional Health and Stress Management

Neil Nedley, MD and Francisco E Ramirez, MD

KEY POINTS

- Well-being can be optimized by leading individuals away from unhealthy lifestyles and toward healthy coping strategies.
- Simple tools are available for bringing positive changes in thinking patterns and improving mood.
- Lifestyle Interventions, improving thinking skills, and specific behavioral interventions have demonstrated the benefit of stress management.
- Many cases of depression and anxiety may be managed successfully with appropriate lifestyle changes

89.1 BACKGROUND

In physics, the term "stress" was originally used to describe the force on an object that leads to bending or breaking. Relaxation, in contrast, refers to enjoyable, leisure activities indulged during evenings or weekends. According to Lumsden, the first time the term "stress" was used was in the 14th century and referred to a context of affliction, adversity, and hardship.[1] Physiologist Hans Selye first popularized the term stress in his book *The Stress of Life*,[2] which reported on his research. Today, we commonly use the term "stress" to describe our response to the problems and concerns that we encounter in life. Deadlines, economic problems, or problems in relationships can trigger stress. These activating events are called stressors and our reaction to them is referred to as stress.

In 1697, Isaac Newton theorized that in the natural world, for every action there is an equal and opposite reaction.[3] The same principle applies to physiological and psychological stress; the stressor is the action, and stress is the reaction. A wholistic definition of stress might well be an inability to cope with a perceived threat (real or imagined) to one's mental, physical, emotional, and spiritual well-being resulting in physiological responses.[4]

Physiological and psychological stress are major factors in both physical and mental illness and must be addressed for optimal well-being and homeostasis.

We live in a world with increased perceived stress. Seventy-four percent of US adults report symptoms due to stress. The demographic reporting the most is the millennials with 86% reporting the effect.[5]

Stress can have negative health effects and has been linked to all leading causes of death including heart disease, cancer, accidents, cirrhosis, and suicide.[6] This is a significant change since 1955 when the leading causes of death were primarily infectious diseases.[7]

Three categories of stress have been identified: *eustress* (the good type, it can motivating or inspiring such as falling in love or meeting someone famous); *neustress* (a type of stress with no consequential effect such as reading about a faraway news report); and *distress* (considered negative, many times just called stress such as a breakup of a relationship). Distress may be further classified as *acute stress* which may be intense but quickly disappears (such as getting pulled over by police and let go without any a ticket) or *chronic stress*, which appears gradually and lingers for some time, from days to months (such as could be found in someone in an entrapped, unhealthy relationship).

Treating distress with medication has been disappointing. It has become clear that many psychiatric medications (benzodiazepines, SSRIs, antipsychotic medications, stimulants, and others) create neurotransmitter imbalances and a degree of dependence. While medications may be necessary in some cases, there are non-drug lifestyle behavior and mental health tools that show significant (and sometimes greater) effects in bringing improvement to many mental health pathologies. This chapter explores practical lifestyle interventions for optimizing well-being and managing stress, anxiety, and depression. Several tools are introduced to assist the clinician in identifying and measuring responses to interventions. Effective strategies for increasing happiness and well-being are explored followed by evidence-based coping tools for stress management. Positive psychology and cognitive behavior therapy (CBT) are explored as helpful tools for empowering patients to regain healthy control of their own thinking. Various evidence-based lifestyle-focused modalities are discussed for managing stress. An introduction of the *Nedley Hypothesis* provides a novel construct for addressing the modifiable factors in both depression and anxiety. Lifestyle changes, both physiological and psychological (learning to manage thoughts) are likely the most effective long-term strategy for dealing with stress and anxiety as well as several other common mental health disorders.

89.2 WELL-BEING AND MENTAL HEALTH

Mental health may be defined as a state of well-being in which every individual realizes his or her own potential,

DOI: 10.1201/9781003227793-105

copes with the usual stresses of life, works productively, and makes a positive contribution to their local community and sphere of influence. This positive perspective of mental health is also emphasized in the World Health Organization's definition of health as contained in its constitution: "Health is a state of complete physical, mental and social well-being and not merely the absence of disease or infirmity".[8] Astute caregivers may observe an otherwise healthy patient quickly deteriorate physiologically when overwhelmed by psychologic stressors. Stress management then is an essential part of an overall healthy lifestyle. The principles of mental health discussed in this chapter are not only important for a healthy mind but also benefit the whole body.

89.2.1 Adaptive Mechanisms of Mental Health

Coping is a positive and constructive response to stress with the purpose of maintaining emotional well-being. Among the common coping mechanisms are the thoughts, behaviors, and emotions that are used to master, tolerate, reduce, or minimize stressful events.

Two main coping strategy categories are present in individuals dealing with stressful situations. The first is *problem-solving* which focuses on specific actions to deal with the stressor; the second relies on *emotions* to respond to the stressor-triggered emotions. Research suggests that those who use a balance of both are better at handling stress.[9]

Another way of categorizing response to stress is *active* versus *avoidant* coping. Active coping focuses on changing the thoughts about the stressful event or events therefore changing its nature. Avoidant coping seeks to evade dealing with stressful events (underlying cause) and tends toward destructive behaviors (like drug or alcohol addiction) or dysfunctional mental states (like withdrawal). Research shows that avoidance coping has been associated with poorer outcomes.[10]

Various instruments have been developed to identify and quantify individual coping styles such as the *Ways of Coping* measure[11] and the COPE Inventory.[12] Either may be useful in the clinician's clinical practice. The *Ways of Coping* measure identifies various coping mechanisms: confrontative coping, seeking social support, planful problem-solving, self-control, distancing, positive appraisal, accepting responsibility, and escape/avoidance. The COPE is more reliable and has been validated.[13] COPE measures include active coping, planning, seeking instrumental social support, seeking emotional social support, suppression of competing activities, faith, positive reinterpretation and growth, restraint coping, resignation/acceptance, focus on and venting of emotions, denial, mental disengagement, behavioral disengagement, alcohol/drug use, and humor.

89.2.2 Factors Affecting Emotional Well-Being and Mental Health

Multiple Factors affect emotional well-being and mental health. It should be recognized by clinicians and patients that positive change is possible. Individuals can learn to improve their coping skills. A review of the literature on some of these modifiable factors may be instructive for clinicians addressing both beneficial and more pathologic coping methods.

Self-worth is the inherent worth of every human being. There is a basic difference between self-worth and self-esteem. Self-esteem refers to pride in oneself and is primarily a measure of a person's belief in how worthy lovable, or capable they are, in comparison to others. While the two are sometimes confused, they are separate constructs. Studies by Emler, a social psychologist, have shown that people with a high opinion of themselves pose a far greater threat to others than those with low self-esteem.[14] Dr. Backus proposes that, when pride is dominant, it negatively affects self-worth. He identifies that the following behaviors identify pride:[15] trying to be noticed, craving attention, looking for compliments, needing to be important, detesting the idea of being submissive, loathing the idea of admitting to wrongdoing, being strongly opinionated, being argumentative, demanding one's own way, wanting control over others, flaunting of individual rights, refusing advice, being critical yet resenting criticism, being oversensitive, and thinking one has excellences that are, in reality, not present.

On the other hand, confident people who have a positive self-worth are more likely to have a better outlook in life, have a positive attitude and less stress, and lead a more productive life.[16] Feeling loved, trusted, and accepted by family[17] and others is associated with an individual who is more comfortable, safe, and secure. Such a person is better able to communicate and develop positive relationships with others.

Examples of how this construct might be useful might be found in the following:

- The breakup of a dysfunctional family is a commonly painful experience for all those involved, especially children. There is evidence that modeling and encouraging healthy self-worth-based responses improve the future mental health and stress levels of all involved.[18]
- Physical problems such as birth trauma, brain injury, or drug abuse may negatively affect brain chemistry and lead to mental illness. These can adversely affect self-worth and the ability to achieve goals leading to unhappiness and even depression.[19] Taking steps to build self-worth may be helpful in these situations
- It is widely understood that abuse leads to an increased likelihood of mental disorders during childhood and adulthood. Sexual, physical, psychological, and verbal abuse often have negative effects that lead to low self-worth, depression, isolation, and anger: all markers for an unhappy life. Interventions that build self-worth are helpful for these individuals.[20]

89.2.3 Positivity and Happiness

Happiness not only increases positive emotions but also improves physical health. Happy people live longer lives,[21] have more stable marriages,[22] are more creative,[23] and tend to be more generous.[24] There are many ways of improving the outlook and happiness of people. Research demonstrates that positive psychology[25] has a significant impact on increasing positivity and happiness.

Happy and unhappy people experience the same level of emotional pain with traumatic experiences. The difference seems to be that happy people tend to bounce back faster. Both groups experience pain, but the happy group realizes that life can, and most likely will, be better in the future. If the attitude is wrong, a negative mindset will follow. The sooner an individual adjusts the attitude, the faster the development of motivation to positive change.[26]

Dr. Martin Seligman, a pioneer researcher in the field of positive psychology, has focused on finding the keys to happiness. He has used the scientific method to better explore the topic. Data was gathered using extensive questionnaires to identify what made people happy. Three dimensions were identified to cultivate a happy, satisfying life. He uses these descriptive phrases: The Pleasant Life, the Good Life, and the Meaningful Life.[27] He proposes therapy that builds upon each of these principles.

The *Pleasant Life* is about enjoying basic things like friendships, family, our surroundings, and fulfilling the body's needs. He proposes that someone can stay pleasantly in this stage or move on to experience the benefits of the next level: *Good Life*. The Good Life occurs when a person discovers their personal identity and values their unique set of character strengths and virtues,[28] the strengths of which are used to improve the lives of others. Seligman believes that, as personal talents are used to make others happy, personal happiness is strengthened. The last stage, the *Meaningful Life*, adds the identification of a sense of meaning that grows out of the character strengths and virtues, not in a selfish way, but rather for a purpose bigger than self. Dr. Seligman proposes that taking care of oneself and cultivating virtues enables individuals to experience the importance of otherness and motivates outward-focused caretaking. As individuals change their focus and efforts from themselves to others, they sacrifice self-centered wants (not needs) for a greater purpose and develop the highest levels of happiness.

89.3 TOOLS FOR IMPROVING HAPPINESS

We review some practical tools that may assist the clinician in helping patients improve their overall well-being.

89.3.1 Journal Thankfulness

Having a gratitude journal is one of the best ways of improving future thought patterns.[29] The act of physically writing out what an individual is thankful for changes the thought focus, enabling the accentuation of positive things that may not have been otherwise noticed. Identifying just three things per day can make a difference. During times of discouragement, the daily logs can be reread as a reminder of the positive parts of life.

89.3.2 Get the Most Out of a Gratitude Journal

Understanding why one sees the world the way they do, will improve control over emotions. Over time, one can observe how the thoughts are changed from negative to positive. On a daily basis, it is easy to see the negative side of circumstances but the thinking can be adjusted through gratitude journaling. The next step is to add three to five things from each day that were liked. The journaler is then encouraged to relive the situation in the memory and ask questions: Why did the situation take place? What was right about it? Why did it happen? Why did the journaler act in the way he/she did? The next step is to consider something that was not liked. After writing it down, one then seeks to understand why the emotional effect occurred and what thoughts and/or actions helped improve the mood. This exercise will help crystallize the understanding of negative thought patterns. Instead of just repeating negative thoughts over and over in one's mind, one learns how to re-focus the mental energy toward a more positive way of thinking.[30]

89.3.3 Practice to Become an Optimist

Individuals should make an effort to have an outlook of hope and optimism for viewing the future. It is better to avoid focusing on the negative, and rather accentuate positive things, even in disagreeable situations or in conflict with other individuals. If considered carefully, there is almost always a positive perspective that may, at the very least identify, the potential for positive consequences.

89.3.4 Leave the Past in the Past

In addition to gratitude, a second key focus with which to address unhappiness is forgiveness. The Western World, and specifically the United States, is a "ventilationist society that deems it honest, just and even healthy to express our anger"[31] This is problematic because anger is the one emotion that gets worse as it is expressed. It is interesting to note how other cultures commonly deal with similar situations. For example, Asian culture tends to deal quietly with difficult situations, problems, and challenges. Individuals of cultures that use approaches that do not give expression to negative emotions are better at coping with life stressors and are happier.[32]

89.3.5 Dealing with Anger

When angry feelings come, individuals have a choice to either deal with them constructively or destructively. They may choose either a controlled response or be controlled by anger. Suggestions to deal with anger more constructively include the following.

Acknowledge anger: There is no need to deny that the emotion exists. Honesty is best. Accepting the situation and focusing on the wisest way to deal with the situation is the better choice.

When the anger emotion presents itself, it is better to think and not just react. There is wisdom in the saying "when angry count to ten". The key is to take the time to think things through; to identify why the anger arose and what effect this may have on others. The focus should be on finding the best way to respond to the situation.

Anger should not be allowed to take control. Individuals should realize that it is ok to feel anger but is not acceptable to hurt and lash out at others. It is best to be under control in those moments of stress.

Anger should be resolved as soon as possible. In dealing with the cause of the anger, constructive communication with those who triggered the feelings should be included. The focus should be on resolving the problem rather than placing blame. If the problem initially appears unmanageable, a third-person mediator may be helpful.

89.3.6 Deal with the Present

Individuals should break the destructive habits of negative thoughts and actions and build the healthy habit of focusing on enjoying the present. These three steps can increase the experience of daily happiness.

89.4 STRESS AND UNHEALTHY LIFESTYLES

In the 1800s, Sir William Osler described a case of angina pectoris on a businessman and theorized that stress may have been the trigger:

> Living an intense life, absorbed in his work, devoted to his pleasures, passionately devoted to his home, the nervous energy...is taxed to the uttermost, and his system is subjected to that stress and strain which seems to be a basic factor in so many cases of angina pectoris.[33]

Interestingly, in a 12-year study of 3730 petroleum industry workers in China, none of whom had diabetes at baseline, those who experienced increasing job stress were 57% more likely to develop diabetes,[34] which then markedly increases their risk of atherosclerosis.[35] Chronic stress can have many negative effects on the human body[36] and even on the thoughts by impairing the function of the frontal lobe;[37] the pathogenesis can be explained by the way the immune system interacts with the nervous system.[38] While too much stress could have negative effects, the right amount of stress could be beneficial, improving immunity and even helping fight cancer tumors.[39]

Recent studies report that stress levels are increasing, especially in the Western World. A report from the American Psychological Association[40] reported that adults continue to report high levels of stress and many say that their stress has increased over the past year. The report says that 75% of adults experienced moderate to high levels of stress in the past month and nearly half reported that their stress has increased in the past year. This is not a problem confined to adults. The report notes that stress is also a top health concern for US teens between the 9th and 12th grades. The rapidly changing modern world, especially the pandemic, has been an important source of problems. Social media, smartphones, and a permanent internet connection give us constant news 24/7 overloading our minds, sometimes augmenting current problems, such as pandemic and economic issues, and sometimes magnifying small issues.

89.4.1 Assessment

A classic test that has been used in the past to give a numeric value to the stress level is the Social Readjustment Rating Scale (Table 89.1), developed by Holmes and Rahe.[41] A value of 200 points or more in one year indicates an increased risk of disease. It can also be used to assign a numeric value to the stress level an individual is facing. Since not everybody reacts the same way to different levels of stress, the assessed value is a rather rough indicator of stress levels.

89.4.2 The Stress Response

Whether we want to acknowledge it or not, stress and anxiety are part of everyday living for most people. The "stress response" is what determines how stress will ultimately affect us. The human body has carefully orchestrated processes to help us deal with hazardous circumstances. In 1929, Cannon described the process as a "fight or flight" response,[42] which has the purpose of enabling survival in situations of imminent danger. The body's response to a stressful situation is designed to be intense but temporary. In the right setting, the effect of stress hormones is generally beneficial,[43] providing resources needed to deal with such emergencies.

Selye, one of the pioneers in the area, divides the stress response into three phases; Phase 1, alarm reaction; Phase 2, state of resistance; and Phase 3, state of exhaustion. [44] There are similar reactions to all types of stressors. The effect of a new stressor is predictable and progressive.

Stage 1 (alarm reaction) helps focus on what should really have attention. Stage 2 (state of resistance) is when the individual chooses whether to fight or flight in the situation. If the stress is not short-term, the individual is exposed to it for days, weeks, months, or even longer, and it will ultimately progress to stage 3 (state of exhaustion). If the stressor persists in this phase, disease is likely to appear.

The questionnaire by Paramount Wellness Institute[45] (Table 89.2) identifies how current culture has affected individual behaviors. There is no score for the test. Its purpose is to bring awareness and help analyze the ways individuals may be creating or alleviating stress

TABLE 89.1
Readjustment Rating Scale

Life Event	Value
Death of spouse	100
Divorce	73
Marital separation	65
Jail term	63
Death of close family member	63
Personal injury or illness	53

responses. Identifying stressors or triggers can help avoid or minimize causes of stress. The recommendation is to focus on how stressors are affecting life and then identify a solution through healthy cognitive and behavioral coping strategies.[46]

89.4.3 Stress Management

One of the first steps in dealing with stress is to identify the stressors. The most powerful strategies for combating stress often involve targeting specific stressors. When stressors cannot be clearly identified, there are other helpful techniques. Cognitive appraisal refers to the perception, interpretation, and evaluation of the stressor. The process is summarized in Figure 89.1,[47] which summarizes the reaction of stress. The evaluation of the event will determine if an individual appropriately copes with the stress or if it will be augmented, activating endocrine responses that may impair immunity and health.

89.5 TOOLS FOR MANAGING STRESS

Everyone copes with their individual stress. Unfortunately, some of the methods used are not helpful and may even worsen the stress. It seems quite logical that the key to good stress management is to maximize healthy responses while avoiding those that are harmful. Harmful ways of handling stress include addictive behaviors (alcohol, tobacco, marijuana, illegal drugs, food), entertainment television, emotional outbursts, overspending, and others. These should be avoided or removed. Positive ways of dealing with stress include simple things like:

- Laughter decreases the body's stress response and increases endorphins.[48]
- Positive interactions with pets release oxytocin and decrease stress hormones.[49]

Identifying healthy responses facilitate healthy stress management.

89.5.1 Calming the Mind and Body

Learning to calm the mind is an essential element in dealing with stress. The popularity of some commonly used methods does not necessarily make them effective. The authors of the study "Mind the Hype: A Critical Evaluation and Prescriptive Agenda for Research on Mindfulness and Meditation"[50] suggest that one of the biggest challenges with the concept of "mindfulness" is that it is an inconsistently and ill-defined term both in the scientific literature and in popular media. The lack of a standard definition makes effective research and its appropriate prescriptive use very difficult to identify. The authors note that sometimes "mindfulness" denotes being consciously aware. Other times it is a practice in which people take a specific posture and focus on breathing or other "objects". Other times it is defined more as a mental faculty such as retention/memory, discernment, or attention. Another point the authors make is that the lay press describes it more as a cure-all panacea for everything. Finally, they point out that due to its nebulous definition, the research is quite likely measuring unknown factors. For example, those who choose to do

TABLE 89.2
How Current Culture Has Affected Individual Behaviors

Life Event	Value	
1. I keep my smartphone on throughout the day so I won't miss any calls.	YES	No
2. I use my Facebook account more often than my email account.	YES	No
3. I tend to leave the water running while brushing my teeth.	YES	No
4. I eat more than one meal prepared outside the house each day.	YES	No
5. During the day, I constantly check emails and text messages as they come in.	YES	No
6. I drive rather than take mass transit to and from work/college regularly.	YES	No
7. I typically take my laptop, BlackBerry, etc. on vacation with me.	YES	No
8. I have been known to flush unused medications down the toilet.	YES	No
9. I get more of my news from comedy channels than newspapers, TV news, or online news sites.	YES	No
10. I spend less than one hour outside each day in a natural setting.	YES	No
11. I regularly interact (leave comments) on websites I visit.	YES	No
12. I find that I rely more and more on the Internet and electronic devices for information (e.g., Online GPS, Google) and less on memory retention.	YES	No
13. More often than not, I record my favorite TV shows and watch them at my preference or watch episodes of my favorite shows online.	YES	No
14. I recycle all cans, bottles, newspapers, etc.	YES	No
15. I start to feel antsy if I cannot check my email, text messages, or Facebook account each hour or more often.	YES	No
16. I spend more time playing video games or surfing the Internet inside than outside in nature each day.	YES	No
17. I check my emails, tweets, Facebook updates, etc. within 10 minutes of waking up each morning.	YES	No
18. I have one or more tattoos.	YES	No
19. I own more than one smartphone and I use them both at the same time (e.g., phone calls, apps, Google).	YES	No
20. I make more than one purchase online each week.	YES	No
21. I dread answering the onslaught of emails each day.	YES	No
22. I get a bit of a rush or excitement when my smartphone goes off.	YES	No
23. I text message my friends and parents more than I call them by phone.	YES	No
24. I watch movies via the Internet or Netflix.	YES	No
25. I make an effort to buy organic produce each week.	YES	No
26. I have more than 50 websites bookmarked on my computer.	YES	No
27. I have more than 250 friends on Facebook.	YES	No
28. I purchase plastic water bottles rather than use a stainless steel bottle.	YES	No
29. I have more than 25 apps on my iPhone/Android.	YES	No
30. I watch at least one YouTube video per day.	YES	No
31. The majority of my purchases are via credit card or debit card, not cash.	YES	No
32. I post an update to Facebook at least once a day.	YES	No
33. I belong to more than one social networking website.	YES	No
34. I prefer to read books via a Kindle or an iPad than hardcover books.	YES	No
35. I post photos and various items on Pinterest and Instagram each week.	YES	No

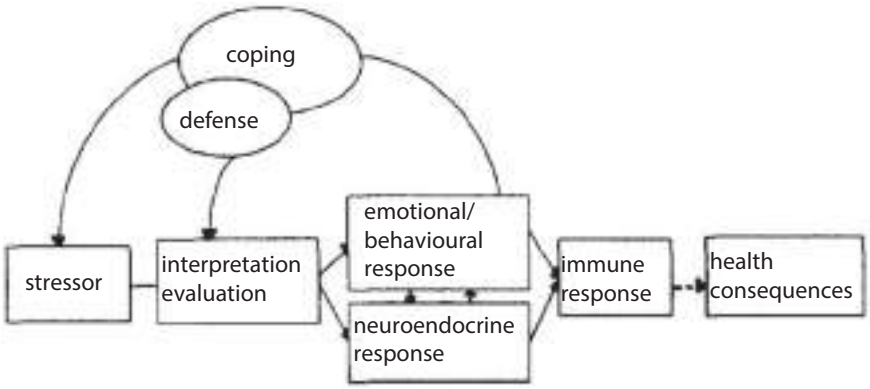

FIGURE 89.1 Cognitive appraisal of stress.

"mindfulness" are more likely to perform more exercise, rest more, eat better, and so on. Therefore, the conclusions may be misleading, especially when done without truly randomly assigned control groups.

Vohs reported that transcendental meditation impairs motivation to complete cognitive and performance tasks and decreases motivation to tackle everyday concerns[51] probably due to a negative effect on the frontal lobes by Eastern meditation.[52] The results were so concerning that he wrote a piece in the *New York Times* titled "Hey Boss, You Don't Want Your Employees to Meditate".[53] Garden reported an increase in depression and suicide among those practicing it.[54] Stress may increase in those who meditate regularly in this way. Schlosser reported that a quarter of those who regularly do Eastern meditation had "particularly unpleasant" psychological experiences related to the practice, including feelings of fear and distorted emotions.[55] Poulin reported that it makes people more selfish and less likely to volunteer.[56] A thorough analysis of the current research was done by Farias and Wikholm who summarized three groups of problems with mindfulness: (1) it is a brand and multimillion-dollar industry with people buying books, apps, and courses; (2) there is an evangelical zeal of mindfulness fans; and (3) the way the scientific studies are reported, in many instances, overstate the benefits and are not reporting or even looking for negative effects, thereby giving a skewed picture. Dr. Farias summarizes, "Currently, with mindfulness, the evidence is not necessarily consistent or conclusive".[57] Their conclusions are not unique, leading psychologists such as Lazarus have documented the negative psychological consequences since the 1970s.[58]

A better alternative may be found in CBT as a time-tested and well-researched mental health management tool that effectively empowers people to handle stress[59] by helping individuals recognize the root causes of stress and dealing with them.[60] CBT operates on the premise that the emotional response is not the result of an activating event but rather emanates from the core belief system. Instead of seeking to avoid activating stressful events, CBT focuses on changing the belief system that makes the emotional consequence worse. Another aspect of CBT focuses on identifying the cognitive distortions that create emotional turmoil. The ten cognitive distortions that Burns delineates are as follows: all-or-nothing thinking, overgeneralization, mental filter, disqualifying the positive, mind reading, fortune teller error, magnification or minimization, emotional reasoning, labeling/mislabeling, and personalization.[61] CBT can also help differentiate needs from wants in order to decrease the physiological stress response. Needs such as air, water, good food, and sufficient warmth are needed for humans to survive. Non-needs such as wanting to be liked by everybody, perfection, or having things our way are nice but optional.[62]

When the mind and body are calm, the levels of perceived stress are diminished. *Relaxation response* is the name given to the physiological effect that is the opposite of stress. Dr. Benson, a professor of psychiatry from Harvard, describes the changes in the body that happen with the relaxation response in this way.[63] On one side, the sympathetic system is activated by stress while the parasympathetic system dominates during the relaxation response. Physiologically speaking, the sympathetic system helps us cope with aggression by activating defense mechanisms and protecting us from imminent danger. On the other hand, the parasympathetic system helps repair, digest, and relax. The relaxation response is the opposite of the stress response in which the heart rate and strength of the contractions increase, blood is shunted to muscles, breathing increases, sweat increases, digestion is slowed, and even glucose increases.

Different techniques have been identified that trigger the relaxation response. Some techniques can help decrease stress such as breaking the day into an achievable to-do list, setting realistic expectations, identifying early signs of stress, making a budget, taking breaks from what is causing stress, or confronting what is stressing you.[64]

We here explore other evidence-based techniques that have been demonstrated to be beneficial and without untoward side effects. Ideally, they are practiced at a set time during the day.

89.5.2 Deep Breathing or Diaphragmatic Breathing

While doing physical exercise, the body requires a higher amount of oxygen to operate. That is why maximal physical

performance necessitates deep breathing.[65] It is known that a low blood oxygen saturation of less than 95% can decrease the ability to perform complex mental tasks. Even people with healthy lungs can decrease oxygen saturation in the body if they have shallow breathing or poor posture. At least one study showed that low oxygen levels can negatively impact mood.[66] Deep breathing can improve and effectively decrease stress.[67] The mechanism by which deep breathing triggers the relaxation response is by bolstering the parasympathetic system's dominance over the sympathetic system.[68]

In a separate study[69] it was found that breathing at a breathing rate of three to six breaths per minute improves oxygen saturation but ideal oxygen levels were reached only during deep breathing at three to six breaths per minute. In a controlled trial of eight weeks, diaphragmatic breathing of four breaths per minute for 15 minutes three times a week decreased stress levels and anxiety while increasing focus and attention.[70]

It is also reasonable to maintain a posture supportive of deep breathing,[71] especially for people who are depressed or are not handling stress well. It is advisable to utilize deep breathing techniques during physical exercise sessions as well as during the day, attempting to breathe deeply at six breaths per minute. It may require a watch at the beginning, but with practice, it is easy to master even without a watch.

89.5.3 Music Therapy

Not all music styles improve mood. Certain music can have the opposite effect. In a recent study, blood pressure measurements were taken and two different types of music were heard. Mozart's Adagio from Divertimento No. 7 had a relaxing effect as shown with a decrease of blood pressure among participants. While a pop-music piece from Queen, Bicycle Race, had the opposite effect, increasing blood pressure.[72]

In a separate music therapy study, participants were encouraged to associate mental images with classical music. Measurements of stress level and mood were taken. The selected pieces were from Respighi, Ravel, Bach, and Brahms, and participants were encouraged to practice introspection. After six sessions over a 12-week period, the 14 volunteers showed improvement on mood tests and reported less depression and fatigue. Also, cortisol, a key hormone in stress, decreased significantly.[73] Measures at 13 weeks showed that mood disturbance, fatigue, and depression were significantly decreased compared with the pre-intervention. Notably, these changes persisted six weeks later, while those in the control group (without music therapy) had no significant changes in cortisol measurements. In this study, participants were not able to select their own music preference, in fact, the age of the participants ranged between 23 and 45 years, a group not commonly exposed to classical music.

McCraty[74] documented the effect of various types of grunge rock in increasing hostility, tension, sadness, and fatigue, while decreasing caring, mental clarity, relaxation, and vigor. Music of the new age genre decreased mental clarity and vigor, and increased fatigue and sadness, while simultaneously improving relaxation, tension, and hostility.

Melodic classical music improved hostility, fatigue, sadness, tension, and relaxation, while decreasing vigor. There was no worsening of any other marks. After 30 minutes of classical music, the stress hormone cortisol dropped by a significant 40%. Interestingly, 30 minutes of techno-music (cyber trip, techno shock, techno magnetic) increased cortisol levels by 40%.[75] A report on the effect of different sounds on anxiety and stress levels identified a six-point improvement with silence as well as a three-point improvement with self-selected music. Heavy metal music worsened it by three points. The most improvement (eight points) in individuals assigned to listen to classical music.[76]

89.5.4 Nature Therapy

Individuals may spend too much time inside buildings. Spending at least 120 minutes a week in nature is associated with better health and well-being.[77] Nature-based interventions have been documented to decrease stress levels, improve depression and anxiety, and improve focus and sleep.[78] A common practice in Japan is called forest bathing, which is simply spending time in nature.[79] Walking for two hours was shown to decrease muscle tension, anxiety, depression, anger, fatigue, and confusion in addition to creating a positive mood.[80]

89.5.5 Bright Light to Improve Mood

Light therapy helps deal with stress by improving emotional control. A double-blind clinical trial in which participants received 30 minutes daily of light therapy for three weeks explored this effect. The light had the same wavelength as daylight. Participants were exposed to pictures of different human faces with various expressions reflecting neutral, angry, or fearful emotions while undergoing an fMRI scan both before and after the light therapy. After three weeks, the brain's ability to control the amygdala (i.e., "fear center") response improved. That is, there was a blunted negative response to faces of fear or anger: the more intense the light, the greater the effect.[81] The researcher commented, "We humans respond naturally to other people's anger and fear. But we observed that the participants responded less to fear in the pictures after the light treatment". The light had an effect on the frontal lobe's ability to control the amygdala, therefore, controlling emotional response. In a randomized study, participants were randomized to pale blue light or red light (with no known benefits to the body) exposure; they were told to use it every morning for one hour over three weeks. Patients who underwent blue light therapy had higher levels of evening melatonin and a drop-off in cortisol, which, at the start of the study, had been elevated.[82]

89.5.6 Sweating Off Stress

Exercise is an integral part of stress management as well. It is understood that general health is improved by a regular and sustainable exercise routine and that excessive exercise can lead to fatigue and injury and decreases the ability to maintain the program in the long term. Exercise is also important for general brain health (stimulating BDNF, etc.) and it is protective against chronic stress effects. Exercise training induces changes at the level of muscle gene expression that can increase kynurenine aminotransferases, enhancing the conversion of kynurenine into kynurenic acid which protects the brain from stress-induced changes associated with depression.[83] Moderate exercise not only decreases current stress but research shows that the effect lasts for extended periods post-workout.[84]

Participation in physical activity is preferred to watching sports as it increases both fitness and well-being. This benefit obviously occurs during exercise, not by simply observing. Research suggests that the emotional ups and downs of watching sports can have a substantial negative effect on the cardiovascular system and level of stress.[85] Under high stress, those who are physically active have less negative cardiovascular risk factor response.[86] There is evidence that only about half of stressed individuals are taking advantage of the stress-relieving effects of exercise.[87] When exercise is performed in nature, the levels of stress decrease even more. Park documented how people who walked in a forest had lower levels of cortisol and blood pressure afterward than those who exercised in a city environment.[88]

89.5.7 Power Rest for Stress

Excessive stress often interferes with sleep and stress often leads people to chronically shorten the nightly rest. A vicious cycle forms. Insufficient sleep increases stress, and the increase in stress worsens sleeplessness. The increased sleeplessness leads to still more physiological and emotional stress.[89] This leads to beginning the day with a sleep deficit and a shortage of the "dream work" process that enables the brain to clean out and organize the emotions of the previous day. A daytime nap may be a tool to assist these individuals with decreasing stress levels. A short nap may allow people to catch up on some desperately needed sleep but has benefits even for those who sleep enough at night. A nap helps keep emotions under control, increases cognition,[90] and improves memory.[91]

The duration of the nap is related to the desired effect. A 15-minute nap is often enough to increase energy levels for the rest of the day.[92] For calming down the nerves and further improving cognition function, a longer nap or exercise[93] may be a better choice than caffeine. Caffeine appears to affect nighttime sleep by interfering with the production of melatonin.[94]

A daily nap habituates the physiology to a certain time to rest during each day. Taking routine daily naps improves the quality of the sleep at night.[95] Ideally, improving nighttime sleep with scheduling, non-drug therapies, relaxing exercises, and good sleep hygiene will also improve stress management capacity

A weekly rest in which participants turn off stressful things in life and enjoy a day with family and friends might be one of the secrets to longevity exercised by those who take a "Sabbath" to put aside the business of life, have a meaningful connection with family and friends, and reassess their purpose in life each weekend.[96] Research of weekly cycles (circaseptum/circaseptan) supports the idea that a weekly rest is necessary to reduce stress. Larsen and Kasimatis provided evidence that the seven-day week is itself a product of an endogenous circaseptan rhythm. Just as the best time for daily rest is at night, Larsen and Kasimatis findings suggest that there may be a certain time during the week that is better for obtaining the weekly rest, as stress hormones were found to be the lowest in their study, summarizing their finding as:

It appears that … there is a strong weekly rhythm in day-to-day mood. This pattern shows a peak around Friday night or Saturday and a trough around Monday or Tuesday. When a sine wave with a 7-day period is superimposed in phase.[97]

89.5.8 Wash Off Your Stress with Hydrotherapy

There is evidence that hydrotherapy (or aqua therapy), the application of water treatments, can help many medical conditions,[98] improve immunity,[99] and could help reduce stress.[100] Toda reported that water bathing reduced salivary cortisol,[101] and Marazziti reported that water treatments increased serotonin, potentially improving mood.[102] Whole body water treatments are beneficial and simple contrast foot baths were documented to reduce the stress response by calming down the sympathetic nervous system.[103] Shevchuk[104] explained the benefits of hydrotherapy in the body by the increase of beta-endorphins (which create a sense of well-being), an increase in blood flow to the brain, activation of the immune system, and increasing neurotrophins, which stress tends to decrease.

89.5.9 Caffeine

Caffeine is a popular stimulant. In the United States, 75% of those under 18 years of age consume caffeine on any given day.[105] It has been observed that caffeine raises stress hormones.[106] The American Psychiatric Association notes that disorders caused by caffeine may be characterized by panic attack symptoms that resemble mental disorders.[107] In light of this, it is ironic that many use caffeine to try to "treat" their stress-related problems. Using caffeine to cover for sleep deprivation does not help mood or cognitive function.[108,109] It is also interesting to note that the alertness associated with caffeine use seems to be limited to the cessation of withdrawal symptoms.[110]

A regular caffeine user who is stopping use should expect withdrawal symptoms such as headache, sleepiness,

laziness, and a decrease in alertness. Usually, days one and two tend to be more severe, however, in the following five days, the symptoms taper off and disappear. DSM-5 named caffeine withdrawal a formal disorder.[111] Historically, the World Health Organization has included caffeine on the list of psychostimulants that produce dependence and withdrawal disorders.[112]

Lifestyle choices can introduce oxidative stress that can have a negative effect. Behaviors such as lack of sleep and excess body fat are widely accepted as some of the sources. Seyedsadjadi[113] documented that caffeinated beverages are also significantly associated with oxidative stress in the body, accelerating aging and increasing the risk of chronic degenerative diseases. It may cause cognitive deficits due to its negative effects on sleep, as it causes sleep deprivation.[114]

89.5.10 Alcohol

Another commonly used "self-treatment" for stress is an alcoholic drink. Similar to the tobacco industry, the alcoholic industry orchestrates public messaging to increase the use of their products and downplay untoward effects. This was well documented in *Alcohol Review* in an article entitled "How alcohol industry organizations mislead the public about alcohol and cancer".[115] Alcohol weakens the ability to cope with stress and anxiety by lowering the level of three key brain hormones (serotonin, GABA, and CRH). This is consistent with animal studies that demonstrate the lowering of brain serotonin and GABA levels in habitual imbibers.[116] These are key neurotransmitters for dealing with anxiety. Alcohol not only interferes with the brain's ability to deal with stress but appears to increase the risk of depressive symptoms.

Interestingly, alcohol stimulates hypothalamic corticotropin-releasing factor neurons. Since alcohol acts directly on the CRF gene, but not on pituitary corticotrophs, alcohol effectively blunts the responses of the hypothalamic–pituitary–adrenal axis to alcohol. Unfortunately, this can be long-lasting, even permanent, negatively affecting how stress is handled in the body.[117] Chronic alcohol use can contribute to long-term anxiety and depression, and in the short term, it also undermines the capability of the body to respond to stress. While some argue for the health benefits of alcohol, at least one meta-analysis showed the absence of any mortality benefit compared with lifetime abstention.[118] Any level of alcohol consumption will decrease brain volume.[119] *Lancet Oncology* reported that alcohol causes 740,000 cancers globally,[120] even light consumption increases the risk of cancer.[121] *The Lancet* reported that there is no benefit in drinking alcohol, especially people under 40 years should not use alcohol.[122] Worryingly, alcohol usage increased during the last COVID-19 pandemic.[123]

89.5.11 Diet and Stress

Many do not realize the connection that exists between diet and mental health. Nutrition is one of several factors interacting together in the pathogenesis of at least some mental illness. For example, many people going through high levels of stress or depression demonstrate a loss of appetite,[124] others respond with midnight polyphagia.[125] Tryptophan, a dietary amino acid, is the dietary precursor of serotonin, a key neurotransmitter in stress and depression. As the body has no significant amino acid stores, tryptophan-rich foods eaten regularly are necessary for optimal function. Large neutral amino acids (LNAA), of which tryptophan is one, compete to enter the brain at the blood–brain barrier through an insulin-dependent carrier.[126] If the diet is moderate in tryptophan and high in LNAA, it may result in low levels of tryptophan in the brain, even with "adequate" tryptophan intake. One example demonstrating this might be seen in comparing the effects of tofu and cow's milk, which is high in tryptophan and very high in LNAA. This soybean curd is high in tryptophan but lower in LNAA and results in significantly greater tryptophan uptake into the brain. The practical application of this was demonstrated in a trial in which individuals were subjected to uncontrolled stress. Those with a diet lower in carbohydrates and higher in protein (tryptophan) had lower brain tryptophan than those consuming the high carbohydrate, lower protein diet. Those who had a diet lower in protein and higher in complex carbohydrates had more depression induced by stress, less energy, and higher levels of cortisol, while the diet higher in carbohydrates prevented those harmful effects.[127] The authors conclude that individuals prone to stress have a higher risk of serotonin deficiency in the brain. As a general rule, animal products are higher in LNAA while plant foods have a lower amount. The solution to the problem is consuming a complex carbohydrate-rich diet (whole plant foods) with adequate tryptophan and lower in LNAAs such as legumes (black eyed peas for example). This is consistent with the recommendation to consume a whole-food plant-based diet in order to help with stress control, reduce anxiety, and improve mood.[128] Tyrosine can help with stress. In a study, those given tyrosine had significantly reduced headache, stress, fatigue, muscle aches, and sleepiness compared with controls.

Improvements were noted in mood and mental states (happiness, mental clarity, hostility, and tension) and cognitive tests (math skills, coding map compass, and pattern recognition) in the tyrosine group.

Feelings of vigor and improvements in blood pressure.[129] Eating in an intermittent fasting pattern, such as eating only twice a day, can bring down stress levels and improve health.[130]

89.6 SPIRITUALITY AIDS STRESS MANAGEMENT

According to research on the longest-living centenaries, one pattern that emerges is the effect of spirituality on stress levels and longevity. Li et al. report that "Frequent attendance at religious services was associated with significantly

lower risk of all-cause, cardiovascular, and cancer mortality among women".[131] People in the Blue zones live in communities with significant religious support. They tend to have a purpose and meaning in life. The Okinawan Japanese call this Ikigai. It is thought to reduce the risk of death[132] and improve mental health.[133] Those who participate in religious activities stress less over finances, health, and daily concerns than non-spiritual types.[134] Participating in prayer and Scripture reading has a positive effect on blood pressure compared with those who do not.[135] Immune function, as measured in IL-6, is better among those who attend religious services on a regular basis.[136] Those with depression recover faster. "Depressed patients with higher intrinsic (inner) religiosity scores had more rapid remissions than patients with lower scores".[137] In another study of 92,000 women, those who attended a religious service at least once a week had a 20% reduction in death even if they were smoking, drinking alcohol, and not doing exercise.[138] Albert Ellis, founder of CBT and rational-emotive therapy, addressed the advantage of spiritual material in mind improvement when he wrote "I think that I can safely say that the Judeo-Christian Bible is a self-help book that has probably enabled more people to make more extensive and intensive personality and behavioral changes than all professional therapists combined".[139] Of interest is an article published in the English newspaper *Metro* entitled, "I'm an atheist who goes to church—here's why you should too". The author shared his experience of fellowshipping with Christian believers and the benefits he experienced.[140] If a strong spiritual element is combined with a healthy lifestyle, it appears to work synergistically in combating stress as loneliness increases stress levels. As Jean-Paul Sartre said, "If you are lonely when you are alone, you are in bad company". Social support confers resilience to stress.[141] Rather than withdrawing when under stress, conscientiously stay connected

89.7 DEPRESSION AND ANXIETY

Depression is a serious and common problem around the world, affecting 400 million people across all ages. It is also the leading cause of disability worldwide.[142] The number of people developing depression has increased since 1915.[143] Major episodes of depression now occur frequently by age 25.[144] Medications for managing anxiety are sometimes used for depression.[145] Anxiety often coexists with depression and may be related to causation.

The common standard for diagnosis of depression and anxiety is that of the DSM-V.[146] The overall risk of depression has increased over time.[147] The incidence of depression for outpatients in a primary care setting is between 15.3% and 22% of all patients seen in consultation.[148] People who commit suicide commonly visit their primary care provider in the month before their suicide.[149] Unfortunately, statistics show that primary care physicians fail to recognize depressive symptoms in 30% to 50% of patients who have depression.[150]

89.7.1 Effective Screening for Depression/Anxiety

Time limitations during consultations may impair proper screening, however, two key screening questions can help identify those that may have depression:

- During the past month, have you often been bothered by feeling down, depressed, or hopeless?
- During the past month, have you often been bothered by little interest or pleasure in doing things?

When used in primary care for patients who are not using psychiatric medications, these two questions have a sensitivity of 97% and a specificity of 67%.[151]

Another quick and easy-to-apply tool used in DSM-V criteria is the Patients Health Questionnaire (PHQ-9), which not only measures the severity of depression but can be used to follow up the treatment of depression.[152] It can be accessed for free at www.phqscreeners.com.

There are other more detailed tests such as the proprietary Beck Depression Inventory II (BDI-II).[153] The BDI-II lists 21 symptoms that are scaled for severity. Though originally designed to be administered by clinicians, it can be self-administered and takes five to ten minutes to complete.

Anxiety affects approximately 3% of patients in primary care settings, while another 4% suffer from social phobia.[154] Among the tools used to diagnose anxiety is the Hospital Anxiety and Depression scale. Its length makes it somewhat impractical for office-based use.[155] A more useful test is the Generalized Anxiety Disorder Scale (GAD-7), which is designed and validated for primary care usage. There is also a short version of two questions called the GAD-2, which has a good negative predictive value. The two questions are as follows:

- Do you feel nervous, anxious, or on edge?
- Are you unable to stop or control worrying?

Another widely used instrument is the Beck Anxiety Inventory (BAI) which measures anxiety by focusing on somatic symptoms. It is also designed as a self-report tool.

A more extensive test is the Depression and Anxiety Assessment Test (DAAT) which measures depression and anxiety, as well as emotional intelligence, and may identify the underlying cause(s) of mental health problems, many of which can be reversed when found. The tool was found to have sensitivity and specificity higher than the Papanicolaou smear (Pap smear).[156]

89.7.2 Management

With the availability of genetic and metabolic testing, approaches to medical problems are slowly moving toward more individualized care. This is the focus of the personalized medicine movement.[157] A recently developed construct demonstrates this in the approach to those with depression and anxiety. As described in the published paper, the

Nedley Hypothesis derives from 100 plus identified "causes" of depression and anxiety from the medical literature.[115,158] These have been categorized into ten categories. The hypothesis proposes that having four of those ten categories active will trigger a depression and/or anxiety episode. An active category is called a hit. These are listed below

1. Genetic hit: Family history of depression or suicide.[159]
2. Developmental hit: Early puberty in girls (menarche of 11 years or earlier), history of depression in adolescence, not being raised by both biological parents,[160] suffered sexual abuse.[161]
3. Nutrition hit: Low dietary tryptophan,[162] low omega-3 intake,[163] diets high in cholesterol,[164] saturated fat,[165] and sugar,[166] marked anorexia among others.[167]
4. Social hit: Absence of social support,[168] negative, stressful life events,[169] grandparents who raise grandchildren,[170] immediate family member is an alcohol or drug addict.[171]
5. Toxic hit:[172] High lead,[173] mercury,[174] arsenic, bismuth, or other toxins.[175]
6. Circadian rhythm: Regular insomnia,[176] sleeping more than nine hours or less than six hours a day, irregularity in eating and sleeping.[177]
7. Addiction: Use of alcohol, tobacco,[178] heavy caffeine,[179] benzodiazepines,[180] or illicit drugs.[181]
8. Lifestyle: Not on a regular exercise program,[182] not exposed to 30 minutes of bright light,[183] not breathing fresh air.[184]
9. Medical condition: Various medical conditions like hypothyroid,[185] hepatitis,[186] autoimmune disease,[187] uncontrolled diabetes,[188] hyperlipidemias,[189] etc.
10. Frontal lobe: Involved in activities that suppress the frontal lobe,[190] not enough activities that stimulate the frontal lobe.[191]

Therapy based on the *Nedley Hypothesis* is focused on identifying the causes of depression and then individualizing treatment with long-term lifestyle changes to address as many of the modifiable causes as possible, with the recognition that not all causes are modifiable. One way of identifying those causes is by taking the DAAT, which will efficiently identify the caregiver with the various categories of cause. With this knowledge, the caregiver can make prescriptive suggestions to improve depression,[192–194] anxiety,[195] and emotional intelligence[196] in a matter of days.[197] The program shows an 88% response rate among depressed participants[198] and a 97% response rate when applied to hepatitis C positive individuals.[199]

89.8 SUMMARY

Lifestyle interventions have been demonstrated to help deal with stress as effectively as non-drug therapy. Positive psychology has proposed practical steps to not only decrease stress but also improve happiness in life. In order to provide optimal care for those with stress, it is important to address health behaviors such as nutrition, exercise, rest, and so on. Unhealthy patterns of thinking should be recognized and changed as long-term stress management requires healthy thinking. Anxiety often develops with long-term stress.

The ten-hit hypothesis has been documented to help identify the triggers of depression and anxiety and aid in their treatment. DAAT has been developed to assist clinicians in quantifying depression, anxiety, and emotional intelligence as well as identifying the potentially reversible causes, thereby allowing efficient identification of actionable goals for therapeutic lifestyle interventions.

CLINICAL APPLICATIONS

- Individuals can improve their mental and physical health by developing healthy coping strategies with which to address life's stressors.
- Focusing on belief system distortion of truth (CBT), activation of the relaxation response, and a healthy diet, along with avoidance of harmful substances, help develop a healing response to stress.
- The *Nedley Hypothesis* has provided a useful evidence-based construct for efficient risk-factor identification ("hits") and effective lifestyle therapy for both anxiety and depression.

90 High-Intensity Therapeutic Lifestyle Change

John Kelly, MD, MPH, FACLM

KEY POINTS

- The strongest and most compelling evidence for the effectiveness of therapeutic lifestyle change comes from studies of intensive therapeutic lifestyle change (ITLC) treatment because it produces the most dramatic treatment effects, just like higher dosing of pharmacological agents. Conversely, few non-intensive lifestyle change programs have been studied directly, and their effectiveness is presumed based on published ITLC studies.
- ITLC can produce dramatic treatment effects in hours or days, such as improved cardiac perfusion and increased insulin sensitivity. Epigenetic studies reveal that gene expression changes within minutes following intensive (dramatic) lifestyle changes.
- ITLC maximizes LM treatment dosing to produce the induction phase needed to transform self-efficacy and enable the patient to sustain lifestyle change. Nothing transforms self-efficacy, and thus lifestyle change goals, more than experiencing a dramatic improvement in one's own health, and no LM treatment can transform health more dramatically than ITLC.
- LM treatment intensity has two components or dimensions—the intensity of contact hours and the degree or extent of lifestyle changes made. Maximally effective ITLC generally maximizes both components.
- Much of the lifestyle change needed by society for good health can be accomplished with relatively mild therapeutic interventions provided with what are known as therapeutic lifestyle changes (TLC). However, for advanced or severe conditions, mild interventions are inadequate and often ineffective. Such cases demand stronger dosing with more dramatic treatment effects. This is where high-intensity therapeutic lifestyle change is required, known as ITLC. This chapter reviews the research and clinical features of ITLC.

The following is a definition of intensive therapeutic lifestyle change (ITLC), which is contrasted and compared with non-intensive therapeutic lifestyle change (TLC).

- ITLC utilizes an intensive, total-immersion approach to change rather than the more gradual, incremental changes commonly recommended by clinicians. This "full court press" includes a comprehensive, multi-factorial lifestyle change approach. If the treatment begins in a residential facility, therapeutic meals are typically prepared and served, exercise is scheduled multiple times a day, educational activities are conducted, and plenty of sleep is included. The patient has four to eight hours of contact with intervention staff most weekdays for a few weeks with decreasing intensity until the patient returns home. Ideally, follow-up contact with supportive interventionists continues by phone, email, text, and/or online for some weeks or months. Follow-up is commonly the weak link in most LM interventions, especially with residential ("inpatient") ITLC treatment. It would be preferable for an ITLC intervention to be followed by TLC treatment with the patient's primary care provider (PCP). Better execution of this aspect depends on more widespread training and experience for clinicians, as well as an appropriate reimbursement system to deliver these medically necessary LM services.
- TLC typically utilizes less intensive interventions with a more incremental, gradual approach to lifestyle change. As such, it provides dosing sufficient to prevent disease but may be inadequate to treat existing disease, especially when the disease is advanced or severe, and requires maximal treatment effect. TLC treatment typically consists of interventions provided as part of a shared medical appointment or educational group program, a series of focused medical visits, or even a clinical encounter during routine medical care. When a patient is fully motivated and ready to make significant changes in personal lifestyle choices, TLC can produce treatment effects as dramatic and extensive as ITLC does. This illustrates the twin dimensions of motivation and intensity—when motivation is high an individual is more likely to invest, time, money, and personal effort in the process, and when the extent of appropriate lifestyle change is maximal, TLC can be as effective as ITLC.

DOI: 10.1201/9781003227793-106

The more severe and advanced the patient's condition, the more extensive and immediate the need for therapeutic treatment. In pharmacological terms, this is accomplished by using a higher starting *dose*. In LM, this involves changing all (or at least the majority) of unhealthy behaviors to healthy ones. Hence the term *intensive* TLC. Established habits, by definition, have an inertia that must be overcome to have real and lasting change. This is accomplished with what can be referred to as an "induction phase". It is commonly more controlled and "restrictive" than subsequent ongoing treatment needs to be. Once the induction phase has replaced the toxic habits with health-promoting ones, it is easier for the patient to maintain the new habits than it was to learn and adopt them. The induction phase may last anywhere from a few days to several weeks, depending largely on the seriousness of the underlying lifestyle disease pathology and the patient's level of motivation.

Another benefit of an induction phase is the transformational impact it has on the patient's self-efficacy and personal goal-setting. The dramatic improvements produced by an immersive and intensive lifestyle change, as well as the simplicity of the changes, transform the patients' perspective about lifestyle change through the development of hope. Patients typically have no idea it could "work so fast, make so much difference, and be so easy". As a result, their confidence and hope are increased, and they embrace higher goals. The transformation experienced in the induction phase enhances the effectiveness of subsequent LM interventions.

This is particularly evident when using motivational interviewing (MI) techniques. MI seeks to assist subjects in making changes of their own choosing. After a transformational personal demonstration of the effectiveness of intensive lifestyle changes, subjects are commonly no longer content with the goals they had previously chosen—they want to achieve more. This phenomenon can be likened to the pharmaceutical loading dose required to reach the therapeutic range.

When less dramatic lifestyle changes are made and no significant improvement is perceived, an opposite effect also operates in which subjects become demotivated to continue lifestyle changes. "Why do all this work?!" they understandably wonder. Generally, unless the patient sees substantive, even dramatic, benefits within three to four weeks, they will abandon the effort to make change. This effect explains why a personalized, quality, intensive induction phase is so important, and why the lifestyle intervention should include the behaviors that have the largest possible treatment effects.

Major research studies of ITLC treatment are instructive and should be used to plan and provide patient experiences. What follows is a review and discussion of select major trials pertinent to the leading lifestyle-related diseases.

- Lifestyle Heart Trial (Ornish, *Lancet* 1990, Ornish, *JAMA* 1998)
- Pritikin Program (Barnard RJ, *Am J Cardiol* 1997)
- Lyon Diet Heart Study (deLorgeril M, *Circulation* 1999)
- CHIP program (Aldana SJ, *J Occup Environ Med* 2005)
- Esselstyn study (Esselstyn CB Jr, *J Fam Pract* 2014)
- DPP (Knowler, *N Engl J Med* 2002)
- Counterpoint study (Lim EL, *Diabetologia* 2011)
- DiRECT trial (Lean MJ, *Lancet* 2018)
- Beta-cell regeneration via FMD (Cheng W-C, *Cell* 2017; Wei S, *Nutri & Metabol (Lond)* 2018)

The one-year results of the Lifestyle Heart Trial (LHT) were first published in *The Lancet* in 1990[1] and the five-year results were published in *JAMA* in 1998.[2] The LHT used a randomized invitational design to assign 28 subjects with CAD to experimental treatment using ITLC and 20 subjects to usual care. The experimental subjects participated in the Ornish Program without statin medications, while the usual care subjects received written advice to make more modest lifestyle changes (NCEP Step II) and to follow the advice of their physicians. Primary outcomes were CAD blockages and cardiac events. Lipids, medications needed, and program adherence were also tracked. Thirty-five subjects participated in the five-year measures: 20 experimental and 15 controls.

At one year, the experimental subjects had a 37% reduction in LDL, a 91% reduction in angina, and a 5.5% regression of stenoses (40% blockage to 37.8%). In contrast, at one year, the controls had a 6% reduction in LDL, a 165% *increase* in angina, and an 8% *progression* of stenoses (42.7% blockage to 46.1%). At five years, experimental subjects had a 7.9% decrease in stenoses while controls had a 27.7% *increase*. The controls *not taking statins* had a 46.7% *increase* in stenoses (40.7% blockage to 50.7). No experimental subjects took statins.

The difference in blockages at five years with ITLC versus enhanced usual care in controls not using statins was striking, with ~7.9% regression v 46.7% progression. That is a combined difference of 54.6%. In other words, the subjects receiving neither ITLC nor statins had an RR of 1.54 for CAD blockages compared with those receiving ITLC without statins.

It is important to understand that the controls received *enhanced* usual care in that they all received written information about the NCEP Step II dietary and lifestyle recommendations. We do not know how many may have received more careful medical care as a result of being in the study, but it is unlikely that any received deficient care.

Another way of looking at the LHT results is that even enhanced usual care is both ineffective and inadequate. It is thus distinctly *not* best practice, evidence-based LM to simply provide patients written information about lifestyle change and consider it to be LM. That kind of care is more similar to the control treatment which, at best, only *slowed* CAD than it is to the ITLC experimental treatment shown to arrest and *reverse* CAD (see Figure 90.1).

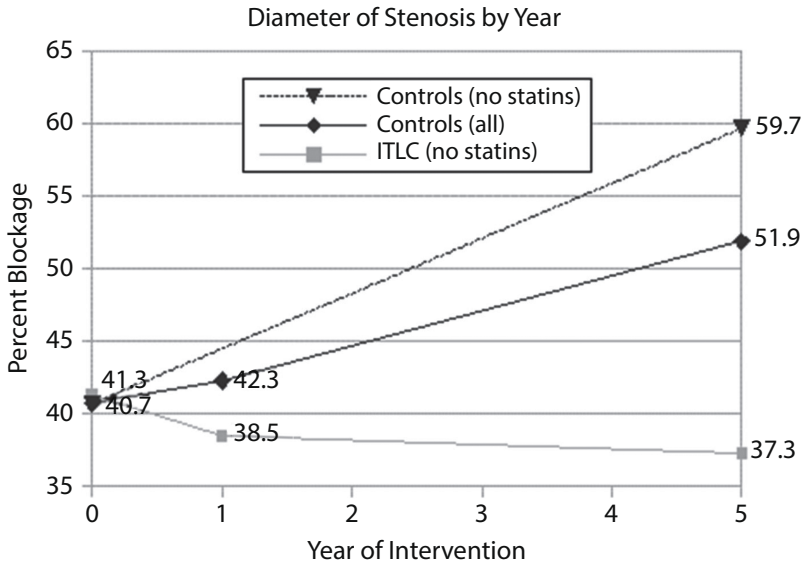

FIGURE 90.1 Change in coronary artery stenosis for experimental and controls.

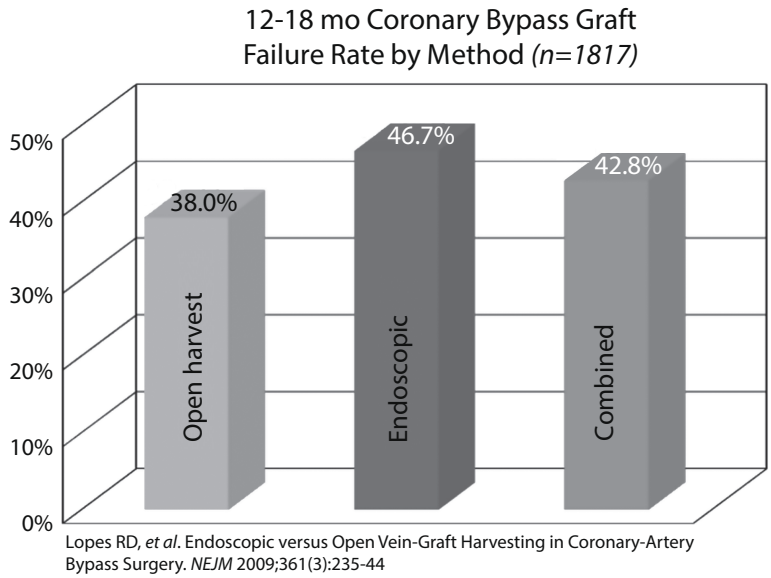

FIGURE 90.2 Bypass graft failure rate by vein harvesting method.

Figure 90.1 shows the changes in the percent blockage of coronary artery stenoses during the five-year Ornish Program. The controls receiving enhanced usual care were dying from CAD while the treatment group was reversing their disease—without medications. (The controls not receiving statins are shown with a dotted red line. All differences were statistically significant.)

These results are in striking contrast to the 12–18-month failure rate for coronary artery bypass grafts reported by Lopes et al. in 2009[3] (see Figure 90.2).

Note that the average failure rate in 12–18 months was ~43%, but the failure rate for the common endoscopic excision technique was ~47%. These patients did not receive any LM care, either ITLC or TLC. Without lifestyle change, the venous grafts occlude faster than the original arteries.

Results from the Pritikin Program were published in 1997[4] The results from this pre- vs post-LM analysis show that an aggressive diet and exercise program, when added to cholesterol-lowering drugs, can result in a dramatic reduction in total cholesterol, as well as in triglycerides. The drugs alone reduced total cholesterol by 20%, whereas the combined drugs plus lifestyle intervention achieved an additional 19% reduction. These results are significantly greater than other published studies combining drug and diet therapy. The conclusion was that diets with 25–30% calories from fat when added to drug therapy have minimal effects on serum cholesterol, whereas the Pritikin 10% fat-calorie diet reduces cholesterol by almost double the amount of the drugs alone. Table 90.1 and Figure 90.3 (adapted from Table 90.1 and Figure 1, Barnard et al.[4])

TABLE 90.1
Effect of Intensive Lifestyle Changes on Serum Lipids in Patients Taking Cholesterol Drugs

Effect of Intensive Diet and Exercise on Serum Lipids in Patients Taking Cholesterol-lowering Drugs

	Before mq/dL	After mq/dL	%Δ

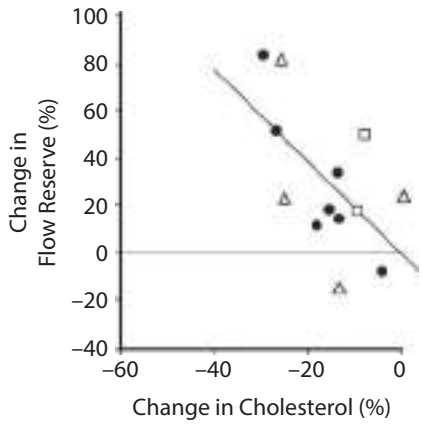

FIGURE 90.5 Change in flow reserve with change in serum cholesterol.

show the changes in serum lipids at baseline, with statins, and with statin plus Pritikin.

Results from 4587 participants in the Pritikin Program from 1977 to 1988 were published in 1991[5] and reviewed in 2005[6] Figure 90.4 shows the lipid-lowering effects significantly exceeded those of the NCEP Step I and Step II dietary interventions (Figure 90.4 adapted from Figure 1, Roberts et al.[6]).

Results from 13 participants in the Pritikin Program who underwent myocardial blood flow and flow reserve studies were published in 1995.[7] The improvements were strongly associated with reductions in serum cholesterol. Figure 90.5 (adapted from Figure 3, Czernin et al.[7]) shows changes in myocardial flow reserve (%) as a function of changes in cholesterol (%). Patients with coronary artery disease are represented by open triangles, patients with hypertension by open squares, and normal participants by closed circles.

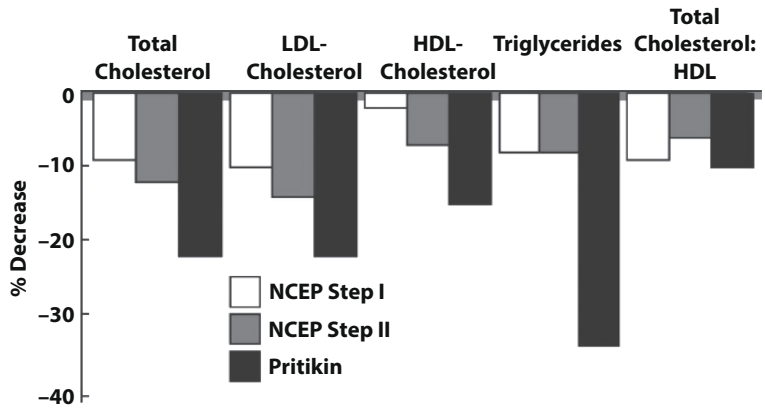

FIGURE 90.4 Changes in cholesterol for NCEP Step 1 and 2 vs Pritikin.

Reductions in cholesterol levels (x axis) were associated with increases in myocardial flow reserve (y = 2.9–1.9x (for x = 0); r = 0.56; SEE, 0.85; P < 0.05).

Results from the first outpatient Pritikin ICR Program (Intensive Cardiac Rehab) were published in 2022 by Racette et al.[8] Outcomes from the Pritikin ICR were compared retrospectively to outcomes from a traditional cardiac rehab program (CR) in 1963 patients treated at a large academic health center. The ICR resulted in improvements (P < 0.001, pre vs post) in all anthropometric measures, dietary patterns, six-minute walk test (6MWT) distance, all short physical performance battery components (SPPB: balance, 4 m walk, chair rise), grip strength, and health-related quality of life. The improvements in anthropometrics and dietary patterns were greater in ICR than in CR. Figure 90.6 (adapted from Figure 1, Racette, et al.) shows changes

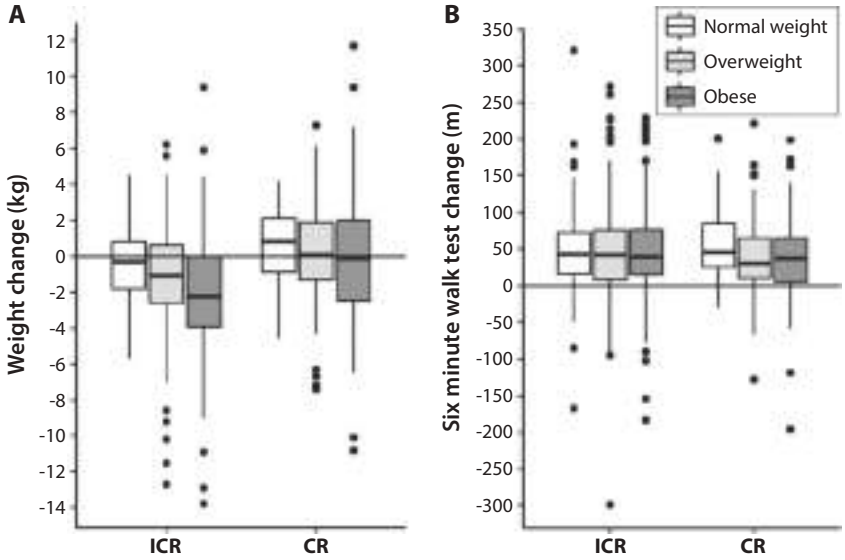

FIGURE 90.6 Change in weight and six-minute walk test by weight category for ICR vs CR.

in body weight and 6MWT distance among patients in ICR or CR. Box-and-whisker plots depicting median change (middle line in each box), IQR (whiskers), and outliers (circles above and below the whiskers) for weight (A) and 6MWT (B) by body mass index category at baseline.

The final results from the Lyon Diet Heart Study comparing a Mediterranean diet to a prudent Western diet for the secondary prevention of heart disease were published in 1999[9] with a mean follow-up of 46 months. The study had been stopped and unblinded after only 27 months because of the dramatic risk reductions with the Mediterranean diet (adjusted risk ratios ranged from 0.28 to 0.53) but the researchers followed up the subjects for the intended term of the study. Table 90.2 shows the outcomes of the study (Table 90.2 adapted from Table 1, deLorgeril et al.[9]).

This study showed impressive outcomes for the Mediterranean diet compared with the NCEP Step II diet with a tremendous reduction in the risk of cardiac events following a myocardial infarction. However, no quantitative measures of CAD or stenoses were collected as was done in the LHT and Esselstyn's first cohort. Thus, this study did not prove that diet could arrest or reverse CAD, as with the other two studies. As of this date, the author knows of no clinical trials proving arrest or reversal of CAD stenoses using a Mediterranean diet without medications as was shown in the LHT and the first Esselstyn cohort. Nonetheless, this study does show that the Mediterranean diet was much more effective than the Step II (prudent) diet in lowering the risk of cardiac events following myocardial infarction.

Table 90.3 and Figure 90.7 describe the end points for the experimental and control groups with the final values for selected measures. The figure shows the survival curve without non-fatal infarction and without major or minor secondary endpoints (Table 90.3, adapted from Table 2, deLorgeril et al.[9] Figure 90.7, adapted from Figure 3, deLorgeril et al.[9]). The experimental group had significantly fewer events. The conclusion was that the Mediterranean diet is an effective secondary prevention compared with the Step II diet.

Results of the Complete Health Improvement Program (CHIP Program) were first published in 1998.[10] Results from a randomized work site study were published in 2005.[11] Results from a community-based randomized study were published in 2005[12] and 2006[13]

The first randomized study determined the behavioral and clinical impact of a work site chronic disease prevention program. Working adults participated in a randomized trial of an intensive lifestyle intervention. Nutrition

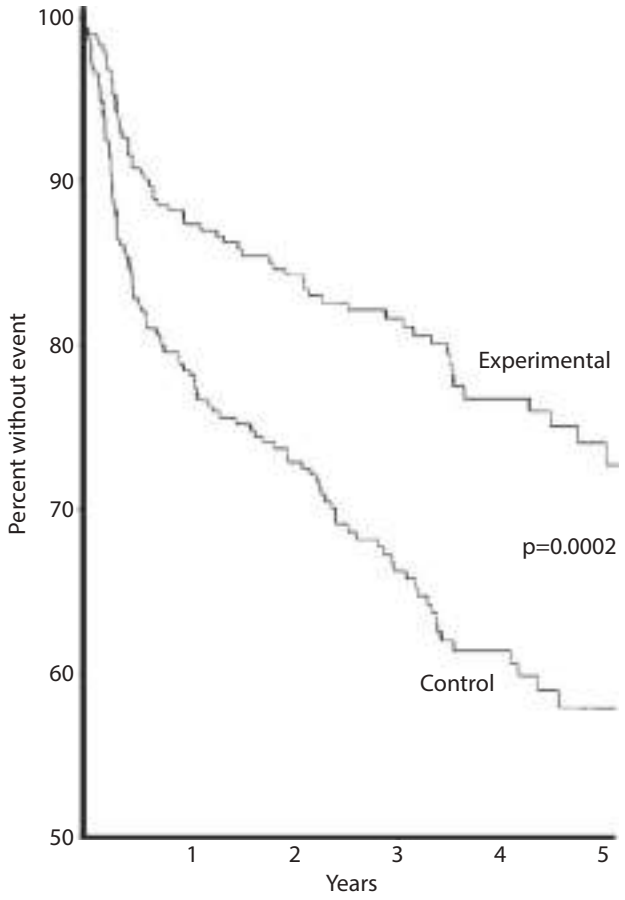

FIGURE 90.7 Changes in the control group vs experimental group.

and physical activity behavior and several chronic disease risk factors were assessed at baseline, six weeks, and six months. Participants significantly improved their cognitive understanding of good nutrition and physical activity and had significantly better nutrition and physical activity behavior at both six weeks and six months. Participants also had significantly lower body fat, blood pressure, and cholesterol. The study concluded that this work site chronic disease prevention program could significantly increase health knowledge, improve nutrition and physical activity behaviors, and reduce many employee health risks.

The second randomized study assessed the clinical impact of lifestyle change education on chronic disease risk factors within a community. Participants included 337 volunteers aged 43 to 81 years from the Rockford, IL, metropolitan area. The intervention group attended a 40-hour educational course delivered over four weeks. Participants learned the importance of making healthful lifestyle choices and how to make improvements in nutrition and physical activity. Changes in health knowledge, nutrition and physical activity behavior, and several chronic disease risk factors were assessed at baseline, six weeks, and six months. Beneficial changes in scores tended to be significant for the intervention group but not for the control group. Variables with improved scores included health knowledge, percent body fat, total steps per week, and most nutrition variables. Clinical improvements were seen in resting heart rate, total cholesterol, low-density lipoprotein cholesterol, and systolic and diastolic blood pressure. The control group experienced comparatively small but significant improvements in health knowledge, systolic and diastolic blood pressure, glucose, and some nutrition variables. For almost all variables, the intervention group showed significantly greater improvements. The study concluded that the lifestyle modification program was an efficacious nutrition and physical activity intervention in the short term with the potential to dramatically reduce the risks associated with common chronic diseases in the long term.

Table 90.4 is drawn from the two RCTs described above, the work site trial with 145 participants[15] and the community-based trial with 348 participants[16,17] These results were actually better than those for the Ornish Program in the Lifestyle Modification Program Demonstration study (LMPD) conducted by Brandeis University, published in 2009[14] and 2014[15]

The five-year results of 22 subjects on the Esselstyn Program were reported in 1995[16] and the 12-year results were reported in 1999[17] These outcomes were described in detail in Dr. Esselstyn's book published in 2007.[18] Results from a second cohort (198 subjects) with an average of 3.7 years on the Esselstyn Program were published in 2014[19] The study relied on a pre- versus post-intervention analysis of self-selected subjects. The first cohort consisted of patients with severe disease and no further conventional

treatment options. Main outcome measures included lipids, medications, and angiographic studies of coronary blockages. The Esselstyn Program uses a non-residential ITLC intervention that includes a five-hour intensive educational session that teaches a strict plant-based diet emphasizing leafy greens with 10%E from fat and no added oils or nuts. In the first cohort, adherence and lipids were monitored biweekly for five years. Adherence was high (77% in first cohort, 89% in second) with consistent improvement or reversal in adherent subjects.

In the first cohort, 17 of 22 subjects were adherent with the 12-year intervention (77%) and showed uniform improvement, with somewhat more improvement at five years than at 12 years. Mean total cholesterol was 137 mg/dL at 5y and 143 mg/dl at 12y. Mean LDL cholesterol was 76 mg/dL at five years and 82 mg/dl at 12 years. Mean triglycerides were 143 mg/dL at five years and 143 mg/dl at 12 years. Eleven of the 17 underwent angiographic analysis at five years and none showed progression, while 8 of 11 (73%) showed regression. There were no adverse events (no angina, no PCI, etc.) during the 12 years although the same 17 subjects experienced 49 coronary events in the eight years prior to starting the treatment. Notice the imaging showing improvement in perfusion and reversal of CAD in Figure 90.8 (adapted from Figures 1 and 2, Esselstyn et al.[19]).

In the second cohort of 198 patients (Table 90.5), 144 of 177 adherent subjects showed improvement (81%) with 39 of them showing reversal (22%), while 15 remained stable (8%) and 18 worsened (10%). This compared with none of the 21 non-adherent subjects showing improvement, eight remaining stable (38%), and 13 with worsening disease (62%).

Results from the Diabetes Prevention Program were first published in 2002[20] The study randomly assigned 3234 non-diabetic persons with elevated fasting and post-load plasma glucose concentrations to placebo, metformin (850 mg twice daily), or a lifestyle-modification program with the goals of ≥7% weight loss and at least 150 minutes of physical activity per week. The participants averaged 51 years with a BMI of 34, 68% were females and 45% were of minority ethnicity.

The average follow-up was 2.8 years. The study ended early because the interventions were dramatically more effective than placebo. The incidence of diabetes was 11.0, 7.8, and 4.8 cases per 100 person years in the placebo, metformin, and lifestyle groups, respectively. The lifestyle intervention reduced the incidence by 58% (95% confidence interval [CI], 48–66%) and metformin by 31% (95% CI, 17–43%), as compared with placebo; the lifestyle intervention was significantly more effective than metformin. To prevent one case of diabetes during a period of three years, 6.9 persons would have to participate in the lifestyle intervention program, and 13.9 would have to receive metformin.

• Data missing for 5 adherent patients and **1** nonadherent patient.

† Percentage of 112 patients who complained of angina at start of intervention.

‡ One patient with A-fib had documented angiographic reversal after 5 years in the study, then refused warfarin 2 years after last angiogram and suffered a nonfatal stroke.

§ P<. 001 for fewer worse outcomes in adherent patients (Fisher's exact test).

¶ One patient enrolled with malpositioned dissecting stents that required CABG.

Before enrolling the patient had 3 stents placed; one occluded at 3 years into the study and was restented.

** Includes 3 cancer-related deaths, 1 fatal pulmonary embolism, and 1 case of pneumonia.

The study concluded that lifestyle changes and treatment with metformin both reduced the incidence of diabetes in persons at high risk, but the lifestyle intervention was almost twice as effective as metformin. Figure 90.9 shows the cumulative incidence in percent for each of the three groups during the period of the study (Figure 90.9, adapted from Figure 2, Knowler et al.[20]). The diagnosis of diabetes was based on the criteria of the American Diabetes Association at the time of the study.[21] The incidence of diabetes differed significantly among the three groups ($P < 0.001$ for each comparison).

Considering the various LM treatment programs with published results described above, they fall into two broad categories—those that have been shown to arrest and reverse existing disease, and those proven to slow the progression or delay the onset of disease. The studies reveal that the standard lifestyle and dietary recommendations are inadequate to arrest or reverse disease, but they can slow progression. For example, the NCEP Step I and Step II dietary recommendations do not prevent the onset or progression of CAD, HTN, or diabetes. And, neither do the ADA dietary recommendations prevent the onset or progression of diabetes. The DPP, for example, delayed the onset of DM2 but did not arrest or lead to diabetes remission. Serum glucose and glycosylated hemoglobin continued to rise in all three groups.[20] In fact, it was only intended to delay the onset of type 2 diabetes, and it has been shown to do that more

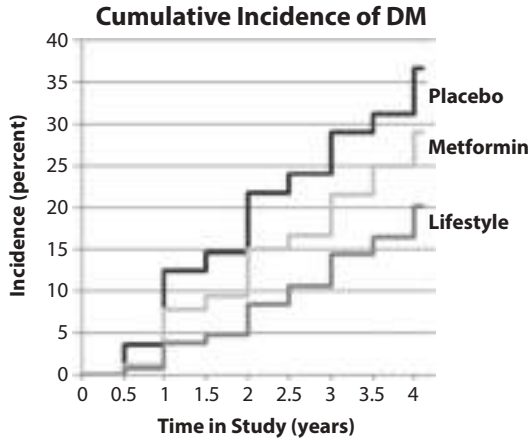

FIGURE 90.9 Cumulative incidence of diabetes in four years for three study groups.

effectively than metformin plus advice to lose weight and eat healthy. Similarly, the DASH diet controlled stage 1 HTN, but has not been shown to normalize blood pressure. The Mediterranean diet demonstrated a reduction in cardiac risk and delayed onset of CVD, but it does not reverse established disease.

The primary reason that some of these LM treatment programs do not reverse chronic disease is that they are not sufficiently intense to achieve this therapeutic effect. As the

descriptions above reveal, the LM treatment programs that demonstrate reversal of disease use intensive interventions that include intensive patient contact and the adoption of dramatic lifestyle changes. They typically use a low-fat, high-fiber plant diet with moderate physical activity.

The treatment of type 2 diabetes and insulin resistance provides an excellent example of the need for and importance of using sufficiently intense lifestyle interventions in order to maximize treatment effect and arrest or reverse disease. The DPP, described above, delays the onset of type 2 diabetes. Nonetheless, it did not demonstrate the arrest or reverse of impaired glucose tolerance (pre-diabetes) or type 2 diabetes, although it did improve diabetes management and reduce the amount of medication needed.

In contrast to the DPP lifestyle intervention, a more intensive lifestyle change, which includes a very low-calorie diet (VLCD), has been shown to arrest and reverse type 2 diabetes in multiple settings. After publishing in 2011 the results of the Counterpoint study using a VLCD to reverse pancreatic and liver triacylglycerol and restore beta-cell function, including early phase insulin secretion[22] the researchers collected data on 77 individuals who initiated the VLCD on their own to reverse their type 2 diabetes. Those results, published in 2013[23] showed that both short-term (<4y) and long-term (>8y) diabetes could be reversed with VLCD by motivated individuals.

The 77 subjects (66 men, 11 women, 56.4 ± 9.7 years) had a median diabetes duration of 5.5 years (3 months to 28 years). Duration was further categorized as short (<4 years) n = 30; medium (4–8 years) n = 25; long duration (>8 years) n = 14. Prior to undertaking energy restriction, diabetes treatments were as follows: metformin (n = 36); sulphonylurea (13); diet alone (10); insulin (6); glucagonlike peptide-1 agonist (3); thiazolidinedione (3); and dipeptidyl peptidase-4 inhibitor (2). Proprietary liquid meal replacements were used by 38 individuals and energy intake was restricted without the use of special products in 34 individuals. Support from a healthcare practitioner during the diet was reported by 27 people and 25 felt that they had a negative response to request for support. The median diet duration was eight weeks (range 1–104 weeks).

Self-reported weight fell from 96.7 ± 17.5 kg at baseline to 81.9 ± 14.8 kg after weight loss ($P < 0.001$). Self-reported fasting blood glucose levels fell from 8.3 mmol/l (5.9–33.0) to 5.5 mmol/l (4.0–10.0) after the weight-loss period ($P < 0.001$). Pre- and post-diet HbA1c was available in 20 subjects and fell from 58 mmol/mol (40–115) (7.5% [5.8–12.7]) to 45 mmol/mol (26–57) (6.3% [4.5–7.4]) ($P < 0.001$). Diabetes reversal was considered to have occurred in 61% of the population. In the non-reversal group, improvements sufficient to allow the discontinuation of antidiabetic medications occurred in five individuals. Reversal of diabetes was observed in 80% of those with > 20 kg weight loss, 63% of those with weight loss 10–20 kg, and 53% of those with < 10 kg weight loss. The mean weight loss in individuals who reported diabetes reversal was 16.0 ± 6.9 kg and was 12.8 ± 4.9 kg in those who did not achieve reversal of diabetes. There was a significant correlation between the degree of weight loss (%) and reported fasting glucose levels (Rs –0.38, $P = 0.006$). Of those achieving loss of > 20% of body weight, only three people did not achieve reversal of diabetes. The reversal rates in the short-, medium-, and long-duration groups were 73, 56, and 43%, respectively, and in those losing > 15 kg in weight, the reversal rates were 82, 64, and 75%, respectively.

This is a striking contrast to the small diabetes remission rate found in the LookAHEAD Trial using what was called "Intensive lifestyle intervention" and standard "Diabetes support and education", published in 2012.[24] Figure 90.10 shows the prevalence of any remission and the estimated duration of remission in the study (adapted from Figures 2 and 3, Greg et al.[24]).

Notice that the prevalence of any remission was ~2% for standard diabetes support and education, and the maximum

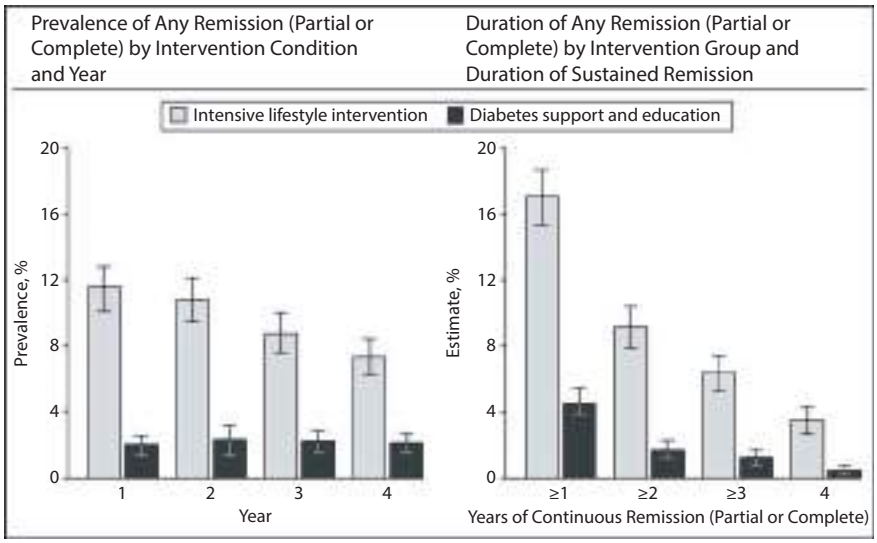

FIGURE 90.10 Prevalence and duration of remission by intervention type over four years.

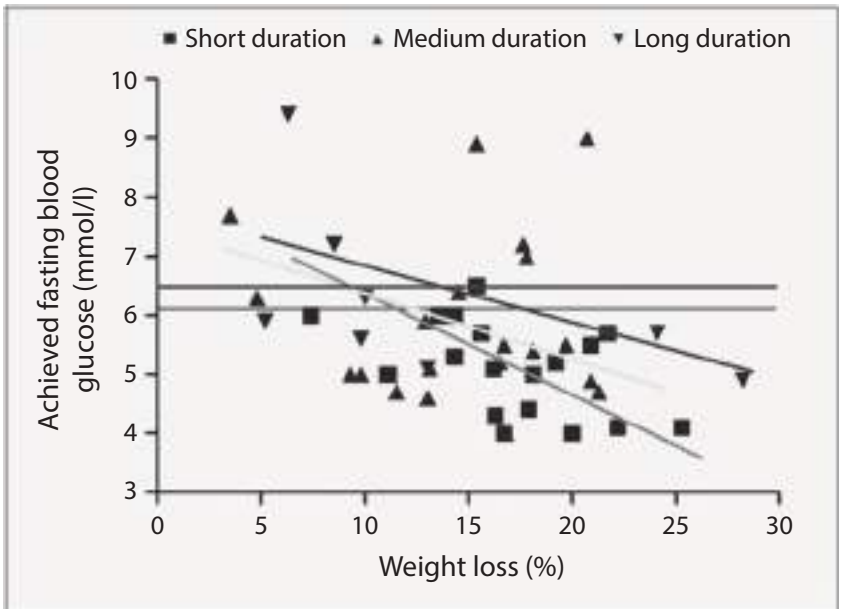

was <12% for the intensive lifestyle intervention. The "so-called2 intensive lifestyle intervention was significantly more effective than the standard diabetes support and education, but much less effective than the very-low-calorie diet in the Counterpoint study.

Longer-term data from eight of the 77 individuals in the Stevens study mentioned above indicate a sustained benefit on blood glucose levels following cessation of tight energy restriction. These individuals, all male, undertook an eight-week period of energy restriction, with four individuals using a meal replacement product. Sustained reversal of diabetes was confirmed by HbA1c in six individuals and by oral glucose tolerance test in two individuals. Details on glycemic control and weight change for these individuals are shown in Table 90.6 (adapted from Steven et al.[23]).

Figure 90.11 shows the self-reported fasting blood glucose levels at the end of the diet period in relation to the degree of achieved weight loss (Figure 10.11 adapted from Figure 1, Steven et al.[23]). The solid line at 6.1 mmol/l represents the diagnostic cut-off for diabetes reversal used in the study, while the solid line at 6.5 mmol/l represents the then accepted cut-off for partial remission, as defined by Buse et al. in 2009.[25] (It should be noted that the Buse et al. consensus has been updated by Riddle et al.[26]) A positive

TABLE 90.6
Time since Intervention, Glycemia, Diabetes Duration, and Weight Changes for Eight Study Subjects

				Weight Δ (kg)	
Subject	Time since diet period	Reported glycaemic control at this time	Diabetes duration	during diet	following diet
1	8 months	HbA_{1c} 40 mmol/mol (5.8%)	4 months	–7.3	+3
2	7 months	HbA_{1c} 36 mmol/mol (5.4%)	3 years	–30.4	–12.4

6	5 months	HbA_{1c} 38 mmol/mol (5.6%)	8 months	–25.4	+5.4
7	3 months	Oral glucose tolerance test Fasting plasma glucose 6.1 mmol/1 2-h plasma glucose 6.3 mmol/1	4 years	–17.5	+2.5
8	3 months	Oral glucose tolerance test Fasting plasma glucose 5.1 mmol/1 2-h plasma glucose 6.0 mmol/1	6 months	–18	–3

Self-reported fasting blood glucose levels at the end of the diet period in relation to the degree of achieved weight loss. The solid line at 6.1 mmol/l represents the diagnostic cut-off for diabetes reversal.

FIGURE 90.11 Fasting blood glucose and weight loss for short-, medium-, and long-duration diabetes.

association is evident between weight loss and achieved fasting glucose, and the shorter the duration of diabetes, the stronger the relationship. Notice the line representing the correlation for short-duration subjects has a greater slope than the line representing the medium-duration subjects, which has a greater slope than the line representing the long-duration subjects.

Building on the success of these two studies, the researchers conducted and published in 2016 results on 30 subjects with type 2 diabetes who consumed a VLCD for six months.[27] The subjects were categorized as responders if they achieved a fasting serum glucose of <7 mmol/L after the VLCD intervention. The non-responders did not recover a first-phase insulin response, nor did their glucose levels normalize, though their weight dropped just like the responders. Evidently, there is a metabolic difference between the responders and the non-responders, perhaps of genetic origin. Figure 90.12 shows the changes in fasting plasma glucose, glycosylated hemoglobin (HbA1c), and weight for responders (●) and non-responders (Δ). (Figure 90.12, adapted from Figure 1, Steven et al.[27] The gray band represents the stepped transition from VLCD to isocaloric eating of solid foods. Data are mean ± SEM.)

The results of another study by the same researchers were published in 2015 showing that a VLCD properly administered and supported would normalize glucose metabolism in about half of diabetics with duration >8 years.[28] Duration of diabetes and achieved fasting glucose were positively correlated such that glucose normalization was more frequent and robust for subjects with shorter-duration diabetes.

The researchers concluded:

> In people with Type 2 diabetes of > 8 years' duration, a therapeutic trial of a very-low-calorie diet may be undertaken with a 50% chance of achieving non-diabetic fasting plasma glucose levels, without any other antidiabetic therapies. For those who do not achieve non-diabetic plasma glucose levels, general health, blood pressure and lipids will be considerably improved. These insights highlight the potential for use of a very-low-calorie diet in long-duration Type 2 diabetes and carry implications for everyday clinical practice.

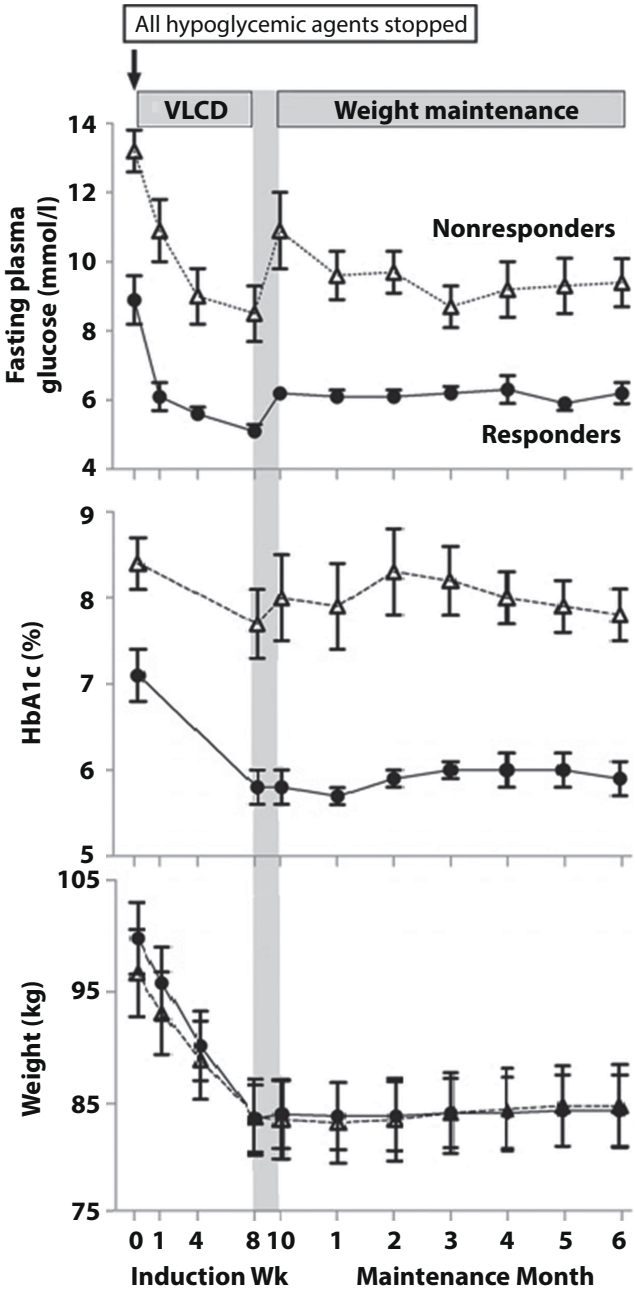

FIGURE 90.12 Changes in fasting serum glucose, HbA1c, and weight in responders and non-responders.

Continued follow-up of subjects from their previously cited studies reveals that responders can maintain normoglycemia for >3 years, even in the presence of modest weight gain (4 kg).[23]

First-year results from the DiRECT Trial by Lean et al. were published in *The Lancet* in 2018[29] and the two-year results in 2019.[30] It was an open-label, cluster-randomized trial with 49 primary care practices in Scotland and England randomized to provide either a weight management program (intervention) or best-practice care by guidelines (control). Subjects were 20–65 years of age who had been diagnosed with T2D within the last six years, with a BMI of 27–45 kg/m^2, and not on insulin. The intervention consisted of withdrawal of antidiabetic and antihypertensive medications, total diet replacement (825–853 kcal/day formula diet for three to five months), stepped food reintroduction (two to eight weeks), and structured support for long-term weight loss maintenance. Co-primary outcomes included weight loss of 15 kg or more (~33 lbs) and remission of diabetes, defined as HbA1c <6.5% (<48 mmol/mol) after ≥2 months off all antidiabetic medications, from baseline to one year. Findings showed that at one year almost half (46%) of participants achieved remission to non-diabetic state off all antidiabetic medications. They concluded that remission of T2D is a practical target for primary care. One-year results are shown in Figure 90.13 (adapted from Figure 2 in Lean et al.[29]). Note the dose-response relationship between weight loss and T2D remission.

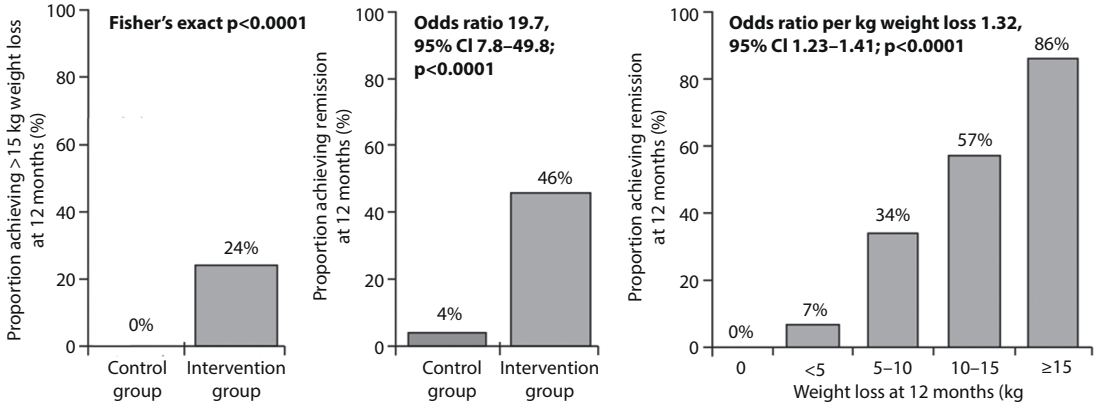

FIGURE 90.13 Weight loss and remission rates in controls vs intervention group in the first year.

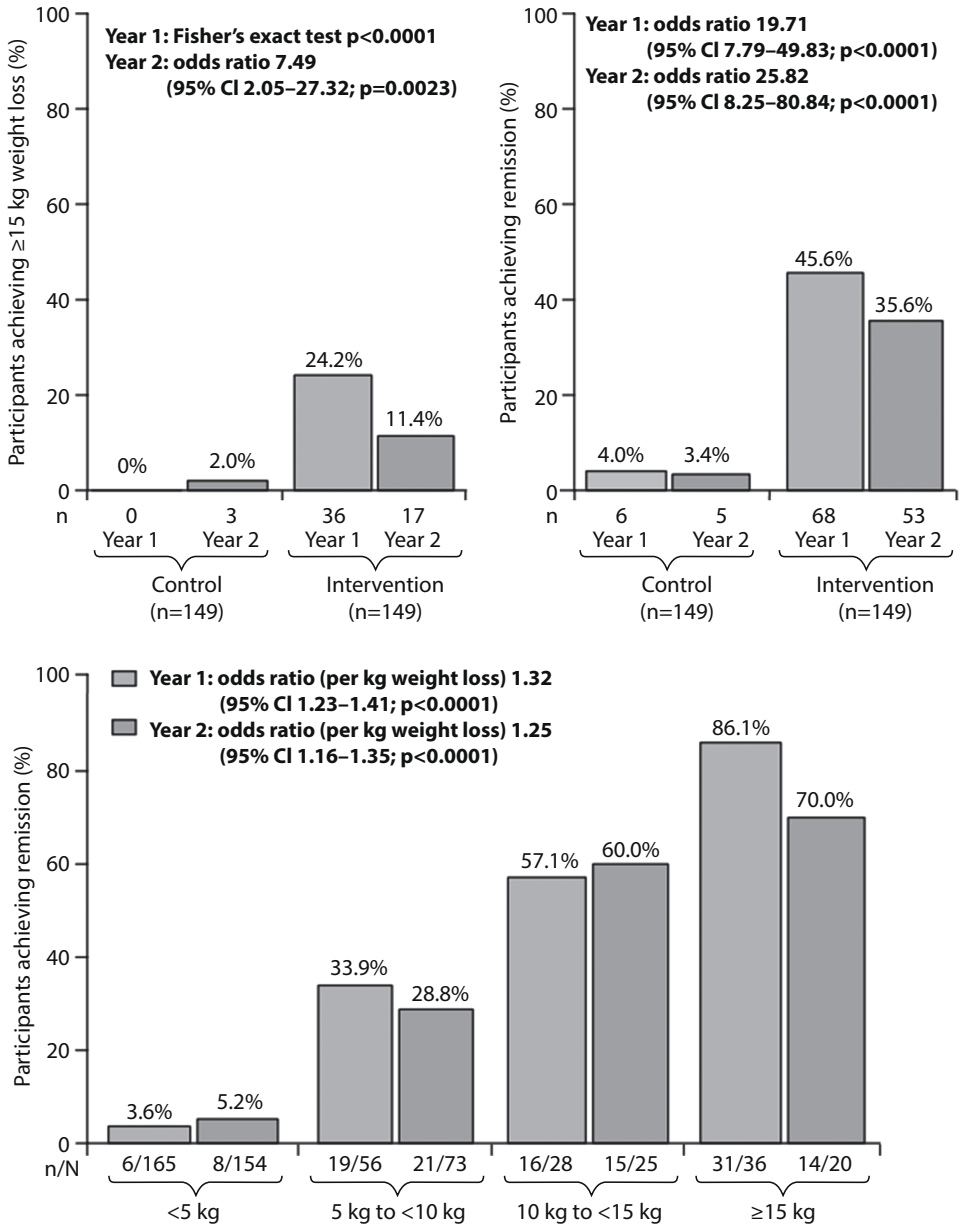

FIGURE 90.14 Weight loss and remission rates in controls vs intervention group in the first two years.

Two-year results revealed decreases in weight loss and T2D remission. Overall remission dropped from 45.6% to 35.6%. The percentage with ≥15 kg weight loss (~33 lbs) dropped from 24.2% to 11.4%, with their remission rate dropping from 86.1% to 70.0%. Figure 90.14 shows the results at two years (adapted from Figure 2 in Lean et al.[30]).

The results of a fasting-mimicking diet (FMD) in diabetic mice were published in 2017 and replicated in 2018.[31,32] This research found that FMD was effective in reversing both type 1 and type 2 diabetes in mice. This was the result of the epigenetic effects of FMD on pancreatic cells that induced beta-cell neogenesis. Figure 90.15 shows the findings of the study.

Similar findings were published in 2018 by another research group, confirming the validity and reproducibility of the treatment effects of an FMD on beta-cells and glycemia (see Figure 90.16; adapted from Figure 1, Wei et al.[32]).

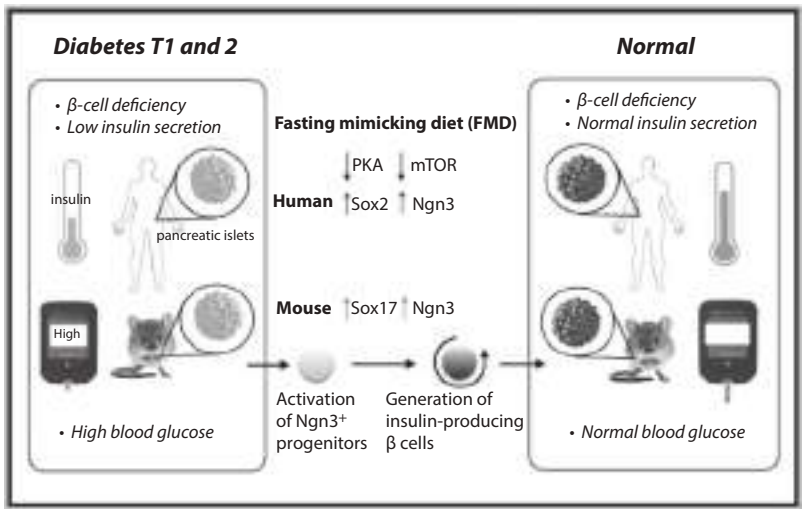
This intensive FMD intervention is also being studied in humans and has produced promising metabolic effects and improvements in the common risk factors for chronic disease.[33] Figure 90.17 shows the findings of the study.

As these results in type 2 diabetes show, lifestyle change has a "therapeutic window" for dosing that largely determines its effectiveness. As with pharmaceuticals and most modalities, an inadequate dosing results in minimal to no significant therapeutic effect. Conversely, when the dosing is too high, toxicity can develop (e.g., too little change in diet and nothing happens, as with the standard diabetes support and education intervention, whereas harm may be caused by a severely prolonged fast). Much of ITLC and TLC is being "under-dosed" and thus is being declared ineffective. More recent research is demonstrating that properly dosed ITLC is highly effective in reversing underlying pathophysiology, even inducing pancreatic β-cell neogenesis in some cases. This was thoroughly reviewed in an analytic review with an ACLM position statement on T2D remission.[34]

Some of the key treatment modalities or components common to the majority of these proven ITLC intervention programs include the following:

- Minimally processed whole plant food diet with little if any cholesterol-containing foods (animal products)
- Fasting with reduced consumption, from portion control to water-fasting and intermittent fasting (IF)
- Abundant regular, moderate exercise, with a gradual increase from inactivity
- Adequate restful sleep, with bedtime well before midnight and early rising
- Generous hydration with water (avoiding sweetened beverages or juices)
- Stress management education including cognitive behavior therapy methods
- Peer group dynamics, with patients supporting one another in lifestyle change (social)
- Spiritual emphases on purposeful living (mental and spiritual)

Therapeutic lifestyle changes are considered "intensive" when large changes are made that dramatically improve biometric measures of health and disease. Therapeutic lifestyle change interventions are considered "intensive" when frequent patient encounters of longer duration are used to help patients make large changes rapidly that dramatically improve biometric measures of health and disease. This type of LM treatment requires close supervision and oversight by an LM clinician trained in LM and licensed to



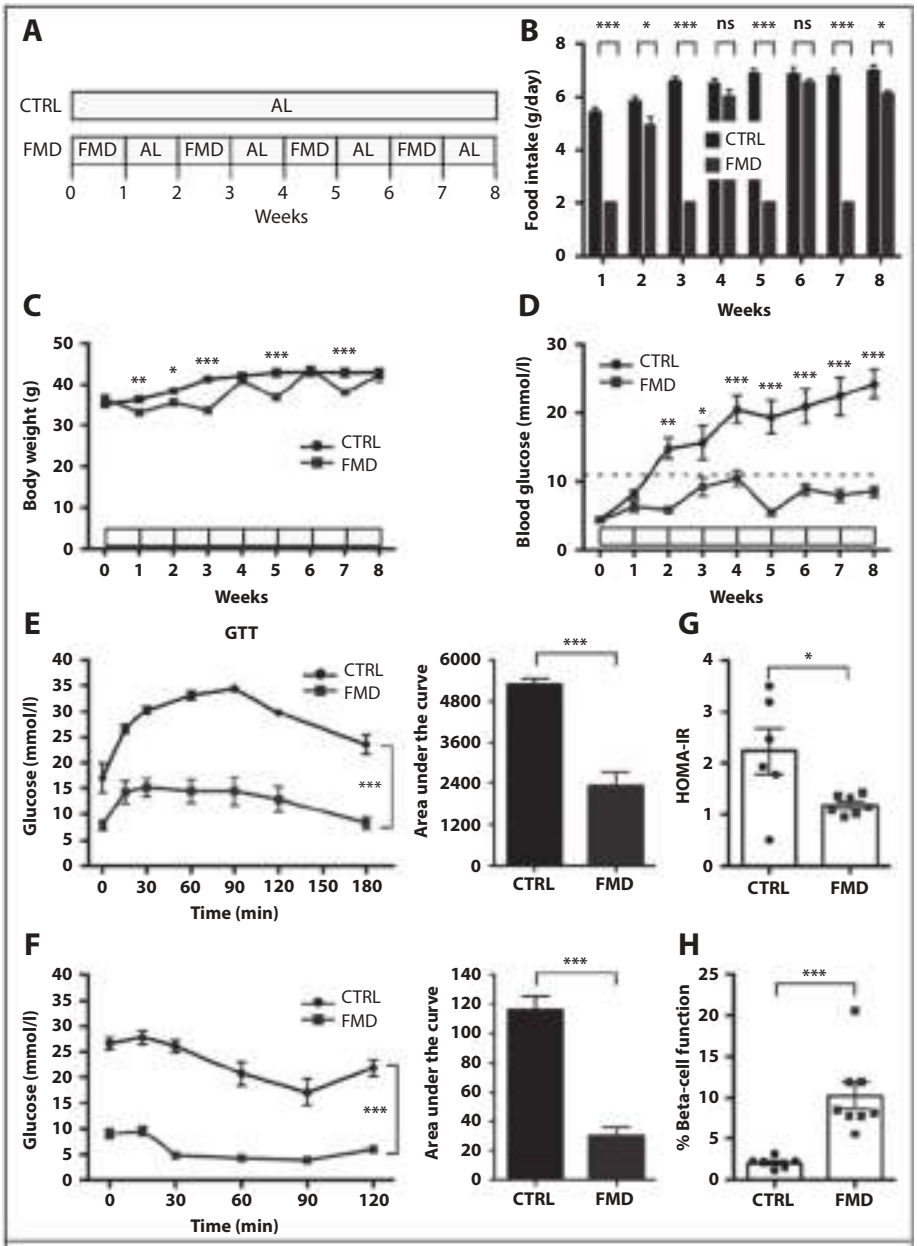


FIGURE 90.15 Graphic abstract of effects of fasting-mimicking diet in human tissue and mouse.

Intermittent FMD intervenes in type 2 diabetes in db/db mice. A Experimental scheme to determine effects of the FMD in T2D in leptin receptor-deficient db/db mice. Six-week-old male db/db mice were assigned to two groups: control and FMD (n = 8 for each group). Each FMD cycle entails 7 days of FMD and 7 days of ad libitum feeding (AL). During free feeding, mice received a regular chow identical to that given prior to the FMD and that given to the ad libitum (AL) controls. B Food intake. C Body weight. D Blood glucose levels. Blood samples were collected on the last day of each cycle. Mice were fasted for 6 h (morning fasting) for blood glucose measurements (n = 8 for each group). A fasting blood glucose level of > 11.1 mmol/L was defined as diabetic (dotted line). E & F Glucose tolerance test and insulin tolerance test at week 9.The area under the curve is shown on the right. G Homeostatic model assessment (HOMA) of insulin resistance (IR) and H steady-state β cell function (%B) at week 9. Data are expressed as the mean ± SEM, n = 8 per group. $p < 0.05$, $^{**}p < 0.01$, $^{***}p < 0.001$, ns for nonsignificant.

FIGURE 90.16 Fasting-mimicking diet intervention changes in type 2 diabetic mice (db/db).

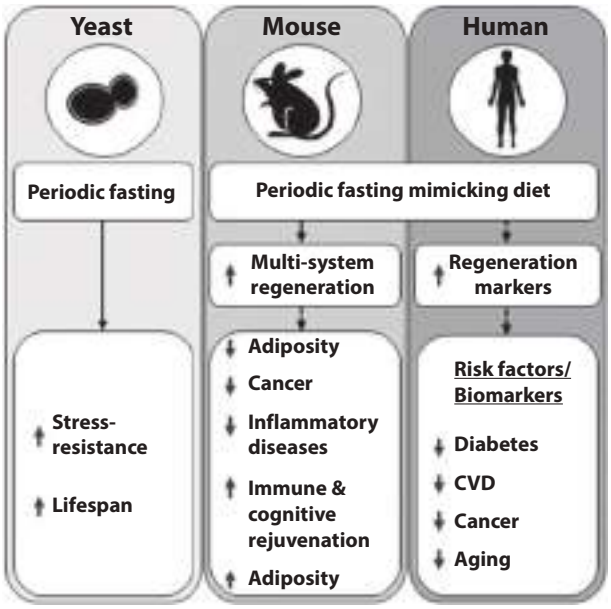

FIGURE 90.17 Graphical abstract of effects of fasting in yeast and fasting-mimicking diet in mice and humans.

deprescribe medications. Intensive cardiac rehab (ICR) LM programs, for example, are "intensive" therapeutic lifestyle change interventions. They produce dramatic improvement in multiple biometric measures of health and disease status and require supervision and oversight by a qualified physician.

ITLC is the form of LM treatment demonstrated by abundant randomized and non-randomized studies to reverse disease. It is not readily provided in the typical medical office setting and it is significantly underutilized. It needs to be followed by appropriate TLC support by PCPs to enable patients to maintain the health-promoting lifestyle choices learned and embraced during ITLC treatment. Often, ITLC is the "missing link" in the practice of LM that could potentiate subsequent LM treatment and make it more effective and sustainable. (In pharmacological terms, it increases dosing and prolongs half-life.) It has been found to be more powerful than many conventional treatments now in use, with many beneficial and no significant harmful side effects.

Sidebar table: Illustrative ITLC Programs

Name and Location	Type/Setting	Strengths	Weaknesses
Ornish Program Franklin, TN	Outpatient, hospital, or clinic	Approved for ICR reimbursement; well-proven effectiveness	Limited availability, cost
Pritikin Program Miami, FL	Live-in residential and outpatient	Approved for ICR reimbursement; well-proven effectiveness; one of the first programs (1970)	Limited availability (outpatient option will help), cost
McDougall Program Santa Rosa, CA	Live-in residential and telemedicine	Among the oldest programs (1970s) affordable; good web support	Limited availability (single location or online)
NEWSTART Program Weimar, CA	Live-in residential	Among the oldest programs (1978)	Limited availability (single location)
Pivio/CHIP Program Loma Linda, CA	Outpatient, hospital, community, corporate, and web	Scalable (video-based); effective (two RCTs); affordable	Australian style recipes; HRA weak
Canyon Ranch Tucson, AZ	Live-in residential	Well-established program	Limited availability (multiple locations); cost
Mastering Diabetes CA	Web-based, focused on type 1 diabetes	Affordable; convenient, and helpful for all forms of diabetes	Limited studies[35]
Other similar programs exist in the United States and the world	Live-in, community, corporate, and web	Varies by program	Varies by program

91 Physician Health Practices and Lifestyle Medicine

Erica Frank, MD, MPH, FACPM and Debora Holmes, MES

KEY POINTS

- Physicians and medical students with healthy personal habits more consistently report counseling their own patients about these habits.
- Given these data, it is increasingly important for medical schools to proactively produce healthy doctors; however, only one study has documented this type of intervention.
- The "Healthy Doctor = Healthy Patient" relationship itself should encourage prevention-oriented healthcare systems to better support and evaluate these positive effects on patients.

91.1 INTRODUCTION

Past studies have found that physicians and medical students who report healthy personal habits more consistently report counseling their own patients about related habits.[1–6]

Most recently, however—instead of merely relying on physicians' self-reported counseling and preventive practices—the relationship between healthy doctor and healthy patient has been assessed through objectively measured clinical experiences. In so doing, researchers have documented a consistent, positive relationship between physicians' and patients' preventive health practices.[7–9]

In addition, this chapter emphasizes the importance of "growing" proactive medical doctors in the good soil of responsive medical schools and universities—although, to date, it appears that only one large-scale study[8, 9] has documented this type of intervention.

The objective establishment of the "Healthy Doctor = Healthy Patient" relationship (a term first used in Frank, Smith, and Fitzmaurice[8]) should, in and of itself, encourage prevention-oriented healthcare systems in order to better support and evaluate these positive effects on patients. This chapter details past studies and methods and provides suggestions and strategies for future and ongoing success in counseling and treatment.

91.2 CONTEMPORARY PHYSICIAN MORTALITY RATES AND WHY THEY ARE LOWER THAN OTHER GROUPS

91.2.1 Summary of Physicians' Health (Men) in the United States

The data shown in Table 91.1 derive from US deaths occurring in 28 states between 1984 and 1995. Among both White and Black men, physicians were, on average, older when they died (73.0 years for White and 68.7 for Black) than lawyers (72.3 and 62.0), other professionals (70.9 and 65.3), and all men (70.3 and 63.6). The top ten causes of death for White male physicians were essentially the same as for those of the general population, although the physicians were more likely to die from cerebrovascular disease, accidents, and suicide; they were less likely to die from chronic obstructive pulmonary disease, pneumonia/influenza, or liver disease than other professional white men.

In this particular collection of data, mortality outcomes suggest that—at least for men—physicians make healthy personal choices.[10] These and other findings[6,11–14] began to seriously dispel the "myth of the unhealthy doctor" several years ago.

91.2.2 Summary of Physicians' Health (Women) in the United States

Other studies had already expressly shed light on reasons for decreased physician mortality as compared with other groups.[12,15] Table 91.2 illustrates certain characteristics of women physicians versus those with different socioeconomic statuses. Women physicians were more unlikely than other women of high socioeconomic status to smoke (and even more unlikely than women who were not of high socioeconomic status). The few physicians (3.7%) who did smoke reported consuming fewer cigarettes per day than other women, and the physicians who had ceased to smoke reported quitting at a younger age than women in the

TABLE 91.1
Occupation and Average Age of Death for US Men over Age 25, Years 1984–1995

Race/ Sex	Occupation	Number of Deaths	Average Age at Death
White men	Physicians	13,790	73.0
	Lawyers	14,389	72.3
	All professionals	214,744	70.9
	All deaths	3,386,475	70.3
Black men	Physicians	372	68.7
	Lawyers	258	62.0
	All professionals	14,059	65.3
	All deaths	443,585	63.6

Source: Data from the National Occupational Mortality Surveillance database.

general population. Women physicians were less likely to report abstaining from alcohol; however, those who drank reported consuming less alcohol per episode than other women and were less likely to experience alcohol binges than women in the general population.[12]

Unlike women in the general population and even unlike other women of high socioeconomic status, women physicians reported healthy behaviors exceeded national goals for the year 2000 in all examined behaviors and screening habits. Women physicians described generally good health habits even when compared with other socioeconomically advantaged women; these physicians self-reported that they had exceeded all examined national goals for personal screening practices and other personal health behaviors.[3,16,17]

91.2.3 Summary of Canadian Physicians' Health

Studies have shown that 90% of Canadian physicians are in good health, and 66% are in very good health (compare this with 70% of 20-to-34-year-old Canadians in the general population who are in very good health). Eight percent of

Canadian physicians are obese (compared with 23% in the general population); 25% of female doctors are overweight and 55% of male doctors (versus 53% and 65%, respectively, in the general population); and 3% smoke cigarettes (versus 18% of women and 15% of men in the general population).[18]

Frank and Segura found in their 2009 study that women physicians ate fruits and vegetables 5.3 times/day and men 4.5 times/day (versus 48% of Canadian females and 34% of males eating fruits and vegetables 5 times/day); 0.8% of women physicians (versus 9% of other women) and 1.3% of men physicians (versus 23% of other Canadian men) binged. Overall, physicians averaged 4.7 hours of exercise each week.[18]

91.3 PHYSICIANS' PERSONAL HABITS AND PATIENT HEALTH

Do physicians' healthier personal habits make a difference clinically? In other words, why should we care so much about physician health?

One of the strongest predictors of health promotion counseling is whether the physician practices healthy behavior. Conversely, many physicians report difficulties in counseling patients about behaviors they themselves do not practice.[19,20]

Physicians are key health role models and advisors who often meet with patients during potentially impressionable times, and their personal health behaviors affect their credibility and ability to engage their patients in similar healthy behaviors.[21] Importantly for the busy doctor, it seems that simply talking to patients about one's personal health practices improves the efficiency of one's health promotion practices. Providers who disclose their personal health practices are perceived as more credible and motivating.[5,21] In fact, the majority of people cite their physician as their primary source of information regarding healthy lifestyle decisions and are more likely to adopt a healthy behavior when their physician recommends it.[14]

Not only is practicing healthy behavior oneself strongly correlated with a physician's counseling of patients on said behavior,[19] this may actually hold true regardless of the physician's actual health status; physicians attempting to improve their own poor habits have been found to counsel patients significantly more often than physicians who were not trying to change their behaviors.[22]

We know that counseling patients makes a difference in their habits and their health and that North Americans' poor behavioral choices regarding diet, exercise, alcohol, and tobacco account for substantial mortality rates—approximately 40% of US mortality[23]—but, even so, physicians do not perform prevention counseling at very high rates.[24–28]

91.4 PHYSICIAN EXERCISE AND HEALTHY PATIENTS

As previously established, those physicians with the healthiest habits are most likely to advise their patients about related preventive habits. This is particularly true for exercise.[29]

North American physicians (and medical students) generally report significantly better exercise habits when compared with their same-age peer groups, which in turn highly correlates with positive mental and physical health outcomes not only for the physicians but also for their patients. As with other healthy habits, findings on exercise highlight the importance of medical school and physician "health interventions" in order to increase present and future rates of physician-delivered exercise prescriptions.[11,14,17,24,27,28,30–46]

91.5 WHICH DETERMINANTS MATTER MOST WHEN IT COMES TO PHYSICIANS COUNSELING PATIENTS?

Determinants surrounding physicians' personal habits—exercise represents but one example—are worth knowing because intervention on malleable variables can then occur, producing physicians with stronger prevention-related skills.

To explore the effect of potential counseling- and screening-related variables in 4501 respondents to the *Women Physicians' Health Study*, a questionnaire-based study of a representative sample of US women doctors was performed.[3] Table 91.3 delineates the study's central findings.

Being a primary care practitioner and having related healthy habits were the most significant correlates of US women physicians' self-reported prevention-related counseling and screening practices. Table 91.4 exhibits these specifics.

91.6 INDIVIDUAL CASE STUDY 1: FOR ONE PHYSICIAN, HEALTHY MEETS MULTITASKING

Before laptop computers emerged on the scene, I (Dr. Erica Frank, chapter co-author) read journals and books that were not too heavy to hold while I pedaled an exercise bike. But once I had ridden a few miles with a laptop secured to the front of my bike, I knew I had found my preferred regular exercise modality. Here was a health-promotion activity that satisfied so many criteria simultaneously! I no longer experienced remorse over wasting time getting a special outfit for exercise, getting to and from my place of exercise, or even performing the exercise itself (no longer feeling that my brain, hands, and quadriceps should all have higher purposes). Additionally, I no longer stewed in boredom while exercising, a serious impediment to any previously regular exercise.

In the thousands of miles ridden since that day, I have not only learned to bike and simultaneously read and write, but even to chair conference calls—although the latter usually with the video function turned off.

And now when I leave home, I also strive for fun, multitasking exercise. As an assistant professor, I would usually commute to and from work on my bicycle, about 20 minutes

to Emory University or to Grady Memorial Hospital each way; this was a wonderful way to begin and end each day. Likewise, I have found it is often an educational and cardiovascular treat to walk around a new urban or biologically rich environment en route to a task. Walking while talking with friends can be fruitful too, whether with a buddy in person or on the phone, a child in a stroller, or as a stroll with a significant other that pays attention to the light, weather, and one's shared ecosystem.

And how do I judge the efficacy of my activities? At age 55 I retain a normal BMI, blood pressure, and lipids without medication, can accomplish without pain any physical feats needed or desired, and sporadically participate in triathlons without special preparation before or any pain after, although always (and contentedly) at the very back of the pack.

INDIVIDUAL CASE STUDY 2: EXERCISE VANQUISHES STRESS

When she had completed the first half of her medical internship in the oncology department of a large community hospital, Verena R. had a very hard time leaving behind the suffering and strokes of fate that her patients endured when she stepped through the hospital's exit door each night. In addition, she lived in staff housing in very close proximity to the hospital—her living room faced the windows of the ward in which she worked. She just could not seem to get away.

That is when Verena took up running. Every day after work, she exchanged her scrubs for running tights and a t-shirt and took off into the nearby forest. Sometimes she listened to music, podcasts, or audiobooks; sometimes her brain needed peace and quiet, and she would simply run and become one with the beautiful natural settings surrounding her.

After an hour or so, Verena would return home drenched in sweat but with a peaceful mind. She was able to create the much-needed distance and larger perspective that allowed her to continue working in the medical profession without sacrificing her own well-being. Six years later, she still runs, having completed several half-marathons, a marathon, and a half-ironman distance triathlon. The sport has given her joy, a healthy body, and best of all, her most important outlet for stress. Thanks to running, she falls asleep happy and content every night.

91.7 A NEW, OBJECTIVE VIEW FROM ISRAEL'S LARGEST HMO

Instead of merely relying on physicians' self-reported counseling and preventive practices, the Healthy Doctor = Healthy Patient[8] relationship was recently assessed through objectively measured clinical experiences.

Frank et al.[7] accessed complete vaccination and screening records from Clalit Health Services (CHS), Israel's largest health maintenance organization, the electronic medical records of (a) primary care physicians who worked in and were also patients in CHS (n = 1488), and (b) these CHS physicians' adult patients (n = 1,886,791),

Eight prevention-related (screening and immunization practices) quality health indicators were chosen:

1. Mammography in women 50–74 years of age
2. Colorectal cancer screening in patients 50–74 years of age
3. Low-density lipoprotein (LDL) measurement every five years for patients aged 35–54 and yearly among patients aged 55–74 years
4. Blood pressure measurement every five years for patients aged <40 years
5. Blood pressure measurement every two years for patients 41–54 years
6. Blood pressure measurement annually for patients ≥55 years

7. Pneumococcal vaccination among patients with a chronic illness and those ≥65 years
8. Annual influenza vaccine among patients with chronic illness and those ≥65 years

For all eight indicators, patients whose physicians were compliant with the preventive practices were more likely ($p < 0.05$) to also have undergone these preventive measures than patients with noncompliant physicians. The investigators also found that more closely related preventive practices showed an even more robust relationship.[7]

91.8 HEALTHIER PHYSICIAN HABITS: PATIENTS RESPOND

As touched upon earlier, providers who disclose their healthy personal health practices are perceived as more credible and motivating; rates of prevention counseling increase and patients become more receptive to health promotion counseling from physicians who demonstrate healthy behaviors themselves.[21,47] Frank, Breyan, and Elon[21] conducted a small study (n = 130) in an Emory University general medical clinic waiting room. They randomized individuals to watch either a standard two-minute video from me (co-author Frank) on healthy diet and exercise habits, or the standard video plus an extra 30 seconds divulging my personal health habits regarding diet and exercise. Patients found me in the "physician-disclosure" video to be significantly healthier ($p = 0.004$), also finding me more believable and more motivating overall. Specifically, regarding both diet and exercise, patients found the extra 30 seconds made me more believable about diet and exercise ($p = 0.006$ and $p = 0.002$, respectively) and also more motivating on diet and exercise ($p = 0.006$ and $p = 0.004$, respectively).[21] Figures 91.1 and 91.2 exhibit these results in graph form.

91.9 DOES COUNSELING ACTUALLY MAKE A DIFFERENCE IN PATIENT OUTCOMES?

Is counseling worth the time? Yes, since tobacco, diet, exercise, and alcohol account for about 40% of US mortality, and counseling from one's physician on these topics increases the likelihood that patients will act healthily.[23]

Surely, then, physicians must be counseling their patients increasingly… and, if not, why not, and what can we do about it?

91.10 THE HEALTHY DOCTOR = HEALTHY PATIENT PROJECT

The Healthy Doctor = Healthy Patient project was a five-year-long action research intervention, performed at Emory University School of Medicine and led by co-author Frank, to improve medical student health, with the hypothesis that this could improve patient health. The scientific foundation of the Healthy Doctor = Healthy Patient principle is as follows:

- North American physicians tend to live longer than their peers.
- Physicians live longer because they have healthier habits (including as medical students) than their contemporaries.
- Four behavioral choices (exercise, diet, alcohol, and tobacco) account for about 40% of US mortality.[23]
- Physicians and medical students with the healthiest habits are more likely to advise their patients about related preventive habits.
- Appropriate physician revelation about healthy personal habits can make physicians more believable and motivating to patients.

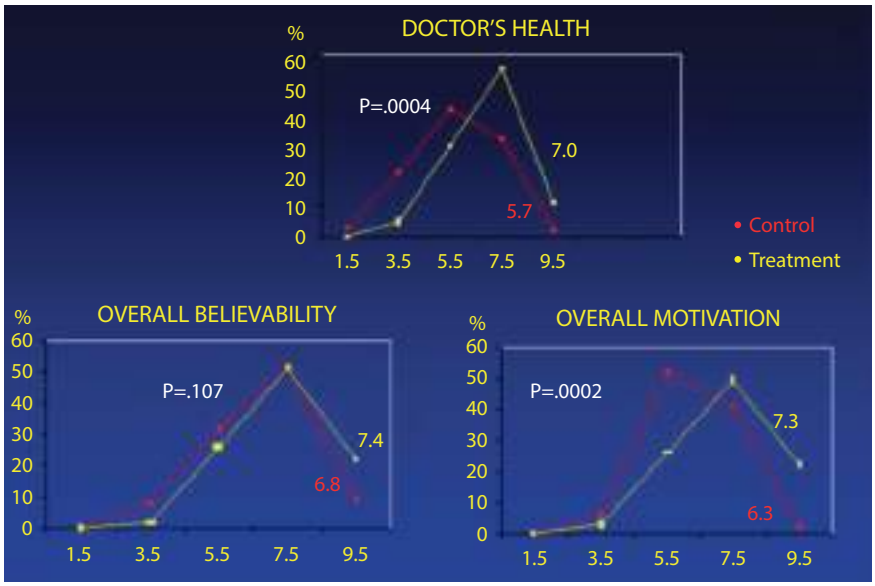

FIGURE 91.1 Emory University waiting room study: doctor's health, overall believability, and overall motivation.

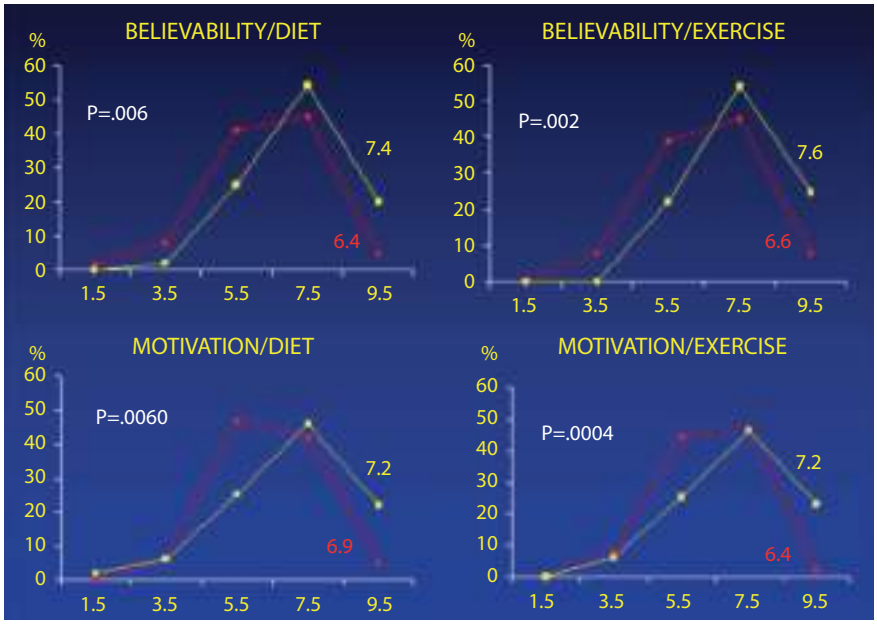

FIGURE 91.2 Emory University waiting room study: doctor's believability with respect to diet and exercise, and doctor's motivation with respect to diet and exercise.

- When medical schools encourage students to be healthy, it positively and significantly influences the students' patient counseling frequency ($p = 0.002$) and their perceived relevance ($p = 0.0007$) of such counseling.
- Counseling patients makes a difference in patients' habits and their health.
- Despite all this, many physicians have areas of potential personal health improvement and do not perform prevention counseling at very high rates.

To determine basic health practices and status, a survey was conducted of medical students (n = 2316 individuals responding to ≥1 survey) in the Class of 2003 at freshman orientation, entrance to wards, and senior year in a nationally representative sample of 16 medical schools (response rate = 80.3%). Most medical students (84%) reported never having smoked cigarettes, and both genders typically drank two drinks per drinking episode (with bingeing more common among men). Students exercised a median of at least four hours per week, and preferred strenuous exercise. Medical students across all years and both genders reported a median of seven hours of sleep per night. Nearly all (97%) reported their health to be at least good, typically with one or fewer days of poor physical or mental health in the past month. Both genders (particularly women) were unlikely to be overweight or obese. Reported rates of any chronic condition were ≤2% except for hypertension among men, and obesity, dyslipidemia, and depression in both genders. Unlike their other relatively positive behaviors compared with their peers, medical students had variable rates of preventive screening.[8,48]

Overall, medical students in the United States were healthy and reported many good health behaviors when compared with other young US adults. However, for some, there was room for improvement, as health behaviors and personal health practices either did not meet national goals or placed students at risk.[48] For example:

- Average daily fruit/vegetable consumption (2.5 servings) was as poor as that of their peers.
- Binge drinking rates (25% females and 43% males) for the previous month were also poor, with no change over medical school ($p = 0.5$).
- Unlike their other relatively positive behaviors as compared with their peers, medical students had low rates of preventive screening.

91.11 MORE ON MEDICAL STUDENTS AND PERSONAL–CLINICAL RELATIONSHIPS

The Healthy Doctor = Healthy Patient relationship ideally begins with freshman medical student interventions: medical schools must concentrate on maximizing the growth of these ideals—and individuals—early on. For example, to determine personal and clinical exercise-related attitudes and behaviors of freshmen US medical students, Frank et al.[49] looked at the 1906 entering freshman medical students (response rate = 87%; average age = 24 years) in the 17 US medical schools surveyed. Students reported a median of 45 minutes per day of exercise, 80 minutes per week each of mild and moderate exercise, and 100 minutes per week of strenuous exercise. Nearly all freshman medical students (97.6%) engaged in some moderate or vigorous exercise in a typical week, with 64% complying with US

Department of Health and Human Services exercise recommendations. Most (79% of) freshmen believed it would be highly relevant to their future practices to counsel patients about exercise; professional predictors included the intention to be a primary care provider, and personal predictors included excellent general health, a prevention emphasis by their personal physicians, and performing more strenuous exercise.[49]

The follow-up study by Frank et al.[2] reported predictors of multiple prevention counseling practices among US medical students. These results are summarized in Table 91.5 and Figure 91.3.

91.12 STUDY: COLOMBIAN MEDICAL STUDENTS' HEALTHY PERSONAL HABITS AND ATTITUDES TOWARD PREVENTIVE COUNSELING

Physician-delivered preventive counseling is important for the prevention and management of chronic diseases. Data from the United States indicate that medical students with healthy personal habits have better attitudes toward preventive counseling.

The following study, the first relating to this association in medical students in developing regions, examined the

TABLE 91.5
Medical Students: Personal Health Behaviors versus Counseling Frequency and Perceived Relevance

association between personal health practices and attitudes toward preventive counseling among first- and fifth-year students from eight medical schools in Bogotá, Colombia.[1,33]

During 2006, a total of 661 first- and fifth-year medical students completed a culturally adapted Spanish version of the Healthy Doctor = Healthy Patient survey (response rate = 78%). Logistic regression analyses were used to assess the association between overall personal practices on physical activity, nutrition, weight control, smoking, alcohol use (main exposure variable), and student attitudes toward preventive counseling on these issues (main outcome variable), stratified by year of training and adjusting by gender and medical training-related factors (basic knowledge, perceived adequacy of training, and perception of the school's promotion on each healthy habit).

The median age and percentage of females for the first- and fifth-year students were 21 years and 59.5% and 25 years and 65%, respectively. After controlling for gender and medical training-related factors, the investigators found that the consumption of five or more daily servings of fruits and/or vegetables, and not being a smoker or binge drinker, were associated with a positive attitude toward counseling on nutrition (OR = 4.71; CI = 1.6–14.1; p = 0.006) smoking (OR = 2.62; CI = 1.1–5.9; p = 0.022), and counseling on alcohol (OR = 2.61; CI = 1.3–5.4; p = 0.009). Data for senior medical students (independent of gender and medical-related training factors) are seen in Table 91.6.[1]

As with the US physician and medical students, a positive association was found between the personal health habits of Colombian medical students and their corresponding attitudes toward preventive counseling, independent of gender and medical training-related factors.

Importantly, these findings also suggest that within the medical school context, interventions focused on promoting healthy student lifestyles can potentially improve these future physicians' attitudes toward preventive counseling.

91.13 INTERVENTION FOR MEDICAL STUDENTS: A LARGE-SCALE CASE STUDY

Our analysis and quantitative assessment of our four-year-long intervention did, in fact, indicate that the intervention had promoted healthy physical habits among medical students.[8,9] The class of 2003 (using the class of 2002 as a control) at Emory University School of Medicine was extensively studied after various interventions were performed throughout their schooling; several specifics are provided in this section to provide potentially useful ideas for other institutions.

Curricular and extracurricular interventions for first-year medical students included the following:[8]

- Orientation lecture on Healthy Doctor = Healthy Patient principles
- Anatomy manual on muscles and related exercises
- Use of students' data in biostatistics class and for homework
- Student presentations on physician health in small group sessions
- Lunchtime panels (with free, healthy lunch) on well-balanced, integrated lifestyles
- A "healthy quick cooking" class
- Personal health prescriptions provided to students subsequent to lifestyle review
- Hike and healthy dinner at an energy-independent mountain lodge

Curricular and extracurricular activities for second-year medical students included the following:[8]

- Working with Problem-Based Learning mentors on the Healthy Doctor = Healthy Patient concept
- Pathophysiology of hepatic disease, lecture on personal practices
- Behavioral science, one-hour talk on medical student alcohol/tobacco use
- Behavioral science, physician panel of former substance users
- Nutrition course, plant-based diet lecture
- Exercise elective and seminar
- Monthly walks/runs
- Sponsored entrance fees for races
- Wine-tasting seminars to teach about more appropriate use surrounding alcohol
- "Health Heads Up", a monthly emailed summary of a half-dozen prevention-related studies written by classmates
- Weekly yoga classes
- Healthy breakfasts before exams
- Healthy Asian cooking class
- Massage with free lunch (talk and demo), with data on the physiological effects of massage
- Principal investigator presented Healthy Doctor = Healthy Patient at the Student National Medical Association meeting in Atlanta
- Lunchtime yoga/meditation seminar by visiting doctor on the health and psychological effects of yoga and meditation (free healthy lunch provided)

- Personal health prescriptions provided to students subsequent to lifestyle review
- Lunchtime talk (free healthy lunch provided) on pathophysiology of stress and what can be done about it

Curricular interventions offered for third- and fourth-year medical students included:[8]

- *All clerkships*: Dr. Frank (principal investigator) met with clerkship directors, encouraging healthy food on occasions (e.g., morning Grand Rounds, lunchtime didactics) where food would typically be offered to the students, and at least one additional clerkship-based personal health promotion activity for the medical students.
- *Dermatology*: letter on the importance of skin cancer prevention for themselves and their patients, a review article on skin cancer-prevention strategies, and a container of sunscreen for their own use.
- *Ethics/medicine*: completed advanced directives and living wills.
- *Ethics/psychiatry*: completed a Beck Depression Inventory and an alcohol (CAGE) screening questionnaire.
- *Family/internal medicine*: tobacco lecture, instruction, and practice with health-risk appraisals (HRAs), and model counseling.
- *Family medicine*: students (and occasional preceptors) kept one-week logs of daily number of fruits/vegetables and exercise amount/type; students wrote descriptions of their ideal lifestyle a decade hence.
- *Gynecology/obstetrics*: articles assigned on women physicians' characteristics during pregnancy, sexual abuse/domestic violence rates, and depression/suicide rates; students given American Cancer Society breast self-exam shower card; students given condoms and emergency contraception offered (as requested).
- *Pediatrics*: presentation on personal health practices on rotation and in life.
- *Psychiatry*: suicide and depression article.
- *Surgery*: presentation on personal health practices of a director.
- *Validation project:* validation study for food-frequency screener, including five in-person, 24-hour recalls; two food-frequency questionnaires; personal analysis of fat and fruit/vegetable intake

In this four-year controlled trial addressing lifestyle behaviors over the course of medical school, the final analysis found that medical student had made improvements in their personal health practices. For instance, control group males increased their use of tobacco products between ward orientation and their senior year, while intervention group males decreased their use—the control males reported twice the tobacco use reported by males in the intervention (43% versus 22%, p = 0.02), although the two groups had previously reported very similar levels (31% versus 29%, p = 0.8).[5,9] Importantly, students' diet counseling and exercise counseling (as reported by standardized patients) were also strongly positively related to the intervention.[9]

Observational Healthy Doctor = Healthy Patient study hypotheses were confirmed:

- Medical students were healthy and reported many good health habits when compared with other young US adults.
- Medical schools' encouragement of students to be healthy significantly influences students' patient counseling frequency (p = 0.002) and perceived relevance (p = 0.0007) of such counseling.[8]
- Medical students' personal health practices are correlated with their counseling frequency (p <0.0001) and perceived relevance (p = 0.008).[2]

A medical student-focused health promotion intervention can improve students' self-reported personal health behaviors, their perceptions of the healthfulness of their medical school environment, and their (objectively measured) standardized patient prevention counseling practices.[9] Likewise, the comprehensive study by Frank et al.[2] found that students reporting a healthier medical school environment also reported highly significantly better patient counseling practices. The remarkable effect of student interventions on the frequency of their patient counseling is exhibited in Table 91.7.

These findings suggest that further refinements and broader implementation of interventions such as those discussed in this chapter could be efficient and valuable methods to improve the health of healthcare professionals and the vast populations of patients they serve.

TABLE 91.7

Effect of Student Interventions on the Frequency of Counseling Patients during Their Examinations

Topic	Crude Odds Ratio (95% Confidence Interval)	Adjusted Odds Ratio (95% Confidence Interval)	P Value from Adjusted Odds Ratio
Diet	1.49 (1.04–2.12)	1.49 (1.01–2.19)	0.04
Exercise	1.65 (1.16–2.35)	1.56 (1.04–2.34)	0.03

Extensive versus minimal/no counseling (adjusted for gender, intended specialty, and agreement, at baseline, with the statement "Physicians have a responsibility to promote prevention").

91.14 INTERVENTION FOR PHYSICIANS

Although physicians' and medical students' personal health practices are better than those of the general population (at least in Canada and the United States), multiple studies suggest the need to further foster physicians' personal preventive practices, both to promote the personal health of physicians themselves and to improve outcomes for their patients.

In addition, such programs need to be studied in order to determine how best to actively encourage physician health and, correspondingly, the Healthy Doctor = Healthy Patient association.[7,8] To date, this chapter's authors know of no such published studies, although we are now collaborating with Bar-Ilan University's (in Safed, Israel) medical school and with www.NextGenU.org's (in >200 countries) free, accredited lifestyle medicine course on such a study. We look forward to encouraging and enabling other such interventions—particularly with readers of this chapter interested in such (Erica.Frank@ubc.ca, efrank3g@gmail.com, and EFrank@NextGenU.org being enduring emails for such purposes).

91.15 BOTTOM LINE

The health of North American (and most other studied physician populations) is, according to multiple studies, very good, although there is room for improvement in our physical (and particularly for our) mental health among both physicians and medical students. Especially when looking through the lens that shows a healthy doctor is more likely to produce a healthy patient, physicians' health status takes on paramount importance.

The medical and healthcare communities, along with North American universities, must implement new approaches to achieve these goals. As physicians, we must (a) discuss ways to simultaneously improve our health and that of our patients, and (b) consider the most important new questions to ask regarding physician health. We must take care of ourselves as well as our patients: when we do, we will witness more positive personal health outcomes for all concerned.

Physician health is rarely systematically promoted anywhere in the world, suggesting that policymakers believe that physicians are already adequately supported. In the few places where support programs for physicians exist, they concentrate heavily on suitability and competence to practice, mental health and illness (especially around substance abuse), and practice-related psychological motivation and physical stamina. The medical profession needs to do more than this, however—a failure to miss these opportunities is also a failure to efficiently improve the health of everyone in the system.[7]

CLINICAL APPLICATIONS

These findings should encourage leaders to test various ways to address and promote the following:

- Physician health, including and especially as a way to encourage patient health.
- Recognition that physicians' patient counseling is strongly related to the physician's own health practices.
- Medical student health through efforts to ensure medical schools produce healthy doctors and avid preventionists.[50]
- Healthcare systems that promote and support physician health around the globe.
- Recognition that physicians can positively influence patient health by counseling patients on prevention and health-promoting behaviors.
- The health of entire patient populations, which profit from more efficient and effective health promotion counseling.[5]
- Further exploration of the correlations between physicians' healthy personal habits and prevention-related counseling and screening, which should encourage new directions for physician training.

92 Physician Burnout

Gia Merlo, MD, MBA, MEd and James Rippe, MD

KEY POINTS

- Lifestyle medicine principles play a vital role in helping to minimize the individual symptoms and risk factors before, during, and after the appearance of burnout syndrome.
- Burnout is a result of stress, improper diet, lifestyle factors, and inadequate support from the workplace environment.
- Implementing mindfulness, primordial, primary, secondary, and tertiary prevention techniques can slow or prevent the progression of burnout.
- Mentoring future generations of medical professionals in lifestyle medicine can minimize the risk of burnout while promoting professional well-being.

92.1 INTRODUCTION

Burnout has been defined in the academic literature within multiple disciplines in medicine as related to chronic, unmanaged work-related stress. We will limit this chapter to physician burnout, although the literature for nurses, physician assistants, and other allied health providers is robust as well. Freudenberger first formally defined burnout in 1974. It is now seen as a multidimensional work-related syndrome consisting of emotional exhaustion, depersonalization, and a low sense of accomplishment from work.[1,2] Prior to the COVID-19 pandemic, physicians were already reporting stressful circumstances at work with over 50% reporting burnout. Physician well-being and self-care are essential for our healthcare system. Self-care has been defined by the WHO as the "ability of individuals, families, and communities to promote health, prevent disease, and maintain health and to cope with illness and disability with or without the support of a health-care provider".[3] This chapter focuses on the current literature on a complex construct of physician burnout while fully acknowledging that organizational interventions will be needed to truly address this burnout pandemic. Lifestyle medicine principles play a vital role in helping to minimize the individual symptoms and risk factors before, during, and after the appearance of burnout syndrome.

92.1.1 Nosology of Burnout Remains Controversial

Burnout is complicated to study since many countries describe it differently. According to the ICD-11's classification in January 2022, burnout is an occupational syndrome correlated with employment rather than individual mental health diagnoses and is regarded independently from mood disorders, adjustment disorders, anxiety disorders, or disorders specifically associated with stress.[4] In North America, burnout is noted to be related to work and not a diagnosable medical condition. The current version of the Diagnostic and Statistical Manual of Mental Disorders, DSM-5-TR, does not include burnout as a diagnostic category.

Two countries are leaders in the burnout space, Sweden and The Netherlands. Since 1997, with the ICD-10 addition of burnout as a syndrome, Sweden has recognized burnout as a disease.[5] Sweden later modified their country's burnout diagnosis in 2005 through the inclusion of an additional diagnostic criterion, difficulty in life management, called *vital exhaustion*. Vital exhaustion encompasses a presentation with remarkable similarity to symptoms of clinical depression, including irritability, two weeks of low energy, emotional lability, difficulty concentrating, sleep difficulties, and dizziness. To uphold qualification as *vital exhaustion*, these symptoms must have a direct impact on the execution of work responsibilities. It is important to note that Sweden citizen's access to care and services, including treatment, sick days, and disability, is contingent on this vital exhaustion diagnosis. The Netherlands similarly considers burnout a diagnosis and uses the term *overstrain* for this diagnosis with a prevalence of 3–7% that spans numerous professions.[6]

92.2 WHAT IS THE EXTENT OF THE PROBLEM?

Recent studies in the United States have shown that 40–54% of physicians report at least one symptom of burnout as assessed by the Maslach Burnout Inventory (MBI) with significant variation between physician practice specialty and setting.[7–10] Academic physicians have noted a 30% lower risk for burnout than private practice physicians.[8–11] Moreover, only 40.9% of private practice physicians contend that they have enough time outside of work for personal/family life, with 14.6% neutral and 44.5% in disagreement with this statement. The physician specialty with the highest burnout includes physicians on the frontline, e.g., primary care and emergency medicine. Notably, women and early career physicians have also been found to be at increased risk for burnout after considering adjustments for professional and personal factors.[12–14]

DOI: 10.1201/9781003227793-108

Several studies have reported that 45–56% of medical students and more than 60% of resident physicians have at least one symptom of burnout even though they enter medical school with higher psychological well-being than their peers.[15–18] Additionally, there is limited data available regarding the risk of burnout for self-identified lesbian, gay, bisexual, and transgender students and physicians, as well as the implications of race in burnout likelihood.

It can be seen that physician burnout may result in a multitude of consequences, including mental health issues for physicians, quality of care, litigation risk, job performance, physicians abandoning the field of medicine, patient satisfaction, and adherence of patients to prescribed treatments, along with countless other repercussions. To further complicate the issue, an unhealthy work environment can generate extensive human and financial costs. As an illustration, studies from 2018 determined that reduced clinical hours and physician turnover have a direct association with an estimated US$4.6 billion in annual costs.[10]

92.3 SYSTEMIC ETIOLOGICAL ISSUES

Multiple systemic etiological issues for developing burnout in the workplace have been identified, including overwhelming stressors in the work environment. Many authors, such as Maslach and Leiter in 1997, have implied that organizations *cause* physicians personal stress and a decreased sense of intrinsic worth with work becoming an obligation, with redistribution of power and questionable citizenship practices of institutions.[19]

As medical educational institutions have altruism as a required quality for future students, the mismatch continues to widen between the nature of the job and the nature of the person attracted to the profession. This mismatch leaves physicians often reporting a lack of control in the workplace with productivity goals misaligned with their internal drives. Physicians may feel overworked with conflicts with management, and experience an overall breakdown in community. Electronic health records, insurance mandates, and the corporatization of healthcare all contribute to stress, as they increase administrative and clerical burdens and decrease autonomy and flexibility, respectively. Unpaid work time including the often cited "pajama charting" time at home in the evenings increases stress and overwork, often contributing to the erosion of the professional versus personal boundaries for physicians.[20]

Race and the systemic and systematic issues in healthcare are emerging topics that also may contribute to the unfair training and work environment for many racial minorities that make up the underrepresented minorities and first generation in healthcare.[21]

92.4 WHAT ARE THE CONTRIBUTING FACTORS TO PHYSICIAN BURNOUT?

In 1977, Maslach and Leiter identified six factors in the workplace contributing to burnout. These six facts include a lack of control over work and responsibilities, an unrealistic workload, a disconnect between the reward and effort required in medical practice, an erosion of trust within the system, a lack of community in the workplace, and a misalignment of values and incentives.[19]

The current literature continues to support the argument that burnout is primarily a systemic issue with clear antecedents as first described in 1977. The authors agree that systemic issues are the primary etiology of burnout; this section addresses personal vulnerabilities that can make physicians especially susceptible to the development of burnout. Historically, society has perpetuated the cultural expectation that physicians must first and foremost care for those in medical need and serve the greater good under all circumstances. Physicians' health and personal desires typically assume secondary status to the required altruist mandate of medicine; however, this expectation is often upheld by providers at the cost of their own health. Is this a strong foundational structure for physicians to have as they counsel patients to take care of themselves? Are we creating a system of double standards?

US medical students are groomed to succeed from an early age to enter the competitive selection process. Medical students typically have a history of academic achievement that comes from years of striving for perfectionism with limited experience with failure. They are often seen as the smartest students in the classroom and serve as mentors and tutors from middle school and beyond. At first, these traits would be seen as admirable. The question is: How are these standards of personal performance potentially affecting the physician in their personal and professional life during their lifespan?

The field of lifestyle medicine has an opportunity to support the health of physicians along with informing physicians on the management of the health of their patients. Systemic organizational issues abound in the healthcare system leading to physicians often expressing a lack of support. How can a physician be expected to help others when they are feeling that they are not receiving adequate psychological support? In addition, the negative treatment of medical students and trainees is commonly described in the literature within our performance-driven medical culture.[22] As students who are unaccustomed to criticism continue through their medical training, one has to wonder how their sense of self holds up to the multiple mistakes that they must make throughout the learning process. Maybe we need to include areas in medical education that allow for failures to be encouraged and supported as part of the curriculum.

Medical students have often excelled in tasks and are inexperienced with the psychological mechanisms to cope with being told that they are inadequate. Overwhelmed with studies and patient care, trainees may psychologically compartmentalize their disappointments within themselves, awaiting time to process the feelings and grieve and mourn the sickness and death that they witness. Trainees experience erosion of their self-care with their laudable personal and professional goals as the time to process often never comes as the workload only increases with every year of

practice. Medical professionals are known to be hardest on themselves and this harshness is mirrored in the healthcare system on multiple levels. This is compounded by the lack of time to grieve and process the emotions associated with the burden of learning to become a physician. These same students and residents who are at times systematically belittled during their own training may adopt the same negative strategies on the next generation of trainees, thereby perpetuating this toxic culture.

92.5 BURNOUT AND MENTAL AND PHYSICAL HEALTH

Considering the stressors in the healthcare environment, physicians react either positively or negatively, resulting in consequences on their health and well-being. With stressors that are persistent and displeasing, physicians may react in ways that worsen their health. This relentless feeling of hopelessness felt by the physicians puts them at a greater risk for burnout.

Stress may also result in physiological changes such as blood-sugar imbalances, hypertension, structural changes in bone density and the brain, muscle tissue loss, and lowered immune responses.[23] The structural changes in the brain are a result of decreased grey matter volume in the hippocampus, as chronic stress impacts the hypothalamic-pituitary-adrenal (HPA) axis.[24] Stress response can be improved by the physician's mental control over the stressor and can be mediated by the prefrontal cortex inhibition of the brain and limbic system structures.[25] Similar to lifestyle medicine, resilience research shows that addressing the stressors proactively and having active coping mechanisms are the most effective ways of combatting stress in the work environment and ultimately lessening the risk for burnout.[26]

Implementing active and healthy responses to stressors has been shown to help the body return to its original state. Such healthy responses align with lifestyle medicine interventions that focus on exercise, diet, and sleep to address the inflammatory response of stress. Research shows that the complex neural processes underlying stress and stress resilience involve genetic, epigenetic, neurobiological, and environmental factors.[27] Addressing these factors with lifestyle medicine interventions will slow or prevent the growth of stress-related burnout.

92.6 SYMPTOMS OF BURNOUT

The five categories of symptoms associated with burnout are discussed further. These include physical, affective, cognitive, behavioral, and motivational symptoms.[28]

92.6.1 Physical Symptoms

Physical symptoms often seen with burnout have been linked to a sympathetic nervous system activated stress response, hypercholesterolemia, type 2 diabetes, metabolic syndrome, musculoskeletal pain, dysregulation of the HPA axis, weakened immune function, systemic inflammation, and cardiovascular disease.[29] The sympathetic nervous system activated stress response from burnout is associated with anxiety symptoms such as increased heart rate and blood pressure, nausea, headache, and restlessness.[30]

92.6.2 Affective Symptoms

Many affective symptoms of depression and anxiety are associated with burnout. These include changes in mood, increased tension, anxious and heightened feelings, and irritability. Evidence supports that burnout along with depression and anxiety are associated with fibrinogen, which is gender-dependent, and the inflammatory marker C-reactive protein (hs-CRP).[31]

92.6.3 Cognitive Symptoms

Cognitive symptoms include helplessness, a cynical perception of others, and pessimism. Additional cognitive impairments, such as subjective memory, executive functions, and less attention, are associated with long-term burnout.[32]

92.6.4 Behavioral Symptoms

Emotional outbursts, medical errors, declined productivity, and increased job turnover are all behavioral symptoms associated with physician burnout. When physicians experience burnout, they are more likely to retire earlier or change their specialty because of the detrimental impact on well-being.[33]

92.6.5 Motivational Symptoms

When physicians experience burnout, they often question their role in the workplace and their decision to become a medical professional. These questions are generally supplemented by decreased motivation and loss of interest.

92.6.6 Overlapping Symptoms

As the symptoms of burnout heavily overlap with psychiatric conditions, such as adjustment disorder and major depressive disorder, the conditions are often difficult to understand within a patient. Early assessment and treatment of psychiatric disorders can occur with a psychiatrist's proficient psychological knowledge and clinical diagnostic experience to reduce the impacts of the illness.[34] Although chronic fatigue, exhaustion, and burnout share some common symptoms, chronic fatigue is not situation-dependent. Also, the lowered energy associated with burnout tends to be prolonged compared with exhaustion.

There are a few biomarkers that have been isolated to help differentiate burnout from other mental health disorders.[35] Decreased DNA methylation at the NR3C1 glucocorticoid receptor gene and the SLC6A4 serotonin transporter gene have been noted in burnout.[36] This pattern

of methylation appears different from that seen in patients who are depressed or in the stress response. There is also increasing interest in the differences in methylation in the BDNF gene in depression, stress, and burnout.[37]

92.7 BURNOUT ASSESSMENT

Table 92.1 summarizes burnout assessment tools.

92.8 A PREVENTION MODEL FOR RISK FACTOR REDUCTION

Since physician burnout is a systemic problem, changing the systems of healthcare and addressing the roots of the problem will require an effort by multiple parties in the system. The National Academy of Medicine is leading the national-level movement to improve the structure, organization, and culture of healthcare.[1] In Merlo and Rippe, specific interventions for burnout to be conceptualized as risk factor reduction using an occupational health prevention model have been proposed.[38] Physicians who practice healthy lifestyles not only affect their quality of life but also result in improved patient care. Prevention can be inordinately helpful in health promotion prior to disease onset. Of note, in occupational health, the standard approach to describe the process of risk reduction includes three levels: primary, secondary, and tertiary levels. While this approach is relevant to the discussion of burnout risk reduction, the Merlo and Rippe Model adds a fourth category—primordial prevention—which can increase the efficacy of the model. Figure 92.1 describes the intervention stages for the effective prevention of burnout using lifestyle medicine.

92.8.1 Primordial Prevention

Primordial prevention is a mechanism that avoids risk factors for burnout before they can affect the individual. This

TABLE 92.1
Burnout Assessment Tools

Assessment Tools	Abbreviation	Number of Items	Cost	Description
Maslach Burnout Inventory-Human Services Survey for Medical Personnel	MBI-HSS	22	Modest	Covers emotional exhaustion, depersonalization, and low sense of personal accomplishment
Oldenburg Burnout Inventory		16	None	Positively and negatively framed items. Covers exhaustion and disengagement from work
Copenhagen Burnout Inventory		19	None	Positively and negatively framed items. Covers personal, work, and client-related burnout
Stanford Professional Fulfillment Index	PFI	16	None for non-profit use with permission	Covers work exhaustion and interpersonal disengagement from burnout and professional fulfillment
Well-Being Index		7 or 9	Free for non-profit and research use with permission	Identify distress in several dimensions with yes/no responses

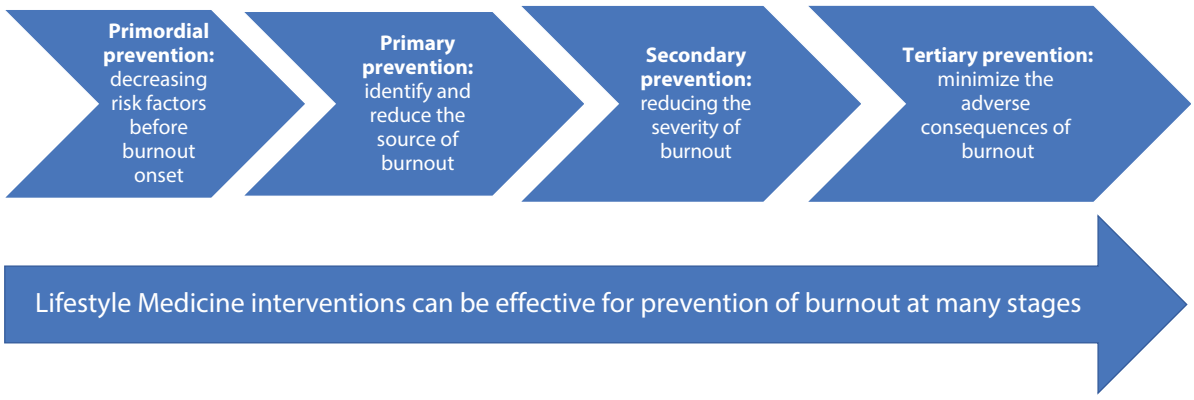

FIGURE 92.1 Individual-focused burnout risk reduction strategies can target primordial, primary, secondary, and tertiary prevention (figure from Merlo G, Rippe J. "Physician burnout: a lifestyle medicine perspective". ***American Journal of Lifestyle Medicine*** 2021, 15(2):148–157.Used with permission of the Editor, Dr. James Rippe).

concept was highlighted by the American Heart Association (AHA) in 2010 as a technique to reduce the impact of heart disease by avoiding risk factors.

Lifestyle medicine welcomes healthy living to decrease risk factors for burnout by intervening in all six pillars of lifestyle medicine. These interventions improve physical and mental health, thus serving as a preventative buffer to burnout. Focusing on forming and maintaining healthy relationships can weaken feelings of loneliness and social isolation.[39] Building these supportive networks in the workplace along with seeking to reduce stigma about burnout, increasing or maintaining job control, maintaining physical well-being through exercise, adequate sleep, and avoiding tobacco and other risky substances are all ways to prevent and reduce the risk factors of burnout before it begins.[40] Strategies that are personalized include self-care, healthy eating, wellness, mindfulness, and social connectedness.

92.8.2 Primary Prevention: Primary Prevention Strategies Can Be Systems-Based and Individual-Focused

92.8.2.1 Systems-Based Primary Prevention

Primary prevention interventions are typically systems-based and seek to identify and minimize the source of burnout by promoting change within the organization. This mechanism emphasizes human care, empathy, compassion, and overall workplace culture that may allow physicians to find purpose in their work. Systems-based primary prevention has six major goals, as outlined by the National Academy of Medicine Clinician Burnout committee:[11]

- Create positive work environments: Reform healthcare work systems by creating work environments that minimize burnout and reinforce quality healthcare. To promote joy in the workplace, organizations should implement programs that support the well-being of healthcare workers and improve patient satisfaction.[41] These designs should be human-centered and followed along with the co-creation of a healthy work culture and organization with physicians.
- Create positive learning environments: Promote learning within the workplace by modifying the education and training of health professionals. The consistent opportunities for growth and learning slow and prevent the progression of burnout and foster professional well-being.
- Reduce administrative burden: Strengthen clinicians' professional well-being by minimizing the pressure and stress from regulations and standards brought by standards-setting entities such as government agencies from all levels, professional organizations, and accreditors.
- Enable technology solutions: Increase the use of technology within healthcare settings to optimize patient care and support the clinician.
- Provide support to clinicians and learners: Encourage seeking support and reducing the stigma surrounding burnout. Supporting the services that prevent and improve burnout will promote professional well-being within the work environment.
- Invest in research: Increase the research on clinician professional well-being by allocating funds and resources.

92.8.2.2 Individual-Focused Primary Prevention

Systems-based primary prevention strategies may also be implemented as individual-focused lifestyle medicine interventions, as described in the primordial prevention section. Despite the similarities, primary prevention addresses the symptoms of burnout after they are experienced by a physician, whereas individual-focused primary prevention will mostly be in the workplace. Primary prevention measures also address the unmet psychological and professional needs of physicians, including workload, community, emotional support, decreasing isolation, and personal issues. One recent study investigated a nine-month facilitated peer group support based on the Balint approach for physicians meeting twice a month and was found to reduce burnout symptoms.[40] Mindfulness has been shown to reduce burnout, reduce medical errors, and increase professionalism.[42] Professional coaching interventions may also be helpful.[43] Enhancing professional self-efficacy represents one of the ways to decrease stress and potentially prevent burnout. Bandura discusses ways to improve self-efficacy through experiences that help in performance mastery either directly or vicariously (watching a colleague affect change). Some suggest that healthcare organizations should adopt a distributive leadership model, and have physicians actively design and lead.[25]

92.8.3 Secondary Prevention Interventions

Secondary and tertiary prevention interventions address the symptoms rather than the root of burnout. Secondary prevention interventions seek to minimize the consequences and severity of burnout after they are noted through early detection and aim to treat the burnout symptoms before their negative impact on the individual and the community. Developing an ongoing screening program using validated approaches standardizes the secondary prevention process. In addition, providing resources for the detected physicians will foster an open community and lessen the stigma surrounding burnout, while promoting a healthy culture of professional well-being. Other examples of secondary prevention techniques that follow lifestyle medicine include stress management programs and mindfulness techniques. Practicing mindfulness effectively guides the physician's

mind toward reducing distress about factors out of their control.

92.8.4 Tertiary Prevention

Since physicians may fail to be noticed by primordial, primary, and secondary prevention, tertiary prevention aims to mitigate the consequences of the ongoing condition. Tertiary prevention utilizes employee assistance programs and referrals to ensure that the individual has the resources to support their health and prevent further deterioration of their well-being. Clinical depressive disorders and anxiety disorders, among other psychiatric disorders, may result from burnout.

92.8.4.1 Nutrition in Depression and Anxiety

Studies show that a healthy diet is associated with a lowered risk of depression.[44] Additionally, one meta-analysis concluded that following a plant-based Mediterranean diet led to a 27–32% risk reduction of depression.[45] Some studies have reported that the link between the gut microbiome and depression and anxiety is improved with probiotics and is influenced by lifestyle factors, including stress, diet, and dietary inflammatory index.[46,47]

92.8.4.2 Exercise in Depression and Anxiety

Many studies show the beneficial impact that exercise has on mood, stress, anxiety, and sadness to treat depression and anxiety.[48–50] Several neurological pathways are involved with these effects, including increased grey and white matter volume, neurogenesis changes in the hippocampus, heightened production of vascular endothelial growth factor, and the formation of new synapses between neurons.[51–53]

92.8.4.3 Tobacco Use and Psychiatric Disorders

Tobacco use is associated with increased risk for psychiatric disorders, namely depression and anxiety.[54,55] Supporting this association, a recently published meta-analysis showed that smoking tobacco significantly increased the risk of depression.[56]

92.9 CONCLUSION

Lifestyle medicine can be influential toward the treatment and prevention of burnout by informing healthcare professionals about intervention measures. Significant literature validates that healthy lifestyles effectively improve health and lower the risk for chronic disease; thus, they should be optimized when addressing burnout. Lifestyle medicine encourages physicians to find a sense of purpose and joy in their work. Working without satisfaction and meaning may misalign providers' values and the healthcare system. Helping patients improve their lifestyles to be healthier and decrease the symptoms of chronic disease within their everyday lives will professionally gratify the physician. Applying lifestyle medicine practices can help reduce the ever-present and significant challenge of physician burnout.

CLINICAL APPLICATIONS

- Applying lifestyle medicine interventions is crucial for minimizing the risk of burnout and promoting healthy lifestyles in lifestyle medicine practitioners.
- Lifestyle medicine clinicians ought to take an active role in medical education to help future generations of medical professionals be more prepared to address self-care and wellness through prevention.
- Physicians can attend to their own self-care by embracing the six pillars of lifestyle medicine, thereby modeling healthy behaviors for others in the healthcare system.

93 Lifestyle Medicine Research

Micaela Karlsen, PhD, MSPH and Kara Staffier, MPH

KEY POINTS

- Lifestyle-based medical treatment is founded on well-established areas of research on health behaviors, including diet, physical activity, sleep, stress management, social connection, and avoidance of risky substances such as drugs and alcohol.
- Original research on how to operationalize lifestyle medicine (LM) in practice is growing, but many gaps remain.
- Guideline development is the ultimate goal of translating evidence into practice.
- More research is needed at all levels in the hierarchy of evidence to advance the field of LM and create an adequate research base for guideline development.
- Clinicians can maximize their contributions by collaborating with academic researchers on larger-scale/more rigorous projects.
- Clinicians whose capacity for research is limited to what can be embedded in existing clinical care may wish to publish case reports, retrospective chart reviews, or results from existing structured programs.

93.1 CURRENT STATE OF LIFESTYLE MEDICINE RESEARCH

The importance of health behaviors in the areas of nutrition, physical activity, sleep, stress management, social connection, and avoidance of risky substances such as drugs and alcohol are well established, with an evidence base comprised of thousands of original works of research. All of these individual domains of health behavior have a multitude of prospective cohort studies and randomized controlled trials demonstrating the positive benefits of eating whole, plant foods, engaging in regular physical activity, maintaining good quality sleep, minimizing chronic stress, nurturing social relationships, and avoiding drugs and alcohol. The top risk factors for chronic disease have been identified as modifiable factors (smoking, high BMI, high blood glucose) influenced by lifestyle choices, such as found in the Global Burden of Disease Study,[1] as well as in large prospective cohort studies such as the Harvard Nurses' Health Study and Health Professionals Follow-up Study.[2] It is known that when individuals, on their own, practice healthier lifestyles, they have better health outcomes.

Due to this extensive foundation of evidence, existing clinical practice guidelines, such as those from the American Diabetes Association, American Heart Association, and American Cancer Society,[3–5] recommend lifestyle approaches as a foundational part of primary care and management of chronic conditions. However, even given this consistent theme in guidelines, the health improvements that are possible following lifestyle modification as medical treatment and the implementation of lifestyle medicine (LM) into standards of care are not yet well-explored. Much more peer-reviewed data is needed on lifestyle treatment as a form of medical care with the ability to treat and/or reverse disease. Subsequently, data is also needed on the factors that facilitate adherence to the prescribed lifestyle treatments in the short- and long-term, and on the capacity of lifestyle-based treatment to work well in the current fee-for-service model and emerging value-based models of healthcare reimbursement.

At the same time, research focused on LM has dramatically increased in peer-reviewed publications in recent years. A Medline/PubMed search for these keywords yields 878 results in total at the end of November 2022, with only 161 of these being reviews. When restricted to the title/abstract (narrowing to articles more centrally focused on lifestyle medicine), a total of 549 results remain, with only 124 being reviews. Additionally, there are also substantial numbers of publications on some of the specific aspects of LM practice that do not necessarily use the keywords "lifestyle medicine", such as physician activity prescriptions and shared medical appointments. Thus, the body of original work is growing and will continue to grow in the future as more professionals become aware of the remarkable results possible with lifestyle interventions, and as academic researchers see the potential of partnering with LM clinicians.

The purpose of this chapter is to provide LM clinicians with an orientation on research methods and strategies to encourage active participation in research.

93.2 WHY DO WE NEED RESEARCH? EVIDENCE LEADING TO IMPROVEMENTS IN CARE

Evidence-based medicine (EBM)[6] has refined our understanding of how to make medical decisions and has emphasized the need for trustworthy clinical practice guidelines based on current, best research evidence to improve the

DOI: 10.1201/9781003227793-109

quality of care. Guideline development is the ultimate goal in translating evidence into practice, and guideline development in the field of LM is just beginning. Developing multidisciplinary guidelines offers the most meaningful opportunity to influence practice decisions, and while most existing guidelines for managing chronic disease mention lifestyle, very few, if any, provide clear and actionable recommendations to help clinicians operationalize a broad injunction to incorporate lifestyle into treatment. Guideline recommendations are optimally based on high-level evidence, such as randomized controlled trials (RCTs) or systematic reviews of such trials, but for many LM interventions for chronic disease, the evidence base is less robust. The field of LM needs more research to be conducted to demonstrate the effectiveness of lifestyle interventions for chronic disease, characterize best practices in LM treatment, and augment the evidence base for developing clinical practice guidelines,

To build a body of evidence, construct a theory, and demonstrate a causal relationship (e.g., showing that lifestyle treatment prompted improvements in health outcomes), a body of consistent evidence from a variety of practice settings is needed. To eventually justify resources being spent on large-scale, rigorous clinical trials, it is often necessary to first produce pilot data, mechanistic data, or survey research to demonstrate proof of concept. Contributing to this pool of observational data creates an opportunity for every LM clinician to get involved, which absolutely relies on the efforts of many to create forward motion and momentum in the research space.

Medical and epidemiological research is often evaluated using the hierarchy of evidence (Figure 93.1), a foundational framework in epidemiology that places lower-cost, easier, and less rigorous research at the bottom and moves up to higher-cost, more complex, and more rigorous research at the top. Evidence making the strongest case for causality is placed at the top. Different variations, including similar diagrams, of the hierarchy of evidence exist and are available online. In a similar vein, a variety of organizations have defined their own "levels" of evidence,[7] such as the Centre for Evidence-Based Medicine[8] or the GRADE Working Group.[9] These evaluations are used in conducting systematic reviews and then sometimes in using the evidence in an evidence to decision-making process to write guidelines.[10] However, all place weaker study designs that are primarily hypothesis-generating at the bottom and strongest designs supporting causality at the top.

Typically, systematic reviews and meta-analyses, which combine and synthesize the results of multiple studies on the same exposures and outcomes, are considered the strongest form of evidence because they provide support for the consistency and repeatability of results (discussed below). It is possible to conduct a systematic review on any type of study, but those that synthesize the results of randomized controlled trials are considered the strongest evidence, followed by those on prospective cohort studies.

While there are several challenges specifically associated with implementing a randomized controlled trial design in lifestyle and behavioral research, with the top challenge being that is difficult if not impossible to randomize individuals to a health behavior and expect them to remain adherent for years following that randomization,[11] that does not mean the goal of RCTs should be abandoned. Many intermediate and short-term outcomes can be examined in an RCT context, and blinding of subjects to their group, though typical in pharmaceutical research, is not necessary. While prospective cohort studies are well-suited to capturing hard endpoints (mortality rates) and outcomes over the lifespan, lifestyle interventions can perform well in an RCT context, and it is important to utilize this highly important form of study design.

In regard to advancing the field of lifestyle medicine research, *conducting research at any level* (depicted in Figure 93.1) *has the potential to make a valuable*

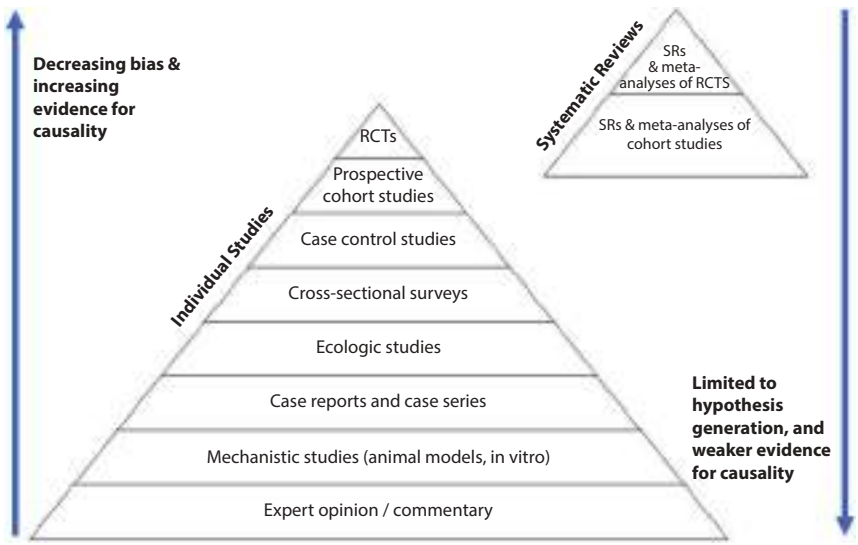

FIGURE 93.1 The hierarchy of evidence. RCT, randomized controlled trial; SR, systematic review.

contribution. Biochemical researchers engaged in mechanistic studies using animal models may wish to consider asking questions relevant to lifestyle medicine practice. Epidemiologists can consider administering cross-sectional surveys to LM practitioners and patients. Clinicians who observe improvements in patients following lifestyle treatment may wish to publish case reports on their results. All stages of research can contribute to the eventual justification of a randomized controlled trial (RCT) on a specific question. The cost of an RCT is high due to the logistics, number of team members needed, data collection and biometric assessments, and follow-up required to run a successful trial. However, the more lower-level evidence that exists, the stronger the justification for funding a larger, rigorous study such as an RCT.

The reason for categorizing evidence in this way is to describe the *relative contributions* made by different types of evidence toward building a case for a causal relationship between the exposure or intervention of interest and the outcome of interest. In public health and epidemiology, the case for a causal relationship is evaluated by considering the breadth of the evidence, and one common conceptual model used is the Bradford Hill Criteria. This set of criteria was first introduced by Sir August Bradford Hill in 1965[12] to create a basis for decision-making in occupational medicine when identifying causes of disease. Though various updates have been proposed[13, 14] for better application to modern epidemiology and medical science, overall, this framework continues to serve as a useful organizational principle for building a theory and identifying gaps in the literature. The original nine criteria are presented in Table 93.1.

To address all of the points in Bradford Hill's list takes more than one or even several studies; thus, growing the body of evidence with a variety of study designs is critical. Table 93.2 presents a summary of study designs, strengths, and limitations. Clinicians interested in participating in LM research can consider which of these are possible, given resources, organizational support, time/bandwidth, and funding.

The selection of a particular design depends on the research question and gaps being filled, the previous evidence in existence, and the resources available to execute a study. In addition to the characteristics of the study design itself, other aspects of the study design affect rigor and feasibility. For example, a prospective study, in which data collection is conducted before the outcome is observed, provides stronger evidence of causality than a retrospective study, in which data collection happens after the outcome has been identified. Cohort studies, case-control studies, and case series may be either prospective or retrospective. Often, a retrospective patient chart review might be less expensive and easier to execute than a prospective case-control or cohort study.

Finally, an experimental design will produce stronger evidence for causality than an observational design because without manipulating the exposures or intervention(s) of interest, it is more likely outside factors (confounders) could influence the outcomes in ways the analysis does not account for.

TABLE 93.1
Bradford Hill Criteria for Causality and Application in Lifestyle Medicine Research

Criterion	Example Applications in Lifestyle Medicine
Strength of the association (the effect size)	Is the effect observed statistically and clinically significant? Does HbA1c drop by a large margin or by a tiny amount with a particular diet or exercise program? With a particular medication?
Consistency (repeatability)	Is the effect repeated across different settings and by different researchers? Are different clinicians and researchers able to reproduce the same drop in HbA1c? A result that is found in one instance and never repeated provides limited evidence that the effect seen is real and not due to chance.
Specificity (result is limited to a particular population or setting)	Is the effect observed broadly or only under certain circumstances? Are all individuals with type 2 diabetes able to reduce their need for medications or is that limited to those who make specific lifestyle changes or undergo specific interventions?
Temporality (cause has to proceed the effect)	Does exposure or intervention lead to the outcome? This is the most important of all the criteria. If any evidence is produced demonstrating the opposite, it does not matter how much convincing data there is of other kinds. Does weight loss happen before dietary habits are changed? If not, then the dietary changes did not cause the weight loss.
Biological gradient (dose-response relationship)	When the dosing of LM treatment goes up, does the effect size also increase? Do patients with type 2 diabetes make greater gains in blood glucose control with larger changes in diet as opposed to more modest changes?
Plausibility (biological mechanism)	Though outcomes in humans may be visible, is there an understanding of why they are happening? What is the biological mechanism that leads to insulin resistance, or reversal of insulin resistance?
Coherence (alignment with existing evidence)	Are the effects observed consistent with other relevant evidence in the field? Is a dietary intervention used to treat type 2 diabetes similar to the kind of diet eaten by populations with very low rates of type 2 diabetes?
Experiment (reducing the exposure reduces the effect)	Can an experiment be conducted to demonstrate a change in the outcome after changing the exposure? When the dosing of LM treatment is reduced, do the same strong effects remain?
Analogy (similarity with other cause-and-effect relationships)	Is there another exposure/intervention that is similar and might produce a similar outcome? Is the blood-cholesterol-lowering effect of eating legumes more similar to the effect of eating vegetables than red meat?

TABLE 93.2
Research Designs Used in Public Health and Medical Research

Design and Definition	Strengths and Best Uses	Limitations
Systematic review Summary of current literature on a particular research question or topic, using predefined inclusion criteria but also following a specific protocol accepted for systematic reviews that involves multiple reviews and a strict inclusion process.	Best used to summarize the weight of the evidence on a particular topic. Most guideline development methods begin with a systematic literature search and screening process that follows systematic review (SR) methodology. All meta-analyses begin with a SR. Because the research question and inclusion/exclusion criteria are defined *a priori*, the risk of bias is minimized. SRs are distinct from narrative reviews, which may introduce the bias of the author around the topic.	Systematic reviews ideally require a team leader with experience in methodology, the participation of a research librarian to assist in searching multiple databases, and multiple team members to properly screen literature, extract data, and help synthesize results. Best practice is to use a team approach.
Meta-analysis Researchers gather data from multiple studies that meet predefined inclusion criteria and analyze data as one dataset	A quantitative synthesis of multiple studies in the field that examined the same exposure and outcome, among similar sample populations. Data from individual studies are pooled and analyzed as one. All meta-analyses begin with a systematic review.	The validity of the results of a meta-analysis depends on how similar the sample populations were to one another, as well as how similarly the exposure and outcome variables were measured. Best practice is to use a team approach.
Randomized controlled trial (RCT) Intervention study with two or more groups, in which individuals or subgroups are randomized to receive either an intervention or a control treatment.	RCTs are typically considered the "gold standard" of research and provide the strongest evidence of causality. Parallel designs are a good choice when there is adequate funding to recruit enough subjects to achieve the desired statistical power. Crossover designs allow investigators to use a smaller number of subjects and test whether the results hold up after exposure to a different experience. Addresses the question of temporality (causes precedes effect), a requirement for causality.	Can be expensive; difficult to randomize lifestyle behaviors over the long term, and results may not apply to long-term outcomes or may have limited external validity. Best practice is to use a team approach.
Intervention trial (single arm) Intervention study with only one group—all subjects receive the intervention.	Can be more affordable and feasible to execute. In clinical settings, a small cohort of patients going through an LM program presents a good opportunity to analyze their results as a single-arm trial and might be something that can be worked into existing workflows with less disruption as compared with planning an RCT.	Because it lacks a control or comparison group, there is less support for specificity, and the case for causality is weaker. Most likely requires a team.
Cohort Compares disease outcomes in more than one group of subjects with different exposures.	Comparing groups of subjects is ideal for being able to generalize results; observational cohort studies allow the study of long-term outcomes. Large sample sizes provide greater statistical power. Cohort studies are a more affordable way to study large groups of people over the long term than RCTs.	Can be expensive to recruit; loss to follow-up may attenuate results. External confounding may be present.
Case-control Compares exposure outcomes between cases (those who have the disease) and controls (non-diseased who were selected to be matched to cases).	Less expensive than cohort studies, no loss to follow-up. Odds ratios can be calculated from case-control studies. Correct application is when the outcome is rare—in these instances, the calculated odds ratio will approximate the risk ratio.	Not typically used when the disease is not rare—in these instances, the odds ratio will overestimate the risk ratio.
Cross-sectional survey A survey that measures a snapshot in time—could be prevalence of disease, death rates, or exposure proportions	Inexpensive compared to RCTs or cohort studies, excellent for generating hypotheses and getting confirming data. Online survey methodology is now a developed field, making it possible to reach disparate geographic or demographic groups in a single study.	Cannot address the question of temporality (cause precedes effect), a requirement for causality.
Ecologic study Assesses correlations between conditions and outcomes in a geographic area—for instance, the correlations between death rates for heart disease by country and average consumption of total dietary fat by country.	Useful for exploratory research to generate hypotheses about possible causal factors for disease, may lead to observational cohort studies and RCTs. It is possible to examine a broad hypothesis and compare patterns across countries, often with publicly available datasets, such as disease burden or consumption patterns.	Ecologic fallacy is attributing the disease outcomes (death from CHD) to the individuals who have the highest rates of fat consumption, when these may, in fact, not be the same individuals
Case reports/series A descriptive study illustrating novel or unusual features of a patient or medical practice.	Case series focus on a number of patients or conditions and how they are related, often describing a similar trajectory through disease and/or treatment. Case reports and series, while lower in the hierarchy of scientific evidence, are valuable as an important mode of communication to make others in the field aware of unusual presentations, complications, or treatments	Case reports and case series are hypothesis-generating and may contribute to the overall coherence of evidence on a topic but, by themselves, do not present strong evidence for causality.
Mechanistic studies Examines precise biological mechanisms in a given cause-and-effect relationship.	Includes in vitro studies and animal models. In vitro studies allow the study of specific mechanisms, are less expensive than studying humans or animals, and pose fewer ethical concerns. Animal experiments allow for the investigation of processes that are common to all or many organisms. Allows measurement and experimentation over the entire life cycle; can ask questions that will not be asked in a human population	Results of in vitro and animal studies may not be generalizable to humans. Further, animal studies may raise ethical issues.

93.3 CONTRIBUTING TO LIFESTYLE MEDICINE RESEARCH FOR CLINICIANS

LM clinicians are uniquely poised to conduct certain levels of scientific research independently, as well as partner with academic/university researchers. There are many advantages to partnering with academic researchers, with some top benefits including the expertise in study planning, data collection, statistical analysis, and scientific writing that most rigorous studies require. Additionally, the work of conducting a study, especially a larger or more rigorous one such as an RCT, will require *substantial bandwidth for extra work beyond what is already required as part of clinical care*. Study recruitment, administration, tracking, data collection, and follow-up with subjects all take time and resources. Finally, there are certain universal requirements for engaging in human subject research that an experienced partner with access to institutional resources can provide, or facilitate access on behalf of the project, such as CITI training and institutional review board (IRB) review of the study protocol, discussed below. Although larger clinical institutions may have access to an IRB, the process would still require significant time on the part of the investigator to prepare materials for IRB submission.

If funding, through either an academic or clinical appointment, supports the effort to conduct research, then it is likely that research is already part of the job/role expectations. If a clinician's role is entirely clinical, the opportunity to engage in research independently is more limited, and the potential for impact can best be maximized by collaborating with an outside group. For many clinicians, the best way to contribute to this effort is to collaborate with academic researchers who have greater capacities in terms of their team members, library support system, facilities, and expertise in scientific methods and writing. For others, who may have more bandwidth, experience, or team resources, there are several ways to get involved directly.

Academic or university researchers have several challenges that would make it appealing to partner with LM clinicians. They often may not have access to a clinical setting in which to deliver medical interventions. Recruitment of subjects is often challenging. Research scientists, while aware of specific requests for funding proposals, may lack an appropriate clinical match to respond to the announcement. They may not be qualified to conduct biometric testing on human subjects or have access to medical facilities to do so. Also of note is the fact that many funding sources are focusing on supporting interdisciplinary, collaborative research; thus, partnering may be appealing.

Clinicians may wish to browse the faculty pages of public health, nutrition, medicine, exercise physiology, and other relevant programs within local universities to find researchers whose interests and experience may be a good fit for LM. A simple email introduction and request to meet may be enough to spark a future collaboration—though it may require multiple conversations and potentially some waiting for the right funding source for an opportunity to take off.

What follows is a discussion of key elements of research involvement, which should provide orientation for some of the nuts and bolts required in conducting research, whether an individual is in a leadership role or simply writing a case report on one patient.

93.4 LITERATURE SEARCH AND REVIEW

No matter how novel or interesting a research question may seem, that novelty needs to be communicated to the larger scientific and medical community. The following questions should be answered when planning a study to justify the project and provide context:

1. What is known and not known about the relevant disease and/or lifestyle intervention—what are the gaps in the knowledge base?
2. What are some proposed mechanisms for the clinical outcomes observed?
3. Why is the study important, and what can other scientists and clinicians learn from this work?

The goal of a literature search is to identify work in the field that is relevant to the research question. In any publication, the discussion of topics such as what is known/not known and proposed mechanisms should be supported by published references, and a literature review is a key tool for identifying appropriate references.

A systematic literature search is conducted using databases such as PubMed and Medline, which are commonly used for health and medicine topics. However, many other databases exist, such as Embase, Cochrane Library, CINAHL, and PsycINFO, and may be appropriate to include depending on the topic. While a comprehensive tutorial on literature searches is out of the scope of this chapter, a brief overview is provided in Figure 93.2. There are many published resources available[15] as well as training materials[16] on how to effectively conduct a literature search.

The nature of novel topics is such that there may not be a good deal of relevant information *directly* related to the

FIGURE 93.2 Workflow of a literature search.

research question, but the literature search finds what is relevant and what provides appropriate background to define gaps in knowledge. For example, if the intended publication is a case report on the use of a whole food, plant-based (WFPB) diet to reverse symptoms of rheumatoid arthritis (RA) in a patient, there may not be literature directly on WFPB diets and reversal of RA. What may exist is literature on diet and autoimmune disease, or on plant-based diets reducing inflammatory biomarkers. Such literature may help to generate a hypothesis about a potential mechanism by which a WFPB could improve symptoms of RA, thus framing the case report presented.

93.5 WORKING WITH AN IRB

The goal of an IRB is to minimize risks for research study participants. IRBs are tasked with ensuring that any risks to human study subjects are appropriate. IRB review applies to research on human subjects. Per the 2018 common rule,[17] *research* is defined as "a systematic investigation, including research development, testing, and evaluation, designed to develop or contribute to generalizable knowledge", and *human subject* is defined as

> a living individual about whom an investigator (whether professional or student) conducting research: (1) obtains information or biospecimens through intervention or interaction with the individual, and uses, studies, or analyzes the information or biospecimens; or (2) obtains, uses, studies, analyzes, or generates identifiable private information or identifiable biospecimens.

Risks to human subjects can include physical risks, psychological risks, social/economic risks, legal risks, and loss of confidentiality with respect to data and identifiable information collected in research. The 1979 Belmont Report[18] released by the National Commission for the Protection of Human Subjects in Biomedical and Behavioral Research outlines ethical principles and guidelines for the protection of human subjects in research. IRB review committees are guided by these principles in their role of protecting the rights and welfare of research subjects.

While human subjects research that is supported, conducted, or regulated by US federal departments *requires* IRB review, most organizations extend requirements to require IRB review for all human subjects research. In addition, it is important to note that even if an investigator is not affiliated with an organization that requires IRB review, most peer-reviewed journals will require IRB review in order for work to eventually be published.

Many health or hospital systems have their own internal IRBs, making it possible for employees to utilize their services directly. For clinicians in private practice, or in systems without such resources, partnering with an academic researcher or other collaborator with access to an IRB will eliminate this problem. An additional solution is to use a commercially available IRB, or "IRB for hire". One consideration with respect to IRBs for hire is that they are typically fee-based per service request and will charge for each change or amendment submitted, as well as any requested re-review of a protocol. Such costs should be factored into a study budget.

The first step when considering any research involving human subjects is identifying which IRB will receive the submission of the study protocol. Most IRBs have guidance and forms electronically available, so it is recommended to access the IRB's resources to determine what type of review the study will be eligible for and determine what components are needed for the submission. IRB staff are generally highly knowledgeable and available to answer questions. While it is recommended to first read forms and guidance published on the website, investigators may contact the IRB for questions and/or clarifications.

Allow adequate time for IRB review. It is not uncommon for a study undergoing a full review to take weeks or months depending on resources and personnel. It is suggested that one reach out to your IRB to inquire about timelines, particularly if the request for review is time-sensitive. In addition, it is not uncommon for IRB reviewers to ask for additional information and/or revisions to a submitted protocol. This process can add additional time, and all queries/comments from the IRB need to be addressed before a review can be finalized.

Finally, the research team should be involved in any IRB submissions. While the principal investigator will likely lead the development of the protocol, other team members such as project managers/coordinators, research assistants, and statisticians can assist with tasks such as completing forms and developing material which may include data collection tools and recruitment strategies and materials, all of which must be submitted for the IRB to review.

It is important to note that some journals do not require IRB approval to publish case reports, as long as the case has provided consent to have his or her data published.

93.6 SELECTING ASSESSMENT TOOLS AND MEASURES

In writing a research protocol, one key component will be the selection of assessments.

The selection of surveys, biometric assays, anthropometric assessments, or other measures will be influenced by the research question, previous work in the field, and feasibility. The goal is to minimize bias (error) while enabling the data collection necessary to answer the research questions.

Objective measures, such as biomarkers, health metrics, and anthropometric measurements performed by a researcher provide data subject to minimal bias. What inaccuracy may exist can be due to data collection errors or instrument variability.

Subjective and self-reported measures, such as survey data or self-reported height and weight, are also important and often more feasible to collect but may be at risk of greater reporting bias. For example, it has commonly been observed that individuals over-report height and

under-report weight.[19] When the research goal is to understand patient experience, survey data or in-depth interviews will be the best assessment to use. BMI calculated from self-reported height and weight on a survey is a common data point used in epidemiological research, even though it is known to be subject to reporting bias.

In nutrition research, for instance, the use of biomarker data paired with survey data can greatly enhance what can be gathered from surveys alone.[20] For example, a dietary assessment survey might be verified with specific biomarkers relevant to the dietary intake of interest, such as using urinalysis to measure urinary amino acid excretion as a measure of protein consumption and comparing that to what was reported on a 24-hour diet recall or food diary.[21]

In the field of LM, biometric data characterizing disease status and risk for disease is of primary importance, such as blood pressure, blood lipids, blood glucose, and BMI. The American College of Lifestyle Medicine has established a recommended set of performance measures (both biometric and surveys) to assess the effectiveness of LM treatment of chronic disease (for more information, visit http://lifestylemedicine.org/measures). Broad and consistent use of these measures will elevate the quality of reporting on LM treatment.

The validity of the selected assessment is an important consideration. *Validity* in research refers more broadly to whether the results of a research study represent the truth in the reference population. *Internal validity* means the extent to which results represent the truth in the study sample, and *external validity* means the extent to which results represent truth in the larger, real-world population.[22] Similarly, the validity of assessment tools refers to the accuracy of the tool in a given set of conditions—Does it measure what it is intended to measure? How well does it capture a true measure of behavior?[23] Repeatability refers to whether the results will be found consistently, from administration to administration, and is a component of validity. Specific types of validity of assessments are presented in Table 93.3.

93.7 CITI TRAINING

In 2000, NIH required human subjects training for personnel involved in NIH grants or contracts involving human subjects research, and the Collaborative IRB Training Initiative (CITI) was born. CITI provides web-based training in human subject research, with over 2500 organizations subscribing, including academic institutions as well as clinical health networks.[24] Learners who are not members of a subscribing institution are able to purchase CITI training for a fee.

The program began with training focused on biomedical research but has since expanded to include a variety of courses including research training for social, behavioral, and education researchers, training on good clinical practice, and training on animal care and biosafety and biosecurity. The trainings contain varying numbers of modules with short quizzes at the end.

In order to submit a protocol to an IRB, all members of the research team will need to have completed the CITI training required by the associated institution. Please visit https://about.citiprogram.org/ to learn more. CITI training does expire, as defined by the institution, typically every three to four years. Individuals are required to complete "refresher" courses to keep training up-to-date.

93.8 EXECUTION OF THE STUDY

Running a research study may require a study coordinator (highlighting the importance of having enough team members) to handle logistics, communications with subjects, and data collection. As the project progresses, it is very important to carefully follow the protocol approved by the IRB and to notify them if any changes are proposed, *before* those changes are made. When changes to a protocol are necessary, typically an amendment will be submitted to the IRB that presents the change to the protocol in detail. The IRB has the opportunity to review this and either accept or reject the proposed amendment.

93.9 PUBLICATION OF RESULTS

There are many resources online for best practices in scientific writing. General principles to keep in mind are to make statements that are direct and concise and avoid unnecessary verbiage. When writing up results and preparing a

TABLE 93.3
Major Types of Validity in Health Research Assessments

Content validity	The extent to which an assessment comprehensively measures what it is designed to measure, while also avoiding measuring things ancillary to the goals of assessment.
Face validity	The extent to which an assessment appears, "at face value" to measure what it is designed to measure. While this is the weakest form of validity because it relies on human intuition, which can be wrong, it is consistent with simply asking direct questions to address research questions. That application is best suited for survey questions on the subjective or perceived experiences of respondents.
Construct validity	The extent to which an assessment measures an identified set of behaviors or variables associated in a meaningful way to create a construct or idea, such as depression, well-being, burnout, or the consumption of a specific dietary pattern.
Criterion validity	The extent to which an assessment, often a survey, correlates with a known gold standard measure.

manuscript, reference managers are essential and allow writers to store and organize references, automatically insert and format citations in appropriate styles for a particular journal, and avoid formatting errors. Common reference managers include Endnote, RefWorks, Zotero (free), and Mendeley (free).

Different journals have very different scopes and submission guidelines. Be sure to carefully check author instructions for the journal to which the submission is planned. Often, submissions that do not follow journal instructions will be quickly returned without review. In selecting a target journal, it is important to read about the journal's scope, as well as review similar published research in that journal, to determine whether the topic is a good fit. This can be particularly relevant to lifestyle medicine. While it is valuable to share lifestyle medicine research with the broader medical community, do not be discouraged if your first, second, or even third submission to a journal is not accepted—keep trying! Journals often reject articles, not because of poor quality but because the topic does not fit within their desired scope.

Either at the time of submission or upon acceptance, an author may be asked to decide whether to publish the paper with *open access*. Open access means that anyone who comes across the paper (in an online search, for example) will have the ability to access the full text, regardless of whether they subscribe to the journal. If the article is not open access, non-subscribers to the journal will need to pay a fee to the journal to purchase the article. Open access fees can be several thousand dollars, but if a viable option, can help broaden the readership of a paper. While many large academic and/or clinical institutions provide library access with subscriptions to journals, individuals without institutional access may be limited in their ability to read papers that are not open access.

93.10 RESEARCH EMBEDDED IN CLINICAL CARE

The opportunity to participate in larger-scale research projects, with the benefit of a team or significant time to devote to a project is not possible for all clinicians. For those who wish to contribute research to the field of LM but face logistical constraints, several options exist that may make it possible to publish outcomes with limited additional resources.

Conducting a retrospective chart review of patient records may be a viable option for describing results from an LM practice or program. Such results could be organized as a retrospective, case-control study, for example, selecting cases of type 2 diabetes remission and matched controls to compare their behaviors prior to the outcome of remission. It could also be organized as a case series, simply describing themes and repeating characteristics of patients with similar outcomes.

If a practice or health system offers structured LM programs, with a clear date of entry, curriculum or repeating sequence of education and content, and a regular/pre-post assessment schedule, it may be possible to frame one or more cohorts in this program as a single-arm clinical trial and conduct a pre-post analysis of outcomes.

Both retrospective chart reviews of many (>3) patients and single-arm intervention trials overlayed on existing programming would be considered human subjects research, and therefore would require IRB approval and likely involvement from other team members besides the primary clinician, even if they are able to be merged into existing clinical care.

Publishing case reports or case series, discussed below, is one of the most feasible points of entry into research for clinicians. As mentioned previously, single case reports, and often case series of only a few patients are usually not required to have IRB approval by peer-reviewed journals as long as patient permission was obtained prior to submission to the journal. Some journals provide their own template consent forms, or, if not supplied by the journal, clinicians may use their own. These consent forms are typically not submitted to the journal but are required to be stored in a secure location with the patient's records.

93.10.1 Case Reports/Case Series

A case report is a descriptive study illustrating novel or unusual features of a patient or medical practice. *Case reports* are narratives describing a patient's trajectory through a disease diagnosis and/or treatment. *Case series* focus on a number of patients or conditions and how they are related, often describing a similar trajectory through disease and/or treatment.[25] Case reports and series, while lower in the hierarchy of scientific evidence, are valuable as an important mode of communication to make others in the field aware of unusual presentations, complications, or treatments.[26] Remember, while RCTs are the "gold standard" of scientific evidence, research questions often do not begin at RCTs. Instead, research often begins with the observation of something novel or interesting on a small scale that could be documented in a case report, allowing for the generation of research questions and future exploratory research.

Importantly, publishing case reports or case series is a very accessible pathway for clinicians who wish to contribute to the body of original research on lifestyle medicine, as they can be conducted without the support structure of a research team, grant funding, or a research institution. As stated, the field of LM needs more evidence at all levels in the hierarchy of evidence.

Since the goal of a case report/series is to inform the scientific community about something novel that has not yet been well documented in the literature, lifestyle medicine cases, which are often outliers in conventional medicine, make excellent case reports! Some examples of outliers include cases that (1) exhibit a previously unknown disease; (2) suggest a previously underreported association of two distinct diseases; (3) exhibit features of disease that widely differ from what is usually observed; (4) show success using

a previously unrecognized treatment or intervention, such as a lifestyle medicine approach.

93.10.2 Case Report Manuscript Guidelines

Not all journals accept case reports! Be sure to check before tailoring a manuscript to a specific journal.

The target journal chosen will have specific guidelines for formatting and manuscript structure, so remember to check the requirements. As previously discussed, most journals will require patient consent for case reports/series. Some journals will provide authors with a specific consent form to use for that journal. Before putting significant time into a case report, it is important to inform the patient of the desire to write a case report, obtain their consent to be included, and answer any questions. It should be made clear that no identifying information will be included in a published report. If including photos to highlight the case presentation, it should be discussed with the patient and appropriate consent obtained.

An additional resource is CARE (CAse REports), a set of guidelines that provides a checklist for complete reporting of case reports.[27] Certain journals require submission of the CARE guidelines to them when submitting a case report, showing that all items on the CARE checklist have been addressed. CARE is a useful resource to help guide the process of collecting data and writing a case report (http://www.care-statement.org/).

Table 93.4 presents the key components of a successfully written case report.

93.10.3 Research Abstracts

Another way to share information with both the scientific and clinical communities is by submitting a research abstract to a professional conference. If accepted, there is typically an invitation to present a research poster or, in limited cases, an oral presentation at the conference. Presenting at conferences is an effective way to not only share work but also engage with other conference attendees, ranging from those who may share similar experiences to those who may be learning about the work for the first time. Abstracts can come in the form of presenting case reports or case series; however, another option is if one is a member

TABLE 93.4
Components of a Case Report or Case Series Manuscript

Title	• Descriptive and clear, should end with "… a case report" or "… a case series"
Abstract	• Concise summary of the case report, usually about 250–350 words or half page • Contains key information such as a few brief sentences on background and significance, summary of the case presentation, and conclusions (what is the take-home message) • *A reader's first look into the paper—the more exciting findings and the relative impact are highlighted, the more likely someone is to read the work!* • *Not* simply an excerpt from the manuscript • Draft abstract last—it is easier to summarize the case report and highlight important findings in the abstract after the report is written!
Background	• Should address why the case is notable and why it is being reported • May also include a brief background on the disease or treatment • Put the case into the larger context of what is already known and/or published (refer to the previous section "Literature Search and Review") • Typically ends with one to two lines summarizing the objective or aim of the case report/series
Case presentation—tell the story!	• This is where the details of the case are documented—keep them relevant! • Document chronologically and include specific dates whenever possible. Remember, you are telling a detailed story. • Interview the patient(s) to fill in gaps in the story and include their perspective • Consider all the following and include as relevant: disease presentation or diagnosis; intervention or treatment; lifestyle and behaviors (sleep, diet, physical activity, substance use, stress, social connectedness); medication use; recovery, including clinical symptoms and patient experience before and after lifestyle intervention; relevant medical history of patient; pre- and post- intervention laboratory results; practitioner decision-making • If documenting a lifestyle intervention or change, provide details such that someone reading the case report could replicate the intervention/change • Multiple pieces of information add richness to a case report

Discussion/ Conclusion	• Place the case into a larger content
	  • What was learned?
	  • Clinical impact?
	  • Future implications?
	  • Potential mechanisms by which lifestyle change produced the observed outcomes
	• Can include strengths/weaknesses of the report
	• Discussion of implications can include public health, clinical, scientific, and/or economic implications, to name a few

of a research team with access to a variety of data, a single component of a project or dataset can be identified as the focus for the research abstract.

The American College of Lifestyle Medicine welcomes abstract submissions to their annual conference (https://lmconference.org/), and accepted abstracts are additionally published in a special issue of the *American Journal of Lifestyle Medicine* following the conference. ACLM abstract submission topics are broad in scope and include topics such as "Science of Lifestyle Medicine", "How of Lifestyle Medicine", and "Business of Lifestyle Medicine". Other professional and academic societies similarly host conferences and sometimes publish accepted abstracts. While these conferences may not be LM-focused, they provide a unique opportunity to introduce LM concepts into more mainstream medical practice. Before embarking on a project that will result in a research abstract, it is recommended to check with the approving IRB to determine whether a review is needed. Finally, care should be taken to meet the commonly early abstract submission deadlines, as they are typically at least three to six months before the actual conference will take place.

93.11 CONCLUSIONS

Lifestyle medicine research is growing, but substantial gaps exist related to the application of what is known about health behaviors in the context of medical practice. Lifestyle medicine clinicians are poised to make meaningful contributions to the field of research, supporting the development of a sufficient evidence base from which to write clinical practice guidelines. Clinicians should feel encouraged to engage with the research process to any extent possible, which may mean participating in large projects and collaborating with academic researchers or publishing results from clinical practice on a more limited basis, such as with patient chart reviews or case reports.

CLINICAL APPLICATIONS

- Guideline development is the ultimate goal of translating evidence into practice.
- Standards and quality in clinical care are most influenced by guidelines.
- Guideline development requires sufficient evidence on a given topic.
- It is critical for as many LM clinicians as possible to participate in the collective work of generating evidence on LM practice.

ACKNOWLEDGMENTS

The authors wish to thank Dr. Richard Rosenfeld for his input on guideline development and Kathy Pollard for her assistance with manuscript preparation.

94 Lifestyle Medicine around the World
The WHO Initiative to Combat Non-Communicable Diseases (NCDs)

James M. Rippe, MD and Garry Egger, MD

KEY POINTS

- The WHO has listed non-communicable diseases (NCDs) as the leading global cause of death resulting in over 71% of all deaths worldwide.
- Risk factors focused on by the WHO include tobacco, insufficient physical activity, harmful use of alcohol, and an unhealthy diet.
- Additional factors include hypertension, overweight and obesity, and dyslipidemia.
- The adverse health implications and economic burden of NCDs are enormous.
- Lifestyle medicine modalities such as increased physical activity, proper nutrition, smoking cessation, healthy sleep, and weight management offer valuable, cost-effective tools to help lower the risk of NCDs around the world.

94.1 INTRODUCTION

There is no longer any serious question that daily habits and actions profoundly impact the likelihood of developing chronic disease. This issue is prominent around the world both in high-income countries (HICs) and low- and middle-income countries (LMICs). The understanding that lifestyle habits impact health has led to a major focus from the World Health Organization (WHO) on lowering the risk of and combating non-communicable diseases (NCDs).[1]

There is a significant role for lifestyle medicine concepts and practices in collaboration with the WHO initiative to combat NCDs around the world. The modalities utilized in lifestyle medicine such as increased physical activity, proper nutrition, weight management, avoiding cigarettes, and decreasing anxiety and stress are all profoundly important to countries around the world.[2–4]

The impact of these concepts has been seen around the world with an increasing number of lifestyle medicine organizations being formed and joining the Lifestyle Medicine Global Alliance. Lifestyle medicine modalities carry virtually no adverse consequences and are highly cost-effective. This makes these modalities highly attractive to countries, irrespective of economic situations within the country.

94.2 EPIDEMIOLOGIC TRANSITIONS

It has been argued that public health transitions through various epidemiologic phases.[5,6] This theory holds that previous epidemiologic transitions have included four basic stages:

- Pestilence and famine
- Receding pandemics
- Degenerative and man-made diseases
- Delayed degenerative diseases

During the stage of "pestilence and famine", infectious disease epidemics and hunger were the most common causes of death in virtually every part of the world. The majority of deaths were caused by such infectious diseases as tuberculosis or plague, various forms of pneumonia, and diarrheal diseases. In addition, high incident child mortality rates resulted in a mean life expectancy of approximately 30 years.

During the next epidemiologic period, the "receding of pandemics" was stimulated by public health advances such as improved food production and distribution as well as sanitary conditions such as cleaner water supplies that reduced deaths both from infectious disease and malnutrition. Heart disease became more prominent as a cause of death, with 10–35% of deaths.

The third epidemiologic stage, called "degenerative and man-made diseases", resulted from continued improvements in economic circumstances as well as changes in diet, activity levels, and behaviors such as smoking. Deaths from infectious diseases decreased dramatically and life expectancy increased to almost 70 years. On the other hand, atherosclerosis resulting from increased consumption of fiber-free calories and decreased physical activity became more prominent in this stage, with coronary heart disease (CHD) and stroke accounting for between 35% and 65% of all deaths.

The fourth epidemiologic stage is called "delayed degenerative diseases"[7,8] In this stage, cardiovascular disease (CVD) and cancer became the major causes of morbidity and mortality. The increases in these diseases have been somewhat mitigated by prevention measures, particularly

DOI: 10.1201/9781003227793-110

in the area of CVD. Also, treatment modalities such as coronary care units and increased use of various technologies, including diagnostic and therapeutic technologies, have become increasingly utilized in lowering the risk of CVD mortality. In addition, various pharmacologic treatments for hypertension and dyslipidemia (e.g., statins) have also contributed to reducing CVD deaths. Moreover, public health campaigns have highlighted that certain behaviors increase the risk of CVD, and lifestyle modalities can reduce these risks. For example, cigarette smoking cessation represents a prominent model of success. In 1955, 57% of men smoked cigarettes, but by 2012, only 20% of men smoked and the prevalence of cigarette smoking among US women fell from 34% to 15.8%. Moreover, campaigns to reduce the prevalence of hypertension and elevated cholesterol also showed some success.

Unfortunately, it appears that we may now be entering a fifth epidemiologic stage, which has been characterized as the "age of inactivity and obesity".[9] Obesity has risen remarkably and rapidly around the world, and other NCDs associated with these such as type 2 diabetes (T2DM) and atherosclerosis have continued to be a problem with dramatic increases, particularly in the area of T2DM. It is in this fifth phase of epidemiologic transition that lifestyle modalities are destined to play critically important roles.

It should be noted that different countries and areas around the world may be in slightly different phases of these epidemiologic transitions, which is largely dependent on the economic situation in each country. Nonetheless, NCDs remain a problem, irrespective of the overall economics established for a given country. For example, between 1990 and 2013 deaths from CVD increased from 26% to 32% of all deaths globally with a particularly rapid increase in CVD deaths in LMICs.[10] The overall increase in CVD deaths reflects a dramatic increase in LMICs, while they are in a slight decline in HICs.

94.3 THE SCOPE OF THE PROBLEM OF NON-COMMUNICABLE DISEASES

Non-communicable diseases (NCDs) are the leading global cause of death, resulting in more deaths worldwide than all other causes combined.[11] These diseases are highly prevalent in every country around the world, irrespective of economic conditions. If these diseases could be somewhat ameliorated, millions of lives could be saved. This is the underlying rationale for why the World Health Organization has launched a major campaign to ameliorate NCDs. This started with the first Global Status Report on Non-Communicable Diseases in 2008, followed by the second report in 2013.[11] These reports intended to provide a baseline for countries around the globe to start to ameliorate NCDs and their risk factors.

Of the over 60 million global deaths that occurred in 2019, over 71%, according to the WHO, were due to NCDs.[1] These were principally from cardiovascular disease (CVD), T2DM, cancers, and chronic respiratory diseases. Nearly 80% of the NCD deaths occurred in LMICs. Over 80% of CVD and T2DM deaths occurred in LMICs as well as almost 90% of deaths from chronic obstructive pulmonary disease (COPD). Unfortunately, NCDs also kill at a younger age in LMICs, where 20% of NCDs occur in people under the age of 60, compared with 13% in HICs.

A large percentage of NCDs are preventable, according to the WHO, with the reduction of four main behavioral risk factors:

- Tobacco use
- Physical inactivity
- Harmful use of alcohol
- Unhealthy diet

These are the main focus of the WHO NCD initiative. Of course, these risk factors are also central to the field of lifestyle medicine. Many of the modalities of lifestyle medicine are highly appropriate and cost-effective in helping to combat these risk factors.

94.4 THE ROLE OF LIFESTYLE MEDICINE IN COMBATING NON-COMMUNICABLE DISEASES

As already indicated, the modalities of lifestyle medicine are critically important to lowering the identified risk factors for NCDs. With this in mind, numerous organizations specifically in lifestyle medicines have arisen around the world. They have joined forces in an organization called the Lifestyle Medicine Global Alliance (LMGA).[12] This organization emphasizes proper nutrition (plant-dominated diet), regular physical activity, restorative sleep, stress management, the avoidance of risky substances (e.g., cigarettes and alcohol), and positive social connections. While the issues of sleep and positive social connections are very important and constitute two of the pillars of lifestyle medicine, they are not the behavioral risk factors focused on by the WHO. Nonetheless, the LMGA has joined forces with the WHO in a combined effort to lower risk factors for NCDs.

Numerous medical organizations around the world have now focused more attention on the area of lifestyle medicine. For example, the American Heart Association changed the name of one of its professional councils from the "Council on Nutrition, Physical Activity and Metabolism" to the "Council on Lifestyle and Cardiometabolic Health".[13] Among the lifestyle medicine organizations, the most prominent is the American College of Lifestyle Medicine (ACLM) which has, of this writing, over 9000 members and has grown an astonishing 1200% in the last five years, making it the fastest-growing healthcare organization in the United States![14] Other prominent lifestyle medicine organizations include those in Australia and New Zealand (Australasian Society of Lifestyle Medicine)[15] and also in the UK with the British Society of Lifestyle Medicine[16].

Medical facilities are also increasingly embracing the role of lifestyle medicine. For example, the Fuwai Hospital in China, which is one of the largest cardiovascular diagnostic and treatment centers in China, has recently established the "China Lifestyle Medicine Alliance" and sponsored annual conferences on healthy lifestyle medicine. The initial conference attracted over 600,000 participants, indicating how widespread and deep the interest in lifestyle medicine is in China and around the world.[17]

94.5 MAIN BEHAVIORAL RISK FACTORS FOR NON-COMMUNICABLE DISEASES

As already indicated, the WHO has focused attention on four risk factors that play a particularly prominent role in the underlying metabolic and physiologic causes of the global NCD epidemic. These include tobacco, insufficient physical activity, harmful use of alcohol, and an unhealthy diet. In addition, the WHO has identified multiple other underlying risk factors for the epidemic of NCDs.

- Tobacco: Over six million people die from tobacco use each year. This includes both direct tobacco use and secondhand smoke.[18] It is anticipated that this will increase to over eight million people by 2030. Tobacco use accounts for 10% of all annual deaths including 71% of lung cancer, 42% of chronic obstructive pulmonary disease, and nearly 10% of cardiovascular disease. China has the largest number of smokers, and it has been estimated 301 million smokers in China in 2010. There is a greater than 50% prevalence in men, while Chinese women are much less likely to smoke (only about 2% of women smoke cigarettes). Secondhand smoke also contributes significantly to the risk of coronary heart disease. Since 2011, approximately 600,000 smokers died every year as a result of exposure to secondhand smoke. Smoking bans have had both immediate and long-term effects in reducing the likelihood of hospital admissions for various tobacco-related issues.
- Insufficient activity: The WHO estimates that approximately 3.2 million people die each year from physical inactivity.[19,20] People who are insufficiently physically active increase their risk of all-cause mortality by 20–30%. Regular physical activity has been shown in numerous studies to cut the risk of CVD in half and significantly ameliorate CVD risk factors including high blood pressure, diabetes, and weight gain and obesity. Insufficient physical activity is currently highest in HICs, but high levels are also increasingly being seen in LMICs.
- *Harmful use of alcohol*: Approximately 2.3 million deaths occur each year from harmful use of alcohol.[11] This amounts to approximately 3.9% of all deaths in the world and over half of these deaths are from NCDs including various cancers of the gastrointestinal tract, CVD, and liver cirrhosis. Per capita consumption of alcohol is highest in HICs, although it is also high in populous areas of LMICs.
- *Unhealthy diet*: It is well known that adequate consumption of fruits and vegetables reduces the risk of cardiovascular disease as well as some cancers such as stomach and colon. In addition, most populations consume more salt than recommended by the WHO for disease prevention.[21] High salt consumption is an important risk factor for high blood pressure and CVD risk. In addition, high consumption of saturated fats and trans fatty acids is also linked to heart disease. Unfortunately, unhealthy diet is quickly rising in LMICs. For example, the amount of fat in the Chinese diet increased from 25% to 35% between 1982 and 2002.
- *Hypertension*: Elevated blood pressure is estimated to cause 7.5 million deaths each year, which represents approximately 12.8% of all deaths.[22] Hypertension is a major risk factor for CVD. Elevated blood pressure has increased across all income groups. It is generally the lowest in HICS.
- *Overweight and obesity*: Over 2.8 million people die each year as a result of being overweight or obese.[23,24] Overweight and obesity increases risk for CVD, stroke, and T2DM as well as certain cancers. Overweight and obesity are increasingly found in LMICs but are most prominent in HICs.[25] For example, in the United States, over 70% of the population is either overweight or obese. Approximately half of this population is overweight and the other half is obese. There is an increasing prevalence of overweight and obesity in young children, particularly in LMICs.
- *Dyslipidemia*: Elevated cholesterol is estimated to cause 2.6 million deaths annually.[11] This increases the risk of CVD and stroke. Raised cholesterol is highest in HICs.

94.6 OTHER RISK FACTORS

In addition to those risk factors identified by the WHO for NCDs, there are a number of other risk factors that can contribute to NCDs or are NCDs themselves.

- *T2DM*: The prevalence of T2DM has grown rapidly in the past 30 years and in many ways is parallel to the increase of overweight and obesity.[26] This is particularly prominent in LMICs. Thirty percent of people with diabetes live in LMICs. In some Pacific Island and Middle Eastern European Countries, there are age-adjusted prevalences between 19% and 25%. In the United States, approximately 11% of people have T2DM. In China, approximately

12% of people have T2DM. India and China have the largest numbers of people in the world with diabetes with 61.3 million and 90.0 million, respectively. Some studies have shown that Asian populations may have a higher risk of developing diabetes at even lower body mass indexes (BMI) because of a greater tendency for visceral obesity. There is also an increase in prediabetes. The Global Burden of Disease Study showed that 366 million people had diabetes in 2011 and almost half of these cases are undiagnosed. By 2030, the number of people with diabetes is expected to increase to 122 million. Various lifestyle medicine modalities to lower the risk of diabetes are well established including weight management, proper nutrition, increased physical activity, and not smoking cigarettes. These are discussed in more detail in multiple chapters throughout this book.

- *Infectious disease*: Healthcare providers tend to not recognize the link between lifestyle habits and practices and infectious disease. We know, however, that physically active individuals reduce their risk of various viral illnesses such as influenza and the common cold. Most recently, the link between lifestyle practices and infectious disease has been dramatically shown in the COVID-19 pandemic. Individuals who have high blood pressure or obesity are three to four times as likely to become infected with COVID-19, be hospitalized, and die from this virus.[27,28] Thus, the same types of modalities that are used to lower the risk of various metabolic diseases such as CVD and T2DM are highly relevant to lowering the risk of viral illness.
- *Alzheimer's disease and dementia*: Alzheimer's disease and dementia are increasingly a problem, particularly as the population around the world continues to age. This is particularly a problem in developed countries. Two countries where there are most individuals with Alzheimer's disease are the United States and China. In the United States, it is estimated that 4.9 million people are living with Alzheimer's disease, and in China, it is estimated that 5.4 million people are living with Alzheimer's disease.[29] The relationship between Alzheimer's disease and other forms of dementia and lifestyle factors is prominent and has been underscored by the collaboration between the American Heart Association (AHA) and the American Stroke Association (ASA) which issued the Joint Presidential Advisory on "Optimal Brain Health".[30] This Presidential Advisory recommended that individuals follow the same healthy practices recommended for reducing the risk of heart disease as a way of preserving optimal brain health and lowering the risk of Alzheimer's disease and other forms of dementia.[31]
- *Aging population*: The good news is that the average life expectancy has continued to rise throughout the world, particularly in developed regions. Average life expectancy is estimated to reach 83 years in developed regions by 2025 and 75 years in less developed regions.[32]

  While increases in life expectancy have been significant in HICs, they are also common in LMICs. For example, LMICs are anticipated to double the number of individuals over the age of 60 between 1995 and 2025. LMICs have increased the likelihood of individuals being over the age of 65 much more rapidly than occurred in more developed countries. All of the modalities of lifestyle medicine are highly appropriate for individuals over the age of 65. Once a person reaches the age of 65, they are highly likely to reach the age of 85. For all of these reasons, lifestyle modalities are highly relevant to the aging population.
- *Environmental exposures*: Environmental pollution represents a major cause of death and disease. Multiple exposures to particulate matter pollution significantly increase mortality and morbidity from CVD.[33,34] The GBD Study showed that approximately 30% of disability-adjusted life years (DALYs) come from environmental risk factors.[10] This is largely tobacco smoke, although there are other forms of air pollution prevalent, particularly in an era of global warming. It is estimated that over seven million premature deaths occur from environmental exposure. This is particularly prevalent in India and China, although it also occurs prominently now in many developing countries. Environmental exposure represents an important and relatively new frontier for the modalities of lifestyle medicine.

94.7 ECONOMIC BURDEN

The economic burden of NCDs results not only from direct costs but also from indirect costs such as loss or productivity.[35–38] In many countries, the economic burden of NCDs is between 5% and 6% gross national product (GNP). It has been estimated that indirect costs may be much more. In many countries, the cost of direct treatment of CVD is 2–3% of their GNP, and approximately double that comes from indirect expenses. The cost of obesity varies between 2% and 8% of all healthcare expenditures in both HICs and LMICs. Given that many NCDs occur in LMICs and occur in younger people than in HICs, the economic burden of NCDs, while difficult to totally compute, could be profound. By any measure, the economic burden is significant.

The economic cost of NCDs, according to the National Institute of Health, is likely to exceed $47 trillion over the next two decades. Thus, there is an enormous economic incentive to solve the issues of NCDs and lessen their impact both on health and economies around the world. By

any measure, the economic burden is significant. One of the most attractive features of lifestyle medicine modalities is that they are cost-effective solutions to the enormous economic burden of NCDs.

94.8 COST-EFFECTIVE SOLUTIONS

Strategies to find cost-effective solutions for NCDs are extremely important. These are likely to vary from country to country depending on the resources available.[39–42] However, it is clear that lifestyle medicine modalities are a highly cost-effective solution. First, there is a relatively small cost to increasing physical activity, reducing smoking levels, and improving nutrition. Moreover, lifestyle medicine modalities have the added benefit of carrying virtually no adverse effects and also impacting multiple chronic diseases simultaneously. For example, consumption of more fruits and vegetables, increased physical activity, lower rates of cigarette smoking, and lower rates of obesity all have positive impacts not only on CVD but also on many of its risk factors, including high blood pressure and dyslipidemia. Moreover, these same modalities significantly reduce the risk of T2DM and even some cancers.

94.9 PUBLIC HEALTH CONSIDERATIONS

A key component of the WHO initiative to combat NCDs involves population-wide strategies. Many of these strategies apply not only to individuals but also could be highly effective on a population-wide basis. The WHO recommends that actions should be undertaken immediately to produce accelerated results related to lives saved, diseases prevented, and high costs avoided. This is such an important area that the WHO has listed ten "best buys" in terms of the reduction of NCDs. These include the following:[42]

- Protecting people from tobacco smoking and banning smoking in public places
- Warning about the dangers of tobacco use
- Enforcing bans on tobacco advertising, promotion, and sponsorship
- Raising taxes on tobacco
- Restricting access to retailed alcohol
- Enforcing bans on alcohol advertising
- Raising taxes on alcohol
- Reducing salt intake and salt content in food
- Reducing trans fat in food and polyunsaturated fat
- Promoting public awareness about diet and physical activity including through mass media

It is clear that most, if not all, of these ten "best buys" from the WHO include lifestyle medicine modalities. The WHO also emphasizes the importance of not only population-wide interventions but also comprehensive programs that involve both individual efforts and population-wide strategies.

94.10 SUMMARY/CONCLUSIONS

NCDs have become an enormous issue around the world in the past two decades. In fact, NCDs now represent over 71% of all mortality around the world. Thus, NCDs result in more mortality than all other diseases combined.

The strategies to reduce NCDs, which are shared by the WHO and the lifestyle medicine community, include lowering the risk of various chronic diseases. The WHO has focused attention on four behavioral risk factors:

- Tobacco use
- Physical inactivity
- Harmful use of alcohol
- Unhealthy diet

These, plus other modalities that are central to lifestyle medicine are all very important. It is incumbent on physicians in the lifestyle medicine community to recognize that the impact of lifestyle medicine is important not only for individual patients but also for populations around the world. This adds a further challenge and an opportunity for those practicing in the area of lifestyle medicine.

CLINICAL APPLICATIONS

- The modalities of lifestyle medicine are critically important for the main behavioral risk factors identified by the WHO. These include the use of tobacco, insufficient physical activity, harmful use of alcohol, unhealthy diet, raised blood pressure, overweight and obesity, and dyslipidemia.
- It is incumbent on lifestyle medicine practitioners to recognize the important worldwide implications for positive lifestyle medicine modalities.
- An increasing number of lifestyle medicine organizations have sprung up around the world offering significant hope that lifestyle medicine modalities can make a major impact on lowering the epidemic of NCDs around the world.

95 Addiction Section Introduction

Joji Suzuki MD, Beth Frates MD, and Irena Matanovic

KEY POINTS

- People suffering from addiction or substance use disorders are not getting the help they require to tackle their medical problems.
- People with addiction problems are similar to people with hypertension and diabetes in that they need specialized care and diagnosis is the first step.
- All clinicians, including lifestyle medicine practitioners, need to become familiar with the signs, symptoms, diagnosis, and treatment options for those people suffering from substance use disorders.

Given that smoking is a major cause of disease leading to heart disease and cancer, two of our major killers, it is important for lifestyle medicine practitioners to be comfortable with the identification, diagnosis, treatment, and counseling strategies that are most effective for people suffering from addictions. Mokdad and colleagues pointed out that smoking was the number one "actual cause of death" in the United States in his landmark article published in JAMA in 2004.[1] On that same list of actual causes of death are alcohol and illegal drugs.

Lifestyle medicine practitioners treat patients who smoke, drink, use cannabis, and use opioids. Knowing the treatment options, identifying people in need of assistance, and recommending appropriate follow-up are all important aspects of lifestyle medicine practice. There are assessment tools that can be used before the clinic visit. In addition, there is a methodology for counseling patients that will open up the conversation for discussions about these habits that are often hidden from physicians. In many cases, patients and family members are in denial themselves. Thus, the role of the lifestyle medicine practitioner is to be a non-judgmental source of information, inspiration, and support for those individuals who are struggling to stay drug- or alcohol-free.

There are addiction specialists who have for trained years in order to effectively help people who are using tobacco, alcohol, and drugs to excess or in a way that is causing them harm physically or emotionally. Many psychiatrists, psychologists, social workers, nurses, and other healthcare professionals are focusing on this population of patients every day. Knowing clinicians who specialize in addictions, the resources available through hospital and community centers, becoming familiar with medications that may help people stay drug-free, identifying technologies that can assist patients, and understanding the value of rehabilitation centers are essential for lifestyle medicine practitioners to help their patients embrace healthy living. People might be eating a healthy diet and exercising, but they may also be drinking too much. Because substance use disorders can be missed and purposefully hidden, lifestyle medicine practitioners will be one step ahead after reading this section. This was a new section in the third edition of the textbook. It has been updated and expanded in the fourth edition. It is evidence that the editors are staying current with the times and supplying practitioners with cutting-edge information.

The naming of this field of medicine has been a source of controversy and even the definition of addiction is something that is not agreed upon by all providers and patients. The history of addictions is reviewed in Chapter 96. The currently favored term and the one used in the DSM is substance use disorders. Substance use disorders (SUDs) refer to a group of disorders that involve the compulsive and repeated use of substances that are associated with negative physical and psychological health consequences.[2] Historically, lifestyle medicine practitioners have not been routinely involved with the assessment and management of SUDs. However, in the context of the growing opioid crisis and the continued contribution of SUDs to adverse health outcomes, every clinician should be aware of the epidemiology, approach to diagnosis, and the basics of SUD treatment. While not every clinician can provide the full spectrum of SUD treatments, it is imperative that clinicians have the basic knowledge and skills necessary to identify and diagnose SUDs, provide basic treatment where appropriate, and refer to local community resources. Today, a variety of effective evidence-based pharmacologic and psychosocial services are available that healthcare providers can utilize in their day-to-day practice. Considering the degree to which SUDs are common in clinical populations, as well as the negative impact on patients, families, employers, and communities, clinicians can no longer opt out of providing these basic services to patients.

There is a long history of humans using a variety of substances for both therapeutic and recreational purposes, which will be outlined in Chapter 96 by Steve Adelman and Sanchit Maruti. The World Health Organization has recognized that substance use remains one of the most common contributing factors to premature death (in the year 2000, alcohol, tobacco, and illicit drug use contributed to 12.4% of all deaths worldwide) as well as other medical,

DOI: 10.1201/9781003227793-112

psychiatric complications that reduce quality of life and contribute to a heavy economic burden through lost productivity, criminal justice costs, and healthcare costs.[3] Today, SUD continues to be a major public health problem in the United States, with over 19 million Americans ages 18 and older (7.8%) suffering from some form of SUD in 2016.[4] National epidemiologic surveys of alcohol and related conditions estimated that lifetime prevalence of alcohol-related disorders is 20.3% and drug use related disorders is 10.3% [5]. When separated by gender, males experience SUD at much higher rates (10.7% of US males) compared with females (5.7% of US females).[6] The typical age at which individuals begin to meet the criteria for a substance use disorder is during young adulthood (ages 18–25). At this age, due to the insufficient development of their frontal lobes, individuals are less able to inhibit risky behaviors and are at heightened risk of developing a SUD. Tobacco remains the most commonly used substance that is associated with considerable morbidity and mortality. While the rate of tobacco use has declined over the past several decades, 28.5% of Americans continue to endorse regular use of tobacco products.[4] More than 480,000 deaths annually are attributable to tobacco use, far overshadowing deaths from all other substance use combined.[7] Behavioral approaches to tobacco use disorder will be addressed in Chapter 97 by Ciccola and SantaBarbara. Alcohol is also frequently consumed in the United States, with 86.4% of the population consuming alcohol at least occasionally at some point in their lifetime.[8] Among those who consumed alcohol regularly in 2014, about 60.9 million (26.9% of the US population) reported binge drinking (defined as drinking more than five [for men] or four [for women] or more drinks in one occasion) and 16.3 million (7%) reported heavy drinking (defined as binge drinking on five or more days in the past month).[8] Binge drinking is an important contributing factor to injuries such as falls and motor vehicle accidents. In the same year, 6.2% of individuals 18 years and older met the criteria for an alcohol use disorder,[6] which causes additional harm to the individual by damaging all organ systems in the body, with a particular focus on the neurologic and cardiovascular systems. The approach to the diagnosis and treatment of alcohol use disorders will be presented by Chen and Slatkin in Chapter 98. Illicit drugs such as cocaine, prescribed medications such as oxycodone and benzodiazepines, and cannabis (now legal in some states) are also used frequently in the United States, with approximately 10.2% of individuals in 2014 endorsing the regular use of such substances.[6] While the use of heroin and cocaine has existed in the United States for the better part of the 20th century, there has been an alarming rise in the non-medical use of prescription medications in the last two decades.[9] This has led to an unprecedented rise in the number of overdose deaths due to misuse of prescription opioids and benzodiazepines. More recently, the misuse of illicitly produced synthetic opioids such as fentanyl has further contributed to the growing number of individuals unintentionally overdosing. The approach to the diagnosis and treatment of opioid use disorders will be covered in Chapter 99 by Dr. Volpicelli, and Bujno and Hasin will review cannabis use disorders in Chapter 100.

Unfortunately, despite the high prevalence of SUDs in the United States, addiction treatment has been largely fragmented from general medical treatment. A typical patient with a substance use disorder seeking help would not receive any substantial assistance from their healthcare provider. A typical primary care physician is well-equipped to handle most of the common illnesses that patients suffer from, including diabetes, obesity, and hypertension. In the context of the growing opioid crisis, this discrepancy in the ability of the healthcare system to help those suffering from SUDs has been exposed.

A major contributing factor for this failure stems from considering SUDs as a moral failing and criminal behavior per se, which has led to a disproportionate use of law enforcement approaches to reduce substance use. Instead of offering treatment, individuals with SUDs were punished for their substance use. Fortunately, as the scientific understanding of SUDs has increased, there has been a shift from the law enforcement approach to the public health approach. Instead of criminalizing the behavior, the growing evidence base pointed to SUD as a chronic disease, not unlike diabetes or hypertension. Treatment for SUD has a considerable impact on the individual but requires ongoing treatment and management of the underlying illness. As in diabetes treatment, there is no cure for SUD even if there is cessation of substance use. Once SUD develops, the individuals remain at heightened risk of relapse, and ongoing attempts at preventing relapse are necessary. As such, a critical component of treatment involves ensuring that patients are engaged with their treatment. One possible strategy for this is to incorporate mobile applications and smartphones to increase patient self-efficacy in managing their SUD. El-Haddad and colleagues in Chapter 102 will review the variety of psychosocial services and peer supports that patients can utilize to support their recovery in the long term.

Healthcare providers of all disciplines have historically been provided with sub-optimal education on SUDs. This meant medical schools devoted minimal time to teaching the diagnosis and treatment of SUDs and employed few faculty members who were experts on SUDs. In graduate medical education, only psychiatry residents are required to complete any rotation in addiction. To this day, internal medicine residents are not required to complete any dedicated rotation in addiction medicine. The limited exposure to addiction education as well as the limited number of preceptors and mentors experienced in the treatment of SUDs has meant that entire generations of physicians are ill-equipped to diagnose and treat SUDs once they begin practicing. As such, the chapters in the addiction section are meant to provide a succinct overview of the common

SUDs encountered by clinicians in their practice and cover the basics of assessment and treatment of these conditions.

CLINICAL APPLICATIONS

1. This addiction section clearly belongs in a lifestyle medicine textbook. It is an important topic as people with addictions often hide or mask their problems when speaking with primary care physicians or other clinicians.
2. Knowing how to recognize different substance use disorders will save the lifestyle medicine clinician time because someone trying to manage an addiction can be preoccupied with that substance (like nicotine for smokers) and thus have difficulty adopting other healthy habits.
3. It is possible that lifestyle medicine clinicians might be the clinicians that patients choose to share their addiction history with after rapport has been created and trust developed. For this reason, these clinicians need to be well-versed in substance use disorder diagnosis and treatment.

96 History of Alcohol and Opioid Use and Treatment in the United States

Sanchit Maruti, MD, MS and Steven A. Adelman, MD

KEY POINTS

- Perceptions of substance use have evolved from widespread use and social acceptance, then to restriction and stigmatization, and now to recognition as a neurobiological phenomenon.
- The COVID-19 pandemic has had a significant impact on individuals struggling with addiction by hindering access to, and efficacy of, treatment.
- Understanding the historical basis of addiction and treatment can assist us in integrating traditional medical management with the growing knowledge of lifestyle therapeutic approaches for the well-being of the individual.

"Whereof what's past is prologue"

William Shakespeare, Scene 1, The Tempest

Human history is replete with the use of intoxicating and potentially addictive substances in various cultures in different epochs of time. Archeologic evidence suggests that alcohol has been consumed by humans over the past 9000 years and opium over the past 8000 years. These substances have been used in religious practices, recreation, and for their medicinal properties. Over the past several centuries, technological innovations, such as distillation, chemical synthetic processes, and the invention of the hypodermic syringe, have increased the potency and availability of these substances and streamlined delivery into the body. Today, alcohol and opioid use disorders are responsible for significant morbidity and mortality throughout the world. With an improved understanding of the neurobiological basis of addiction, lifestyle medicine approaches can potentially contribute to prevention and recovery.

96.1 ALCOHOL

The earliest record of excessive use of alcohol as an illness was described during the 5th century by Herodotus. At the beginning of the colonization of America, alcohol was consumed by men, women, and children throughout the day as the fresh water supply was not often safe for consumption. Colonists adhered to the traditional belief that distilled spirits were *aqua vitae* or the water of life. Over the next 200 years, alcohol was routinely consumed in general society. Between 1780 and 1830, there was a proliferation of distilleries resulting in a tripling of per-capita consumption of alcohol. Even the first president of the United States, George Washington, was actively involved in making alcohol. In fact, in 1799, the year of George Washington's death, his distillery produced nearly 11,000 gallons of spirits, making it the largest whiskey distillery in America at the time.

Despite this widespread acceptance, excessive consumption of alcohol was causing increasing concern. Early Native American tribes used plant-based medicinals to decrease cravings and induce aversion to alcohol. In 1774, the abolitionist and educator Antoine Bénézet warned of alcohol as a "poison" and in 1784, Dr. Benjamin Rush wrote the "Inquiry into the effects of ardent spirits on the human mind and body". In this work, he described the symptoms and progression of excessive alcohol use. Additionally, Dr. Rush was one of the first physicians to recognize that excessive alcohol use was an illness that required medical treatment. He believed that the properties of alcohol, rather than the choice of the individual, are responsible for the illness. He was an advocate for humane treatment and argued that individuals with this condition can be restored to full health with a return to society through proper medical treatment. These concerns and recommendations from important societal figures led to the beginning of the American Temperance movement.

During the 19th century, there emerged increasing medical evidence of the harms caused by excessive drinking, including the recognition of delirium tremens in 1813 by Dr. Thomas Sutton, the identification of the triad of ophthalmoplegia, ataxia, and confusion by Dr. Carl Wernicke, and the description by Dr. Sergei Korsakoff of memory defects and confabulation associated with chronic, excessive alcohol use. By the mid-century, there was increasing recognition of excessive alcohol use as a medical condition. In 1849, Dr. Magnus Huss compiled the chronic effects of intoxication and formulated the term "Alcoholism". Concurrently, there was growing social support for the establishment of physician-directed inebriate asylums to provide specialized residential care. In 1864, the New York State Inebriate Asylum opened, and by the late 1870s, large hospitals such as Bellevue created inebriate wards to provide care for patients in urban settings. It is noteworthy that during this time many patented medications for treating addiction contained alcohol, cocaine, morphine, or opium.

DOI: 10.1201/9781003227793-113

The diagnostic term that emerged from the medical field in the 19th century was "inebriety" with further specifications based on the substance of interest.

One of the earliest addiction organizations, the American Association for the Cure of Inebriety (AACI) was created in 1870. This organization held regular meetings and published the first specialized medical journal, the *Journal of Addiction*. The founding principles of the AACI appear now to have been remarkably forward-thinking and recognized "inebriety" as a curable disease that was either inherited or acquired. They advocated for the civil authorities to support the establishment of specialized treatment facilities for the scientific treatment of inebriety in place of penal methods.[1] The growing evidence of the medical etiology of addiction encouraged the American Medical Association (AMA), which was founded in 1847, to support the creation of the American Medical Temperance Association (AMTA) in 1891. As the historian William White summarizes, "The field of addiction medicine experienced professionalism and specialization between 1830 and 1900". Thus, the approach to addiction in the United States in the 18th and 19th centuries was formed by the combined influences of medicine, morality, and social activism.[2]

Despite the medical progress, during the same time in 19th century America, momentum was building for connecting excessive alcohol use to a moral failing. In 1826, the American Temperance Society was formed with the premise of reducing alcohol use rather than complete abstinence. In 1827, Reverend Lyman Beecher published, "Six sermons on the nature, occasion, signs, and remedy of intemperance". He described the individual who excessively used alcohol as "addicted to sin". He championed the concept of abstinence on an individual and societal level. The 1830s saw the emergence of Teetotalism, which promoted complete abstinence from all alcoholic beverages. Mutual Aid Groups first started in the 18th century with early Native American recovery circles. In 1840, the Washingtonian Movement was founded by six individuals who had achieved sobriety from former alcohol use. The premise was that a fellowship of individuals could support each other's sobriety by conducting outreach to individuals who were struggling with excessive alcohol use, relying on each other, sharing their experiences with alcohol, and nurturing an environment of comradery. These principles were eventually incorporated into the Alcoholics Anonymous organization.

96.2 OPIOIDS

Opium is derived from the poppy *Papaver somniferum* and contains the opiates morphine and codeine. The first references to opium cultivation are from 6000 BC in lower Mesopotamia. Opium's use spread to different parts of the world with evidence from an Egyptian papyrus of cultivation in Egypt in 1500 BC. In 460 BC, Hippocrates noted the usefulness of opium for treating internal diseases, epidemics, and diseases of women. In the 16th century, Paracelsus created laudanum, which was a tincture of opium for the treatment of pain. In the 17th century, Dr. Thomas Syndenham, renowned as the "English Hippocrates", compounded a proprietary form of laudanum and promoted it for a variety of medical conditions. The use of opium and laudanum soon became widespread in Europe and the United States for the treatment of cardiac ailments, infectious diseases, mental conditions, and pain by patients of all ages, including children. In 1804, Friedrich Sertürner isolated morphine (after the Greek god of dreams, Morpheus) from opium, and by 1827, the Merck pharmaceutical company began the manufacturing and marketing of morphine.

In the 1850s, the work of Drs. Francis Rynd, Charles-Gabriel Pravaz, Louis-Jules Béhier, and Alexander Wood led to the creation and clinical use of the hypodermic needle. The combination of the increased potency of morphine over opium and the ability to inject the solution directly into the bloodstream catalyzed the increasing use of morphine. The discovery of the hypodermic syringe occurred just before the start of the US Civil War, and the use of injected morphine during the treatment of war injuries is reported to have resulted in addiction in thousands of veterans after the war.[3] In 1874, C.R. Wright synthesized diacetylmorphine from morphine[4] Chemists at Bayer Pharmaceuticals optimized the synthetic process and Bayer marketed diacetylmorphine under the brand name "Heroin" (from the Greek word *heros*), as a "safe, nonaddictive" alternative to morphine from 1895–1910 for pain and coughs. It is noteworthy that during this time, consumption of medications with opioids was considered normal and with minimal risk. Women were widely prescribed opioids after childbirth, or to treat "female problems" (menstrual cramps). In the 1800s, opioids and cocaine were mostly unregulated. The anthropologist Dr. Marcus Aurin writes that until the latter part of the 19th century, "It was viewed perfectly normal for individuals to take regular daily doses of opium as a 'constitutional' for vague conditions".[5] This acceptance and lack of regulation led to the development and commercialization of hundreds of patented medicines containing opioids during this time period.

96.3 ADVERSE EFFECTS OF LEGAL AND SOCIETAL CHANGES ON ADDICTION TREATMENT

The period of 1900–1935 saw a decrease in medical influence on addiction treatment in the United States as increasingly pejorative characterizations of individuals with substance use disorders led to a shift from viewing substance use as a medical condition or socially normative behavior and instead to judging it as a weakness in character and a willful, selfish choosing of sin over virtue.

In the 1890s, the Anti-Saloon League was the leading organization lobbying for prohibition in the United States. It allied with the Women's Christian Temperance Union and the Prohibition Party to support the passage of the Eighteenth Amendment to the United States Constitution

in 1919. This law made the production, transport, and sale of alcohol (though not the consumption or private possession) illegal. In parallel, there was soaring public sentiment against the availability and use of opioids. The combination of the availability of morphine and the hypodermic needle had resulted in growing opioid addiction rates in individuals. In addition, social sentiment started shifting when there were increasing cases of addiction among the immigrant population, such as railroad workers who emigrated from China. The first drug control ordinances in US history were issued in San Francisco in 1875 in an attempt to stop the spread of "opium dens".

The US government began taxing opium in 1890, and the passage of the Pure Food and Drug Act of 1906 forced manufacturers to disclose the ingredients of their products, so consumers would know the content of their medications. Shortly after, in 1909, the Smoking Opium Exclusion Act banned the importation, possession, and use of "smoking opium". Although the Act did not regulate opium-based medications, it became the first federal law to ban the use of non-medical substances. On a global level, Charles Henry Brent, an American Episcopal bishop convened the Brent Commission, which recommended that narcotics be subject to international control. In 1912, the United States and many other countries signed the International Opium Convention, which regulated the import, manufacture, and sale of morphine. Shortly afterward, the Harrison Narcotics Tax Act of 1914 was passed. This law regulated and taxed the production, importation, and distribution of opiates and cocoa products. It deemed that physicians could prescribe or dispense opioids to their patients if they kept records.

However, the moral sentiment affected medical opinion, and the US Public Health Service advocated that addiction was not a medical problem but a social one. In 1919, the AMA passed a resolution opposing outpatient treatment of opioid addiction. In 1919, the Webb amendment to the Harrison Act made offering maintenance treatment an "illegitimate medical practice" and a federal offense. During this time, many physicians were indicted under the Harrison Act and several actually went to jail. The *United States v. Behrman* Supreme Court decision in 1922 resulted in the closure of nearly all clinics treating opioid addiction, as it made it illegal for doctors to prescribe opioids to addicts under any circumstances. Thus, over the course of 50 years, the pendulum had shifted from the medical and multi-factorial perspective of addictions espoused by the ACCI to one emphasizing moral responsibility, legal regulation, and punitive consequences.

96.4 A REVIVAL OF ADDICTION TREATMENT IN THE UNITED STATES

The benefits to society of punitive legislative actions did not materialize as promised. After the passage of the Eighteenth Amendment, crime rates increased as the criminal element became wealthy from the profitable, violent, illicit market for alcohol. Prohibition started becoming unpopular across the country as the federal government and law enforcement agencies were not able to take adequate countermeasures. As a result, society became willing to reexamine and reengage with the problem of addiction. With increased awareness and support, treatment approaches were reconsidered. Publication of medical research offered physicians a voice advocating for treatment. The pendulum swung back toward a clinical perspective through a series of legislative actions and court decisions. In 1925, the *Linder v. United States* Supreme Court decision ruled that the federal government overstepped its power to regulate medicine in the Behrman case. In 1929, the Narcotic Farms Act allocated funds for the US Public Health Service to construct and operate two residential treatment facilities. Ultimately, the Twenty-First Amendment, which repealed the Eighteenth Amendment, was ratified by a majority of states at the end of 1933.

Another pivotal development in the treatment of addiction was the founding in 1935 of Alcoholics Anonymous (AA), a non-profit mutual aid society, by Bill Watson and Dr. Bob Smith. They posited that the primary purpose of the alcoholic was to "stay sober and help other alcoholics achieve sobriety". Subsequently, they published the "Big Book" and developed AA's 12-step spiritual and character development program. Although AA was not the first mutual aid group, it is the oldest and largest still operating with over two million members worldwide and 100,000 active groups. AA has served as inspiration for scores of mutual support groups that focus on specific substances and sub-populations. In 1949, the Minnesota Model (also known as the Abstinence Model) was created, which proposed the blending of professional and trained non-professional (recovering) staff who integrated the principles of AA. In addition, patients received individualized treatment plans with active family involvement in a 28-day inpatient setting. More recently, the Self-Management and Recovery Training (SMART) non-profit organization was founded in 1994 as a mutual support organization based on evidence-based scientific knowledge. SMART Recovery emphasizes the four-point program in the process of recovery including: (1) building and maintaining motivation, (2) coping with urges, (3) managing thoughts, feelings, and behaviors, and (4) living a balanced life using principles of motivational enhancement therapy (MET) and techniques taken from cognitive behavior therapy (CBT). In contrast to AA and other 12-step approaches, individual goals in SMART Recovery may include moderation of substance use rather than complete abstinence.

Starting in the 1930s, pharmacologic developments started providing hope and medical credibility to conceptualizing addiction as a medical condition. Methadone was discovered in 1937 in Germany and ultimately gained Food and Drug Administration (FDA) approval in 1947 for treating pain. By 1965, Dr. Marie Nyswander and Dr. Vincent Dole published evidence hypothesizing that heroin addiction was a metabolic condition and that methadone could be

used as a medication to treat this illness. In 1970, the FDA approved methadone for medically assisted withdrawal ("detoxification") and in 1973 for maintenance therapy. Other medications for the treatment of opioid use disorder include naltrexone which was synthesized in 1963 and FDA approved in 1984, with its extended-release injectable version receiving FDA approval in 2010. Buprenorphine was discovered in 1966 and received FDA approval for treating opioid use disorder in 2002.[6] Medications for the management of alcohol use disorder were discovered and developed over roughly the same time period, with disulfiram, a deterrent medication that increases adverse reactions to alcohol, receiving FDA approval in 1951, followed by oral naltrexone, which works to decrease craving and reinforcing effects of alcohol, being approved in 1994 and its extended-release injectable version in 2006. Acamprosate, another medication intended to decrease craving, received FDA approval in 2004.[7]

Support from state and federal governments allowed a foundation for enhancing treatment and conducting and disseminating research. The Addiction Research Center was founded in 1948 and served as a precursor for the formation of the National Institute on Drug Abuse (NIDA), which was formed by the Drug Abuse Office and Treatment Act in 1972. In 1992, NIDA became part of the National Institutes of Health (NIH). The Comprehensive Alcoholism Prevention and Treatment Act created the National Institute on Alcohol Abuse and Alcoholism (NIAAA) in 1970. In addition, in 1992, the Substance Abuse and Mental Health Services Administration (SAMHSA) was established by Congress to improve the quality and availability of treatment and rehabilitative services for individuals with substance use disorders and mental illness. The Narcotic Addict Treatment Act was passed in 1974 and it recognized the use of opioid medication to treat opioid addiction as critical and, for the first time in federal law, defined "maintenance treatment". The Drug Addiction Treatment Act (DATA), which was passed in 2000, allows providers to dispense or prescribe schedule III, IV, or V controlled substances for opioid addiction in treatment settings other than traditional opioid treatment program (OTP) settings. This has allowed patients with opioid use disorder to receive care in outpatient settings as they would for any health condition. Coverage for treatment was made easier by the Mental Health Parity and Addiction Equity Act (MHPAEA) of 2008, which required health insurers and group health plans to provide the same level of benefits for mental and/or substance use treatment and services that they do for medical/surgical care. The passage of the Comprehensive Addiction and Recovery Act (CARA) of 2016 allowed for improved access to treatment by expanding prescribing privileges to nurse practitioners (NPs) and physician assistants (PAs) until 2021.

There are several instances of government collaboration with professional organizations. The Provider's Clinical Support System for Medication-Assisted Treatment (PCSS-MAT) is an example of a national collaborative effort led by the American Academy of Addiction Psychiatry (AAAP) in partnership with the American Osteopathic Academy of Addiction Medicine (AOAAM), the American Psychiatric Association (APA), and the American Society of Addiction Medicine (ASAM). PCSS-MAT is a national training and mentoring project developed in response to the prescription opioid misuse epidemic and the availability of pharmacotherapies to address opioid use disorder.

These initiatives have led to a better understanding of the neurobiological basis of addiction. Research has outlined the processes of neuroplasticity fundamental to learning and memory. The identification of various receptors such as α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA), N-methyl-d-aspartate (NMDA), and gamma-aminobutyric acid (GABA) and their neuroanatomic distribution has been coupled with greater knowledge of the effects of neurotransmitters such as dopamine, glutamate, and GABA. Synthesizing the findings of biochemical research with behavioral studies has shed greater light on functional significance.[8] This has allowed concepts such as triggers, cravings, preoccupation, anticipation, and withdrawal to be viewed from a biological perspective.

Despite these active initiatives, a large treatment gap exists in the United States for patients suffering from addiction. In 2019, only 10% of patients with substance use disorders (SUDs) who needed treatment received it in a specialty treatment facility in the past year.[9] Addiction is a chronic condition with a significant public health impact. The incidence and prevalence of addiction can potentially be decreased by the use of evidence-based lifestyle therapeutic approaches that can help guide and empower individuals to replace potentially harmful substances with healthy habits.[10] For example, improved knowledge and skill building for stress management can have a significant effect on individuals having alternatives to alcohol and tobacco use. This can, in turn, have salient and systemic benefits for the individual and society.

96.5 COVID-19

Plagues and pandemics have had a significant pernicious effect on humanity. The plague of Justinian (541–549 AD) accounted for approximately 100 million deaths worldwide. Subsequently, 62 million individuals died of the Black Death from 1347–1351. Both of these pandemics were due to the bacterium *Yersinia pestis*. In the 1918–1919 influenza pandemic, heavy alcohol intake was recognized as a risk factor for poor outcomes.[11] As of August 2022, over one million individuals in the United States died as a result of COVID-19.

During the COVID-19 pandemic, a substantial number of Americans experienced increased psychological distress due to losses, logistical challenges, and uncertainty. Accompanying the resulting increased psychological distress was an increase in the use of alcohol and drugs as coping mechanisms.[12,13] Concurrently, there was decreased access to timely high-quality treatment. Provisional data indicate that there were approximately 100,306 drug

overdose deaths in the United States during the 12-month period ending in April 2021, an increase of 28.5% from the 78,056 deaths during the same period the year before.[14]

96.6 SUMMARY

Humans have used mind-altering substances for thousands of years for a variety of reasons. Substance use in the United States has undergone cycles of acceptance, widespread use and underappreciation of risk, and the recognition of problematic use leading to the criminalization of substances and stigmatization of users, to the legalization of certain substances and medical treatment. Access to treatment has vacillated based on cultural perceptions, social norms, legal decisions, and legislative actions. Addiction continues to pose a significant challenge. In 2019, approximately 20.4 million individuals aged 12 or older were diagnosed with SUDs in the past year. This statistic was comprised of 14.5 million individuals with an alcohol use disorder and 8.3 million with an illicit drug use disorder.[9] Additionally, there were a record number of deaths due to overdose.[14] These data potentially underestimate the prevalence of negative consequences of addictive substances since they do not include individuals whose use causes harm or increases risks but does not meet the full criteria for a substance use disorder.

The current opioid epidemic highlights the significant morbidity, mortality, and devastating economic and societal costs of this condition. However, the scientific and medical advances coupled with the economic benefits of treatment represent hope for individuals, their families, and society. SAMHSA summarizes this sentiment: "Behavioral health is essential to health; Prevention works; Treatment is effective; People recover".

CLINICAL APPLICATIONS

- Humans have utilized alcohol and opioids for thousands of years for a variety of reasons including for medical, recreational, and spiritual purposes.
- Although the use of these substances was initially accepted in society, the increased potency, widespread availability, and improvement in methods of delivery resulted in significant pernicious consequences for the individual and society at large.
- Societal perception and treatment availability have vacillated from viewing addiction through a lens of morality and deviance to the recognition of it as a treatable, chronic medical condition.
- The ongoing COVID-19 pandemic has worsened access and adherence to treatment for substance use disorders.
- With increasing personal and professional demands and increasingly limited resources, this time presents an important opportunity to utilize evidence-based lifestyle medicine approaches to prevent addiction and enhance recovery.

97 Behavioral Approaches to Enhancing Cigarette Smoking Cessation

Joseph T. Ciccolo, PhD and Nicholas J. SantaBarbara, MS

Worldwide, more than eight million deaths can be attributed to cigarette smoking each year.[1] In high-income countries like the United States, significant strides have been made to reduce the smoking prevalence among certain segments of the population, but there are some areas where gains have been minimal. Going forward, it will be critical to identify those who are most at risk for the negative consequences of cigarette smoking, identify those who need active intervention, and inform treatment recommendations, such as what type or dose of treatment is needed.[2] Hence, the purpose of this chapter is to:

- Provide a brief overview of the health consequences and prevalence of cigarette smoking in the United States.
- Conduct a review of the literature on key behavioral approaches and strategies that have been used to enhance smoking cessation.
- Highlight the research done in various settings and across different populations of vulnerable and at-risk smokers.
- Summarize some of the most effective treatments and promising new research initiatives that are currently underway.

KEY POINTS

- In the United States, smoking remains the leading cause of preventable disease, disability, and death, with more than 16 million Americans currently living with a disease caused by smoking.
- Both pharmacological aids and behavioral strategies can help people quit and remain abstinent with some evidence that these techniques augment the effectiveness of each other.
- Technology-based interventions leveraging the ubiquitous nature of mobile phones have shown preliminary efficacy in helping people quit.
- Exercise may also help increase short-term abstinence while also improving other markers of physical health.
- Targeted behavioral interventions that build on the current and unique needs and skills of those who smoke, and are grounded in theory, will ultimately give smokers the best chance to achieve long-term abstinence.

97.1 HEALTH CONSEQUENCES OF SMOKING

The negative health effects that result from cigarette smoking are clear. Evidence shows that any exposure to tobacco smoke is harmful because it contains more than 7000 chemical compounds.[3] Indeed, smoking harms nearly every organ of the body and can cause cardiovascular disease, stroke, periodontitis, aneurysms, pneumonia, chronic obstructive pulmonary disease (COPD), asthma, erectile dysfunction, and low bone mineral density.[4] Cigarette smoking can also cause cancer of the lung, bladder, cervix, esophagus, oral cavity, larynx, stomach, kidney, uterus, and pharynx.[4] Lastly, smoking has additional adverse effects on early childhood and reproductive health, including infertility, preterm delivery, stillbirth, low birth weight, and sudden infant death syndrome (SIDS)[4].

In the United States, smoking remains the leading cause of preventable disease, disability, and death.[4] More than 16 million Americans are living with a disease caused by smoking. In total, cigarette smoking is responsible for more than 480,000 deaths per year (approximately 1300 each day), including more than 41,000 deaths resulting from secondhand smoke.[4] Overall, it is estimated that the total economic cost of smoking is more than $300 billion a year, including nearly $170 billion in direct medical care for adults.[4]

97.2 SMOKING PREVALENCE AND EPIDEMIOLOGY

In the United States, about 12.5% of the adult population (aged 18 and over)[5] and 1.5% of youths (middle and high school students) currently use cigarettes.[6] Smoking differs by demographic groups and is more common in those who are non-cisgender, a person of color, non-heterosexual, not currently married, uninsured or receive Medicaid, have not completed high school education, live below the federal poverty line, experience anxiety, and those with a disability.[5]

97.3 RATES OF SMOKING CESSATION

Both the risk and the severity of many diseases caused by smoking are directly related to how long the smoker has smoked and the number of cigarettes smoked per day. As such, it is beneficial to quit smoking at any age.[4] More specifically, after quitting, the risk for a heart attack drops sharply after just one year; stroke risk can fall to about the same as a non-smoker's after two to five years; risks for cancer of the mouth, throat, esophagus, and bladder are cut in half after five years; and the risk for dying of lung cancer drops by half after ten years.[3]

The most recent estimates indicate that 68% of current smokers would like to stop smoking, 55.4% made a past-year quit attempt, and 7.4% were able to quit for more than six months over the past year.[7] Interest in quitting is reported to be higher among certain demographic groups, such as females, those aged <65 years, and those with a post-high school education.[7] In general, cessation rates are higher among those who participate in a smoking cessation program when compared with those who try to quit without any assistance. Unfortunately, from 2000 to 2015, fewer than one-third of US smokers used evidence-based cessation methods when trying to quit smoking. As such, the low prevalence of cessation may be related to the low use of evidence-based cessation treatments.

97.4 PHARMACOLOGICAL AIDS FOR SMOKING CESSATION

The earliest studies on smoking cessation did not recognize the addictive nature of cigarette smoking. Modern-day approaches now consider that the nicotine in cigarettes is a highly addictive drug, and this has led to a wealth of research on using medication to help smokers quit. Overall, the combination of behavioral counseling and medication has been shown to be more effective than either treatment alone.[8–10] Unfortunately, a significant proportion of those attempting smoking cessation are willing to use any type of medication. As such, it is important to recommend that all smokers wishing to quit seek out some type of behavioral support and use some type of medication (except when medically contraindicated).[8,9] Prior to describing several different behavioral approaches to enhancing smoking cessation, a clarification of the medications that often accompany treatment is needed.

Currently, there are several US Food and Drug Administration (FDA) approved first-line medications shown to help increase long-term smoking abstinence rates. These include over-the-counter (OTC) products (e.g., nicotine gum, nicotine lozenge, and the nicotine patch) and prescription-only medications (e.g., nicotine nasal spray, nicotine inhaler, sustained-release bupropion, and varenicline). When used properly, nicotine replacement therapies (NTRs) can significantly reduce nicotine withdrawal and have been shown to increase the rate of quitting by 50–70%.[11] Bupropion, an antidepressant, has also been shown to be an effective medication for smoking cessation.[12] It can reduce withdrawal symptoms and decrease nicotine's rewarding effects by blocking the reuptake of norepinephrine and dopamine in the mesolimbic system and nucleus accumbens, a key area for nicotine reinforcement.[13] Varenicline, the newest medication, has been shown to triple abstinence rates in smokers when compared with an unassisted quit att empt.[8,13,14] Varenicline attenuates the rewarding effects of nicotine and it can reduce the symptoms of nicotine withdrawal. Importantly, all of these medications can have side effects, and many of them have not been extensively studied in certain subpopulations of smokers (e.g., adolescents).[13] Given that the combination of behavioral counseling and medication is ideal, more studies on how to best combine these strategies for all smokers are needed.

97.5 BEHAVIORAL SMOKING CESSATION STRATEGIES

Extensive scientific and community resources have been used to examine ways to reduce cigarette use and increase smoking cessation. Strategies that have been used range from population-level (e.g., government-based initiatives and media-based campaigns) to individual-level interventions that have targeted a wide array of people who use cigarettes. The following review covers the various types of behavioral smoking cessation interventions that vary from minimal contact to intensive counseling. The programs described later can be classified based on the type of approach used, the population targeted, and the setting in which it is delivered. Regardless of their classification, all of the programs attempt to provide those who use cigarettes with the information and behavioral skills thought to be necessary for achieving initial cessation and sustained abstinence.

97.6 COUNSELING AND THERAPY-BASED APPROACHES

97.6.1 Individual Counseling

Individual or face-to-face counseling is a well-established method for delivering smoking cessation treatment. The treatment can be delivered by practitioners with varying levels of education and training (e.g., tobacco treatment specialists, psychologists), and it can be done in different formats, for varying lengths of time (e.g., 10–60 min sessions), and across a wide-ranging number of sessions. Individual counseling can also be combined with self-help components, medication, group counseling, and/or telephone/Internet assistance.[15] Currently, there is significant evidence to support using individual counseling, as it has been shown to increase the likelihood of quitting smoking by 40–60% when compared with less intensive treatments

(e.g., self-help without medication).[15,16] Going forward, it will be important to identify the most effective and cost-effective intensity and duration of individual counseling for smokers, particularly those who do not typically present for treatment and are hard to reach.

97.6.2 Group Therapy

Delivering a smoking cessation intervention in a group format has been used for more than 25 years, and it remains popular.[17–19] Using group therapy may be particularly helpful because it can provide members with a unique opportunity to learn about the challenges other smokers face when trying to quit. This can generate important and potentially therapeutic emotional experiences that often arise from listening to and analyzing the behavior of others.[17,20] While it is not yet clear whether group therapy is more or less effective than more intensive interventions (e.g., individual counseling), existing data indicates that smokers have a 50–130% greater chance of quitting in a group when compared with just using self-help materials.[19] Future studies will be needed to determine if group-based interventions are more cost-effective behavioral approaches for smoking cessation.

97.6.3 Telephone Counseling

A clear benefit of telephone counseling is that it can be used as a substitute for face-to-face contact to reach a large number of smokers at a much lower cost. There are two approaches to telephone counseling: proactive and reactive. Counselors use a proactive approach when they call smokers in an attempt to support a quit attempt or prevent relapse. These calls are typically made as part of a larger effort to expand the level of support given to the smoker, which may have initially included smoking cessation counseling or the provision of self-help materials or pharmacotherapy. Reactive telephone counseling occurs when a smoker calls a quit line, such as 1-800-QUIT-NOW.[21] Quit lines may be regional or national and may provide the caller with counseling at the time of the call, a future (proactive) call, mailed materials, access to pharmacotherapy, a recorded message, or a mixture of these components. Research suggests receiving a call-back from a counselor after the original call from the smoker (i.e., reactive counseling) can increase the rate of smoking cessation when compared with self-help materials or brief advice during the original call.[22] Other research has shown that proactive telephone counseling, which is more likely to reach those who may not be as ready or motivated to quit as those who call a quit line, can increase smoking abstinence in the short term; however, the long-term effect of this is less clear.[22] In addition, there is some evidence for a dose-response relationship with the number of proactive calls, with multiple calls increasing the chances of quitting over other minimal interventions such as self-help materials or pharmacotherapy (e.g., nicotine replacement therapy) alone.[22] New research should further examine the efficacy of proactive and reactive calls, including ways to standardize the number/length of calls.

97.6.4 Motivational Interviewing

Motivational interviewing (MI) was originally developed in the early 1980s as a treatment for substance use disorder.[23] It is an individually administered, client-centered counseling approach to elicit behavior change by helping individuals explore and resolve ambivalence.[24] MI seeks to reduce resistance to change by developing a discrepancy between an individual's current behavior and their values and goals. Some training is required to administer MI, but it can be delivered successfully by physicians, nurses, and other healthcare personnel. The first study to use MI for nicotine dependence was published in 1998,[25] and about 40 trials have been completed.[26] Overall, MI does not seem to be an efficacious treatment for smoking cessation. Studies have tested an array of treatment combinations, such as one to 12 session treatments, ranging in total time from five to 315 minutes.[26] Results show no significant effect of MI on smoking cessation when compared with no intervention or other types of behavioral support.[26] Future research should rigorously test standardized MI protocols, and include fidelity assessments, as many of the current studies suffer from bias and imprecision.[26]

97.7 SMOKING CESSATION IN MEDICAL SETTINGS

Considering that smoking contributes to the development of a myriad of medical problems, it is not surprising that smoking is more common in a variety of medical populations. The "5 As" smoking cessation framework (*ask*, *advise*, *assess*, *assist*, and *arrange*) is specifically designed to be applicable to brief medical visits.[8] This framework calls for all clinicians to assess smoking status at each visit (i.e., *ask*). The identification of smokers can be increased by treating smoking status as a "vital sign"[27] and building prompts into electronic medical records.[28] Having such an identification system increases the likelihood that clinicians will provide cessation interventions.[8,29] Some clinicians may worry that repeatedly bringing up smoking cessation during visits will decrease patient satisfaction; however, this does not seem to be the case.[30,31]

Providing strong, personal advice to quit (i.e., *advise*) only takes a few minutes and has clear empirical support. Specifically, physicians providing strong advice to quit can increase the likelihood of quitting even when relatively little time is spent (e.g., <3 minutes).[8] Although the absolute increase in quit rates due to brief advice may only be 1–3%,[32] the cost of advice is low and the reach is high, so its potential public health impact is great.

Discussion of a patient's willingness to make a cessation attempt at this time (i.e., *assess*) will identify patients who are currently interested in quitting and those who are not,

so clinicians should be ready to use treatment techniques for both groups.[33] For those who are ready to quit, the clinician can *assist*. Assistance strategies include developing a quit plan (including setting a quit date); recommending and/or prescribing pharmacotherapy; referring the patient to additional counseling, quit lines, or web support; providing practical counseling (e.g., problem-solving barriers to cessation); and providing social support. Notably, quit rates increase as time spent counseling increases.[8] Finally, following up in person or by phone (*arrange*) provides an opportunity to reinforce cessation or encourage another quit attempt if the patient has relapsed. Ideally, a first follow-up contact would occur within a week of the quit date and a second within a month of the quit date.[8]

For smokers currently uninterested in quitting, the "5 Rs" (*relevance*, *risks*, *rewards*, *roadblocks*, and *repetition*) provide a framework for increasing motivation and are consistent with the MI approach described earlier[8] In this framework, patients are asked (not told) about the personal *relevance* of smoking, perceived personal *risks* of smoking and *rewards* of quitting, and perceived *roadblocks* to successful cessation (for which the clinician can suggest solutions). These steps can be repeated at each visit (*repetition*). Studies have shown that the 5 Rs approach increases the likelihood of future quit attempts in those with initially low motivation to quit smoking.[34]

Integrating smoking cessation services into regular systems of medical care is ideal because when treatment is delayed or in another location, fewer patients follow through on referrals than when treatment is easily assessable.[33] Although cessation services could be integrated into almost any medical encounter (including some non-traditional contexts such as pharmacies and dental offices),[35,36] two of the most important are considered in the following sections: primary care visits and inpatient hospital stays.

97.7.1 Primary Care Visits

In the United States, it is estimated that 70% of people who smoke see some type of primary care provider (PCP) each year.[37] Thus, primary care-based cessation interventions can reach most cigarette users. In addition, PCP providers have long-standing relationships with their patients and may be in a unique position as trusted clinicians to provide influential advice that will lead to a quit attempt. It may be frustrating for the provider to repeatedly spend time discussing smoking cessation with the same patient; however, because intention and motivation to quit can fluctuate on a week-to-week basis,[38] assessing motivation to quit at every contact will catch more patients when they are ready to make an attempt. An additional advantage of conducting a smoking cessation intervention in primary care is that pharmacotherapy options can also be discussed and prescribed on the spot if the patient is ready to make a quit attempt.

Due to time and logistical constraints, many PCPs may be limited in the amount of follow-up support they can provide for a quit attempt. In fact, evidence suggests that PCPs arrange for follow-up at a much lower rate than they provide the other components of the 5 As.[39] However, it is becoming increasingly common for large primary care practices to have embedded behavioral health providers. These providers are often trained in smoking cessation[40] or could easily be trained to provide smoking cessation counseling services (e.g., through Tobacco Treatment Specialist certification).[41] Thus, PCPs may be able to refer to an "in-house" provider for continued services. When such a referral is not available, a quit line may be able to provide follow-up support. Such quit-line referrals have also been successfully integrated with primary care–based pharmacological interventions.[42]

97.7.2 Inpatient Hospitalization

Hospitalization can be considered a "teachable moment"[43] when the health effects of smoking are salient and patients are more likely to accept cessation treatment.[8] In addition, US hospitals are now smoke-free, so inpatients will likely experience temporary abstinence regardless of their desire to quit.[44] Clinical guidelines[8] indicate that smoking status should be assessed upon hospital admission and documented on the problem list and discharge summary. People who smoke should be offered NRT while in the hospital even if they are not considering quitting, as a positive experience with NRT relieving withdrawal symptoms may increase NRT use during future attempts.[8,33]

Given that hospitalized patients are acutely ill, it is particularly important to consider possible contraindications for psychopharmacology in this setting. For example, the FDA package inserts recommend that nicotine replacement should be "used with caution" for two weeks following a myocardial infarction and bupropion lowers the seizure threshold.[8] The cardiac risk of varenicline was called into question,[45] but more recent evidence suggests that risk may be lower than originally reported, for example, in reference [46]. Thus, with certain patients, inpatient providers must weigh the medical risk of prescribing pharmacological cessation aids with the benefit of an increased likelihood of cessation.

97.8 COMMUNITY-BASED APPROACHES

97.8.1 Mass Media Campaigns

Mass media, which includes television, film, the Internet, radio, newspapers, magazines, billboards, and cigarette packaging, can play a key role in shaping smoking-related knowledge, attitudes, and behaviors.[47] Mass media campaigns can be designed either to directly target individuals' behavior or to influence the social and political landscape, which can lead to a change in social norms around smoking.[48] Overall, campaigns that are theoretically based and broadcasted at a sufficient intensity (i.e., contact time with the message), frequency (i.e., number of contacts), duration (i.e., days to years), and across multiple channels (i.e.,

television, radio) have been found to be the most effective.[49] Importantly, it is somewhat difficult to isolate the specific effect of mass media campaigns, particularly when they are part of a complex set of interventions.[49] As such, the cost-effectiveness of mass media campaigns is likely high, given that they can positively influence behavior and reach large populations quickly and efficiently, but more research is needed in this area. Future studies will need to investigate the benefits of using methods of communication beyond in addition to the most common (e.g., television, radio), such as social media (e.g., Instagram), as it is becoming increasingly more effective in reaching a wider cross-section of the population, particularly adolescents.

97.8.2 Worksite Programs

There are numerous adverse effects associated with employees who smoke, such as increased healthcare costs and disability, greater absenteeism, poorer job performance, and an increased risk of injury.[50] As a result, employers may be motivated to provide support for effective worksite smoking cessation programs to offset the potential costs related to the negative health consequences of smoking.[51] There are several advantages to conducting a cessation program in such an environment, including (1) access to a large, stable population; (2) the potential for high participation and compliance; (3) a socially reinforcing network and positive atmosphere; (4) an opportunity to include a diverse or hard-to-reach population; and (5) the ability to run a program that can be tailored to the interests, challenges, and needs of a particular group.[52] To date, research has tested programs targeting smokers using individual and group counseling, self-help materials, pharmacological treatment, and social support techniques. Other initiatives tested include environmental cues (e.g., posters), financial or material incentives, and health promotion programs.[52–54] Among these, the programs that specifically target individual smokers have shown the largest effects, such as group and individual counseling, and pharmacotherapy. There is little evidence that the other methods are as helpful, but it may be that tailored programs are needed for certain subgroups (e.g., younger smokers) to be effective overall.[55] Nonetheless, more studies are needed, as participation in worksite interventions has been lower than expected, and most of the research has been conducted in traditionally stable worksites, which are becoming less common with advancing technology and increasingly mobile employees. Lastly, more data detailing the specific costs of worksite smoking cessation programs and the relevant associated potential economic outcomes such as reduced absenteeism and increased productivity are needed.[52]

97.9 TECHNOLOGY-DRIVEN APPROACHES

97.9.1 Internet-Based Interventions

In the United States, about 93% of the population uses the Internet.[56] Unlike real-time counseling via telephone and individual or group counseling, Internet-based services can potentially provide smokers with the option of finding information at any day or time they choose.[57–59] To date, there have been about 70 trials. There is some evidence to suggest that interactive and tailored Internet-based interventions, with or without behavioral support, are moderately more effective than non-active controls at six months or longer.[60] In addition, there does not seem to be a difference between Internet and other active smoking cessation treatments.[60] Future research efforts need to use rigorous evaluation methods to determine the effectiveness of Internet-based components, and examine potential mediators, such as e-mails, group chats, and other ways of engaging users and providing support during the quitting process. More information on factors, such as usability and sociability, that make people spend more time on sites or return to the sites more often will also be important to investigate.

97.9.2 Mobile Phone Interventions

It is estimated that 97% of the US population owns a mobile phone, and 85% own a smartphone.[79] As such, researchers have been examining the efficacy of using text messages and app-based interventions for smoking cessation. These interventions allow for the smoking treatment to be delivered directly to the person who smokes with minimal direct contact and to a large number of people at a very low cost. Additionally, people who smoke can engage with an app and/or receive messages anywhere they can use their phone when it is most appropriate or convenient and without threats to confidentiality.[62] To date, there have been less than 30 published studies testing phone-based smoking cessation interventions. There is a moderate amount of evidence to support the use of (automated) text messaging interventions for smoking cessation, while there is less evidence for app-based interventions.[62] Outcomes have included both self-report and biologically verified assessments. New research is needed to determine if sustained effects can be achieved over longer periods of time (e.g., greater than six months), what role apps may play, and if they can aid quitting attempts. Future research will be continually challenged by the quick turnover in technology. Studies testing theory will likely be more relevant and sustainable than those that only examine the latest and most technologically advanced gadgets.

97.10 SMOKING CESSATION IN SPECIAL POPULATIONS

97.10.1 Young Adult and Adolescent Smokers

According to the US 2021 National Youth Tobacco Survey, 1.5% of middle school students and high school students smoke cigarettes.[63] Given that 90% of smokers begin smoking before the age of 18[4] prevention and cessation initiatives are a high public health priority. There is some evidence to suggest that family-based,[64] school,[65] and peer-led programs[66] can help prevent use, but more work is needed. To date, there have been about 40 intervention studies examining tobacco (i.e., cigarettes, nicotine) cessation using a variety of approaches, including behavioral support and pharmacotherapy. Increases in the likelihood of quitting have ranged from 34–60% depending on the program, with the strongest effects being shown for motivational enhancement.[67,68] Caution is needed when interpreting these results, however, as the larger body of evidence on cessation programs for teens and adolescents is considerably heterogeneous. Few studies have used biological indicators of being quit or they defined being quit in various ways.[67–69] Other problems include biased samples, a poor description of the intervention used, and/or the use of complex intervention strategies that combine theoretical approaches.[67,68] Overall, future research will likely benefit from programs that include multiple components, specifically those that take the young person's intrapersonal (e.g., motivation, perceptions) and interpersonal factors (e.g., behavioral support) into consideration.[68] Additionally, it will be important to investigate demographic (e.g., household income) differences and long-term outcomes, and use study designs that include adequate attention control groups.

97.10.2 Minority and Disadvantaged Smokers

The tobacco industry has spent several decades targeting and marketing its products to various minority and disadvantaged groups, including Native Americans, sexual minorities (i.e., lesbian, gay, bisexual individuals), and those with low socioeconomic status (SES) (i.e., low levels of education, income at or below the poverty line, unemployed).[70–72] Unfortunately, this strategy has worked, and the rates of smoking and smoking-related death and disease are significantly higher among these groups when compared with the general population e.g., [5, 73]. As such, research investigating the unique needs of these various subpopulations is critical. To date, behavioral smoking cessation interventions have shown some success, for example, in reference [74], and several key intervention characteristics have been identified, such as using a proper level of health literacy for those with lower levels of education,[75] tailoring the intervention components for their cultural appropriateness,[76] and reducing financial burden for those with low income.[77] Moreover, multi-component interventions and those incorporating mindfulness training, financial incentives, motivational interviewing, and/or extended telephone-delivered counseling may also be particularly effective in the short term.[78] Overall, there is a great need to conduct future high-quality, rigorous research in this area, as it will help us to better understand how these populations can and will quit. It may be one of the only effective ways to reduce the current disparities that exist.

97.10.3 Pregnant Smokers

Given the negative impact of smoking on fetal development and the harmful effects of secondhand smoke on children, there is great interest in exploring smoking cessation interventions for pregnant and postpartum women. It is currently estimated that 54% of persons who smoke will quit when they become pregnant,[79] and 40% start smoking again within six months after delivery.[80] Rates of smoking are also higher among certain populations (e.g., those with less education and lower income).[80] Behavioral support has been the most widely used and promoted intervention for this population,[81] although pharmacotherapy (e.g., nicotine replacement therapy, bupropion) has also been used in combination with behavioral support or as a stand-alone treatment.[82] Recently, a Cochrane review summarized the effects of over 100 studies testing various psychosocial cessation programs including counseling, health education, feedback on fetal health, incentives for quitting, social support, and exercise.[81] Effects were shown to vary depending on the stage of pregnancy, length of time in the postpartum period, and program used, but there was relatively strong evidence to suggest that counseling, feedback, and incentives help pregnant and postpartum women quit.[81] It is important to note that even if complete abstinence is not achieved, a reduction in cigarettes smoked is also a beneficial outcome. More specifically, a significant reduction in the number of infants born with low birthweight[83] or those being admitted into a neonatal intensive care unit has been shown among women who participated in a psychosocial intervention to quit.[81] In the future, it will be necessary to test more rigorous behavior-focused interventions integrating prenatal and postpartum care.[84]

97.10.4 Mentally Ill Smokers

The percentage of individuals with a chronic mental illness (e.g., depression, schizophrenia) who smoke cigarettes has been reported to be 27–65%.[85–87] These higher rates can be attributed to an array of complex psychosocial and biological mechanisms,[88] and they ultimately contribute to the increased incidence of tobacco-related disease and premature death in this population.[89] Research suggests that traditional smoking cessation treatments that work with the general population are also effective for those with mental illness, but there may be differential effects. For example, there is some evidence that contingency management may be particularly effective for those with schizophrenia and posttraumatic stress disorder (PTSD),[90] while cognitive behavioral therapy has been shown to be helpful for those

with depression and anxiety.[91] Regardless of the type of mental illness, it is important to determine how smoking cessation treatment should be integrated with treatment for mental illness. Healthcare providers have been concerned that smoking cessation could exacerbate mental illness (e.g., via increased negative effects from nicotine withdrawal), thus, individual treatment plans based on the patient's acute responses to quitting may need to be developed. It is notable, however, that multiple well-designed studies in this area suggest that smoking cessation significantly reduces mental illness severity, for example, reference [92]. Going forward, it will be important to test the effects of smoking cessation programs in community behavioral healthcare settings, as the current research in this area is often biased with samples of relatively stable patients who have consistently attended treatment.[93] Newer studies should also consider examining innovative programs and harm reduction approaches for those who are not able to quit with standard programs.[94]

97.11 OTHER BEHAVIORAL APPROACHES

97.11.1 Exercise

The US Department of Health and Human Services promotes using exercise as an aid for quitting smoking,[8] and a wealth of clinical trial and acute laboratory-based research has examined the use of exercise as an adjunct to treatment. Overall, it appears that exercise might be helpful for increasing short-term abstinence because it can reduce nicotine cravings and many of the withdrawal symptoms that often accompany quitting, such as negative effects and weight gain.[95,96] However, the majority of studies have not shown strong or consistent effects.[95] This is likely attributable to numerous factors including insufficiently intense interventions, a lack of equal contact between the intervention and control conditions, small sample sizes and inadequate power, and poor adherence to the exercise programs. Going forward, studies will need to test the use of exercise as an explicit strategy that the smoker can use to quit. Lastly, studies should consider the impact of making multiple behavior changes (i.e., quitting smoking and beginning an exercise program) and the amount of time and effort required to change.

97.11.2 Electronic Cigarettes

Significant controversy exists over the safety and use of e-cigarettes, as there are continually new products being put on the market, and the long-term effects of use are not known. Key concerns over e-cigarette use include variability in the amount of nicotine delivered per puff, the potential for dual addiction (adding e-cigarettes to tobacco cigarettes) and increased tolerance to nicotine, low amounts of nicotine present in cartridges listed as containing no nicotine, and marketing to children and adolescents.[97]

To date, there is moderate evidence showing increased quit rates when comparing e-cigarettes with nicotine and NRT.[98] Such findings support the view of some smoking cessation scientists who have called for a harm-reduction approach, given that e-cigarettes may pose a lower carcinogenicity than regular cigarettes.[99] Nonetheless, the current scientific evidence for long-term use is inconclusive, and there is a substantial need to conduct future high-quality, well-designed, rigorous research that will examine the efficacy and safety of e-cigarettes as an aid for smoking cessation. Research is ongoing with studies exploring important factors beyond smoking cessation, such as the type of e-cigarette used, its nicotine content/delivery, and the characteristics of a typical user (e.g., demographics) and their patterns of use (e.g., frequency, duration, inhalation).[100]

97.11.3 Abrupt Quitting and Gradual Reduction

The traditional behavioral method used to quit smoking is to smoke as normal until a predetermined "quit day" and then abruptly stop using all cigarettes. An alternative approach that has gained some support is to gradually reduce the number of cigarettes smoked prior to quitting completely. This gradual reduction in nicotine intake could potentially reduce withdrawal symptoms, increase self-efficacy for quitting, and reduce the likelihood of relapse.[101,102] The value of this approach is somewhat controversial because there is concern that short-term decreases in smoking will not be maintained and that future quit attempts and motivation to quit will ultimately be undermined.[103] However, research shows that smokers using the reduction method have been able to maintain abstinence, and this technique may be more attractive to smokers less motivated to quit. In fact, a 2019 Cochrane review found no differences in quit rates when comparing the effects of abrupt quitting versus gradual reduction, and these effects held whether or not behavioral support, self-help materials, or nicotine replacement were used.[104] As such, there is empirical support to suggest that smokers should be given a choice of quitting methods.[105] Future research will need to better determine which types of smokers benefit the most from each method, and how this can help to inform future policy and intervention development.[106]

97.12 SUMMARY AND CONCLUSIONS

Worldwide, there is an urgent need to reduce cigarette smoking. This chapter has described a range of approaches and strategies that have shown promise for changing smoking behavior in various settings and across several populations. Overall, targeted behavioral interventions that build on the current needs and skills of those who smoke are the most effective.

CLINICAL APPLICATIONS

- People who smoke should be matched with a cessation program based on their preference, motivational level, and previous experience with quitting. This includes strategies ranging from low intensity (brief advice) to high intensity (medication with individual counseling).
- Given the clear role that cultural and socioeconomic factors play in smoking status, future cessation programs need to focus on the social and contextual issues that promote and support cigarette smoking. In particular, new efforts are needed to counteract the tobacco industry's long history of targeting disadvantaged groups.
- Smoking cessation programs should be incorporated into existing medical systems and community-based organizations, increasing the likelihood that these strategies will be disseminated to, and effectively used by, the populations with the highest level of smoking prevalence and greatest need for help.

98 Alcohol Use Disorders
Diagnosis and Treatment

Chwen-Yuen Angie Chen, MD and Sara C. Slatkin, MD

KEY POINTS

- Alcohol use disorder (AUD) has a high prevalence in the United States, with substantial societal costs from its sequelae.
- Effective screening tools exist, which can be easily implemented in clinical practice.
- An understanding of the neurobiology of addiction can assist healthcare providers in diagnosing and treating AUD.
- Motivational interviewing and harm reduction are best practiced with an understanding of the stages of this disease.
- Evidence-based treatments are available for withdrawal management, prevention of return to use, and harm reduction, which includes pharmacotherapy, behavioral therapies, mutual supports, and alternative modalities.
- During the COVID-19 pandemic, alcohol use increased, which resulted in significant physical and mental health consequences, and the full extent remains to be seen.
- WHO is currently developing an action plan (2022–2030) to effectively implement a global strategy to reduce the harmful use of alcohol, as a public health priority.
- In 2023, Canada issued a final report on guidance for reducing harmful alcohol use; it is based on the principle of autonomy and a right to know the risks of use and recommends two standard drinks or less per week to avoid cancer risks.

Case Presentation

Ms. Howard is a married 48-year-old who presents to establish care in a community primary care practice. She has no specific concerns. On routine questioning, she admits to increasing her intake from one to two glasses of red wine with dinner to mostly a bottle of wine every day since the start of the pandemic. Sometimes, on the weekends, she will drink more, adding an additional cocktail or two. Upon further social history, she explains that she has been under a lot of stress as an attorney and mother of middle school twins, both of whom struggled with distance learning and now reintegration into in-person school. Her alcohol use slowly escalated because work was mostly from home and, therefore, drinking started with lunch with minimal consequences. She is now waking up in a panic at night, is slightly shaky in the morning, and has been unable to stop drinking for more than one day. She is craving alcohol daily at around 4 pm if she has not had a drink by lunch. She finds that the "Xanax" her sister gave her is helping with these shakes and anxiety episodes. Her family history is significant for her father's premature death at age 40 from a boating accident, which may have been alcohol related. On exam, she has elevated blood pressure and, on cardiac auscultation, an audible S4; she has no stigmata of chronic liver disease but has a fine tremor in her hands. At the conclusion of the history taking and the physical exam, the care provider contemplates how to assess the patient's likelihood of alcohol use disorder, how to follow up a positive screening test, and how to provide counseling and treatment to prevent disease progression.

98.1 EPIDEMIOLOGY

The Bureau of Labor Statistics reports that 1% of gross annual income is spent on alcohol in the United States; this averages to $11 per week.[1] Calculations of the prevalence of alcohol use disorder (AUD) vary greatly depending on the methods employed. Factors to consider when reviewing this information include diagnostic criteria, sample size, and sample characteristics, in particular, age and geographic location.[2]

We have chosen to cite the figures from Grant et al.; this study utilized the DSM-V classification of alcohol use disorder. In-person interviews were conducted from June 2013 to October 2014, as part of the National Epidemiologic Survey on Alcohol and Related Conditions III (NESARC-III). The sample size was 36,309. Respondents were selected using probability sampling from the population of non-institutionalized civilians, over the age of 18, and in the United States. In order to determine its generalizability, the sample was compared with the characteristics noted in the American Community Survey from 2012. The following differences were noted in the Grant study sample:

- There was a greater percentage of men included
- More participants aged 60 to 69 were included
- Fewer participants in the age ranges of 30 to 39 and 40 to 49 were included

The prevalence of alcohol use disorder in the 12 months prior to the study interview was 13.9%. The lifetime prevalence was 29.1%.[3]

DOI: 10.1201/9781003227793-115

As highlighted by Dr. Marc A. Schukit in an accompanying editorial, this study reveals a 49.4% increase in the prevalence of AUD, compared with a prior estimate in 2001–2002. Striking increases were noted in certain populations, including women, African Americans, participants over the age of 65, and participants aged 45 to 64.[4]

The mean age of onset was 26.2. The mean age of onset decreased with increasing severity: 30.1 for mild, 25.9 for moderate, and 23.9 years for severe. The odds of 12-month and lifetime diagnoses were higher for men compared with women. The highest prevalence was among white respondents, compared to Black, Asian, Hispanic, or Pacific Islander, independent of severity. Native American respondents though had higher rates of both lifetime and 12-month alcohol use disorder compared to the white population sampled. Regarding education level, in this sample, respondents who had attained post-secondary education had higher odds of any degree of substance use, compared with respondents who had attained up to high school level. Other identified predictors of increased prevalence included:

- Previously and never married, as compared to currently married or cohabitating
- Annual family income of less than $69,999
- Residence in an urban area
- Residence in the Western United States, compared with the South and the Northeast

The percentage of respondents with AUD in the prior 12 months who sought help or treatment was 7.7; among those with alcohol use disorder in their lifetime, the percentage was 19.8. The mean age at treatment was 3.2 years greater than the mean age at diagnosis, 29.4 years versus 26.2 years; 3.6% and 8.7% sought treatment from healthcare providers among those with 12-month and lifetime alcohol use disorder, respectively. Other common treatment sources were 12-step programs and designated outpatient and residential rehabilitation facilities.[3]

The study by Grant et al. highlights the current conflict related to alcohol use disorder: the vast discrepancy between the rising prevalence of high-risk drinking and alcohol use disorders and the percentage seeking treatment. We urge universal screening in primary care for alcohol use and, also, suggest approaching screening with the variables we have outlined above to understand the characteristics associated with higher odds of AUD. Although there has been persistence in higher rates of lifetime diagnosis of alcohol use disorder among men, it also must be noted from the Grant study that there has been an alarming increase in AUD in women as exemplified in our opening case.

It has also been established that a family history of AUD increases the likelihood of developing a use disorder and, therefore, including this in family history taking is a relevant part of screening.[5]

Additionally, we would also like to bring awareness to the case of bariatric surgery, particularly Roux-en-Y gastric bypass, which is associated with a higher prevalence of AUDs. One study showed the highest prevalence in postoperative year two.[6] The cause is only postulated, with multiple theories offered. One contributing factor may be related to the change in anatomy after Roux-en-Y. Ethanol is metabolized initially by alcohol dehydrogenase (ADH) most available in the stomach, which after the bypass procedure may be significantly diminished therefore leading to higher concentrations of ethanol being absorbed more rapidly. It is highly recommended to perform alcohol use screening in this population.[7]

98.2 NEUROBIOLOGY

98.2.1 Pharmacology of Alcohol

Ethanol, also known as ethyl alcohol, is the form of alcohol for consumption. The compound is formed from two carbon atoms and one hydroxyl group. A standard alcohol drink, in the United States, contains 0.6 fluid ounces of ethanol (Figure 98.1). Ethanol is a central nervous system depressant and may have additive sedative effects when mixed with barbiturates, benzodiazepines, or opioids, and even with some antidepressants and antipsychotics.

Alcohol is readily absorbed into the bloodstream from the stomach, small intestine, and colon, given its water solubility. It is distributed to all tissues. As muscle tissue contains 7.5 times as much water as fat tissue, individuals with larger muscle mass have larger volumes of distribution and, thus, lower blood alcohol levels; therefore, due to average body composition, men and women have startlingly different responses to the same quantity of alcohol ingested.[8] Notably though, controlling for total body water and weight, women have 20 to 25% higher blood levels than men after consumption of the same amount of alcohol; it is postulated that women have lower levels of gastric metabolism, due to lower expression of ADH.[2]

Ethanol is not a potent compound in the central nervous system; effects are not observed until the blood concentration is at least 5–10 mmol/L.

Ethanol acts by directly binding to membrane-bound ligand-gated ion channels, of which gamma-aminobutyric acid type A ($GABA_A$), N-methyl-D-aspartate (NMDA), glycine, neuronal nicotinic, and 5-hydroxytryptamine type 3 ($5\text{-}HT_3$) are the most notable; binding is specific, and it is inhibitory at some channels and excitatory at others. It also acts on voltage-dependent calcium channels. Additionally, the compound can directly interact with secondary messenger proteins.[9]

Ethanol is primarily metabolized enzymatically in the liver. ADH degrades the molecule to acetaldehyde by first-order kinetics, or in other words, at a constant rate; further conversion to acetate is by acetaldehyde dehydrogenase. Additionally, mixed-function oxidases, including MEOS-CYP2E1, are also involved.

Pharmacodynamically, during initial ingestion, alcohol results in a state of disinhibition. With further consumption, the following are characteristics: impaired judgment,

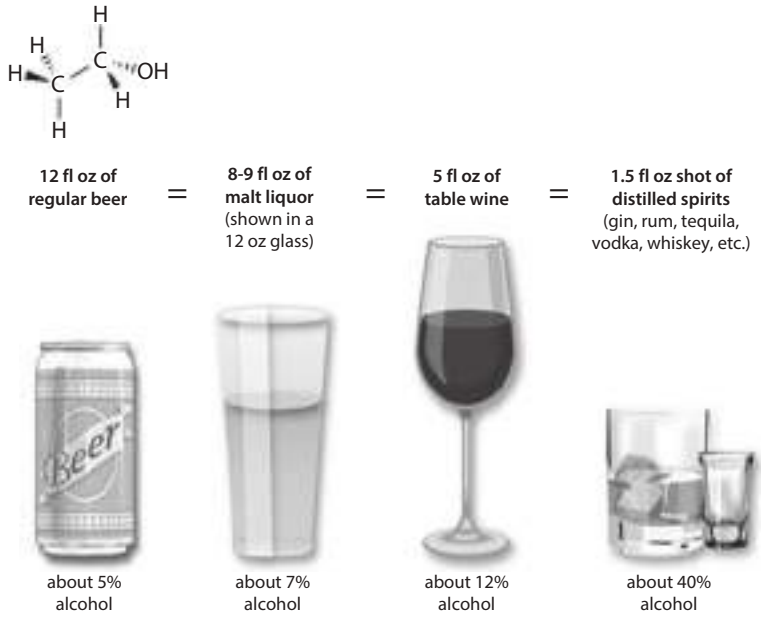

FIGURE 98.1 The chemical compounds of alcohol and a standard drink.

slowed reaction time, emotional outbursts, and ataxia. Classically known sedative and hypnotic effects are at higher blood levels (Figure 98.2). As commonly warned, alcohol potentiates the depressive effects of benzodiazepines and barbiturates if co-ingested because these agents also act on the same $GABA_A$ receptors.[2]

In summary, most notable, in terms of pharmacokinetics, is ethanol's ease of absorption and distribution, yet low potency, but diverse and specific interactions in the central nervous system.

98.2.2 Stages of Addiction

Mainstream public health publications and websites from recovery centers characterize the stages of addiction into a three-stage or a four-stage model. Additionally, central to the practice of addiction medicine are Volkow and Koob's theories.

The three-stage model is described as early, middle, and late/end. The early stage is defined by developing tolerance to alcohol; a patient may identify that his or her pattern of drinking is different from that of his or her peers. In the next phase, patients have cravings for alcohol, have symptoms of withdrawal, and suffer consequences in their personal and/or professional lives. The final stage, titled late or end, is characterized by loss of control; patients at this stage have suffered serious personal and physical consequences from alcohol use.[10]

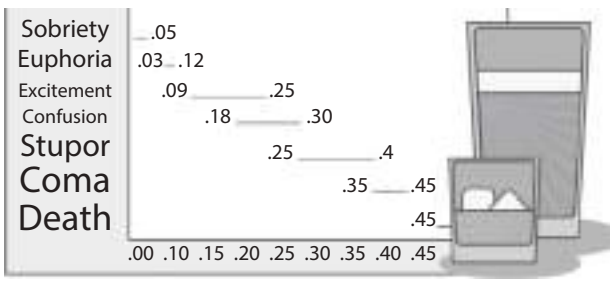

FIGURE 98.2 Stages of alcohol intoxication based on blood alcohol level.

The stages in the four-stage model are adaptive, dependence, progression, and conclusion. The first stage also includes the development of tolerance; it is also characterized by the use of alcohol as a coping strategy for challenging emotions, or more colloquially as an "escape from reality". In the next stage, the patient's amount of alcohol consumption is increased; a patient may start to plan his or her life around drinking and may make frequent excuses to consume more. The progression stage, which is similar to the third stage of the first model described, is unique for the "loss of control" experienced with respect to alcohol; drinking becomes an almost constant and solitary activity. The conclusion stage is defined by physical symptoms and serious personal and professional consequences.[11]

Volkow, Koob et al. emphasize the concept of alcohol use disorder as "an acquired disease of the brain". This brain disease model has three stages, which we summarize in Table 98.1. This model has informed critical advances in the prevention and treatment of this disease, as well as in public policy.[12]

Volkow has also taught another conceptualization to understand the addicted brain compared with a normal control. Addiction confers tremendous saliency on the substance, an overriding preoccupation, with minimal control over the drive to use. And, the memory of use, the positive associations, drives the saliency.

TABLE 98.1
Stages in Volkow and Koob's Brain Disease Model[12]

Stage	Clinical Characteristics	Behavioral Characteristics	Neural Pathways
Binge and intoxication	Pavlovian conditioning: repeated rewarding experiences with alcohol become associated with environmental stimuli	Substance-seeking behavior and binge use	Increased dopamine in the basal ganglia (nucleus accumbens and ventral tegmental areas)
Withdrawal and negative affect	Symptoms of withdrawal	Dysphoria	Desensitization of the reward circuits to dopamine and corticotropin-releasing factor dysregulation (amygdala and habenula)
Preoccupation and anticipation/craving	Inability to resist urges to use or follow through on plans to stop use	Impaired executive functioning	Impaired dopamine and glutamate signaling in the prefrontal cortex insula and allocortex

Dr. George F. Koob describes addiction and thereby alcohol use disorder as a "Reward Deficit and Stress Surfeit Disorder", complementary and supportive to Volkow's theory. He defines alcohol use disorder as: "a compulsion to seek and take a drug, loss of control in limiting intake, and the emergence of a negative emotional state when access to the drug is prevented". He highlights a transition in the disease state from impulsive use to compulsive use. This later stage is supported by circuits of negative reinforcement, used as a means to combat a negative emotional state, which is caused by dysregulation of the brain's reward circuit and recruitment of the brain's stress systems.[14] In other words, there is a reward deficit, as addiction progresses, more alcohol is required to get the same benefit, equivalent to the pathophysiologic phenomenon of tolerance. Moreover, there is also a stress surfeit, where there is an excessive sympathetic response to lack of alcohol, which is manifested clinically as withdrawal. Over time, baseline set points in the brain are reprogrammed, termed an allostatic state, in which the amount required to regain a pleasurable state is increased (more work to achieve homeostasis, the downward spiral, and, thus, a deficit is created. There becomes a new normal that is actually a perpetual state of negative emotions, which Koob often refers to as the "dark side of addiction".[13]

In summary, alcohol use disorder follows a progression from initially rewarding use into a growing tolerance. Negative emotions and physical symptoms, which include cravings and withdrawal, ensue; these states are often accompanied by costly personal and professional consequences, along with the loss of self-control, leading to more drinking. A destructive cycle is created, leading to continued and increased use of alcohol.

98.2.3 $GABA_A$ Receptors

We would like to highlight the role of $GABA_A$ receptors in the short- and long-term effects of alcohol use in the central nervous system, as they are a prominent therapeutic target. It is thought that ethanol activates $GABA_A$-associated ion currents in the mesolimbic dopamine system; thus, alcohol intake, through $GABA_A$ signaling, has a strong impact in the reward circuit of the brain, as discussed in the prior section on the stages of alcohol use. With repeated exposure to ethanol, the ion current through these receptors is diminished; additionally, the synthesis is downregulated at the mRNA level.[9]

98.2.4 Dopaminergic Pathways

As we have stressed the role of the reward circuit in the pathogenesis of AUD and discussed its activation downstream of $GABA_A$ receptors, we would like to highlight some specifics regarding these pathways and alcohol intake.

- There is a dose-dependent relationship between alcohol intake and dopamine release from the nucleus accumbens.
- The negative mood in alcohol withdrawal is associated with inhibition of dopamine action in the limbic system.[15]
- With chronic use, the persistent release of dopamine "hardwires" the amygdala; a restructured pathway is then created, the activation of which is associated with specific environmental cues related to the individual's pattern of alcohol use. Thus, the addicted brain is readied for craving, reward for use, and relapse.[16]

98.3 DIAGNOSIS

The first step, as always, is recognition, and the importance of this task is highlighted by the societal cost of AUD. The CDC estimates a cost of about $249 billion, as of 2010, averages to $2.05 per drink in expenses related to workplace productivity losses, healthcare expenses, criminal justice costs, and expenditures related to motor vehicle accidents.[17]

98.3.1 Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) Criteria for Diagnosis

In clinical practice, consistent with our colleagues in addiction medicine, we employ the diagnostic criteria from the DSM-5 (Figure 98.3).[18]

A problematic pattern of alcohol use leading to clinically significant impairment or distress, as manifested by at least two of the following, occurring within a 12-month period:

Impaired Control

1. Alcohol is often taken in larger amounts or over a longer period than was intended.
2. There is a persistent desire or unsuccessful efforts to cut down or control alcohol use.
3. A great deal of time is spent in activities necessary to obtain alcohol, use alcohol, or recover from its effects.
4. Craving, or a strong desire or urge to use alcohol.

Social Impairment

5. Recurrent alcohol use resulting in a failure to fulfill major role obligations at work, school, or home.
6. Continued alcohol use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of alcohol.
7. Important social, occupational, or recreational activities are given up or reduced because of alcohol use.

Risky Use

8. Recurrent alcohol use in situations in which it is physically hazardous.
9. Alcohol use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by alcohol.

Physiological Indicators

10. Tolerance, as defined by either of the following:
    a. A need for markedly increased amounts of alcohol to achieve intoxication or desired effect.
    b. A markedly diminished effect with continued use of the same amount of alcohol.
11. Withdrawal, as manifested by either of the following:
    a. The characteristic withdrawal syndrome for alcohol
    b. Alcohol (or a closely related substance, such as a benzodiazepine) is taken to relieve or avoid withdrawal symptoms.

FIGURE 98.3 DSM-5 diagnostic criteria.[18]

Patients meet the diagnosis if at least two of the listed 11 criteria are met within a 12-month period. The sub-classifications are based on the number of criteria met:

- Mild: 2–3
- Moderate: 4–5
- Severe: 6 or more

This staged diagnosis replaces the prior DSM diagnoses of "alcohol abuse and dependence". Legal problems are no longer a criterion and "craving" has been added, as criterion 4.[19]

98.3.2 Screening Tools

We, in agreement with the US Preventative Screening Task Force, recommend screening all adults for AUD at least once a year.[20] Much of the downstream consequences of alcohol use can be prevented with screening and early intervention for any indication of problematic use. Recent Canadian guidance on alcohol use was published in 2023 (Canada's Guidance on Alcohol and Health: Final Report: www.ccsa.ca/canadas-guidance-alcohol-and-health). The report concluded that there is a continuum of risk associated with weekly alcohol use where the risks of developing cancer and other alcohol-related consequences are reduced if one drinks two[2] standard drinks or less per week.

We support the three-tiered screening approach described by Dr. Fleming, as published with the support of the National Institute on Alcohol Abuse and Alcoholism (NIAAA), an NIH institute and an excellent reference on this topic (Table 98.2).

Level 1 consists of a single question: on any one occasion: "In the past three months, have you had more than five alcoholic drinks?"; this screening was initially proposed in 1998 and has since been repeatedly validated. Its value also lies in its brevity and ease of administration. If a patient responds yes or if time permits and a patient has admitted to alcohol use, the level 2 screen is employed, which further quantifies the patient's alcohol intake.

A more extensive screen, such as the Alcohol Use Disorders Identification Test (AUDIT), Figure 98.4, is suggested if a male patient reports an intake of more than 14 drinks per week or four drinks per day and if a female patient reports an intake of more than seven drinks per week or three drinks per day; a level 3 screen can also be used if there is high suspicion for alcohol use disorder at lower amounts of self-reported intake.[21] The AUDIT indicates harmful or hazardous drinking at scores greater than eight for men under age 60 and at greater than four for

TABLE 98.2
Three-tiered Screening Approach[21]

Level	Indication	Technique
1	All adults, annually	On any single occasion during the past three months, have you had more than five drinks containing alcohol? Positive: affirmative response
2	Positive level 1 screen OR all patients with alcohol use	1. On average, how many days per week do you drink alcohol? 2. On a typical day when you drink, how many drinks do you have? 3. What is the maximum number of drinks you had on any given day in the past month? Positive:Men: more than 14 drinks/week or four drinks/dayWomen: more than seven drinks/week or three drinks/day
3	Positive level 2 screen OR if high suspicion of misuse	Use the Alcohol Use Disorders Identification Test (AUDIT)

Questions	0	1	2	3	4
1. How often do you have a drink containing alcohol?	Never	Monthly or less	2 to 4 times a month	2 to 3 times a week	4 or more times a week
2. How many drinks containing alcohol do you have on a typical day when you are drinking?	1 or 2	3 or 4	5 or 6	7 to 9	10 or more
3. How often do you have 5 or more drinks on one occasion?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily
4. How often during the last year have you found that you were not able to stop drinking once you had started?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily
5. How often during the last year have you failed to do what was normally expected of you because of drinking?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily
6. How often during the last year have you needed a first drink in the morning to get yourself going after a heavy drinking session?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily
7. How often during the last year have you had a feeling of guilt or remorse after drinking?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily
8. How often during the last year have you been unable to remember what happened the night before because of your drinking?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily
9. Have you or someone else been injured because of your drinking?	No		Yes, but not in the last year		Yes, during the last year
10. Has a relative, friend, doctor, or other health care worker been concerned about your drinking or suggested you cut down?	No		Yes, but not in the last year		Yes, during the last year

FIGURE 98.4 Alcohol Use Disorders Identification Test (AUDIT)[22]

women, adolescents, and men over the age of 60; a score of 13 or more in women, and 15 or more in men, is likely to indicate alcohol dependence.[22] For patients with a positive AUDIT, we recommend utilizing the DSM-5 criteria to further clarify a possible diagnosis of AUD.

98.3.3 Special Populations: Elderly

We would like to highlight screening and diagnosis in the geriatric population, patients over the age of 65. The disease entity is of high prevalence in this population, at least 1% to 3% but perhaps as high as 33%, as there is a substantial degree of underrecognition and misdiagnosis. Various reasons for this phenomenon have been identified including reluctance to disclose on the part of patients, lower degree of suspicion from healthcare providers, atypical patient presentation, due to multiple comorbid diagnoses, and provider lack of knowledge of diagnostic tools and criteria.

The NIAAA recommends no more than one drink per day for patients over the age of 65, as the equivalent intake

of alcohol results in higher blood levels due to unique differences in body composition; in addition to inquiring about current consumption patterns, it is crucial to determine lifetime alcohol use. The AUDIT remains a validated screening tool in this population; various experts and studies also support the use of the CAGE questions.

The consequences of underdiagnosis, and, thus, lack of treatment, are devastating in this population and include worsening of chronic diseases, commencement of and/or exacerbation of neuro-psychiatric conditions, especially dementia, and greater cardiovascular and gastrointestinal diseases. Alcohol use has been implicated in the pathogenesis of urinary and fecal incontinence, falls, syncope, heart failure, aspiration pneumonia, and malnutrition in the elderly.[23,24]

98.3.4 Special Populations: College Students

Alcohol consumption among college students is common; in one study, 40% of college students polled reported intake of five or more consecutive drinks in the past two weeks.[25] The Harvard School of Public Health College Alcohol Study (CAS) has provided significant information on the harms of binge drinking in this population. This study has correlated this behavior with lower academic performance, risky sexual behavior, and antisocial behaviors, including vandalism and those resulting in legal consequences.[26]

Effective intervention has focused on prevention, particularly on education regarding the consequences of excessive alcohol use. The NIAAA has taken a very proactive role on this topic, since 2002, and has a task force to develop evidence-based preventative strategies.[2] We highly encourage providers who treat this population to reference the NIAAA-sponsored site, CollegeDrinkingPrevention.gov, for up-to-date research and recommendations on this subject. It includes educational material for college students and parents, as well as tools for colleges to influence the culture surrounding alcohol use on campus.

98.3.5 Special Populations: Physicians

As members ourselves, we felt it especially important to include physicians in our special populations section. Throughout our careers, we have experienced and heard anecdotes of colleagues' drinking behaviors, but it may not be apparent to most in the field how pervasive this issue is and what the consequences are for the medical community.

Alcohol use disorder among physicians is common: 10 to 12% of doctors develop a substance use disorder, of which alcohol use disorder is the most prevalent, at about 50%. The specialties most at risk are anesthesia, emergency medicine, and psychiatry. The hallmarks of this disease in this population are delayed diagnosis and end-stage presentation, which is speculated to be due to high professional stigma and underreporting by colleagues.[27] We also theorize that the lack of uniformity between state-specific policies, at the level of the medical board and otherwise, may also influence the willingness of physicians to seek help depending on the risk to their professional licensure.

Thus, we encourage maintaining vigilance and sensitivity surrounding the diagnosis of AUD in this population; it affects not only patient safety and delivery of care but also the culture of wellness in our profession. We recommend becoming knowledgeable about one's local institutional bylaws around physicians' well-being and state medical board procedures on the reporting and handling of SUDs among physicians.

According to the website of the Federation of State Physician Health Programs (www.fsphp.org), at the time of this writing, there are 47 states and the District of Columbia that have a Physician Health Program (PHP); three additional states are now participating, Delaware, South Carolina, and Wisconsin, since our last publication. The states that do not have a PHP are California, Nebraska, and South Dakota. A confidential PHP where physicians can seek guidance on treatment, before significant patient care and physician health are jeopardized, is essential to an effective program. Equally important is the compassionate rehabilitation of the impaired physician who has temporarily lost their privilege to practice so that he or she may be successfully reintegrated into medical practice.[28]

98.4 MEDICAL COMORBIDITIES

Alcohol has known pathophysiologic effects on almost all body organ systems.

Regarding the brain, the following areas are most impacted: the cerebellum, the limbic system, and the cortex. The physical size of the organ has been observed to decrease, and there are known delays in neurotransmitter processing. The clinical effects include mood changes, memory loss, seizures, loss of motor coordination, impaired temperature regulation, and decreased learning ability. Additionally, the risk of ischemic stroke is increased; it has been noted, among binge drinkers, that the risk is 56% more likely.

Cardiovascular implications include cardiomyopathy, atrial fibrillation, ventricular tachycardia, and hypertension.

The most publicly known physical consequence is liver damage, which proceeds along a spectrum of disease from steatosis to hepatitis, to fibrosis, and then to cirrhosis. Additional gastrointestinal effects include acute and chronic pancreatitis, gastritis, and GERD.

There is a strong association between alcohol use and cancer risk. Cancers of the following organs have been associated with alcohol use: mouth, esophagus, pharynx, larynx, liver, colon, rectum, and breast.

Effects on the hematopoietic system are also well studied. A deleterious effect on both the adaptive and the innate immune systems has been documented. Ethanol exerts a bone marrow suppressive effect resulting in pancytopenia. It has direct effects on circulating platelets and white blood cells, which results in loss of function.

Regarding the genitourinary system, in men, there is a decrease in erectile capacity and testicular atrophy. In women, amenorrhea, decreased ovarian size, and infertility have been noted, as well as an increased risk of spontaneous abortions. Notably, also, ethanol use during pregnancy can result in fetal alcohol syndrome.[29] According to the Centers for Disease Control and Prevention and the American Congress of Obstetricians and Gynecologists, no amount of alcohol is safe during pregnancy, and alcohol use during pregnancy is a leading cause of preventable birth defects.

98.5 TREATMENT

98.5.1 Withdrawal Management

98.5.1.1 Withdrawal Symptoms and Timeframe

The first step in managing alcohol withdrawal is establishing the diagnosis, which has two criteria:

1. Recent cessation or reduction in alcohol consumption, with a history of regular, prolonged use.
2. Symptoms and signs of alcohol withdrawal, not explained by another medical illness.

Symptoms of alcohol withdrawal include hypertension, tachycardia, diaphoresis, tremulousness, dilated pupils, disorientation, hyperarousal, and seizures. Signs include anxiety, insomnia, hallucinations, paranoia, nausea, and irritability.

Alcohol withdrawal syndrome has a characteristic timeline of distinct symptoms and complications. Withdrawal symptoms, such as those listed above, begin immediately within six hours, depending on the severity, and can last up to six days. The seizure risk is highest between six and 72 hours. Hallucinations can occur between days one and seven. Delirium tremens are typically between two and 14 days.[30,31]

98.5.1.2 Inpatient versus Outpatient Setting

The American Society of Addiction Medicine (ASAM) considers the following patients to be safely monitored on an outpatient basis:

- Patients with mild withdrawal symptoms
- Patients without a history of withdrawal seizures or delirium tremens
- Patients without significant comorbid medical or mental health conditions

Additionally, ASAM advocates that patients managed in an outpatient setting have a reliable person to assist in their care, have easy access to emergency services, if required, and have regular clinic follow-up appointments.

ASAM has an extensive online resource, titled CONTINUUM, which allows clinicians to match patients to appropriate levels of care, at asamcontinuum.com.[2]

98.5.1.2.1 Use of the CIWA Protocol

The Clinical Institute Withdrawal Assessment, revised iteration (CIWA-Ar) is a validated tool for the treatment of alcohol withdrawal. It contains ten symptoms, which can be rated based on severity (Figure 98.5). The total score can then be used to guide pharmacologic treatment.[32] In clinical use, the tool is commonly embedded within the electronic health record and used in the management of hospitalized patients with alcohol withdrawal; regular assessments are then scheduled and completed by a healthcare provider, including the bedside nurse. An associated order set can then be used to administer medication, most commonly benzodiazepines, based on the total score obtained.

Several limitations are immediately apparent, even without extensive familiarity with this scoring system. The symptoms cataloged are similar to other medical and psychiatric conditions, which are often comorbid at the time of withdrawal.[33] Additionally, the scoring system is subjective, as the patients are self-reporting the severity and the tool does not include vital signs. But despite these limitations, the implementation of the CIWA-Ar protocol has been shown to limit the duration of benzodiazepine use and reduce the incidence of major complications, including severe agitation requiring restraints and alcohol withdrawal hallucinations.[34]

98.5.1.2.2 Medications in Acute Withdrawal

Benzodiazepines are the mainstay in the treatment of alcohol withdrawal. This clinical practice has been demonstrated in large clinical trials showing the superiority of this class, in terms of overall symptom management of withdrawal, delirium, and seizures, in addition to facilitating entry into rehabilitation programs, compared with other active agents and to placebo. It has also been clearly shown that the use of short-acting benzodiazepines, in particular alprazolam, and lorazepam, increases the risk of dependence and addiction to these agents, as compared with longer-acting agents, chlordiazepoxide and diazepam.[31,32]

In our clinical practice, with hospitalized patients, we use our initial assessment and subsequent trends on the CIWA-Ar assessment to guide dosing. For patients with severe withdrawal symptoms at presentation and correspondingly high CIWA-Ar scores, we start scheduled long-acting benzodiazepines, most commonly chlordiazepoxide or diazepam. We then order short-acting benzodiazepines, most commonly lorazepam, in a range to be given in response to the CIWA-Ar score.

In liver failure, lorazepam, oxazepam, and temazepam are the safest options in the drug class, due to metabolism by conjugation or Phase II metabolism that avoids the CYP450 pathway; only lorazepam is available IV.[35]

Adjunctive and alternative agents are becoming more commonly used in acute withdrawal, and thus, we would like to summarily highlight alternative regimens and rationales for their use.

Nausea and vomiting. Ask "Do you feel sick to your stomach? Have you vomited?"
Observation:
0—No nausea and no vomiting
1—Mild nausea with no vomiting
2—
3—
4—Intermittent nausea with dry heaves
5—
6—
7—Constant nausea, frequent dry heaves, and vomiting

Tremor. Ask patient to extend arms and spread fingers apart.
Observation:
0—No tremor
1—Tremor not visible but can be felt, fingertip to fingertip
2—
3—
4—Moderate tremor with arms extended
5—
6—
7—Severe tremor, even with arms not extended

Paroxysmal sweats
Observation:
0—No sweat visible
1—Barely perceptible sweating; palms moist
2—
3—
4—Beads of sweat obvious on forehead
5—
6—
7—Drenching sweats

Anxiety. Ask "Do you feel nervous?"
Observation:
0—No anxiety (at ease)
1—Mildly anxious
2—
3—
4—Moderately anxious or guarded, so anxiety is inferred
5—
6—
7—Equivalent to acute panic states as occur in severe delirium or acute schizophrenic reactions

Agitation
Observation:
0—Normal activity
1—Somewhat more than normal activity
2—
3—
4—Moderately fidgety and restless
5—
6—
7—Paces back and forth during most of the interview or constantly thrashes about

Tactile disturbances. Ask "Do you have you any itching, pins-and-needles sensations, burning, or numbness, or do you feel like bugs are crawling on or under your skin?"
Observation:
0—None
1—Very mild itching, pins-and-needles sensation, burning, or numbness
2—Mild itching, pins-and-needles sensation, burning, or numbness
3—Moderate itching, pins-and-needles sensation, burning, or numbness
4—Moderately severe hallucinations
5—Severe hallucinations
6—Extremely severe hallucinations
7—Continuous hallucinations

Auditory disturbances. Ask "Are you more aware of sounds around you? Are they harsh? Do they frighten you? Are you hearing anything that is disturbing to you? Are you hearing things you know are not there?"
Observation
0—Not present
1—Very mild harshness or ability to frighten
2—Mild harshness or ability to frighten
3—Moderate harshness or ability to frighten
4—Moderately severe hallucinations
5—Severe hallucinations
6—Extremely severe hallucinations
7—Continuous hallucinations

Visual disturbances. Ask "Does the light appear to be too bright? Is its color different? Does it hurt your eyes? Are you seeing anything that is disturbing to you? Are you seeing things you know are not there?"
Observation:
0—Not present
1—Very mild sensitivity
2—Mild sensitivity
3—Moderate sensitivity
4—Moderately severe hallucinations
5—Severe hallucinations
6—Extremely severe hallucinations
7—Continuous hallucinations

Headache, fullness in head. Ask "Does your head feel different? Does it feel like there is a band around your head?"
Do not rate for dizziness or lightheadness; otherwise, rate severity.
0—Not present
1—Very mild
2—Mild
3—Moderate
4—Moderately severe
5—Severe
6—Very severe
7—Extremely severe

Orientation and clouding of sensorium. Ask "What day is this? Where are you? Who am I?"
Observation:
0—Orientated and can do serial additions
1—Cannot do serial additions or is uncertain about date
2—Date disorientation by no more than two calendar days
3—Date disorientation by more than two calendar days
4—Disorientated for place and/or person

Total score:_____ (maximum = 67) Rater's initials_____

FIGURE 98.5 The Clinical Institute Withdrawal Assessment (CIWA).

Carbamazepine is a well-studied alternative agent. It is better than placebo and equal to oxazepam for mild to moderate withdrawal. It is effective in the prevention of alcohol withdrawal seizures, but it has no known activity for the prevention of delirium tremens. As compared with lorazepam, patients treated with carbamazepine in acute withdrawal had fewer protracted symptoms, and in the long term, had a lower risk of relapse.[35]

Valproic acid alone has been studied in two double-blind, randomized control trials. One study reported lessened withdrawal symptoms, a higher rate of completion, and fewer seizures, as compared with a traditional CIWA-Ar-driven protocol with oxazepam as needed. The dose used was 500 mg three times a day of week one.[37] The second study had similar results.

To reiterate the topic of anticonvulsants, to date, there are no published studies regarding the use of gabapentin in acute withdrawal.[35] There is, however, expanding clinical experience using gabapentin in high doses, 600–900 mg three times a day, as an adjunctive or stand-alone agent for the management of alcohol withdrawal; in patients requiring high doses of benzodiazepines, using gabapentin has decreased rates of delirium and shortened the duration of benzodiazepine use, with higher success of prolonged abstinence.

Electrolyte management and vitamin supplementation is another aspect of treatment in acute alcohol withdrawal. We would like to emphasize the administration of thiamine prior to the use of glucose, in patients undergoing withdrawal and with concomitant malnutrition, to prevent Wernicke–Korsakoff syndrome; we dose thiamine 100 mg IV three times daily during acute withdrawal. In hospitalized patients, the repletion of magnesium, potassium, and phosphate can be completed as needed and at least daily, pending on levels and trends.[37] Sustained abstinence from alcohol will reverse these metabolic derangements. Daily

supplementation with thiamine 100 mg, folic acid 1 mg, and a standard dose multivitamin is required initially; in our clinical practice, we prescribe a one-month supply of supplements to our patients, which we have found to be sufficient if patients maintain sobriety and have a healthy diet.[38,39]

98.5.2 Maintenance of Sobriety and Relapse Prevention

Understandably, in the acute clinical scenario, much importance is placed on executing a safe and successful detox, we argue that at least equal emphasis must be placed on developing a plan for sustained abstinence at the same time. Patients, however, are often reluctant to pursue total abstinence; the clinical interaction is improved by assessing readiness for change and by educating on the neurobiology of AUD. This may require monitoring patients through stuttering attempts at controlled drinking in order for them to be convinced of their addiction.

The highest risk of relapse is at three months and one year from the date of sobriety.[40] The following patient characteristics are associated with an even higher risk of relapse: lower level of educational attainment, more problems related to their alcohol use (including legal and psychosocial), unemployment, and consumption of large quantities of alcohol.[41]

Relapse is often a part of the process of recovery and need not be considered treatment failure. Just as one would not withdraw treatment from a brittle diabetic, one continues to treat through each relapse, welcoming the patient to develop new insights and new ways of coping with stress, managing drinking triggers, adjusting medication regimens, and addressing comorbid psychiatric conditions as indicated. It should be mentioned here as well that the risk for relapse is high in those with untreated or undertreated comorbid psychiatric conditions.

Comorbid psychiatric conditions highly associated with AUD include antisocial personality disorder, bipolar disorder, certain anxiety disorders (e.g., social phobia, panic disorder, and post-traumatic stress disorder [PTSD]), schizophrenia, and major depression.[42,43]

98.5.2.1 Pharmacologic Treatments

Currently, the FDA has approved three medications for the treatment of AUD, disulfiram, acamprosate, and naltrexone, which is approved in both an oral and depot formulation (www.niaaa.nih.gov/publications/brochures-and-fact-sheets/treatment-alcohol-problems-finding-and-getting-help#pub-toc3). There is an excellent table by Dr. Peter Friedmann which lists dosage, precautions, and common adverse events.[41] All these medications have proven efficacy in clinical trials and are greatly underutilized for this indication.

In clinical practice, through shared decision-making with our patients, we now routinely offer the use of naltrexone, either the oral or injectable form. We often initiate this medication as close to the time of detox as possible because of its growing success in reducing the risk of relapse and heavy drinking. According to the COMBINE trial, naltrexone with medication management counseling alone increased the number of abstinent days and decreased cravings during the four-month study period. The most common side effects of naltrexone are nausea and dizziness, therefore, it is recommended that patients start at a low dose, take with food, and take the medication before bedtime, for the first few days at least. There is no significant harm if patients drink while taking naltrexone. Naltrexone can sometimes cause depression and is relatively contraindicated in patients with a prior suicide history or a current or prior severe depression. The treatment team and patient need to assess the risk benefit of potential side effects versus the harms of continued drinking. If oral naltrexone is tolerated, then the month-long injectable form may be offered. Liver enzymes are monitored as naltrexone undergoes hepatic metabolism.[44]

Additional medications used for the maintenance of sobriety include those in the classes of anticonvulsants, antidepressants, and GABA agonists, which have been studied in randomized trials, but as mentioned, are not FDA-approved for this indication. Topiramate has been shown to decrease heavy drinking and increase abstinence rates. In patients with comorbid depression, selective serotonin-reuptake inhibitors (SSRIs) have been demonstrated to reduce recurrent alcohol intake. In early onset AUD, ondansetron (Zofran) has been shown to reduce consumption of alcohol as well.[41]

GABA agonists that have shown efficacy in the maintenance of sobriety include baclofen, sodium oxybate, gabapentin, pregabalin, and tiagabine. The mechanism is thought to be mediated more successfully through the B subtype of GABA and results in reduced dopaminergic-reward circuit activity in response to cues, craving, and protracted withdrawal symptoms.

We would like to comment on gabapentin specifically, given its mention in other sections of this chapter. In multiple, placebo-controlled studies, at varying doses, it has been shown to decrease the risk of relapse, reduce heavy consumption, and control craving. We commonly use the dose of 300 mg twice a day, as used in one positive study.[45]

In conclusion, multiple pharmacologic therapies have an evidence base for the treatment of AUD in the early recovery period, yet no one treatment has proven more efficacious than another.

98.5.2.2 Behavioral Treatments

It should not be understated that behavioral, non-pharmacologic treatments for AUD are necessary for recovery. These treatment techniques can be employed in the form of motivational interviewing to engage a reluctant patient in treatment, even prior to detoxification. After detoxification, these therapies are crucial for ensuring medication adherence, assessing for and treating comorbid psychiatric disease, and addressing triggers for relapse.

The following behavioral interventions have been proven effective in AUD:

- Psychotherapy, individual and group
- Behavioral therapy: aversive therapy, cue exposure, relaxation training, contingency management, and skills training (rational thinking, problem-solving, effective conflict resolution)
- Cognitive behavioral therapy, specifically identifying and changing automatic thoughts and triggers related to compulsive alcohol intake
- Family and couples therapy[46]

We would like to highlight the results of Project MATCH, a five-site study sponsored by the NIAAA; its objective was to determine patient characteristics associated with more successful outcomes with specific behavioral treatments. Three types of treatments were included: cognitive behavioral therapy, motivational enhancement therapy, and twelve-step facilitation therapy. At the one and three-year follow-ups, a consistent pattern emerged: patients with high levels of anger had better outcomes in motivational enhancement therapy than the other two treatment modalities, and patients with low anger did better in 12-step facilitation and cognitive behavioral therapy. Additionally, patients with social networks who tend to drink were more likely to have improved outcomes in 12-step facilitation. Overall, though, the conclusion, at the one- and three-year follow-ups, was that no one treatment modality was superior.[47]

We strongly advocate for clinical partnerships with behavioral health specialists, psychologists, and psychiatrists in the treatment of AUD.

98.5.2.2.1 Mutual Help Groups

Mutual help groups are a highly effective form of peer-led support to prevent relapse. Many unique groups exist and have demonstrated sustained recovery among their participants. An excellent reference on the topic is *Circles of Recovery: Self-help Organizations for Addictions* by Keith Humphreys. Featured examples, with meetings nationally, internationally, and with accessible websites, include:

- Refuge Recovery, a Buddhist meditation approach to recovery and is abstinence-based
- Smart Recovery, which is CBT-based and abstinence-based
- Lifering, which is a secular group
- Women for Sobriety
- Alcoholics Anonymous (AA)[48]

We would like to highlight AA in more detail due to its historical and cultural relevance along with its longevity and the available evidence of efficacy. On its website, AA describes the organization as: "an international fellowship of men and women who have had a drinking problem". It is non-professional, self-supporting, apolitical, and available in almost all communities. According to the AA Preamble: "the only requirement for membership is "a desire to stop drinking".

We have shared the 12 steps of AA in Figure 98.6 to increase your familiarity with the program and for your easy reference to share with patients and colleagues.[44] A specific component of the program is that new members are partnered with another member as a sponsor, who can provide mentorship throughout the process of recovery. After prolonged abstinence, members can volunteer to become sponsors, embodying the AA principle that one must "give it away to keep it". It is now common knowledge that the power of service, or volunteerism, is commonly emotionally uplifting and can reduce symptoms of depression and feelings of hopelessness, especially when one can use their own experiences to help another out of the depths of despair. This is at the heart of 12-step recovery.

Multiple trials have compared the outcomes of patients with AUD who engage in AA and those who do not, and a positive association has been demonstrated repeatedly in terms of decreasing the risk of relapse and improving psychosocial well-being. The greatest effect is seen with relatively treatment naïve patients who actively engage in all the service components of AA early in their recovery.[49,50]

The following patient characteristics have been associated with a higher rate of program completion: greater self-motivation, African American, having a formal religious background, prior attendance at formal religious functions, belief in the disease model of addiction, more social personality, and greater participation in the group's activities.[51]

In our opinion, a treatment plan for AUD is not complete without the inclusion of mutual help groups. In our practice, we strongly encourage our patients to join a group; we emphasize to patients that each mutual help group, even if part of the same organization, has its own traits and personality, therefore, if a patient has a negative experience with one group to continue their search for another.

98.5.2.4 Alternative Treatments

We would like to share some alternative treatments for AUD that have been supported by the ASAM.

98.5.2.4.1 Herbal Remedies

Isoflavone compounds, from the root of the kudzu plant (*Pueraria lobata*), have shown efficacy, in animal and human studies, in reducing the amount of alcohol consumed. One dose studied was 3 g of extract daily.

98.5.2.4.2 Acupuncture

Conventional acupuncture treatment has been shown to decrease a patient's craving for alcohol on self-reported scales. The effect is proposed to be mediated through the release of endogenous opioids.

98.5.2.4.3 Transcutaneous Electrical Acupuncture Stimulation

If patients desire a non-invasive approach, transcutaneous electrical stimulation at traditional acupoints has also

THE TWELVE STEPS OF ALCOHOLICS ANONYMOUS

1. We admitted we were powerless over alcohol—that our lives had become unmanageable.
2. Came to believe that a Power greater than ourselves could restore us to sanity.
3. Made a decision to turn our will and our lives over to the care of God as we *understood Him*.
4. Made a searching and fearless moral inventory of ourselves.
5. Admitted to God, to ourselves, and to another human being the exact nature of our wrongs.
6. Were entirely ready to have God remove all these defects of character.
7. Humbly asked Him to remove our shortcomings.
8. Made a list of all persons we had harmed, and became willing to make amends to them all.
9. Made direct amends to such people wherever possible, except when to do so would injure them or others.
10. Continued to take personal inventory and when we were wrong promptly admitted it.
11. Sought through prayer and meditation to improve our conscious contact with God as we *understood Him*, praying only for knowledge of His will for us and the power to carry that out.
12. Having had a spiritual awakening as the result of these steps, we tried to carry this message to alcoholics, and to practice these principles in all our affairs.

FIGURE 98.6 The 12 steps.

shown efficacy, which is presumed through the same mechanism stated above.[2]

98.5.2.4.4 Brain Stimulation

Transcranial magnetic stimulation (TMS) is becoming a more widely used modality in psychiatric practice. Studies have been published, although of small sample sizes, revealing conflicting results. Some studies have shown a benefit in reducing craving and in achieving abstinence in refractory AUD.[52,53]

98.5.3 When to Refer

Addiction medicine specialists welcome referrals, and consultations can provide the following services:

- To clarify the diagnosis of alcohol use disorder
- To guide the process of detoxification
- To assist with determining the level of care required for detoxification and early recovery
- To initiate pharmacologic treatment and coordinate care with providers of non-pharmacologic treatments (including, but not limited to, psychotherapy, mutual help groups, and alternative treatments), individually tailored to patients' goals
- To develop a relapse prevention plan
- When other substance use disorders are comorbid, such as benzodiazepines and opioid use disorders

The website of the American Board of Addiction Medicine (www.abam.net) has a search tool, *Find a Doctor*, to locate a board-certified specialist in your geographic area.

98.6 AUD AND THE COVID-19 PANDEMIC

Anecdotally in our clinical practice and as published in multiple studies, alcohol use and thus risk of AUD and relapse has increased during the COVID-19 pandemic, including a 25% rate of increase in alcohol-related deaths between 2019 and 2020, which outpaced the16.6% increase in all-cause

mortality.[54] In a large, survey-based study, 75% of adults reported alcohol use on one additional day per month; women surveyed had a large increase in heavy drinking and in consequences related to alcohol use.[55] In a British survey of predominantly male respondents, of white ethnicity, with known AUD, at the start of the pandemic, 43% endorsed an increase in use and 17% with prior clinical abstinence reported relapse.[56] It is postulated that stress and isolation are the primary drivers.[57] Furthermore, it is likely that alcohol use exacerbates COVID-19 infection due to lung-specific and immune system-mediated pathways.[58] In a recently published article, there is growing evidence that even one to two standard drinks may contribute to brain volume losses.[59] What we have discovered, thus far, is that it will likely take decades to understand the impact of the COVID-19 pandemic on the prevalence and severity of AUD. As the WHO has begun an initiative for reducing the harms of alcohol use, we strongly encourage annual screening for substance use and comorbid psychiatric diagnoses as the pandemic continues and beyond, and also advise heeding the warning that there may be no safe amounts of alcohol use when it comes to cancer risk or overall health risks.[60,61]

98.7 SUMMARY

Returning to our case presentation, it cannot be emphasized enough the benefits of screening, especially during the COVID-19 pandemic. Ms. Howard drinks more than the recommended amount. Additional relevant history may be if she has experienced withdrawal or if tolerance has developed. It is important to determine if she has suffered any negative consequences from her drinking; for example, is her continued unemployment a personal choice or perhaps from the downstream changes in motivation and mood from alcohol use? How does a possible family history of alcohol use play into her risk for alcohol use disorder? As a woman, her risk for breast cancer increases with the amount of alcohol she uses, how do you counsel her? What are her thoughts on birth control if she is still capable of childbearing? What medical work-up would you want to follow after her initial visit to establish care? For Ms. Howard, it is important to include routine monitoring of her alcohol intake over time, as part of her overall preventative care, to prevent the progression of any use disorder if she has this diagnosis, or if she does not, to minimize harmful or heavy use in which she does engage.

CLINICAL APPLICATIONS

Risk Factors for AUD	Male gender, Caucasian or Native American, attainment of post-secondary education, previously or never married, annual income less than ~70,000, resident in an urban area or the Western United States, history of bariatric surgery.
Neurobiology of addiction	A progression from use that is initially rewarding but later develops into a growing tolerance and state of negative emotions and physical symptoms, which includes cravings and withdrawal and is often accompanied by personal and professional negative consequences and the loss of self-control, which sets up a destructive cycle.
Screening tools	Initial screening, of all adults, annually: On any single occasion during the past three months, have you had more than five drinks containing alcohol? If yes: assess for number of alcoholic drinks per week If male and more than 14 drinks/week or if female and more than seven drinks/week, complete the AUDIT
Treatments for detoxification	Refer to the ASAM criteria for matching patients to levels of care. Options include scheduled long-acting and as needed short-acting benzodiazepines, with the options for adjunctive use of high dose gabapentin. Utilize the hospital CIWA-Ar protocol for PRN benzodiazepine use in the inpatient setting.
Treatments for maintenance of sobriety and relapse prevention	A combination of pharmacologic and behavioral treatments. FDA-approved medications include disulfiram, acamprosate, and naltrexone (PO and IM). Behavioral treatments include individual psychotherapy, behavioral therapy, CBT, and group therapy, including mutual help groups.

99 Diagnosis and Treatment of Opioid Use Disorders

Joseph R. Volpicelli, MD, PhD

KEY POINTS

- Identify risk factors for opioid use disorders.
- Consider opioid use disorders when use exceeds clinical needs and is associated with medical and psychosocial adverse consequences.
- Aim to reduce opioid craving and relapse to excessive opioid use.
- Use medications such as methadone or buprenorphine for stabilization and naltrexone to reduce opioid craving and relapse.
- Encourage combined use of medications with psychosocial support.
- Make use of motivational techniques to help engagement and treatment persistence.

99.1 INTRODUCTION

The diagnosis and treatment of opioid use disorders represent an excellent example of how lifestyle medicine provides a sound foundation to better understand and treat patients suffering from this serious medical problem. The opioid epidemic in the United States has dramatically worsened in the past several years. In 2020, nearly 100,000 people died from drug overdoses, and opioids were involved in 70% of overdose cases.[1] While over-prescription of opioids may have initially contributed to the opioid crisis, highly potent synthetic opioids such as fentanyl have played an increasingly important role in opioid addiction and overdose. The risk of overdose deaths and opioid addiction can be effectively treated; however, many people cannot access evidence-based treatments.[2] The COVID-19 pandemic worsened limited access to treatment in rural, poor, and minority populations. For example, a recent study reported that drug overdose deaths in Black and Indigenous people increased by 44% and 39%, respectively, in 2020 [3].

In this chapter, I will discuss the diagnosis of opioid use disorders and help readers understand the risk factors, appropriate use of opioids, misuse, and ultimately opioid addiction. The three medications currently used to treat opioid use disorders and the integrated role of psychosocial support will then be reviewed. Finally, new digital and medical treatments will be presented.

99.2 RISK FACTORS FOR OPIOID USE DISORDERS

Opioids have an essential role in treating patients with severe pain that is not well controlled with other therapies. However, risks associated with opioid use include diversion, overdose, and addiction. In order to help reduce the incidence of these adverse consequences, healthcare providers need to be aware of the risk factors for opioid misuse. These risk factors can be broken down by looking at (1) physician prescribing practices and (2) patient characteristics and social factors associated with opioid misuse.

Physician prescribing practices often go through large cycles in which opioids are used sparingly or excessively. In the late 1990s and early 2000s, the wave of the liberal use of opioids peaked and was thought to contribute to the current opioid epidemic.[4] This wave was set in motion by reports that chronic pain was being inadequately treated and caused significant undiagnosed morbidity.[5] The advent of longer-acting opioids was widespread because it allowed patients to experience a full night's sleep or complete an entire eight-hour workday. It was thought that longer-acting opioids posed a reduced risk of addiction. Confidence in the efficacy and safety of chronic opioid use was based on limited case studies and the endorsement of medical societies.[6] In clinical research studies, the use of opioids occurs in the context of close monitoring. However, in the actual practice of opioid treatment, clinicians often prescribed many pills without sufficient follow-up visits to assess efficacy—this led to the accumulation of a large supply of unused medications, which were easily misused and diverted.

The past decade has seen a marked decline in new opioid prescriptions as new prescriptions fell about 50% from 2012 to 2017.[7] This decline is related to educational activities designed to help the prescribing clinician monitor chronic opioid use and to be especially attentive to the early signs of opioid misuse such as dose escalations, early refills, and prescriptions by multiple clinicians. One way that clinicians can improve opioid monitoring is to look at risk factors in their patients that predict opioid misuse.[8]

Short-term opioid use for acute pain does not pose a risk for most patients, but several clinical factors predict misuse when opioids are prescribed for chronic pain. Risk factors for opioid use disorder include past or current substance use

DOI: 10.1201/9781003227793-116

disorders involving opioids or other drugs, including alcohol; patients with co-existing psychiatric disorders; history of trauma; and social or family environments that encourage misuse.

Clinicians can more effectively monitor patients on chronic opioid treatment using rating instruments that can predict patients at risk for opioid use disorders. A popular instrument (Table 99.1) is the Screener and Opioid Assessment for Patients with Pain-Revised (SOAPP-R), a 24-item self-administered screening tool developed and validated for those persons with chronic pain.[9] Any individual who scores more than 18 on the SOAPP-R is rated as being at risk for opioid misuse.[10]

99.3 DIAGNOSIS OF OPIOID USE DISORDER (DSM-5 CRITERIA)

The fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) set the gold standard for defining when someone crosses the threshold where opioid use becomes a disorder.[11] The specific criteria can be grouped by three clusters of symptoms that center around (1) impaired control and drug craving, (2) biopsychosocial impairment, and (3) pharmacological adaptation. As Table 99.2 shows, to meet the criteria for an opioid use disorder, one needs at least two of the specified 11 criteria, with increased severity as the number of criteria endorsed rises.

The first cluster includes taking excessive doses of opioids or chronic use of opioids beyond clinical needs. Typically, attempts to cut down and control opioid use are unsuccessful. Uncontrolled use of opioids can lead to doctor shopping or other time-consuming activities to obtain opioids and excessive time required to recover from the drug's pharmacological effects. These behaviors are typically accompanied by cognitive craving and a strong desire to use opioids.

The second cluster centers around the psychosocial consequences of impaired control over opioid use. Consequences include impairment in functioning at home, at school, or at work. Opioid use continues despite impaired relationships with friends and family. Over time, much of a patient's life centers around the use of opioids, and the patient gives up time for other important activities related to hobbies, friends, family, and work. Opioid use can lead people to put themselves in unsafe situations, such as dangerous neighborhoods, to buy opioids, or engage in illegal activities to afford the cost of opioids.

Finally, the third cluster involves psychological adaptation to opioids, which can take the form of tolerance (the need to take higher doses of opioids to get the desired effect) and characteristic withdrawal symptoms that follow the abrupt discontinuation of opioid use. Clinicians often incorrectly assume that the presence of withdrawal symptoms is a cardinal feature of addiction. However, opioid withdrawal is neither a necessary nor sufficient symptom to diagnose an opioid use disorder. For example, patients with chronic pain or being treated for opioid use disorders may be on opioid agonists and experience withdrawal symptoms if their medical treatment is abruptly discontinued but will show no signs of impaired control or adverse biopsychosocial consequences of opioid use.

TABLE 99.1

Screening Tool to Assess Risk for Opioid Misuse In Pain Patients

Screener and Opioid Assessment for Patients with Pain (SOAPP)® Version 1.0 - 14Q

Name: _____ _____ _____ _____ _____ _____ _____ _____ ___ Date: _____

The following are some questions given to all patients at the Pain Management Center who are on or being considered for opioids for their pain. Please answer each question as honestly as possible. This information is for our records and will remain confidential. Your answers alone will not determine your treatment. Thank you.

Please answer the questions below using the following scale:

0 **= Never, 1 = Seldom, 2 = Sometimes, 3 = Often, 4 = Very Often**

1. How often do you have mood swings?
2. How often do you smoke a cigarette within an hour after you wake up?
3. How often have any of your family members, including parents, had a problem with alcohol or drugs?
4. How often have any of your close friends had a problem with alcohol or drugs?
5. How often have others suggested that you have a drug or alcohol problem?
6. How often have you attended an AA or NA meeting?
7. How often have you taken medication other than the way that it was prescribed?
8. How often have you been treated for an alcohol or drug problem?
9. How often have your medications been lost or stolen?
10. How often have others expressed concern over your use
11. How often have you felt a craving for medication?
12. How often have you been asked to give a urine screen for substance abuse?
13. How often have you used illegal drugs (for example, marijuana, cocaine) in the past five years?
14. How often, in your lifetime, have you had legal problems or been arrested?

Please include any additional information you wish about the above answers. Thank you.

TABLE 99.2
DSM-5 Criteria for Opioid Use Disorder

Opioid Use Disorder Diagnostic Criteria

A problematic pattern of opioid use leading to clinically significant impairment or distress, as manifested by at least two of the following, occurring within a 12-month period:

1. Opioids are often taken in larger amounts or over a longer period than was intended.
2. There is a persistent desire or unsuccessful efforts to cut down or control opioid use.
3. A great deal of time is spent in activities necessary to obtain the opioid, use the opioid, or recover from its effects.
4. Craving, or a strong desire or urge to use opioids.
5. Recurrent opioid use resulting in a failure to fulfill major role obligations at work, school, or home.
6. Continued opioid use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of opioids.
7. Important social, occupational, or recreational activities are given up or reduced because of opioid use.
8. Recurrent opioid use in situations in which it is physically hazardous.
9. Continued opioid use despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance.
10. Tolerance, as defined by either of the following:
    a. A need for markedly increased amounts of opioids to achieve intoxication or desired effect.
    b. A markedly diminished effect with continued use of the same amount of an opioid.

Note: This criterion is not considered to be met for those taking opioids solely under appropriate medical supervision.

11. Withdrawal, as manifested by either of the following:
    a. The characteristic opioid withdrawal syndrome (refer to Criteria A and B of the criteria set for opioid withdrawal).
    b. Opioids (or a closely related substance) are taken to relieve or avoid withdrawal symptoms.

Note: This criterion is not considered to be met for those individuals taking opioids solely under appropriate medical supervision.

Specify if:

- **In early remission**: After full criteria for opioid use disorder were previously met, none of the criteria for opioid use disorder have been met for at least three months but for less than 12 months (with the exception that Criterion A4, "Craving, or a strong desire or urge to use opioids", may be met).
- **In sustained remission**: After full criteria for opioid use disorder were previously met, none of the criteria for opioid use disorder have been met at any time during a period of 12 months or longer (with the exception that Criterion A4, "Craving, or a strong desire or urge to use opioids", may be met).

Specify if:

- **On maintenance therapy**: This additional specifier is used if the individual is taking a prescribed agonist medication such as methadone or buprenorphine and none of the criteria for opioid use disorder have been met for that class of medication (except tolerance to, or withdrawal from, the agonist). This category also applies to those individuals being maintained on a partial agonist, an agonist/antagonist, or a full antagonist such as oral naltrexone or depot naltrexone.
- **In a controlled environment**: This additional specifier is used if the individual is in an environment where access to opioids is restricted.

99.4 TREATMENT OF OPIOID USE DISORDERS

There is a broad set of options for the pharmacological treatments of opioid use disorders. These options range from medications that fully stimulate opioid receptors (opioid agonist), and partially stimulate opioid receptors (partial opioid agonist), to medications that completely block opioid receptors (opioid antagonist). Each approach has advantages and disadvantages that will be presented below.

99.5 METHADONE MAINTENANCE TREATMENT

Methadone, a long-acting full opioid agonist, has a long history of treating opioid use disorders. Treatment involves a daily oral dose of methadone given in a specialized outpatient clinical setting. Patients are started on a small dose of methadone (10–30 mg) to relieve withdrawal symptoms. The daily dose is gradually increased until the patient no longer experiences opioid craving and the opioid receptors are saturated, so any illicit opioid will have little pharmacological effect.

Once stabilized, patients are carefully monitored during their methadone treatment by daily attendance at specially licensed clinics where the day's methadone dose is administered. These visits also include regular monitoring by prescribing clinicians to review the appropriateness of the current methadone dose with respect to withdrawal symptoms, side effects, and clinical response.

Regular urine drug screening monitors treatment effectiveness to assess for illicit opioids and other illicit drugs. Urine drug screens positive for illicit drugs should not be used to withhold methadone treatment. However, they should trigger appropriate therapeutic responses to identify if the patient's treatment needs are being met. For example, if a patient's urine sample shows continued illicit opioid use despite being in methadone maintenance treatment (MMT), it may signal that the patient needs a higher methadone

dose. There is no set rule for how long someone should stay in MMT. However, it is commonly believed that the longer a patient remains in treatment, the better the outcome.

In general, patients who are clinically stable and are being slowly tapered off MMT experience little difficulty until the daily methadone dose reaches 30 mg or less. As the daily dose drops below 30 mg, opioid withdrawal symptoms often emerge between methadone doses. Additionally, the euphoria-blocking and anti-craving effects of methadone are much diminished at this low-dose level.

99.5.1 Advantages

1. It is safer for the patient to take methadone under medical supervision than to take illicit opioids of unknown composition, thereby reducing the risk of opioid overdose.
2. Methadone is taken orally, thereby avoiding intravenous routes of administration that can lead to infections such as HIV or hepatitis.
3. To obtain illicit opioids, people often spend considerable time in risky criminal behavior, whereas methadone allows patients to focus on productive prosocial activities.
4. Methadone has a long history of clinical use. A substantial body of research shows its effectiveness in reducing HIV transmission, the death rate associated with opioid addiction, and criminal activity.

99.5.2 Disadvantages

1. Methadone is a full opioid agonist and, like other opioid agonists, leads to physiological adaptation so that after chronic use, one becomes physically dependent on methadone to avoid withdrawal symptoms.
2. Given the risk of diversion of methadone, its use is restricted to centers licensed through state and federal agencies in specialized opioid treatment programs (OTPs). These programs restrict access to methadone, so a patient in a methadone program is often required to obtain their daily dose at the center, thus leading to trips to the OTP. This daily trip can be time-consuming and restricts outside travel plans for patients who do not live near their OTP.
3. Most people on methadone do not experience severe side effects, but some of the troubling side effects include disturbed sleep, nausea and vomiting, constipation, dry mouth, decreased sex drive and difficulty having orgasms, menstrual irregularities, and weight gain.
4. The major risk associated with methadone is overdose. Overdose is a concern in the initial stages of MMT and when methadone is used in combination with other depressant drugs.

99.6 BUPRENORPHINE OFFICE-BASED TREATMENT

The use of buprenorphine to treat opioid addiction became possible with the Drug Addiction Treatment Act of 2000 (DATA 2000), which allowed qualified physicians to obtain a DEA waiver to prescribe specific controlled substances to treat addictions. Buprenorphine is a mixed agonist-antagonist with different effects depending on the opioid subtype. The mu-opioid receptor is critically important in the effectiveness of opioids in blocking pain and producing addiction. Buprenorphine partially stimulates the mu-opioid receptor. The formulation of buprenorphine used to treat opioid use disorders is typically a combination product in which buprenorphine is mixed with naloxone in a four-to-one ratio. This combination is less prone to misuse because naloxone is an opioid antagonist, so when injected or inhaled, this ingredient blocks the euphoria from buprenorphine. When taken as prescribed (sublingually), the naloxone is not absorbed and therefore does not block the effects of buprenorphine.

Buprenorphine's partial agonist effect complicates the initial induction. In cases where someone is already taking a full opioid agonist, for example, heroin or Percocet, the use of a partial agonist can precipitate opioid withdrawal. However, if someone is already in opioid withdrawal, using a partial agonist will reduce opioid withdrawal symptoms. So, to avoid precipitated withdrawal, it is recommended that the patient should refrain from any opioid use for 12–24 hours or show signs of withdrawal before the first dose of buprenorphine.

The first dose of buprenorphine (2–4 mg) is typically given in the clinician's office, where withdrawal signs can be monitored. For most patients, the next hour or two show decreasing withdrawal symptoms, but for some patients, the buprenorphine precipitates increased opioid withdrawal. Adjunctive medications such as clonidine, an alpha-2 agonist, can help decrease precipitated withdrawal symptoms. Once the patient feels stable and has a reduction in baseline withdrawal, the patient can return home with a prescription for buprenorphine and instructions to repeat the small dose of buprenorphine to relieve any subsequent withdrawal symptoms of drug craving. The dose of buprenorphine on the first day should not exceed 8 mg. Doses may be increased if needed for symptomatic relief of withdrawal symptoms or high opioid craving. Most patients are typically stabilized with a target dose of 8–16 mg daily. If side effects occur, the dose of buprenorphine should be lowered until the side effects are managed. In 2017, an extended-release version of buprenorphine (Sublocade) was introduced in which patients only need monthly subcutaneous injections.[12]

There is no clinical consensus on how long one should be maintained on buprenorphine. Like methadone, one assumes that the longer one stays on buprenorphine, the better. Consistent with the theory that some people have a natural inborn deficiency in endogenous opioid activity,

some clinicians suggest that, like treating other chronic medical conditions (i.e., diabetes, hypothyroidism), one should be maintained on buprenorphine indefinitely.

When deciding to discontinue buprenorphine treatment, it should be kept in mind that, like methadone treatment, one must slowly reduce the dose of buprenorphine to avoid withdrawal symptoms. The dose reduction rate depends on the patient's clinical needs and is negotiated by the patient and clinician together.

99.6.1 Advantages

1. Like methadone, buprenorphine effectively relieves opioid withdrawal symptoms, reduces drug craving, and reduces high-risk behavior such as sharing dirty needles and engaging in illegal activities to obtain illicit opioids.
2. Unlike methadone, buprenorphine can be used in a doctor's office without requiring daily trips to a specialized clinic for observed dosing.
3. With a small dose of naloxone, there is less chance of misusing buprenorphine to obtain an opioid "high", presumably reducing the risk of diversion.
4. Given the reduced state and federal licensing regulations, more clinicians can provide treatment for a larger pool of patients.

99.6.2 Disadvantages

1. Only available from clinicians who obtain a waiver from the DEA to prescribe buprenorphine.
2. Like methadone, chronic use creates a physical dependence on buprenorphine to avoid withdrawal symptoms.
3. Some patients find it difficult to discontinue buprenorphine because of persistent withdrawal symptoms.
4. Even with the addition of naloxone to block euphoria from injected or inhaled buprenorphine, there is still a substantial risk of diversion.

99.7 NALTREXONE AND XR-NALTREXONE

Naltrexone is an opioid antagonist used to prevent relapse to opioids in patients who have completed opioid detoxification. Naltrexone blocks opioid receptors in the brain, so opioids such as heroin or opioid pain relievers will have their pharmacological effects blocked, and the opioids will no longer produce a "high" or euphoria, thus decreasing the motivation to use opioids. The FDA first approved oral naltrexone to treat opioid use disorders in 1985, but because of poor patient adherence, it was generally not used clinically. The FDA approved an extended-release formulation in 2010 (Vivitrol). Administered by intramuscular injection, XR-naltrexone blocks opioid receptors for up to one month.

Before starting naltrexone, one must have completed opioid detoxification and preferably been opioid-free for at least seven days. One can use several protocols to safely withdraw someone from opioids without opioid medications. These protocols typically involve adding clonidine, an alpha-2 agonist, and other adjunctive medications to provide symptomatic relief.[13] Adding low doses of naltrexone early in the detoxification process may facilitate the transition to XR-naltrexone.[14]

Managing opioid withdrawal symptoms is aided by using two scales that measure the severity of withdrawal symptoms. The Subjective Opiate Withdrawal Scale (SOWS) is an 18-item scale designed to be self-administered to rate common signs and symptoms of opioid withdrawal and monitor these symptoms over time (Table 99.3).[15] The Clinical Opiate Withdrawal Scale (COWS), shown in Table 99.4, is an 11-item self-report scale that measures the severity of opioid withdrawal symptoms from the clinician's perspective.[16] The integration of clinical observations from the COWS and subjective observations from the patient's perspective gives a fair overall assessment of the severity of withdrawal.

Following opioid detoxification and a seven-day opioid-free interval, the administration of naltrexone is unlikely to precipitate opioid withdrawal symptoms. Oral naltrexone tablets, with a typical dose of 50 mg per day, can be prescribed by any physician. Medication adherence is best accomplished using the XR-naltrexone formulation of naltrexone, which is supplied as a depot intramuscular injection that the patient receives monthly in the gluteal region. After the first dose of naltrexone, the patient should be observed in the office for the next hour to observe for the presence of withdrawal symptoms. If the injection precipitates withdrawal symptoms, the use of clonidine and other ancillary medications can help relieve symptoms.

There is no recommended length of treatment with naltrexone, but as with methadone and buprenorphine, it is assumed that the longer one stays on naltrexone, the more sustained the recovery. Ultimately, the duration depends on clinical judgment and the patient's needs. Unlike methadone and buprenorphine, there is no physical dependence associated with naltrexone, so it can be stopped without the need to taper to avoid withdrawal symptoms. Patients who discontinue antagonist therapy need to be aware that after a sustained period of abstinence, there is no longer opioid tolerance. They should be mindful of the increased risks associated with an opioid overdose—especially the increased risk of death.

99.7.1 Advantages

1. Not only has it demonstrated its effectiveness in preventing relapse to drug use following opioid detoxification, but it has also been shown to decrease cravings.
2. Currently, it is the only approved medication for opioid dependence that is not a controlled substance. There is no need for a special DEA waiver for clinicians to prescribe naltrexone.

TABLE 99.3
Subjective Opiate Withdrawal Scale

Subjective Opiate Withdrawal Scale (sows)[1]

The SOWS is a self-administered scale for grading opioid withdrawal symptoms. It contains 16 symptoms whose intensity the patient rates on a scale of 0 (not at all) to 4 (extremely) and takes less than 10 minutes to complete. Patient Instructions: please score each of the 16 items below according to how you feel right now. Circle one number only.

Item	Symptom	Not At All	A Little	Moderately	Quite a Bit	Extremely
1	I feel anxious	0	1	2	3	4
2	I feel like yawning	0	1	2	3	4
3	I am perspiring	0	1	2	3	4
4	My eyes are teary	0	1	2	3	4
5	My nose is running	0	1	2	3	4
6	I have goosebumps	0	1	2	3	4
7	I am shaking	0	1	2	3	4
8	I have hot flushes	0	1	2	3	4
9	I have cold flushes	0	1	2	3	4
10	My bones and muscles ache	0	1	2	3	4
11	I feel restless	0	1	2	3	4
12	I feel nauseous	0	1	2	3	4
13	I feel like vomiting	0	1	2	3	4
14	My muscles twitch	0	1	2	3	4
15	I have stomach cramps	0	1	2	3	4
16	I feel like using now	0	1	2	3	4

Total score: _____ reference:

1. Handelsman L, Cochrane KJ, Aronson MJ, Ness R, Rubinstein KJ, Kanof PD. Two New Rating Scales for Opiate Withdrawal. 1987. *American Journal of Alcohol Abuse* 13, 293–308.

3. Naltrexone does not display abuse potential.
4. XR-naltrexone is effective for 30 days, so there is no need to take a daily dose of medication to ensure medication adherence.

99.7.2 Disadvantages

1. To prevent the occurrence of acute opioid withdrawal in opioid-dependent patients, the patients must be entirely opioid-free for a minimum of seven to ten days before starting naltrexone treatment.
2. The XR formulation is expensive, at over US$1000 per shot, but the cost is typically not paid by the patient since commercial and Medicaid insurance covers it.
3. Chronic use of naltrexone will lead to loss of opioid tolerance and increased sensitivity to opioids. This could increase the risk of opioid overdose.
4. Since naltrexone is an opioid blocker, opioid pain medications will be less effective. While pain control can often be effectively managed without opioid pain relievers, in those cases where opioids are needed, it is necessary to adjust the dose to obtain a therapeutic response.
5. Side effects from the injection of naltrexone include pain and induration.

99.8 INTEGRATION OF PSYCHOSOCIAL SUPPORT IN TREATMENT

Pharmacotherapy alone is rarely a sufficient treatment for drug addiction.[15] Therefore, clinicians have an added responsibility to patients with opioid addiction problems that go beyond prescribing medications.

At a minimum, psychosocial treatment should include the following: psychosocial needs assessment, supportive counseling, links to existing family supports, and referrals to community services. In addition, the patient should be assessed for comorbidity concerning psychiatric disorders, physical consequences of opioid use, family issues, legal consequences, and vocational and financial issues. Excessive use of alcohol and other drugs should also be assessed.

The frequent presence of these problems shows the key role of psychosocial services in addressing the needs of patients and improving treatment outcomes.

99.9 PSYCHOSOCIAL TREATMENT MODALITIES AND ADJUNCTS

Several modalities are offered to provide psychosocial services, such as Cognitive Behavioral Therapy (CBT). CBT helps patients identify risk factors that bring on relapse and helps teach patients more appropriate coping skills.[17,18] There is little research data to show psychotherapy works

TABLE 99.4
Clinical Opiate Withdrawal Scale

Clinical Opiate Withdrawal Scale (COWS)
Flow-sheet for measuring symptoms for opiate withdrawals over a period of time.
For each item, write in the number that best describes the patient's signs or symptom. Rate on just the apparent relationship to opiate withdrawal. For example, if heart rate is increased because the patient was jogging just prior to assessment, the increase pulse rate would not add to the score.

Patient's Name: _____ Date: _____ Enter scores at time zero, 30min after first dose, 2 h after first dose, etc. Times: _____ _____ _____ _____			
Resting Pulse Rate: (record beats per minute) *Measured after patient is sitting or lying for one minute* 0 pulse rate 80 or below 1 pulse rate 81-100 2 pulse rate 101-120 4 pulse rate greater than 120			
Sweating: *over past ½ hour not accounted for by room temperature or patient activity.* no report of chills or flushing subjective report of chills or flushing flushed or observable moistness on face beads of sweat on brow or face sweat streaming off face			
Restlessness *Observation during assessmen*t 0 able to sit still 1 reports difficulty sitting still, but is able to do so 3 frequent shifting or extraneous movements of legs/arms 5 Unable to sit still for more than a few seconds			
Pupil size 0 pupils pinned or normal size for room light 1 pupils possibly larger than normal for room light 2 pupils moderately dilated 5 pupils so dilated that only the rim of the iris is visible			
Bone or Joint aches *If patient was having pain previously, only the additional component attributed to opiates withdrawal is scored* 0 not present 1 mild diffuse discomfort 2 patient reports severe diffuse aching of joints/ muscles 4 patient is rubbing joints or muscles and is unable to sit still because of discomfort			
Runny nose or tearing *Not accounted for by cold symptoms or allergies* 0 not present 1 nasal stuffiness or unusually moist eyes 2 nose running or tearing 4 nose constantly running or tears streaming down cheeks			
GI Upset: *over last ½ hour* 0 no GI symptoms 1 stomach cramps 2 nausea or loose stool 3 vomiting or diarrhea 5 Multiple episodes of diarrhea or vomiting			
Tremor *observation of outstretched hands* 0 No tremor 1 tremor can be felt, but not observed 2 slight tremor observable 4 gross tremor or muscle twitching			
Yawning *Observation during assessment* 0 no yawning 1 yawning once or twice during assessment 2 yawning three or more times during assessment 4 yawning several times/minute			
Anxiety or Irritability 0 none 1 patient reports increasing irritability or anxiousness 2 patient obviously irritable anxious 4 patient so irritable or anxious that participation in the assessment is difficult			
Gooseflesh skin 0 skin is smooth 3 piloerrection of skin can be felt or hairs standing up on arms 5 prominent piloerrection			
Total scores with observer's initials			

Score:
5-12 = mild;
13-24 = moderate;
25-36 = moderately severe;
more than 36 = severe withdrawal

as a standalone treatment, but it can benefit patients with co-existing emotional distress when combined with pharmacotherapy.[19] Self-help groups such as 12-step (AA or NA meetings) groups may be beneficial for some patients and should be considered an adjunctive form of psychosocial support. Alternatives to 12-step meetings include Self-Management and Recovery Training (SMART), Recovery and Moderation Management (MM), Rational Recovery (RR), and Secular Organization for Sobriety (SOS). However, it should be kept in mind that the acceptance of patients who are maintained on medication for opioid treatment is often challenged by many 12-step groups and may be a deterrent to patients adhering to medication.

An important component of any pharmacological treatment is to engage and keep patients in treatment. Motivational enhancement therapy (MET) is designed to help motivate people to engage in new behaviors that promote health. Research shows that this approach helps with nicotine and alcohol use disorders. A relatively innovative approach was derived from MET but is explicitly designed to be integrated with medical treatment. The BRENDA approach is designed to help improve treatment retention and medication adherence and can be implemented by a wide range of healthcare professionals, including those without formal psychotherapy training. The BRENDA approach is relatively easy to learn and stands for six core components that a healthcare provider addresses with each patient: Biopsychosocial evaluation; Report to the patient on assessment findings; Empathy; Needs identified by patient and treatment provider; Direct patient advice; and Assessing the patient's reaction to advice and adjusting treatment when needed.[20]

99.10 FUTURE DIRECTIONS

Challenges in delivering quality patient care limit the effective treatment of OUD. Part of these challenges involves systemic inequalities in the access to evidence-based treatments in poor and underserved areas. Limited access to care was especially prominent during the height of the COVID-19 pandemic, which contributed to the dramatic increase in opioid overdose deaths. Less than 30% of people with OUD receive life-saving medications, and fewer still receive integrated medical and psychosocial care.[21] Many patients with access to treatment fail to initiate care, and many are inconsistent or drop out of treatment prematurely. Future directions on OUD treatment focus on getting more people into treatment and then helping them to stay in treatment.

In order to help facilitate getting people to treatment, harm reduction strategies have focused on going directly to sites where opioids are sold. At these safe sites, medical personnel are available to provide naloxone in case of overdose and offer social support to help people obtain social services and medical treatment.[22] In addition, barriers to treatment are also being reduced as methadone take-home restrictions are being eased;[23] physician limits on the number of patients they can treat with buprenorphine have increased from 100 patients to 275 patients.[24] Emergency departments are offering buprenorphine onsite to overdose patients and are facilitating a "soft handshake" with local providers to help engage patients in treatment.[25]

New medicines are being developed to help medication adherence. While both naltrexone and buprenorphine have extended-release injections that provide medical coverage for a month, newer formulations, including implants, promise to increase the efficacy of the medication for six months or more.[26,27] Novel pharmacological strategies include using cannabis[28] or low-dose psychedelics such as ketamine, psilocybin, or ibogaine.[29,30]

Finally, digital technology has proven especially helpful during the pandemic as in-person visits became more difficult due to COVID-19 restrictions. Virtual visits (telehealth) are increasingly popular and have been shown to be effective.[31] A new evidence-based treatment option is the use of digital therapeutics. These online programs can deliver psychotherapy (typically CBT) to patients anywhere or anytime there is an internet connection and can be integrated with the use of medications, improving patient outcomes and retention.[32]

99.11 CONCLUSIONS

Despite challenges from treatment access, there is encouraging news in fighting the opioid epidemic. Increased attention to the harms associated with opioid misuse has reduced excessive opioid prescribing. Understanding when patients cross the line from appropriate use to having an opioid use disorder allows us to identify those people who can receive help from one of three very different medical approaches to treatment. New pharmacotherapies are currently being studied that may further aid in treating OUD. Adding psychosocial support addresses the comorbid medical and psychosocial complications of opioid use disorders and promotes a full recovery. An integrated medical and psychosocial program can help promote the effectiveness of treatment by addressing co-existing psychopathology and patient engagement. Finally, challenges presented by the opioid pandemic have encouraged new regulatory and digital strategies to further enhance treatment engagement, adherence, and retention.

CLINICAL APPLICATIONS

Practice Tips

Assess

- Opioid misuse, diversion, and addiction, particularly in chronic pain patients
- Medical and psychosocial consequences of excessive opioid use
- Opioid tolerance and withdrawal symptoms
- Comorbid anxiety and mood disorders
- Interest in medical and psychosocial treatment
- Adherence to treatment recommendations

Assist

- Understand the difference between the appropriate use of opioids to treat pain and opioid use disorder
- Discuss the advantages and disadvantages of various medical treatments
- Prescribing and monitoring appropriate medications
- Referral for self-help and psychosocial counseling
- Monitor progress in treatment in collaboration with patient needs

Arrange

- A list of other healthcare professionals and self-help groups for a coordinated care plan
- Referral to addiction specialists when appropriate
- Referral to psychologist or psychiatrist if appropriate

100 Cannabis Use Disorder and Treatment

Julia M. Bujno, BS and Deborah Hasin, PhD

KEY POINTS

- Cannabis is the most commonly used psychoactive drug in the US.
- Legalization of cannabis for medical and recreational use has led to increases in the availability and acceptability of cannabis use.
- Cannabis potency, adult use, use-related problems, and cannabis use disorder diagnoses are increasing.
- Healthcare providers, policymakers, and the general public need to be aware of the significant harms and risks associated with cannabis exposure throughout the life course to prevent potential adverse consequences of use.

100.1 INTRODUCTION

Cannabis is the most commonly used psychoactive drug in the US, with ~12% of the population aged 12 or older reporting past-month use.[1] Changes in state laws legalizing cannabis for medical and recreational use have coincided with changes in public perception of cannabis use. While adults and adolescents increasingly view cannabis as harmless,[2–4] and some can use cannabis without harm, significant risks are associated with use.[5] A major concern about cannabis legalization is that increased availability and acceptability of cannabis may lead to increases in use and adverse consequences.[6,7] Evidence suggests national increases in cannabis potency,[8] adult use[2,3,9–11] and cannabis use disorder (CUD) diagnoses,[10,12–15] with 20–30% of users now meeting criteria for CUD.[16] Healthcare providers should have information about physical, mental, and psychosocial problems associated with cannabis use, and the implications of these for clinical practice. This chapter provides an overview of the harms and risks associated with cannabis use, including CUD, and recommendations for screening, assessing, and treating CUD.

100.2 HARMS AND RISKS ASSOCIATED WITH CANNABIS USE ACROSS THE LIFESPAN

100.2.1 Prenatal Exposure

Cannabis is the most commonly used drug during pregnancy, and maternal cannabis use during pregnancy is increasing.[17,18] Between 2019 and 2020, past-month marijuana use among pregnant women increased from 5.4% to 8.0%.[1] Although many women see cannabis as a natural, safe substance to use throughout pregnancy,[19] potential risks of prenatal cannabis exposure include anemia, low birth weight, need for neonatal intensive care,[20] greater frontal cortical thickness,[21] and impaired executive functioning during childhood.[22] The American College of Obstetricians and Gynecologists recommends that women who are pregnant, contemplating pregnancy, or breastfeeding not use marijuana.[23]

100.2.2 Childhood Exposure

Cannabis exposure during childhood is often via unintended ingestion of cannabis or high-potency edible cannabis products. Acute symptoms of childhood cannabis exposure include lethargy, ataxia, dizziness, hypotonia, seizure, respiratory depression, and vomiting.[24–26] Childhood exposure can lead to the increasing need for emergency care, especially in states with legal cannabis use.[24, 27]

100.2.3 Adolescent Exposure

Concerns about adolescent cannabis use include potentially negative impacts on brain development,[28–30] educational outcomes,[31,32] cognition and IQ,[32–36] life satisfaction and achievement,[37] and risk for later addiction,[32,38,39] depression, anxiety, and suicidality.[40,41] Because common underlying causes could lead to cannabis use as well as these other outcomes, studies of early cannabis use and later impairments are not considered conclusive.[24] To gain further information, the Adolescent Brain Cognitive Development Study[42] is conducting extensive neurocognitive testing and brain imaging before children begin using cannabis and repeatedly assessing the children over a ten-year period to investigate the relationship between early cannabis use, neurocognitive development, and other developmental outcomes. Many programs exist to prevent early adolescent use, and cannabis use remains illegal for those younger than age 21 even in states with legal adult recreational cannabis use.

100.2.4 Adult Exposure

100.2.4.1 Driving Safety

Evidence indicates that Δ-9-tetrahydrocannabinol (THC), the major psychoactive component of cannabis, impairs motor and cognitive functions required for safe driving[43,44]

DOI: 10.1201/9781003227793-117

and increases the risk of injury or fatality due to driving while intoxicated.[45] Driving under the influence of cannabis (DUIC) increases the risk of fatal and non-fatal motor vehicle accidents.[24,44,46–48] Legislation prohibits driving while under the influence of cannabis, but unlike the tests and devices to detect and prevent alcohol-related driving risks (e.g., roadside breathalyzer tests), determining whether a driver is impaired due to cannabis use is complex. Detection of cannabis in biological specimens does not necessarily indicate acute intoxication, and a test like a breathalyzer has not yet been developed for cannabis. Nonetheless, various methods of roadside detection of cannabis use, including biological and behavioral measures, are being developed and tested.[49] Recreational cannabis laws (RCLs) may increase traffic fatalities[50] and medical cannabis laws (MCLs) are associated with increased prevalence of DUIC.[51] Additionally, higher intoxication levels of cannabis perceived as safe for driving correspond to frequent DUIC[52] and cannabis users may have a false sense of safety at given intoxication levels.[53]

100.2.4.2 Cannabis Use Disorder

The Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) of the American Psychiatric Association provides specific criteria for making CUD diagnoses.[54] The earlier fourth edition (DSM-IV) included legal problems as a CUD criterion. This was removed in DSM-5 and criteria for craving and cannabis withdrawal (Table 100.1) were added.[55] To meet the criteria for DSM-5 CUD, a cannabis user must report two or more out of 11 DSM-5 criteria. CUD diagnoses are classified by severity,[54] with two to three criteria considered "mild", four to five considered "moderate," and six or more considered "severe".

Older studies indicated that cannabis users rarely become dependent,[56] leading to a present-day misconception that the risk of developing CUD among cannabis users is low.[57] However, recent national data indicate that one out of five lifetime cannabis users meet the criteria for DSM-5 CUD, and 23% are considered symptomatically severe.[58,59] CUDs are associated with many psychosocial problems and impairments in functioning.[60]

Cannabis use is clearly a precursor to the development of CUD, but in terms of causality, the etiology of CUD is complex.[61–64] Both genetic[65] and environmental factors contribute to the development of CUD. Social-ecological models of substance use[66–69] suggest that environmental factors (e.g., availability and desirability of a substance) normalize use and reduce perceived risks. These factors contribute to increases in use, and thus may also lead to increases in heavy use and the risk of developing CUD.[70]

100.2.4.3 Cannabis Withdrawal

Cannabis withdrawal is defined as three or more of the symptoms shown in Table 100.2 following cessation of prolonged use.[54] Preclinical,[71–74] clinical,[71,72,74–79] and epidemiologic[75,79] studies have established a cannabis withdrawal syndrome after cessation of use. Cannabis withdrawal is most intense during the first week of abstinence and can persist for as long as a month after use.[45,71,80–83] Up to one-third of cannabis users in the general population[75,76,79] and 50–95% of heavy users in treatment or research studies[71,78,84,85] report cannabis withdrawal. Cannabis withdrawal is moderately heritable,[86] implicating both genetic and environmental etiologic factors. In contrast to widespread knowledge of withdrawal from other substances (e.g., alcohol, opioids),[87] healthcare providers and the general public lack awareness of cannabis withdrawal.[88]

TABLE 100.1
DSM-IV and DSM-5 Criteria for Cannabis Use Disorder

	DSM-IV Abuse[a]	DSM-IV Dependence[b]	DSM-5 CUD[c]
Hazardous use (e.g., driving under the influence)	X		X
Social/interpersonal problems related to use	X		X
Neglected major roles to use	X		X
Legal problems	X		
Withdrawal			X
Tolerance		X	X
Used large amounts/longer than intended		X	X
Repeated attempts to quit/control use		X	X
Much time spent using		X	X
Physical/psychological problems related to use		X	X
Activities given up to use		X	X
Craving[d]			X

[a]One or more criteria within a 12-month period.
[b]Three or more criteria within a 12-month period.
[c]Two or more criteria within a 12-month period.
[d]New criterion added in DSM-5.

TABLE 100.2
DSM-5 Cannabis Withdrawal

A. Cessation of heavy, prolonged cannabis use (i.e., daily or almost daily use over at least a few months).
B. Three or more of these symptoms within a week after cessation of heavy, prolonged use:
   1. Irritability, anger, or aggression
   2. Nervousness or anxiety
   3. Sleep difficulty (e.g., insomnia, disturbing dreams)
   4. Decreased appetite or weight loss
   5. Restlessness
   6. Depressed mood
   7. At least one of these physical symptoms causing significant discomfort: abdominal pain, shakiness/tremors, sweating, fever, chills, headache
C. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
D. The symptoms are not due to another medical condition or another mental disorder, including intoxication or withdrawal from another substance.

Cannabis withdrawal can be impairing[89] and cannabis or other substances can be used to relieve withdrawal symptoms. Cannabis users who experience withdrawal are more likely to have trouble quitting use[71,85,90] and have poor treatment outcomes.[78,84,89,91] Many cannabis withdrawal symptoms overlap with depressive or anxiety symptoms.[92] Thus, cannabis could be used as attempted treatment or self-medication for anxiety or depressive symptoms, but unintentionally perpetuate a chronic problem with cannabis withdrawal instead. Thus, reports of ongoing depression or anxiety among regular cannabis users warrant clinical attention and concern.

100.2.4.4 Psychiatric Comorbidity

CUDs are strongly associated with other substance and psychiatric disorders, including alcohol and nicotine use disorders, and mood, anxiety, personality, and posttraumatic stress disorders.[58,93] The associations with psychiatric disorders become stronger as CUD severity increases.[58] However, whether the relationship between CUD and comorbid psychiatric disorders is causal remains unclear.[94] A prospective study suggested that cannabis use predicted incidence of other substance use disorders (SUDs) but not mood or anxiety disorders,[95] whereas genetic research indicates that shared genetic risk underlies the comorbidity between CUD and major depression[64,96,97] or that CUD may potentially cause major depression.[98]

Cannabis use and CUD are strongly associated with psychosis,[13] with higher levels of use leading to increased risk.[24] Individuals considered ultra-high-risk (UHR) for psychosis (i.e., those with subclinical psychotic symptoms and/or genetic risk and impaired functioning) have higher rates of cannabis use and CUD and higher rates of positive psychotic symptoms (i.e., unusual feelings, thoughts, or behaviors) than nonusers.[99] Efforts to determine whether a causal relationship exists between cannabis use and psychosis have focused on long-term prospective studies, with some supporting a causal relationship[31,100,101] but debate remains.[102,103] Nevertheless, cannabis use, and particularly heavy use, is characterized as one of the strongest modifiable risk factors for developing a psychotic disorder.[104] Concerns also exist about increasing cannabis potency in a changing legal environment.[101–103] As the legalized recreational market in the US produces and distributes stronger forms of cannabis,[105,106] the public needs information on the risks associated with heavy cannabis use, including the risk for psychosis.

100.3 CLINICAL IMPLICATIONS

100.3.1 Screening and Assessment of Cannabis Use Disorder

Screening and assessment are important for detecting, evaluating, and treating CUD. Screening seeks to identify cannabis users who are at risk for or currently have problems related to use. To determine the severity of problems and inform the course of treatment, patients screened as being at risk are further evaluated through assessment.

100.3.1.1 Screening for Cannabis Use Disorder

In non-mental health settings (e.g., primary care, emergency rooms), all patients should be screened for cannabis use. Patients at highest risk for cannabis-related harms (e.g., adolescents, individuals with concurrent psychiatric or substance use disorders) and those who report problems that could be caused or exacerbated by cannabis use (e.g., mood disorders, psychosis) should be screened more frequently.[107] Patients can be screened for cannabis use with brief self-report measures or by urine toxicology tests.

Brief self-report measures provide an economical, efficient means of cannabis screening. To reliably identify those at risk prior to using more extensive assessments, brief screening measures make use of cut-off scores that balance the needs for sensitivity and specificity.[108] Studies suggest that self-reports of cannabis use are fairly accurate, as long as no adverse consequences (e.g., criminal charges) are associated with acknowledging use.[109] However, self-report typically has lower sensitivity than biological drug

TABLE 100.3
Cannabis Use Disorder Screening and Assessment Tools

	Age	Timeframe	Mode	Coverage
Timeline Followback Method[186]	Adolescents and adults	Past week–past two years	Clinician-administered; self-administered	Use patterns (e.g., number of joints smoked per day, number of days used or % days used)
Severity of Dependence Scale[187,188]	Adolescents and adults	Past year	Self-administered	Five-item scale to assess the severity of psychological dependence (e.g., worry about cannabis use, desire to stop using cannabis)
Alcohol, Smoking, and Substance Involvement Screening Test[189]	Adults	Past three months	Clinician-administered	Eight-item scale to assess use patterns and use-related problems (e.g., health, social, legal, or financial problems due to cannabis use, unsuccessful attempts to control/quit cannabis use)
Marijuana Problem Scale[190]	Adults	Lifetime	Self-administered	Nineteen-item scale to assess use patterns and use-related problems
Marijuana Smoking History Questionnaire[191]	Young adults	Lifetime	Self-administered	Twenty-one-item scale to assess use patterns and use-related problems
Cannabis Problems Questionnaire[192]	Adults	Past three months	Clinician-administered	Fifty-three-item questionnaire to assess use-related problems
Cannabis Abuse Screening Test[193]	Adolescents	Lifetime	Clinician-administered; self-administered	Six-item scale to screen for use-related problems
Cannabis Use Disorders Identification Test—Revised[194]	Adolescents and adults	Past six months	Self-administered	Eight-item scale to screen for use-related problems
Cannabis Use Problems Identification Test[195]	Adolescents and adults	Past year	Self-administered	Sixteen-item scale to screen for use-related problems
Marijuana Screening Inventory[196]	Adults	Lifetime	Self-administered	Thirty-one-item scale to screen for use-related problems
Marijuana Consequences Questionnaire[197]	Young adults	Past six months	Self-administered	Fifty-item questionnaire to assess use-related problems
Marijuana Withdrawal Checklist[198]	Adults	Most recent period of abstinence	Self-administered	Fifteen-item scale to screen for cannabis withdrawal symptoms
Cannabis Expectancy Questionnaire[199]	Adults	Current	Self-administered	Forty-five-item questionnaire to assess positive and negative cannabis use outcome expectancies
Marijuana Craving Questionnaire[200]	Adults	Current	Self-administered	Forty-five-item questionnaire to assess craving
Marijuana Quit Questionnaire[71]	Adults	Lifetime	Self-administered	Questionnaire (176-item) to assess use, use-related problems, quitting experiences, and craving

testing.[110–112] Table 100.3 shows a selection of commonly used self-report measures to screen for cannabis use and related problems.

When properly administered (e.g., observed sample collection), biological (e.g., urine, hair, saliva, blood) drug testing for recent cannabis use has the advantage of objectivity and, barring technical problems, practically 100% sensitivity.[110] However, cannabis can be detected for weeks after last use,[113] especially among chronic users, and may not indicate cannabis-related problems[114] or CUD. In addition, biological drug testing is more intrusive and expensive than self-reported measures, so it is typically reserved for screening high-risk populations (e.g., psychiatric or substance disorder patients and employees in safety-sensitive workplaces).

100.3.1.2 Assessing Cannabis Use Disorder

A positive result from self-reported or biological screening for cannabis should be followed by a review of a patient's medical history and a physical exam to identify possible medical risks and consequences of use. In contrast to screening, assessment is a lengthier, more complex process intended to formulate a diagnosis and inform treatment. A comprehensive assessment includes identification of the type, amount, frequency, and consequences of a patient's cannabis use, perception of use and readiness to change, other substance and psychiatric disorders, family history of substance use problems, and social factors that may contribute to cannabis use. A number of valid, reliable scales and questionnaires have been developed to quantify use and assess DSM-5 CUD[115] (Table 100.3).

100.3.2 Cannabis Use Disorder Treatment

A CUD diagnosis has implications for subsequent care. Treatment for SUDs in general, and for CUD specifically, is rare. Among those with current and lifetime DSM-5 CUD diagnoses, only 7.2% and 13.7% received any intervention specifically for cannabis problems.[58] In addition, despite increases in adult cannabis use and related problems, the proportion of patients who have received treatment for cannabis use has not changed since 2003.[116] Thus, CUD remains seriously under-treated in the US general population.

The US Preventive Services Task Force recommends screening for health risk factors, including substance use using the Screening, Brief Intervention, and Refer to Treatment (SBIRT) model, an evidence-based practice to identify and reduce problem substance use through counseling.[117] The SBIRT model is well-established for primary care patients engaging in risky alcohol use,[118] but its effectiveness for other substances remains unclear.[119] Nevertheless, patients in non-mental health settings should be screened for cannabis use and those identified as at risk for cannabis-related problems advised about potential harms associated with cannabis use and referred to specialized substance use treatment if needed.

Outpatient treatment for CUD is more typical but may occur in an inpatient setting if a patient is acutely psychotic, suicidal, or requires hospitalization to treat another substance use or psychiatric disorder. Psychosocial interventions for CUD are the most effective; trials of medication treatments have inconsistent or weak results.[120–123]

100.3.2.1 Psychosocial Interventions

Psychosocial interventions increase patient awareness of the negative consequences of cannabis use, enhance motivation to reduce use, manage painful feelings, and improve social skills, social support, and interpersonal functioning.[120] Randomized trials show the strongest efficacy for cognitive behavioral therapy (CBT), motivational interviewing/motivational enhancement therapy (MI/MET), and their combination.[120] CBT involves the identification and management of external triggers, thoughts and behaviors that encourage substance use, and teaches better coping skills. CBT is particularly effective at reducing cannabis use and even one CBT session can help individuals with CUD abstain from cannabis over time.[124,125] MET is a directive, patient-centered psychotherapy approach that helps individuals resolve ambivalence and increase motivation to reduce substance use through empathic, supportive counseling. A meta-analysis indicates that MI is effective in reducing cannabis use in adults and achieving abstinence from cannabis use in adults and adolescents.[126] MET combines MI with personalized feedback and education regarding patterns of substance use often.[120] MET can reduce cannabis use and the severity of CUD.[120,127] Combinations of CBT and MET are often more effective than either alone.[120] In addition, contingency management, which uses behavioral reinforcement techniques (e.g., a voucher incentive) to promote treatment adherence or abstinence, can effectively reduce cannabis use when provided in combination with CBT or MET.[120,128] However, although contingency management alone has been found to be generally effective in reducing other SUDs, evidence about its efficacy in treating CUD remains unclear.[129–131]

Individuals with CUD who lack access to structured psychotherapy may benefit from drug counseling or referral to a mutual help group like Marijuana Anonymous. Drug or addiction counseling includes individual and group sessions aiming to reduce substance use through fact-based education about use and health risks and suggestions for minimizing harm.[120] Mutual help groups for addiction aim to help individuals achieve and maintain abstinence. Based on the 12-step principles of Alcoholics Anonymous, Marijuana Anonymous is widely available and does not charge dues or fees for membership or attendance.

100.3.2.2 Pharmacological Interventions

Currently, no medication for the treatment of CUD is approved by the US Food and Drug Administration (FDA).[132] N-acetylcysteine and gabapentin have yielded the most favorable results in clinical trials, while other medications (e.g., antidepressants and anticonvulsants) have shown mixed or negative findings.[133,134]

100.3.3 Use of Cannabis for Pain

Chronic pain is common among US adults.[135–138] Prescription opioids have been widely prescribed for chronic pain[139,140] despite inconsistent evidence for analgesic benefits.[141] The serious risks of opioid use,[140,141] including physical dependence, addiction, transition to heroin use, and overdose,[142–144] have made opioids a well-known US public health crisis. Consequently, calls have been made to substitute medical marijuana for opioids[145] due to its advantages (e.g., analgesia[146] and lack of fatal overdose[147]).

Many medical marijuana patients use cannabis for pain relief, some as a partial or complete substitute for prescription opioids,[148–153] while others continue to use or abuse prescription opioids. Individuals use cannabis for pain relief in states with and without MCLs.[154,155] Enactment of MCLs has been followed by lower rates of opioid prescriptions,[156,157] hospitalizations for opioid use disorder,[158,159] overdose,[160,161] and opioids detected in fatally injured drivers.[162] However, a recent review found low/insufficient evidence that plant cannabis is an effective treatment for chronic pain.[163] Medical marijuana also has its problems, including cognitive/motor impairments,[164] other side effects,[146] and lack of standard product formulations.[165] A large-scale general population follow-up study showed that among adults with pain, those using cannabis at baseline were more likely (not less likely) to have an opioid use disorder three years later.[166] Concerns are emerging that over-reliance on medical marijuana may lead to further downstream substance problems in

the general population[166–169] and that experiencing pain is a growing risk factor for CUD.[170] Therefore, providers should inform patients that cannabis is not entirely risk-free, and can have side effects or lead to adverse health outcomes.

100.3.4 Use of Cannabis for Psychiatric Conditions

Evidence is lacking for the efficacy of cannabis in the treatment of depression or anxiety disorders,[24,146,171–173] although personal testimonies suggest that cannabis relieves depressive and anxiety symptoms.[174,175] Online product advertising may enhance the impression that cannabis can treat mood or anxiety problems (e.g., "green Prozac"[176,177]). Consistent with this, many medical marijuana patients report using cannabis to treat these symptoms.[152,153,171,178–181] However, when asked about actual symptom relief, less than half report such relief,[179] while others report that anxiety symptoms return on cessation of use,[182] suggesting that symptoms may be due to unrecognized cannabis withdrawal.[171] Several cannabis withdrawal symptoms overlap with depression and anxiety symptoms (Table 100.2). Individuals may use cannabis for short-term relief of depression and anxiety symptoms, unaware that use could perpetuate a longer-term withdrawal problem and have adverse effects on the course of depression.[183] Furthermore, some research shows that MCLs are associated with lower rates of antidepressant and anti-anxiety prescriptions.[156,157] Since evidence suggests cannabis is ineffective in the treatment of depression and anxiety disorders[24,146,171] and that use may result from confusion between withdrawal and depressive or anxiety symptoms, substituting cannabis for FDA-approved medications is a concern. Clinicians, especially those treating younger patients or patients with symptoms of mental illness, should explore with patients whether a cannabis use/withdrawal cycle may be perpetuating depressive or anxiety symptoms. Some patients may not be receptive to the idea that cannabis is contributing to their symptoms rather than alleviating them. However, continued respectful and empathic discussion and perhaps some self-monitoring may help in this regard. Efforts at cessation of use for a period of time may clarify if the depression or anxiety reflects cannabis withdrawal or is independent of cannabis use.

While some evidence indicates that cannabis has adverse effects on the course of posttraumatic stress disorder (PTSD),[184] other research suggests that synthetic oral cannabinoids may be helpful for treating some aspects of PTSD.[102] Medical marijuana is specifically authorized as a treatment for PTSD in 27 states.[185]

Since cannabis use is characterized as one of the strongest modifiable risk factors for developing a psychotic disorder, children and adolescents with a family history of psychosis or prodromal symptoms should be informed of the risks and strongly advised to not use cannabis.[104]

100.4 CONCLUSION

As attitudes and laws about cannabis use evolve and the prevalence of cannabis use increases, healthcare providers, policymakers, and the general public need to be aware of the risks associated with cannabis use. Clinicians should screen and assess all patients for cannabis use and cannabis-related problems, inform cannabis users of potential adverse consequences of use, and refer those with CUD to treatment. Additionally, further research should:

1. Identify risk factors for adverse cannabis-related outcomes and changes in such risk factors amid a changing legal and social landscape.
2. Further develop screening and assessment measures to detect cannabis use and cannabis-related problems, including CUD.
3. Provide information on the efficacy of interventions aimed at increasing awareness of cannabis risks and reducing use, particularly among those with a higher likelihood of adverse consequences.
4. Understand the relationships between cannabis use and cognitive functioning, cannabis withdrawal and psychiatric disorders, opioid use and marijuana laws (both for medical and recreational use), and postnatal outcomes related to using cannabis during pregnancy.

While much has been learned about cannabis, its use, and its consequences, further investigation is needed to expand the evidence base for clinical care aimed at preventing negative cannabis-related health outcomes alongside a rapidly evolving social and legal environment.

CLINICAL APPLICATIONS

- Healthcare providers should screen and assess all patients for cannabis use and use-related problems, inform cannabis users of potential adverse consequences of use, and refer those with CUD to treatment.
- Patients at highest risk for cannabis-related harms (e.g., adolescents, individuals with concurrent psychiatric or substance use disorders) and those who report problems that could be caused or exacerbated by cannabis use (e.g., mood and anxiety disorders, psychosis) should be screened for cannabis use and advised about potential risks more frequently.
- Patients who use cannabis for pain relief should be informed that cannabis is not entirely risk-free and should be closely monitored for adverse health outcomes, including cannabis withdrawal and CUD.
- All women who are pregnant or contemplating pregnancy should be advised about the potential risks of prenatal cannabis use in order to discourage use.

101 Digital Health Technology for Behavior Change

Bjorn Hansell, MD, Valerie Black, MBA, CWC, John Chan, MD, Christopher Dove, MD, PhD, Mindy Hong, PhD, MSPH, Patricia Zheng, MD, Courtenay Stewart, DO, Mark Berman, MD, FACLM, and Jeffrey Krauss, MD, DipABLM

KEY POINTS

- Digital health technology is a rapidly growing field, encompassing FDA-approved prescription digital therapeutics, direct-to-consumer health apps, and social media platforms where patients exchange knowledge and experiences.
- The impact of digital health technologies has been applied and scientifically validated in a wide range of conditions, spanning from mental health and substance abuse to cardiometabolic and musculoskeletal conditions.
- It is important that digital therapeutics and health apps are built on validated principles of behavior change and lifestyle medicine.

101.1 INTRODUCTION

Lifestyle medicine stresses the importance of simple and powerful behaviors to prevent and treat diseases and requires less advanced technology than traditional medicine. Indeed, many behavior change strategies have demonstrated remarkable success in promoting healthy behaviors without using any technology.[1–4] Nevertheless, behavior change is notoriously difficult to achieve, and this chapter describes how digital health technology can support patients in their efforts.

Digital health is a discipline that includes everything from traditional healthcare services delivered over telehealth to wearable devices, innovative digital therapeutics, digital processes, decision support systems, and comprehensive digital services that integrate all of the above. The main driver of the field is the potential to increase access to healthcare, improve the efficiency of healthcare delivery, and make medicine more personalized and precise.[5] In addition, digital tools have brought healthcare into people's homes and empowered patients to take a more active role in their health and healthcare.[6]

The phenomenon of digital health builds on the underlying digital revolution, driven by improvements in data processing power and internet connectivity of mobile devices. The proportion of the world's population that had access to the Internet reached 62.5% in 2022, more than double the number in 2012; 92.1% accessed the Internet primarily via a smartphone, and the average user was online for almost seven hours per day.[7] In the United States, 93% of the population uses the Internet, and 31% of adults report being constantly online.[8,9] Digital technologies have become so intimately integrated into modern life that sociologists describe life as taking place in a mixed physical and digital presence, a "metaverse".[10]

Starting in 2020, strict lockdown measures due to COVID-19 led to increased adoption of digital health. There was a 154% increase in telehealth visits during the third week of March 2020 compared to the same period in 2019.[11]

US venture capital investment in digital health doubled to $29.1 billion,[12] and the number of health-related apps available surpassed 350,000[13] in 2021. The Center for Medicare Services has broadened its reimbursement to include remote patient monitoring and telemedicine visits, and The Food and Drug Administration has advanced its capacity to oversee and increase digital health technologies through its Digital Health Innovation Action Plan.[14]

It is difficult to generalize the impact of digital technology on health.[15] Studies have shown that digital technologies can impact the morphology of the growing brain, and others have indicated a correlation between social media use and mental health. Among adolescents, both low and excessive use of digital technology is related to decreased well-being, whereas moderate use is related to increased well-being. The impact on short-term measures of hedonic well-being is more potent than on long-term measures of life satisfaction.[16] Among seniors, there is an association between training on social media and better cognitive function, improved mental health, and improved physical well-being.[17]

This chapter describes the most critical digital health technologies and how to combine them into comprehensive digital health services. We start by discussing how health apps and wearables impact health. In the section about digital therapeutics, we describe the treatment of medical

DOI: 10.1201/9781003227793-118

conditions like diabetes and depression using apps. We also touch on the emerging phenomenon of digital prescription therapeutics, software medical devices that require a prescription from a healthcare professional. We describe how healthcare professionals can use social platforms to disseminate health information and interact with patients. Lastly, we review text messaging and discuss how emerging technologies may contribute to future lifestyle medicine interventions.

An important aspect of digital health is the increasing use of electronic medical records and customer relationship management platforms to guide care processes, collect and analyze patient data, and communicate with patients over telemedicine. We have omitted these technologies since they are not primarily used to promote behavior change.

Throughout the chapter, we provide practical considerations for implementation. Whether designing a digital health service for a small practice or a large organization, adopting one digital health technology is not enough to drive success.[18,19] The user interface, ease of use, financial incentives, training, staffing, and workflow integration are essential. Lastly, services should be grounded in behavior change techniques, such as self-monitoring, positive feedback, barrier identification, or motivational interviewing.[20,21]

101.2 HEALTH APPS

A software application ("app") runs natively on a mobile, wearable, or stationary device. It can also run in a web browser. The connectedness of mobile and wearable devices makes these applications excellent vehicles for effective and efficient lifestyle interventions. This section will describe apps that impact *general health and wellness*, while the section about digital therapeutics describes those that treat a *medical condition*.

It is important to note that while some apps deliver a fully automated user experience, many include human interactions.

101.2.1 Outcomes

The evidence base for health apps is growing but still nascent. Study outcomes depend on several factors, like the underlying behavior change techniques, the technical quality, and the usability. Publications seldom report on the impact of each of these factors, making it difficult to draw systematic conclusions about why some health apps work better than others. Furthermore, mobile technology's rapid advancement and adoption have rendered many research findings out of date shortly after their publication. Nevertheless, individual studies have shown that mobile interventions can successfully encourage positive lifestyle changes and monitor adherence to a program.

Weight management and nutrition. Despite the abundance of weight management programs that offer apps, most programs rely mainly on interpersonal interactions, and there are very few high-quality randomized controlled trials (RCTs). However, a recent meta-analysis of digitized lifestyle interventions utilizing self-monitoring to promote weight loss concluded that they were moderately effective and yielded higher adherence than traditional lifestyle programs.[22] A systematic review of 41 studies concluded that automated nutrition apps had a low to medium impact on nutrition behaviors, such as caloric intake and nutrition scores, and clinical outcomes like BMI and blood lipids. Overall, evidence suggests that mobile applications may be helpful as low-intensity approaches or adjuncts to conventional weight management strategies. However, insufficient evidence supports their use as standalone intensive approaches to weight management.[23]

Physical activity. Most smartphones have embedded accelerometers that can track step counts, and GPS for tracking location to track distance. In addition, apps often implement classic behavior change techniques such as goal setting, self-monitoring, social support, feedback on behavior, and instructions. A 2017 systematic review of 21 RCTs concluded that the studied apps had a statistically significant but small effect on sedentary behavior compared with usual care and a small to medium effect on total physical activity and walking that was not statistically significant.[24]

Mindfulness and mental health. Many mobile applications support mindfulness through guided meditations, relaxation techniques, and resilience training. While these applications have become quite popular, a 2022 systematic review concluded that although studies indicate a potentially positive effect on symptoms of depression and anxiety in a non-clinical population, more rigorous RCTs are required to provide reliable evidence.[25]

Smoking cessation. According to a 2019 Cochrane review, there is moderate-certainty evidence that automated text message-based interventions result in higher quit rates than minimal smoking cessation support. However, the evidence regarding smoking cessation apps was very low certainty, and more RCTs are needed.[26]

101.2.2 Considerations for Implementation

The success of health apps often depends on whether they build on clinical knowledge and evidence-based behavior change techniques. Core features belong to clusters like "goals and planning", "feedback and monitoring", "shaping knowledge", and "social support".[27,28] Unfortunately, commercially available apps often fail to embrace established evidence. In a study of weight-loss app features, the average app included only 18.83% of the strategies included in the landmark Diabetes Prevention Program.[29] Likewise, clinical guidelines for diabetes care emphasize education on a healthy diet, tight glucose control, and the role of exercise. However, a review of 137 diabetes mobile applications showed that less than 38% included this kind of education.[30]

It is crucial to evaluate the functionality of apps diligently. The Mobile App Rating Scale can be used to analyze

an app's functionality, aesthetics, user engagement, and information quality.[31] In addition, developers should assess the risk of loss of reputation, loss of privacy, poor quality of patient data, poor lifestyle or clinical decisions, and inappropriate clinical actions.[32]

101.3 DIGITAL THERAPEUTICS

Digital therapeutics or "software as a medical device"[33] are digital tools intended to treat disease through psychological and behavior change techniques, either standalone or together with pharmacological agents. They often track biometrics using wearable sensors and utilize apps or text messaging to send information and reminders to patients. On the back end, they may include clinical assessment tools, clinician-monitored dashboards, and HIPAA-compliant data storage.[34] Many programs also incorporate remote coaching, a practical option for behavioral counseling when in-person programs are not accessible or convenient.

Digital therapeutics are available directly to consumers and are sometimes paid for by employers and health plans. Prescription digital therapeutics is a subset that requires approval by the Food and Drug Agency and is available only through a healthcare provider.

Digital therapeutics can collect a high volume of user data, ranging from traditional clinical biomarkers to personalized physiologic parameters and social patterns.[35] They can create longitudinal data sets and run analytics that provide insight into the effectiveness of specific program features.

101.3.1 Outcomes

Research on digital treatment solutions began around 2000.[36] Recent research has shown that digital therapeutics can improve access, quality of care, and safety of services.[33] The accessibility and quality of care, combined with the precision of technological advancements, have allowed digital health to transform modern healthcare practices. Digital therapeutics have improved outcomes in many areas, including COPD, asthma, substance abuse, depression, musculoskeletal pain, weight loss, and diabetes.[37–41] The constant growth of clinical trials and review papers in the digital health world reflects the potential of digital therapeutics for improved patient care.[42]

Diabetes. One online diabetes prevention program consisting of a weekly lifestyle medicine curriculum, health coaching, support groups, digital scales, and activity tracking saw participants undergo a 0.8% reduction in HbA1c after four months.[43] The study also showed significantly improved diabetes distress and medication adherence between baseline and follow-up.

Hypertension. A lifestyle modification program that delivered medically validated non-pharmacological interventions through a smartphone app showed a significantly greater reduction in ambulatory systolic blood pressure compared with a control group; 22.2% of the digital therapeutic group achieved morning home blood pressure of less than 135/85 mmHg at 12 weeks, versus 10.4% in the control group.[44]

Substance abuse. The first FDA-authorized prescription digital therapeutic was for the treatment of opioid use disorder. It resulted in improved clinical outcomes, high levels of treatment retention, and fewer hospital encounters after 24 weeks of the treatment.[45]

Mental health. Digital therapeutics for mental health have surged after the COVID-19 pandemic. A study of an evidence-based sleep and mindfulness program found decreased stress levels and improvements in mindfulness and self-compassion for college students.[37] A digital meditation program that focuses on improving mental, emotional, and social health through daily guided meditation playlists found a 14% reduction in stress and a 27% reduction in irritability after only ten days of using the program.[38]

Chronic musculoskeletal pain. Many studies have shown strong short-term improvements in pain and function,[39,46,47] and a digital health intervention incorporating physical exercise, education, and psychosocial support found that improved clinical outcomes could be maintained longer term, with 72.2% of participants achieving a clinically important difference in pain after one year, compared to 56.2% of non-participants.[40] A recent study found that individuals who used a back pain treatment app reported a significant improvement in sleep quality alongside pain reduction,[41] while others have shown improvements in mental health conditions.[46,47]

101.4 SOCIAL MEDIA

Social media are interactive technologies and digital channels that facilitate the creation and sharing of information, ideas, interests, and other forms of expression through virtual communities and networks. Some of the most popular social media websites, with more than 100 million registered users, include Facebook, TikTok, WeChat, Instagram, Twitter, Tumblr, and LinkedIn.[48] There are also health-oriented social networks, one example being "Patients Like Me", a platform where patients support each other and share personal experiences of living with a disease.

101.4.1 Outcomes

A Cochrane Review of social media interventions for different health conditions found that they may be effective in increasing physical activity and well-being. For other health outcomes, the evidence was uncertain.[49]

Social Support and Connection. Social connections are critical for overall health and healthy habits.[50] With loneliness affecting 25%–60% of older adults,[51] online options may help fill an in-person void. Online social support is precious for chronically ill or immobile individuals who can share illness-related concerns or questions with close

friends and family without straining offline relationships.[52] For people living with chronic conditions, social networks can provide a supportive space for daily self-care, a space to strengthen social ties and exchange knowledge, and a place to mobilize and raise collective awareness about illness-specific concerns.[53]

Social connections are known to influence obesity patterns.[54] A 2015 study evaluated variables that may contribute to weight loss in an online weight loss community and found that greater embeddedness in the online network was the variable with the highest statistical significance for weight loss.[55] In a survey of weight loss forum members, the major social support themes were encouragement and motivation, information, and shared experiences. Members reported that they valued convenience, anonymity, and non-judgmental interactions as unique characteristics of Internet-mediated support.[56]

Patient knowledge exchange. Online social networks can support patients in managing their health and can be valuable tools for high-quality and affordable health care.[53,57,58] As patients share their own experiences, they spread technical and medical knowledge, but also "patient knowledge" that helps others navigate day-to-day life.[52]

Decreased reliance on clinicians. Analysis of 16,492 messages from a smoking cessation network showed users took control of their cessation with various tactics, such as virtual bonfires and pledges. None of the messages mentioned the role of a physician in their smoking cessation efforts, suggesting the behavior change effort in this community was primarily self-propelled.[59]

Data collection. Patient-shared data can be collected online to create research databases. For example, a social network of ALS patients collected data on outcomes for those using litium off-label, and saw no clinical effect within the first 12 months,[60] highlighting the potential of patient-generated data to accelerate clinical discovery.

101.4.2 Considerations for Implementation

It is possible to utilize several social network mechanisms in interventions for behavior change. Network members can influence social norms by engaging in or endorsing a behavior or by rewarding or punishing others for engaging in the behavior. They can also establish communication norms that make it more socially acceptable to talk about certain health-related topics.[61]

Many affordable social media tools are available to use in lifestyle interventions, and guidelines encourage healthcare providers to engage with patients on social media. If the target audience is present on an established social media platform, clinicians may engage with them there while observing ethical guidelines. These guidelines tend to mention five moral themes: "the importance of patient confidentiality", "defamation is unacceptable", "privacy cannot be guaranteed", and "the responsibility to maintain public trust".[62]

101.5 WEARABLES

Wearable electronic devices are worn on the skin's surface, detecting, analyzing, and transmitting information concerning vital signs, movement, and the ambient environment. They have quickly become ubiquitous, and people with an interest in measuring and analyzing bodily functions has evolved from a small subculture, the "Quantified Self" movement, to a mainstream movement.

Beginning with the Fitbit in 2010,[63] wearables have evolved from simple data collection tools to extensive platforms designed to drive behavior change.[64] Wearables can provide data on users' heart rate and rhythm, oxygen saturation, blood glucose, and activity levels. They can also provide insights into users' sleep, stress levels, and mood.[64] Wearable usage has increased in the past decade, with an estimated 533.6 million shipments of wearable technology in 2021. Hearables (internet-connected devices worn on or in the ears) have recently surpassed smartwatches as the most widely used wearables category.[65] Healthcare practitioners are now beginning to adopt wearables for patient monitoring in the treatment of a growing number of medical conditions, including diabetes, cardiovascular disease, and movement disorders.[66]

Physical activity trackers are the most abundant wearables. They measure the pulse rate and have built-in accelerometers to track steps, physical activity, and sleep. Some trackers can calculate exercise performance measures like power output, oxygen saturation, and VO_2 max. Trackers and their corresponding smartphone applications are accurate to within 25% of actual step counts and can measure heart rate with less than 10% deviation. The average error for energy expenditure is around 30%.[67,68]

101.5.1 Outcomes

The general effect on lifestyle and health of the widespread adoption of wearable and sensor technologies is unknown.

Physical activity. While trackers may be able to promote physical activity in the short term, their effect on health and longevity is debatable.[69] Accelerometers are used for many clinical purposes, like measuring frailty in a geriatric population,[70] detecting falls,[71] monitoring real-world physical activity,[72] quantifying upper limb gestures in post-stroke rehabilitation,[73] and monitoring gait.[74]

Weight management. Wearable devices have been advertised to help maintain weight and a healthy lifestyle by tracking physical activity and other biometrics. Weight management programs that include wearables offer more significant and long-lasting benefits.[75,76]

Glucose monitoring. Continuous glucose monitors are applied on the skin and measure glucose levels in interstitial fluid. They provide a detailed view of glucose metabolism and collect vast amounts of data for longitudinal analysis. Use of these devices has increased since the FDA approved an easier to use type of CGM in 2017,[77] though the devices were previously adopted internationally and shown to be

accurate.[78] Studies have found that real-time continuous glucose monitoring systems can be clinically valuable, especially in reducing severe hypoglycemia in type 1 diabetes patients who may be unaware of these episodes.[79]

Mindfulness and stress. There is evidence that biofeedback from wearable devices can help reduce anxiety.[80] For example, devices can utilize electroencephalography (EEG) to enhance mindfulness training[81] or monitor stress by measuring electrodermal activity,[82] heart rate, and heart rate variability.

101.5.2 Considerations for Implementation

As devices and sensors vary, it is hard to make generalized comments about how to best design, test, and utilize them. However, Patel and colleagues present a generic outline for how to design and adapt devices to facilitate behavioral change.[83]

First, the user needs to be motivated to use the device. A survey of 6223 individuals showed that more than half who purchased a wearable device stopped using it, with one-third quitting before six months. However, 80% of over 35,000 people were still using wearable activity trackers after six months of a health insurance wellness program, which suggests that it is possible to achieve sustained use by stimulating self-motivation in a comprehensive program.[84]

Second, the device must be able to track its target behavior accurately. Multiple systematic reviews have shown that wearable devices that monitor physical activity tend to underestimate energy expenditure and overestimate sleep time.[68,85,86] The FDA provides formal regulatory guidance over medical devices and monitors the quality of devices in which accuracy is critical to patient health (e.g., continuous glucose monitors).[87,88]

Last, and perhaps most important, wearables are most effective when part of broader wellness programs involving peer groups, gamification and competition, and regular interaction with healthcare providers. Also, it is essential to display data in a way that stimulates users' motivation.[89,90]

101.6 TEXT MESSAGING

The Short Message Service (SMS) is the most widely used data application globally; 67.1% of the world's population own a mobile phone, and they open 90% of text messages within three minutes.[91,92] In addition, text messaging is part of many health apps and social media platforms.

The literature for text messaging applications is more extensive compared with other digital health technologies. The first study was published in 2002, the first systematic review in 2009, and the first systematic review of reviews in 2014.[93]

The benefits of using text messaging for behavior change are numerous. Patients perceive them as personal while being low-cost, instant, easy to use, and scalable.[93–95] Text messages can push information directly to the intended audience and are less likely to be misplaced than print materials. It is possible to precisely design messages to patients' needs, for example, by sending reminders at specific moments of decision-making. Text messages are less invasive than phone calls, and receiving text messages is associated with a small dopamine release.[93,94] Lastly, text messaging can mirror elements of in-person counseling, such as tailored advice, behavioral monitoring, goal setting, and feedback.[95]

Text messaging interventions may be particularly beneficial for low-income populations, given the ubiquity of cellular phones and the low cost of implementation. Text messaging can be cost-effective and impactful in settings with a limited healthcare workforce, limited financial resources, a high disease burden, and hard-to-reach populations.[96,97]

101.6.1 Outcomes

Text messaging has contributed to positive outcomes in many lifestyle interventions.[93] Scientific reviews have shown benefits in a wide range of conditions spanning diabetes self-management, cardiovascular disease, weight loss, physical activity, smoking cessation, and medication adherence.[26, 93, 98–100]

101.6.2 Considerations for Implementation

Various scientific reviews have investigated how to design a text messaging intervention.[94,95] Abroms et al., in particular, have specified a process that starts with understanding the critical behavior change mechanisms and goals for the population of interest. Next, determine the communication objectives of the intervention, identify appropriate behavior change techniques, and determine other theoretical constructs.

While few text-messaging studies explicitly mention behavior change theories, some programs have applied them together with the Transtheoretical Model of Behavior Change, the Health Belief Model, Behavior Learning Theory, and the Information Motivation Behavior Model.[95,99]

Other areas of consideration include:

- *The message content* may include reminders, motivational messages, educational material, goal setting, feedback, and behavior-tracking nudges. Other considerations include the length of the message,[101] the sender of the message, style of writing, cultural and linguistic appropriateness,[94,102] literacy level of the population (generally, avoid higher than the eighth-grade level for adults), and the need for translations.[95] Messages may use text, images, videos, emojis, and website links.[93,103] Standard libraries are increasingly available with empirically tested content.[94,102]
- *The frequency of messages* varies widely in studied interventions, from multiple times daily to weekly, and various recommendations exist in

the literature.[98,103–106] Some studies provide more messages during critical behavior change periods. Some only send messages at the request of users, and others vary in frequency based on their users' text habits or program adherence (e.g., a higher frequency when adherence is low).[95]

- *Interactivity.* A key consideration is whether the intervention should be one-way (provider to the patient only) or two-way (patient also sends information to provider). Bidirectional systems are likely to be more complex and resource intensive. Most studies have used some degree of bidirectional communication, but the literature is mixed regarding its benefits.[98,99,107]
- *Tailoring and personalization.* It is possible to tailor the content of messages to subgroups or even individual users. Several reviews have reported that personalized messages are more likely to catch the user's attention, be remembered, be discussed with others, be perceived as interesting, and feel personally relevant.[94]
- *Data security, confidentiality, and privacy.* Each country has laws and regulations for collecting, storing, or transmitting personal health information (e.g., HIPAA in the United States). Designers should aim to implement secure messaging systems. If using SMS, patients need to understand the privacy risk before using the service.
- *User testing.* It is vital to user-test the acceptability and effectiveness of text messaging programs.[94]

Numerous comprehensive resources are available to further assist with developing text messaging programs.

101.7 EMERGING TECHNOLOGIES

101.7.1 Multi-omics

Remarkable advancements in the speed and cost of gene sequencing technology[108] have given rise to the concept of multi-omics. This term encompasses our knowledge about the human genome, epigenome, transcriptome, proteome, metabolome, and microbiome.

There is an association between nearly 150 genetic variants and obesity, and researchers attribute half of the inter-individual variance in body size to genetics.[109] Numerous studies show that genes influence our ability to lose or gain weight.[110–112] Furthermore, genes influence metabolism, food preferences, and eating behaviors. A limited number of genes have been found that may affect exercise adherence and tolerance.[109]

Other areas of multi-omics may be relevant to lifestyle change. Epigenome-wide association studies have shown that physical activity and high-fat diets may impact weight loss by altering the DNA methylation pattern in tissues that are important for energy homeostasis.[109] Furthermore, the trillions of bacteria, archaea, fungi, and viruses that make up the gut microbiome are known to affect food processing, metabolism, vitamin synthesis, and weight regulation.[112]

Knowledge of one's multi-omic profile in itself can influence behavior. For example, identifying BRCA mutations can lead patients to undergo mastectomy, but it is unclear if this can be used to motivate lifestyle change. A Cochrane review showed little to no effect of communicating DNA-based disease risk on patients' smoking status and physical activity.[113]

Recent research has focused on developing personalized multi-omic profiles and understanding the temporal changes to an individual's omic profile. In addition to vast sequencing data, the UK Biobank subsets harbor data on cognitive function, mental health, metabolism, and activity.[114] Researchers have demonstrated that omic data collection might benefit patients in real-time by collecting serial omics profiles (including whole genome sequencing, transcriptomics, and wearables) over several years. They showcased a range of medical and lifestyle interventions adopted by the study participants based on elevated cardiac, cancer, and metabolic disease risk.[115] Understanding complex, personal biology is only possible after enumerating these rich datasets corresponding to a spectrum of wellness and disease.

101.7.2 Virtual and Augmented Reality

Both virtual and augmented reality have surged in popularity in recent years. Virtual reality (VR) is an artificial, computer-generated simulation of an environment through a headset. Augmented reality (AR) is a similar technology that adds computer-generated enhancements to reality.

There is reason to believe that these technologies may be helpful for behavior change. In 2016, an AR game called Pokémon Go (Niantic, Inc.) for iOS and Android devices led to a "population-level" surge in fitness tracker step counts.[116] By 2019, the application had been downloaded more than one billion times, and a study found that users with high interest in the game increased their activity by 26% (1479 steps/day) and were almost three times as likely to meet official physical activity guidelines.[117] Another study showed that the number of participants achieving a goal of 10,000 steps per day increased from 15.3% to 27.5%.[118] Notably, both studies reported significant improvements in sedentary, overweight/obese, and older users. Unfortunately, the

intervention results were short-lived, and the number of daily steps returned to pre-installation levels by week six.[119]

VR has made slower advances in preventing and treating lifestyle-associated diseases. Examples of situations where VR interventions have been successfully tested are respiratory therapy among COPD patients,[120] gait-training in movement disorders,[121] hand therapy after stroke,[122] and chronic low back pain.[123]

107.7.3 New Sensor Types

Miniature electronics, advances in wireless data transmission, improved optics, the steady growth of computing power, and nanotechnology are driving the development of novel wearables. A common theme is for sensors to capture standard physiological data (e.g., pulse, blood pressure, ECG, blood glucose, temperature) via a miniaturized, continuous monitor. The form factor is often novel, such as stick-on tattoos, bandages, microfibers, or minimally invasive implants.[124–126] Some sensors also promise novel physiological measurements, such as caloric intake or hydration.

The most widespread new sensor types are ECG monitors and continuous glucose monitors. The Apple Watch's single-lead EKG monitor has enabled the widespread identification of clinically actionable arrhythmias.[127,128] The Zio Patch (iRhythm, Inc) is a standalone single-lead ECG monitor that has seen widespread use to detect atrial fibrillation, especially in post-hospitalization patients after cryptogenic stroke or transient ischemic attack.[129] The FDA approved the first very-thin filament continuous glucose monitor (CGM) in 1999. Hybrid closed-loop systems that use data from a CGM to control an insulin pump are gaining popularity fast due to their superior impact on glycemic control.[130,131] The commercial success of these products demonstrates an opportunity for devices targeted directly to consumers and to organizations with a vested interest in preventing chronic disease. Possible future use cases include devices that can detect blood pressure, stroke symptoms, seizures, and pressure ulcers.

Data sharing from these new sensors to healthcare systems increases slowly due to privacy concerns, antiquated software, and lack of market incentives. Better data integration could improve patient enrollment and engagement in lifestyle change programs.

107.7.4 Artificial Intelligence and Machine Learning

Artificial intelligence (AI) is the ability of computers to mimic facets of human cognition and has the potential to influence and augment nearly every facet of healthcare. AI has already been implemented successfully in predictive medicine, medical research, epidemiology, health monitoring, medical training, and treatment of lifestyle-associated illnesses.[132,133] However, the more general incorporation of AI into conventional healthcare and consumer-focused platforms has been slow. The most rapid advances have occurred in precision oncology and AI-enhanced radiology.[134]

Machine learning is an analytical method that allows analytics software to be trained on historical data to make predictions from new data sets.[135] The capacity of the software to make predictions improves as it gets access to more data. For example, researchers trained a machine-learning

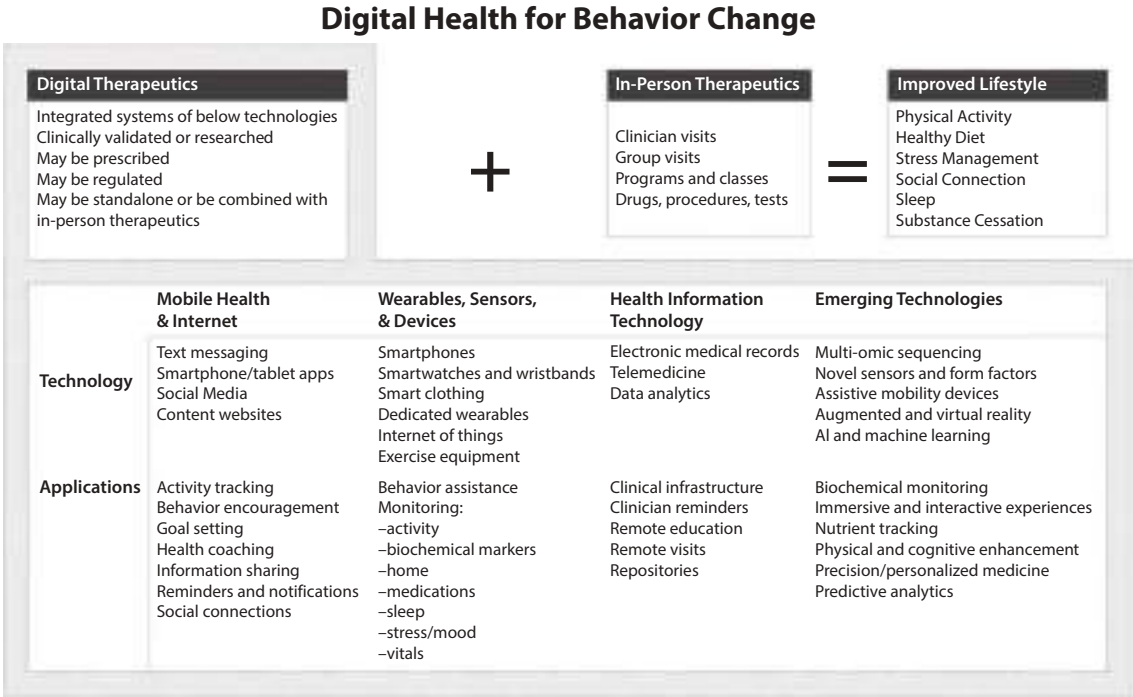

FIGURE 101.1 An overview of current and emerging digital health technologies for behavior change.

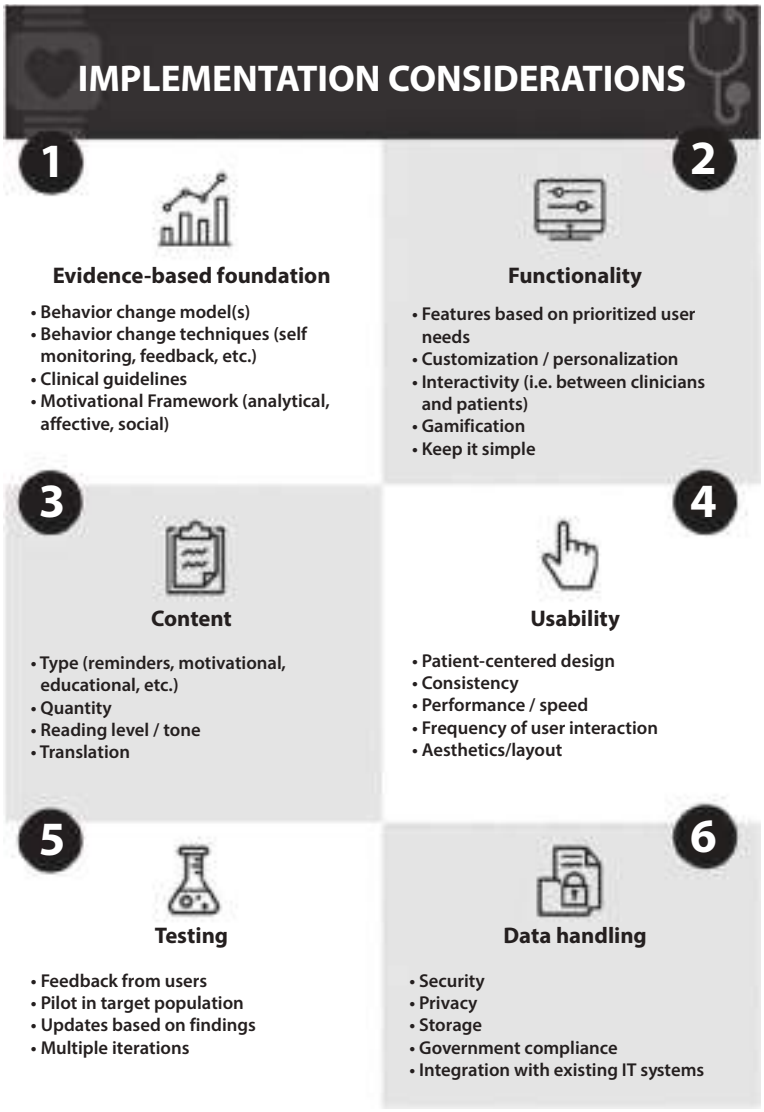

FIGURE 101.2 Multiple considerations may determine the success of digital health technology implementations.

algorithm to predict postprandial blood glucose on data from an 800-person cohort.[136] Input parameters included information from continuous glucose monitors, meal tracking, physical activity, laboratory values, and gut microbiota. The resulting algorithm successfully forecasted blood glucose levels in another group of patients. A separate small RCT demonstrated that diet recommendations based on the algorithm rivaled the impact on postprandial glucose recommendations from a human expert. Other studies have discovered novel disease comorbidities based on EHR data,[137] screened patients for atrial fibrillation from wearable data,[138] and diagnosed upper respiratory diseases such as COPD by the sounds of coughing.[139]

101.8 SUMMARY

Mobile phones, wearable devices, and social media are pervasive in our daily lives and influence our behaviors. The increasing adoption of these technologies drives the use of these technologies in healthcare. Furthermore, a shift toward value-based reimbursement models may lead providers to focus more on outcomes and costs and stimulate their demand for digital health products that monitor and encourage healthy behaviors at scale.

Even though research is lagging, there is sufficient evidence to support that digital health technologies can drive behavior change. This chapter emphasizes that digital health products should be integrated with people and processes and carefully designed to promote simple, powerful, and healthy behaviors fundamental to lifestyle medicine.

CLINICAL APPLICATIONS

- There is clear evidence that carefully designed digital health interventions can drive positive lifestyle change.

- Digital health tools can be used as standalone applications, but they are generally more successful when integrated with people and processes.
- It is important to base digital health products and services on evidence-based behavior change techniques like encouragement, goal setting, health coaching, education, and nudging, and fostering social connections.
- Self-monitoring of physical activity, biochemical markers, medication adherence, sleep, stress, mood, or vital signs can help drive behavior change.
- Whether developing a tool or using an existing one, implementation considerations include an appropriate behavior change framework, content and functionality designed for the target audience, good usability, sufficient user testing, and proper data handling.
- Digital therapeutics are evidence-based digital health programs that prevent, treat, or reverse disease. They typically combine many of the technologies covered in this chapter, are studied in clinical trials, and may require regulatory approval. Prescription digital therapeutics are a subset that requires FDA approval and are available only through a healthcare provider.
- It is difficult to predict the impact of specific digital health interventions due to their complexity. Therefore, it is crucial to validate them in clinical studies before offering them to patients.

102 Psychosocial Interventions for the Treatment of Substance Use Disorders

Saria El Haddad, MD, Miriam Chickering, RN, Monthe Kofos, DO, Kimberly Evans, MD, Diana Nguyen, DO, Leah A. Kofos, Esq., andErica Frank, MD, MPH, FACPM

KEY POINTS

- Psychosocial interventions are an evidence-based component of treating various drug problems and addictive behaviors.
- Interventions that have proven effective include behavioral couples therapy, family therapy, cognitive behavioral therapy, dialectical behavioral therapy, community reinforcement approach, contingency management, individual drug counseling, motivational interviewing, brief intervention, 12-step facilitation (TSF), and peer support.
- Psychological interventions can be integrated into a comprehensive treatment plan at every level of care.

This chapter will discuss the evidence for psychosocial interventions for substance use disorders, describe common psychosocial interventions, and discuss how psychosocial interventions may be integrated at different levels of care for people experiencing substance use disorders (SUDs). The National Academy of Medicine, formerly called The Institute of Medicine (IOM), defines psychosocial interventions as "interpersonal or informational activities, techniques, or strategies that target biological, behavioral, cognitive, emotional, interpersonal, social, or environmental factors to improve health functioning and well-being". Psychosocial interventions can be used for drug and process addictions at various stages of treatment and different levels of care. Psychosocial interventions can prevent, identify, and treat SUDs and are useful for rehabilitation and social reintegration. Psychosocial interventions are used alone or in conjunction with pharmacotherapy, depending on the addictive disorder, the required level of care, and available evidence.

Current literature describes robust evidence for using different interventions in specific conditions. However, a significant disparity exists between the published recommendations and their application in the clinical setting. This is due to multiple factors, including:

- Difficult access to the data
- Lack of uniform training
- Insurance coverage
- Quality measurement
- The fragmentation and poor coordination between primary and specialty care

102.1 EVIDENCE-BASED INTERVENTIONS

In 2015, The National Academy of the Sciences (IOM) convened an expert committee to identify key steps to ensure the successful implementation of psychosocial interventions for individuals receiving mental health and substance use services and devised a patient-centered framework (Figure 102.1) that can be used to evaluate evidence to assist with the establishment of standards of care for people experiencing SUDs. This framework relies on continuous patient feedback to inform the overall process and feed the cycle of evidence-based intervention.[1]

Current psychosocial interventions vary tremendously, giving patients and their treatment teams a wide range of options to address their individual needs. Currently, the most commonly used interventions are behavioral couples therapy (BCT), family therapy, cognitive behavioral therapy (CBT), dialectical behavioral therapy (DBT), community reinforcement approach (CRA), contingency management (CM), individual drug counseling (IDC), motivational interviewing (MI), brief interventions (BIs), 12-step programs, and peer support. Psychosocial interventions are used across a wide spectrum of SUDs and are often used in conjunction with other substance use treatments.

102.2 COMMON PSYCHOSOCIAL INTERVENTIONS

102.2.1 Behavioral Couples Therapy

This intervention has been mainly used to treat alcohol and drug use disorders. It aims to reduce drug use while improving overall marital satisfaction for both partners. In BCT sessions, the therapist arranges a daily sobriety contact in which the patient states his or her intent to refrain from drinking or using substances that day. The patient's partner acknowledges and supports the patient's efforts to remain abstinent. The sobriety contract can also include

DOI: 10.1201/9781003227793-119

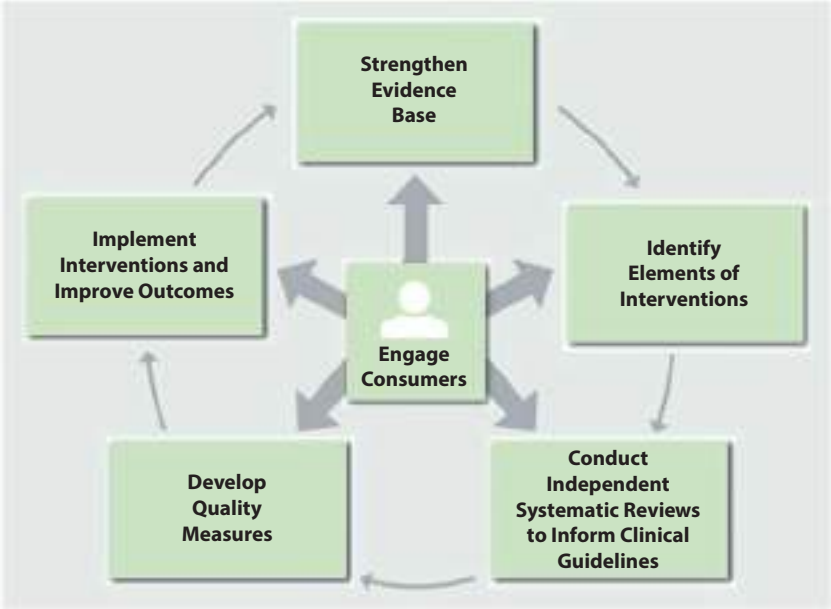

FIGURE 102.1 IOM committee's framework for developing standards for psychosocial interventions (adapted from www.ncbi.nlm.nih.gov/books/NBK321279/).

urine toxicology screens, administering medications by the partner, attending other counseling sessions, or 12-step meetings for the patient and partner. BCT uses a series of assignments to improve relationship functioning and increase positive feelings. This type of intervention also encourages shared activities and constructive communication between the partners because these relationship factors are conducive to abstinence.[2] BCT has proven effective in reducing substance use, decreasing negative outcomes associated with substance use (such as loss of job or housing and injuries), and improving partner satisfaction. Compared with individual-based treatment protocols, BCT has been more cost-effective and successful in reducing partner violence and improving child well-being.[3]

102.2.2 Family Therapy

This intervention is used to treat drug use and the harmful behaviors associated with it. Family therapy is particularly relevant during adolescence, when substance misuse may cause a variety of problems, including psychiatric symptoms, academic difficulties, and high-risk sexual behavior. A wide theoretical basis supports both family therapy and couples therapy. Family therapy is usually provided when a young person's addictive disorder, and the means of treating it, are considered best addressed using a systemic approach. Here, the underlying idea is that treating an individual in isolation would not solve the family system problems enabling or resulting from drug use. Specialists can deliver family therapies in outpatient settings or a patient's home, allowing some flexibility for the patient. Evidence in support of multidimensional family therapy and couples-based therapy in reducing drug use and related problems is accumulating. The use of family-based interventions (e.g. The Strengthening Families Program) for preventing and treating adolescent substance misuse is also well supported.[4–6]

102.2.3 Motivational Interviewing

MI is a low-intensity, patient-centered approach to addressing SUD and other psychosocial barriers based on the Stages of Change model (i.e., pre-contemplation, contemplation, preparation, action, and maintenance). Rather than prematurely pushing patients to exit their current stage, MI focuses on meeting patients in their respective stages and uses various techniques to enhance their motivation to progress to their next stage when ready. This is accomplished by employing an empathic approach to heighten awareness of ambivalence about change, promote commitment to change, and enhance patients' self-efficacy. MI employs techniques such as the OARS (Open-Ended Questions, Affirmations, Reflective Listening, and Summaries) to explore and help resolve ambivalence about substance use-related behavior. This therapeutic style seeks to elicit "change talk" from patients and a commitment to change. It offers patients standardized assessment and feedback and a collaborative structure to develop an individualized and realistic change plan.

While MI can be conducted in any setting and is often informally used in treatment settings, it is usually combined with additional interventions, such as cognitive behavioral therapy, and administered for 15 to 45 minutes for one to four sessions. Sessions lasting under 20 minutes appear less effective, and more success is associated with increased sessions.[7]

Motivational enhancement therapy (MET) goes further by providing a more structured intervention based on a greater degree of systematic assessment with personalized feedback. Involvement of a significant other is encouraged in at least one of the MET sessions.[8]

102.2.4 Brief Interventions

BIs use the collaborative conversation style of motivational interviewing to address problematic or risky drug use, usually over five to 35 periods. Personalized feedback is provided on a patient's substance use, enabling the patient to understand his or her use in relation to other people's use. In this approach, the therapist asks permission to discuss possible drug or alcohol use and provides a standardized screening questionnaire to assess the patient's substance use. The therapist then asks questions about the benefits and harms of substance use to elicit a motivation to change. In concluding the brief session, the therapist and patient negotiate a plan for change and follow-up. Brief interventions can employ several models. One such example is utilizing the "5As"—ask, advise, assess, assist, and arrange; another is the brief negotiated interview (BNI) model—raising the subject, discussing the pros and cons of substance use, providing feedback, assessing readiness for change, and action planning. The BNI model is also used in the process of Screening, Brief Intervention, and Referral to Treatment (SBIRT), which has shown strong effectiveness with alcohol as a public health approach to harm reduction. Since 2004, the United States Preventive Services Task Force (USPSTF) has recommended screening and brief interventions with adults and providing brief counseling to patients with alcohol or substance misuse. The American College of Surgeons' Committee on Trauma also requires screening and brief intervention in all Level I and Level II Trauma Centers. Individual studies, systematic reviews, and meta-analyses have found that SBIRT lowered the frequency and severity of drug and alcohol use and lowered the risk of physical trauma, as well as the length of hospital stays and the number of emergency room visits, improved overall health and substance-use-related outcomes such as housing, employment, and criminal behavior, and constituted a cost-effective approach to address a broad spectrum of use.[9–11] The evidence for drug-related BIs is less well established.[12] However, one must consider the difficulty of running long-term trials where significant reductions in drug use could be observed and the overall benefit of identifying and intervening in drug use despite the lack of available evidence for drug-related BIs.

102.2.5 Cognitive Behavioral Therapy

CBT was developed in the 1950s–1960s by American psychiatrist Aaron Beck. CBT rests upon the cognitive model, where a situation results in an automatic thought, leading to a reaction that manifests itself in three ways: an emotion, a behavior, and a physiological response. CBT further acknowledges that while automatic thoughts are specific to a situation, these may impact underlying core beliefs—a second type of cognition. Providers rely on Socratic questioning (i.e., specific guided questions to the patient) to help patients evaluate their automatic thoughts and core beliefs. According to the Beck Institute, the following are key components of CBT:

- Therapeutic alliance, which encourages a highly collaborative environment between provider and patient.
- Setting goals with patients, which can create a sense of hope.
- Following the structure of the CBT sessions, which leads to greater efficiency on the provider's end and increased understanding on the patient's end.
- Cognitive conceptualization, which allows for increased understanding by the provider of the patient's core beliefs and automatic thoughts.
- Teaching the patient to be their own therapist, which encourages independence and self-reliance.[13]

In addition, CBT incorporates structured practice outside of sessions, including scheduled activities, self-monitoring for negative automatic thoughts, and thought recording of any automatic thoughts and resulting emotions, behaviors, and physiological responses.[14]

With regard to treating SUD, CBT can prove highly effective. Over 20 years, clinical trials conducted by Carroll et al. that focused on CBT treatment for SUD showed progressively larger effect sizes for CBT over the comparison or control conditions.[15] Most approaches follow two key principles when addressing SUDs:

1. Functional analysis of drug use (i.e., understanding drug use with respect to its antecedents and consequences).
2. Skills training (i.e., coping skills, interpersonal skills, additional cognitive skills).[16]

An articulated agenda usually exists for each CBT session. The clinical discussion surrounding SUD treatment focuses on issues related to substance use, although the provider may also incorporate additional relevant topics. Compared with other behavioral approaches, CBT is a highly structured, brief intervention (12–24 weeks) organized closely around well-specified treatment goals.

102.2.6 Dialectical Behavioral Therapy

DBT was initially developed to treat those suffering from borderline personality disorder (BPD), specifically patients endorsing increased suicidality. It is now considered an adjunct treatment for several psychiatric conditions. Traditionally, treatment lasts one year and takes place in an outpatient setting, utilizing four modes: individual

psychotherapy, group skills training, out-of-session coaching, and therapist consultation team meetings.[17,18] DeCou et al. (2019) explain that there are five sets of treatment strategies in DBT, that are used in all four modalities:

1 Dialectical strategies
2 Core strategies (i.e., validation and problem-solving) including standard CBT procedures, which encompass behavioral assessment, psychoeducation, orienting to treatment rationale, contingency management, skills training, exposure, and cognitive modification strategies
3 Communication strategies (i.e., irreverent and reciprocal communication styles)
4 Case management strategies (i.e., consultation-to-the-patient, environmental intervention, consultation-with-the-therapists)
5 Structural strategies (i.e., targeting within sessions, starting and ending therapy)[18]

Patients may waver between eager voluntary engagement in their treatment and adamant refusal to cooperate with treatment guidelines and therapeutic boundaries. Providers must adapt their treatment strategy accordingly.

DBT can also be used to address SUD. Treating SUD in patients with BPD is notoriously difficult; however, opinions are split on whether to treat the SUD before the BPD or concurrently.[19,20] Evidence on the subject remains limited. In patients who do not suffer from BPD, many studies have documented the effectiveness of DBT in treating alcohol use disorder and other concurrent SUDs.[21]

10.2.7 Community Reinforcement Approach

CRA is a comprehensive cognitive-behavioral intervention for treating SUD by focusing on environmental contingencies that impact and influence the patient's behavior. The basis of this approach, formed from the foundation of operant conditioning, utilizes familial, social, recreational, and occupational events to support the individual in changing his or her drinking and/or using behaviors to achieve success in abstinence. The goal is to rearrange multiple aspects of an individual's life so that a sober lifestyle is more rewarding than one dominated by substances. CRA integrates several treatment components: building the patient's motivation to quit by highlighting the negative and positive consequences of drinking/using; partnering with the patient to create a plan for abstinence; analyzing the patient's use pattern; increasing positive reinforcement; learning new coping, problem-solving, and basic skills to obtain and maintain a job; and involving significant others in the recovery process. Two variants of CRA have been created and utilized for substance users and their families. The Adolescent Community Reinforcement Approach (A-CRA) focuses on adolescents, and Community Reinforcement and Family Training (CRAFT) involves family engagement to encourage treatment-resistant individuals to seek help.[22–24]

10.2.8 Contingency Management

CM approaches are based on behavioral principles of reinforcement that reward specific behavioral goals related to recovery. CM is not a type of psychotherapy and is a purely behavioral intervention. Either monetary or non-monetary rewards are contingent on objective evidence such as negative toxicology results, treatment adherence, or progress toward treatment goals. The most common contingencies are vouchers with monetary value that can be redeemed for goods and services, specific material prizes, or draws from a "fishbowl" that contains cards that vary in their reinforcing value from simple praise to vouchers worth $1 to $100. Schedules (fixed or intermittent) and magnitude of reinforcement vary and have implications for the overall cost of clinical implementation. Abstinence incentives have been effectively used for treating amphetamine, cocaine, alcohol, tobacco, and marijuana use disorders and are effective in patients with a wide variety of demographic, psychosocial, and substance use characteristics.[25]

10.2.9 Individual Drug Counseling

IDC is based on the philosophy that addiction is a complex disease that negatively impacts the individual physically, mentally, and spiritually. Therefore, IDC aims to address these needs in the individual holistically. IDC incorporates two important elements: endorsement of the disease model and the spiritual dimension of recovery. These elements differentiate IDC from other forms of treatment currently in use and reflect the influence of the 12-step philosophy.

IDC is distinct from psychotherapy by setting predominantly short-term goals related to addiction recovery. This treatment utilizes substantially concrete behavioral approaches and focuses primarily on the present. IDC has been developed for adult male and female outpatients with cocaine use disorder, but all of its overall tenets are appropriate for use in treating other drug addictions.

IDC is manualized and includes patient education about a biopsychosocial and spiritual approach to recovery, attention to building a therapeutic alliance, monitored drug testing, and encouragement of 12-step (e.g., Alcoholics Anonymous) participation.[26]

10.2.10 Twelve-Step Facilitation

TSF therapy aims to increase the patient's active involvement in Alcoholics Anonymous (AA) or other 12-step-based mutual help groups. This approach was systematized in a manual for The National Institute on Alcohol Abuse and Alcoholism's project MATCH and delivered as 12 sessions of individual therapy in which the therapist utilizes the AA therapeutic framework as well as cognitive behavioral therapy and motivational enhancement therapy. The therapist conveys that addiction is a chronic, progressive, and potentially fatal illness, for which the only viable therapeutic goal is total abstinence from alcohol, achieved

one day at a time by following a 12-step program of recovery. Each therapy session is divided into three parts. The first part reviews relevant events of the past week (including urges to use, drinking behavior, and recovery-oriented activities) and progress on past homework assignments. The middle portion introduces new material related to the 12 steps. The session's conclusion includes a homework assignment and developing a plan for recovery-oriented activities (meeting attendance, sponsor contact). A sponsor can be pivotal in the success of 12-step group-based approaches to SUD treatment.[27]

10.2.11 Peer Support

Historically, providers have recognized the importance of peer support in improving mental health, with several globally recognized psychiatrists, such as Vikram Patel, MD, stating that "The key to promoting youth mental health is through the strengthening of the fundamental nurturing qualities of the family system and community networks while explicitly acknowledging the rights of young people".[28] This approach recognizes how a person's peer network affects their mental health. In part, this can be done by focusing on policymaking that strengthens peer relationships to address difficulties in people's lives. Much research has been done in India and is being developed across many countries with a focus on youth and young adult populations, which translates into benefits later in life. Peer support models can improve the capacity for helping people with problems like substance use as there is a large shortage of mental health professionals and continued stigma in seeking professional help.[28]

Peer support can be divided into two broad categories: mutual aid group modalities that typically follow the 12-step model and peer-delivered recovery support services that incorporate various domains ranging from one-to-one recovery coach services to group settings. Mutual aid programs are voluntary, not-for-profit groups where people meet to discuss and address shared problems, such as alcohol, drug, or other addictions.

Participants support each other, with senior members often mentoring or "sponsoring" new ones. Prominent examples include Alcoholics Anonymous and Narcotics Anonymous. Other groups exist with similar purposes, such as SMART Recovery. In addition to helping drug users, some self-help groups support the family members of people with substance-related problems. Self-help groups are used to assist people with recognizing their drug-related problems, providing support during drug treatment, and helping users maintain abstinence and prevent relapse. These groups aim to create substance-free supportive networks around individuals during recovery and provide opportunities to share experiences and feelings. Former substance users or community peers lead these groups, which are located in various settings, including but not limited to community centers, healthcare facilities, and prisons. This model is traditionally informal and is based on a bidirectional relationship of mutual support. All members are requested to follow a single pathway for recovery guided by the 12-step literature.

Peer-based recovery services are delivered through formal structures and specialized roles that deliver services to individuals across various domains. A peer recovery coach (PRC), also called a "peer specialist", "peer mentor", or "substance abuse outreach worker in recovery", often leads the group sessions. PRCs may work as volunteers or offer paid services. In recovery community centers, they organize and lead educational, advocacy, and sober social activities. They also work in churches and other faith-based organizations, recovery homes and sober housing, the prison system, probation and parole programs, drug courts, HIV/AIDS and other health centers, and addiction and mental health treatment agencies.[29] Historically, group leaders did not typically receive formal training, but this is gradually changing.[30] Such training is not yet standardized across the country, as there is a wide range of training and certification programs, but there is a movement toward a single training model. In 2015, SAMHSA published guidelines describing peer support workers' core competencies, with the most recent list of competencies (most newly updated in 2022) detailed below as directly indicated on their website:

- **Recovery-oriented**: Peer workers hold out hope to those they serve, partnering with them to envision and achieve a meaningful and purposeful life. Peer workers help those they serve to identify and build on strengths and empower them to choose for themselves, recognizing that there are multiple pathways to recovery.
- **Person-centered**: Peer recovery support services are always directed by the person participating in services. Peer recovery support is personalized to align with the specific hopes, goals, and preferences of the people served and to respond to specific needs the people have identified to the peer worker.
- **Voluntary**: Peer workers are partners or consultants to those they serve. They do not dictate the types of services provided or the elements of recovery plans that will guide their work with peers. Participation in peer recovery support services is always contingent on peer choice.
- **Relationship-focused**: The relationship between the peer worker and the peer is the foundation for peer recovery support services and support. The relationship between the peer worker and peer is respectful, trusting, empathetic, collaborative, and mutual.
- **Trauma-informed**: Peer recovery support utilizes a strength-based framework that emphasizes physical, psychological, and emotional safety and creates opportunities for survivors to rebuild a sense of control and empowerment.[31]

Empirical evidence connecting peer support to SUD treatment is promising yet limited. Peer support might be

especially useful in substance detox units.[32] It may improve inpatient and outpatient treatment outcomes for dual-diagnosis patients. This review acknowledges that research remains limited to "specific clinical SUD populations for whom services are most commonly provided (those in outpatient, residential and transitional care settings, and recovery community centers)"[32] Peer support may also play a role in emergency departments; however, Liebling et al. state that "evidence of improved patient outcomes is needed before widespread adoption".[33] In low- and middle-income countries, peer support may be useful as a treatment to compensate for reduced healthcare personnel; however, more research is again needed.[34]

102.3 INTEGRATING PSYCHOSOCIAL INTERVENTIONS IN THE TREATMENT PLAN

Psychosocial interventions are used across the spectrum of SUD levels of care. In the 1980s, a collaborative effort created a national set of criteria for providing outcome-oriented and results-based care in treating addiction. Combined with the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) classification of substance use disorders, the American Society of Addiction Medicine (ASAM) criteria have become the most widely used and comprehensive guidelines for placement, continued stay, and transfer/discharge of patients with addiction and co-occurring conditions.[35,36] Adolescent and adult treatment plans are developed through a multidimensional patient assessment (Figure 102.2) over five broad levels of treatment (Figure 102.3) based on the degree of direct medical management; the structure, safety, and security provided; and the intensity of treatment services provided.

Psychosocial interventions are often a component of a comprehensive treatment plan that includes medication assisted treatment (MAT), an evidence-based treatment for individuals with alcohol and opioid use disorder. FDA-approved medications are prescribed to relieve withdrawal symptoms and reduce cravings, and include methadone or buprenorphine for opioid use, naloxone to prevent opioid overdose, and acamprosate, disulfiram, or naltrexone for alcohol use disorder. Medications combined with

FIGURE 102.2 The six dimensions of the multimodal assessment (retrieved from https://www.asam.org/resources/the-asam-criteria/about).

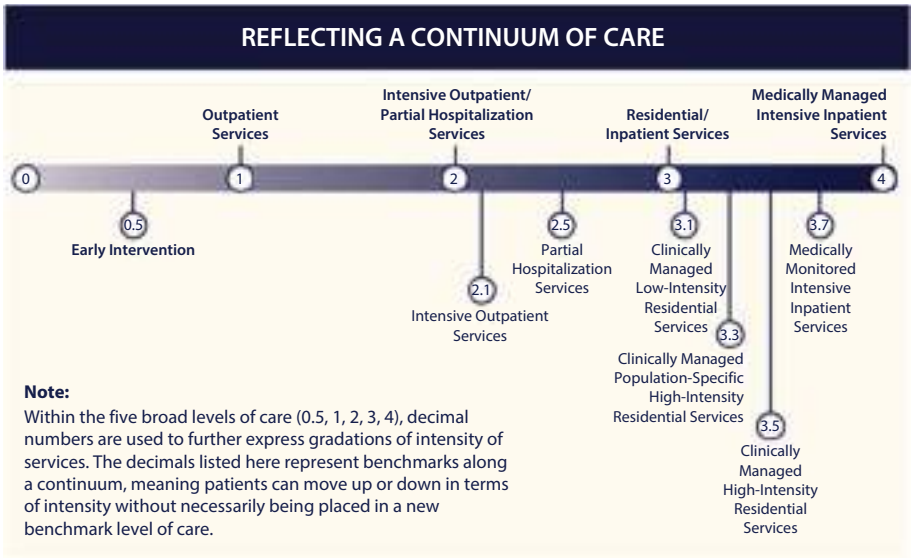

FIGURE 102.3 The ASAM levels of care (retrieved from https://www.asam.org/resources/the-asam-criteria/about).

counseling and therapy are tailored to the individual's needs to help patients sustain recovery and gain the skills needed to live a self-directed and independent life.

102.4 CONCLUSION

Psychosocial interventions are now well established as part of drug treatment and recovery processes, and ongoing research in support of their use is proliferating as they play an important role in treating various SUDs and addictive behaviors. Psychosocial interventions help individuals improve insight into their problematic substance use, progress through the stages of change, improve adherence to a treatment plan, and reinforce their achievements. Such interventions also support family members and create or strengthen social networks to help facilitate recovery.

CLINICAL APPLICATIONS

- Psychosocial interventions are an evidence-based, crucial component of treatment for substance use disorder.
- While psychosocial interventions do not replace MAT, they provide crucial tools to individuals in recovery.
- Psychosocial interventions are especially helpful in supporting family members and social networks of individuals who experience substance use disorders.

103 The Digital World and Addiction Treatment

Mitika Kanabar MD MPH FASAM Dip ABLM, Miriam Chickering, RN, BSN, NE-BC, Monthe Kofos, DO, Leah A. Kofos, Esq., Roshan Bhad, MD DNB, and Erica Frank, MD, MPH, FACPM

KEY POINTS

- The digital landscape for helping patients with substance use disorders has changed since the COVID-19 pandemic with newer ways to seek health education, medical attention, psychotherapy, and self-help meetings.
- Several methods are used to assess the feasibility of mobile health applications for addiction treatment. This field is emerging and may even provide increased access to care for some people.
- The commonly used apps without prescription are for counting sober days, journaling, and accessing self-help meetings. Some applications may be deceptively portrayed and, in fact, may encourage substance use, so care must be taken before subscribing.
- There is an emerging field of digital therapeutics as a prescription for people with substance use disorders to be used in conjunction with regular medical care.
- As lifestyle medicine clinicians, we should continue to advocate for using technologies for overall health, including sleep and mindfulness-based applications.

103.1 INTRODUCTION

Digital solutions are among the fastest-growing areas of delivery of healthcare access.[1] Health solutions applications are available on both Android and iPhone devices, and even in a 2017 survey, there were already more than 300,000 apps available for this purpose alone.[1] During the COVID-19 pandemic, there has been a large growth in access to mobile phone technology. An estimated 85% of all US adults owned a smartphone in 2021 compared with 35% in 2011, and nearly 97% of US adults owned a cellphone of some kind.[2] Since the COVID-19 pandemic and subsequent mandates for physical distancing, increasing numbers of transactions now occur online globally, be it shopping, banking, or even medical visits. At the same time, the social isolation during and in the aftermath of the pandemic has led to a worsening mental health situation in the United States for adults as well as adolescents.[3] Social isolation also led to defaulting to and the overuse of digital applications/appliances and associated adverse consequences like behavioral addictions, eye complications, and so on.[4]

There are many ways in which the digital matrix can both positively and negatively impact care for patients with substance use disorders. In this chapter, we will examine the overall experience of patients with substance use disorders and the technologies available for the treatment of these disorders from a holistic perspective. In addition, the chapter will review technologies and applications that are shown to be detrimental to mental health and may even worsen addiction problems.

Globally, about three million people die each year from alcohol use (5.3% of deaths).[5] In the United States, only one of every five patients with a substance use disorder seeks medical help. Opioid overdose annual deaths in the United States increased from January 2020 to January 2023 by nearly 45%, a tragically concerning increase.[6] In 2020, in the United States, only 6.5% of people needing care for a substance use disorder were able to receive substance use treatment at a specialized facility.[7] This means that a large proportion of patients seek care for addiction outside of specialized facilities or may not seek or receive help at all, contributing to the huge treatment gap that exists globally for addictive disorders.

Crucially, the treatment of substance use disorders by primary care providers, including initiation or refill of suboxone treatments, is an integral part of this approach. With increasing suboxone inductions in primary care, we hope and expect there will be enhanced access to treatment services and improved patient outcomes. In light of the addiction epidemic in the United States, there is a pressing need for easily accessible care. The statistics for overdoses, mortality, and morbidity related to substance use disorders highlight the urgency of increasing access to care.

The US Surgeon General Dr. Vivek Murthy has declared loneliness as a public health concern in the country as of May 2023.[8] It is widely recognized that loneliness can have a negative impact on addiction in numerous ways, such as exacerbating substance abuse, hindering access to recovery

DOI: 10.1201/9781003227793-120

environments, and contributing to gaming addiction.[9–11] The Surgeon General is urging everyone to find ways to connect socially beyond the digital screen and use technology within apps more effectively. This call to action is expected to spur innovation both online and offline and create new communities with meaningful connections over the next few years.

Stigma is a significant contributor to the issues surrounding addiction treatment, including isolation and inadequate access to care.[12] In our practice as addiction medicine clinicians, we all appreciate the amount of courage it takes for patients to walk into our clinics. Digital tools like telemedicine and apps can be developed to help people overcome the stigma associated with addiction, whether it is self-imposed or imposed by others.[12] By making care more accessible, such digital tools can also encourage more people to seek help.[13–15]

103.2 OVERVIEW OF MOBILE APPLICATIONS AND HEALTHCARE

Before the 2007 launch of the iPhone, mobile communication was somewhat limited except in the case of the Blackberry phones.[16] Slowly, more people started using this technology, with other models that were more affordable getting introduced to the market.

Currently, many apps used in healthcare (or any other field) begin as startups. One of the key ways that these functionalities are built is that they are eventually dependent on a singular question: "What is the problem that you (or your app) are trying to solve?"[17] Given the breadth of services now available online, we can examine these applications or "Apps" in this mindset.

The term used for mobile healthcare applications is mHealth, as per the World Health Organization.[18] Given the wide variety of applications available for different purposes, there is no central governing body for their use. Over time, applications phase in and out, depending on their success.

Prior to the pandemic, addiction medicine treatment applications primarily focused on sobriety and treatment approaches. However, since the pandemic began, there has been a significant rise in demand for applications that provide access to care and allow patients to see prescribers. Even before the pandemic, multiple telemedicine startups were already striving to make care more accessible for individuals with substance use disorders. Since the COVID-19 lockdowns began, an increasing number of people have been accessing care using these modes of delivery. Across the globe, people are increasingly turning to mobile applications for convenient and cost-effective access to healthcare services. This allows people to easily manage their healthcare needs while juggling other commitments, such as work and family. Moreover, the growing availability of affordable smartphones and data plans has made this option accessible to more people than ever before.

103.3 MOBILE TECHNOLOGIES SPECIFIC TO THE FIELD OF ADDICTION MEDICINE

Applications specific to addiction medicine are available on Android and the Apple App Stores. These can range from health promotion, information, and monitoring to treatment and self-help. There are applications even designed to curb digital addictions, such as gaming, gambling, or Internet use.

mHealth applications fall into two broad categories, prescription digital therapeutics (PDTs), which require a prescription from a physician or treatment provider, or general apps available in the app store. Some mental health apps can be accessed in both ways, either with a personal payment option or covered through insurance after prescription, such as the Calm app. Notably, the demand for the Calm app was so high that it reached unicorn status in 2019.[19]

103.3.1 Health Education and Prevention Apps and Websites

Increasingly, people are accessing health information and are subject to advertising for substances on social media or other websites. In response to the COVID-19 pandemic, many in the cannabis industry began to rely heavily on social media to advertise their pop-up sales and home delivery services.[20] Similarly, efforts for prevention and information dissemination should be placed where they will have a high chance of viewership. The Health Belief Model and the Theory of Planned Behavior highlight how risk perception can change our individual approaches to experimenting with substances.[21, 22] E-cigarette companies have long claimed that they helped people quit smoking, which reduces the perception of risk, especially in the youth.[23]

A recent study in Mexico of a health information app called "What happens if you go too far" in Spanish, found it was effective in increasing risk perception of using tobacco, alcohol, and marijuana in adolescents.[24]

Universities are creating game-style versions of informational applications to help users make decisions based on real-life experiences. For instance, imagine you are a high school student on a field trip and someone offers you a pill to enhance the experience. Depending on your response, the game will progress in different directions, while also educating you about substances in general.[25]

In a study looking at web-based solutions for people who used drugs (PWUD) in New York City, it was found that nearly a third of the people accessing the pharmacies under study looked up health information through a website, and 35% of these patients also enrolled in text messaging.[26]

103.3.2 Screening

There are mobile applications that can be used for screening addictive disorders, e.g., cannabis, alcohol, and addictive behaviors. Some apps are being studied for clinical

utilization. The screening apps can detect harmful versus dependent use and can help users seek early treatment.[27–29]

103.3.3 Substance Use Disorder Diagnosis and Treatment

As previously mentioned, the number of opioid overdose cases in the United States is steadily increasing. In fact, as of January 2023, approximately 105,000 individuals died from opioid overdose within a 12-month timeframe.[6] Only 35% of US patients with a history of opioid use disorder have access to medications for maintenance treatment such as buprenorphine or methadone.[30] This makes access to telemedicine applications vital to increase access to care. With the COVID-19 emergency, the provisions of the Ryan Haight Act were relaxed and clinicians could prescribe medications for opioid use disorder using only telemedicine, without an in-person physical exam.[30,31] This increased the ease of access to treatment. Given the physical distancing for COVID-19 lockdowns, this became the new default way of providing outpatient addiction care.

When the Veterans Administration looked at the COVID-19 pandemic telehealth use, it was found that patients with access to video visits had better retention in treatment compared with those with either office-only or telephone-only consultations.[32] Patients who were non-service-connected, older, male, Black, or experiencing homelessness were less likely to have access to telemedicine in the same study. Disparities in access to telemedicine in socially disadvantaged populations exist for other specialties as well.[33] In a recent study published in *JAMA Psychiatry*, receipt of medication for opioid use disorder via telehealth increased the odds of treatment retention while it decreased the odds of having a medically treated overdose.[34]

Outside of telemedicine services, there are targeted apps for several different substance use disorders as well as non-substance or behavioral addictions.

103.3.4 Alcohol Use

Telemedicine and digital technologies have increasingly been adopted as tools to manage and treat alcohol use disorder (AUD), particularly in response to the rise in alcohol consumption during the COVID-19 pandemic. AUD, a medical condition marked by an impaired ability to control or stop alcohol use despite adverse health and social consequences, affects at least one in every 20 adults in the United States.[35] However, a small fraction of those diagnosed with AUD receive treatment, indicating a significant gap in the healthcare system.

The advent of telemedicine has begun to bridge this gap, offering accessible treatment options to individuals dealing with AUD.[36] Virtual AUD treatment programs, unconstrained by physical locations, can provide patients with customizable treatment plans tailored to their specific needs and preferences. These plans often incorporate a mix of medication-assisted treatment, group counseling, behavioral therapy, peer support, and various digital tools such as chatbots and digitized adherence and accountability software.[37] Emerging studies highlight the effectiveness of telehealth in AUD treatment, showing that virtual care interventions can successfully reduce substance use and provide timely care for individuals who would otherwise be waitlisted for treatment.

A review of the efficacy of telehealth in addiction treatment during the COVID-19 pandemic revealed promising results. The study, which included a literature review and responses from California addiction treatment providers, found that telehealth treatment was as effective as in-person treatment in terms of retention, therapeutic alliance, and substance use. The study concluded that telehealth could improve patient engagement in addiction treatment by enhancing access and convenience but recommended additional research to determine the optimal balance of in-person and telehealth services.[38]

The effectiveness of web-based alcohol e-help programs was found to reduce problematic and dependent alcohol use in the latest four-country study funded by WHO. Thus, web-based applications that can be easily transformed into mobile applications can be game changers for reducing harmful/dependent use in developing countries.[39]

Despite the promising results, further research is required to determine the optimal mix of in-person and telehealth services and how best to tailor telehealth to each patient's circumstances.

103.3.5 Opioid Use

PDTs are apps that require a prescription from a physician or treatment provider as mentioned before. Notable in this category is reSET or reSET-O. It is a PDT that utilizes cognitive behavioral therapy along with contingency management-based rewards.[40] In a pilot study, it was reported to have a high attrition rate (53%) but those who did continue to use the app gave feedback that it was a safe space to disclose any recurring substance use. This app would be prescribed along with medication services in an outpatient treatment setting. Local policies and staffing to have contingency management available in clinic can be difficult, although the app can be used without providing monetary rewards from the clinic to the patients. The app was FDA approved for clinical use in 2019 and claimed better treatment retention than care as usual.[41]

Other pilot apps are also under study, e.g., the HOPE app from the University of Virginia, which includes daily check-ins and stress management tools for patients in their medication assistant treatment (MAT) clinic.[42] MATx is a mobile app to help healthcare practitioners provide evidence-based MAT for opioid use disorders. It was developed by the Substance Abuse and Mental Health Services Administration (SAMHSA) to provide training to clinicians prescribing medications for opioid use disorder (MOUD) management.[43] Newer apps have also been developed to prevent opioid overdose by using contactless sonar technology

to detect respiratory depression and other clinical factors associated with an opioid overdose (Nand Kumar, 2019).

103.3.6 Smoking and Other Nicotine Use

Several apps are available for smoking cessation on the iPhone and Android app stores. Also, web-based information is widely available for quitting smoking. "Kick It California" is one of the most comprehensive web portals helping people quit smoking, vaping, or smokeless tobacco in a youth-friendly manner,[44] also, there is access to phone-based coaching using their portal. Their Quit Coaches help patients with a text messaging program, and there is an app-based version of this program called "no butts". Several apps are designed on CBT principles and can also have a subscription model. The "Q sense" app was evaluated for helping participants combat smoking cues and remain abstinent.[45] While participant self-report was inconsistent, the geo-tagging feature was helpful in identifying smoking locations and providing support. A randomized control trial for a Facebook-based smoking cessation intervention did not find a significant abstinence rate.[46]

103.3.7 Methamphetamine Use

A recent study using a therapy online option application called Echo-App found a significant increase in motivation to stay sober while reducing cravings for methamphetamine use.[47] The app uses a virtual image of a therapist with an interactive interface to assess depression and anxiety scores on PHQ-9 and GAD-7, respectively. The treatment module offers therapy options to the client as well. Work is in progress to look at "wearables" (e.g., smartwatches) for ecological momentary assessment of alcohol and methamphetamine use—such as heart rate and sleep duration.[48]

103.3.8 Non-Substance or Behavioral Addiction Treatment

"Smartphone addiction" is a still novel concept, with overuse of the internet or phone being under study and not included in either the Diagnostic and Statistical Manual, Fifth Edition (DSM-5) or the International Classification of Diseases, 11th Revision (ICD-11). If it meets the criteria for inclusion, it will probably fall under behavioral addictions or non-substance use disorders. A recent study found a relationship between loneliness, depression, and smartphone addiction in college students.[49] There are several apps available for cutting back on screen time such as the default iPhone Screen Time app and Android Google Family apps. From a therapeutic perspective, writers did not find evidence-based apps for this purpose. There are several apps for general use to reduce screen time on the app store, offering various rewards such as scholarships for college students (e.g., Lock and Stock app).

Chapter co-author Dr. Kanabar did a community-based project called Screen-Win for pilot testing decreasing screen time in 2021 and found reductions in screen time by up to 30% in participants for a two-week challenge. This tool is still in the process of development.

Gambling disorder has been included in the DSM-5 and is a significant problem worldwide. Currently, there are several protocols under study for developing apps to quit gambling.[50,51]

Internet or non-Internet gaming found a place in the ICD 11. In the DSM-5 it is still a condition needing further study.[52] Given that currently it is not a billable service, there is very little insurance-based healthcare coverage and no treatment consensus available for the treatment of gaming disorder in the United States.[53] Currently, some study protocols are being developed in this area. Interestingly, an app offering virtual reality-based intervention was effective in its pilot study to cut down time spent on gaming by young adults.[54]

103.3.9 Therapy-Only Access Apps

Therapy or generally cognitive behavioral therapy-based apps are widely available and probably the most used in any mental health treatment. Apps such as Woebot, Ginger, and myStrength can be covered by insurance in many settings and help provide training in coping skills. This plays a role in increasing round-the-clock access to strategies for anxiety and mood mediation and may decrease healthcare burden to a small extent.

103.3.10 Relapse Prevention and Further Education

Counting apps are widely used by patients for recording the number of days they have been sober. Also used are several podcasts, YouTube videos, or other audiobooks available on apps such as Libby, Scribd, Kindle, Audible, or other apps for the purpose. Both clinicians and patients can listen to available information during a long commute or other pockets of time, providing excellent asynchronous learning and reinforcement of treatment principles. Several podcasts are in fact available for clinicians to follow, such as The Addiction Files, This Week in Addiction Medicine from the American Society of Addiction Medicine, and Behind the Evidence podcast.[55–57] Mutual-help groups as covered below also have their apps available for use.

103.4 MUTUAL- OR SELF-HELP

Recovery through mutual or self-help groups has been a mainstay of addiction treatment for nearly a century. Alcoholics Anonymous was started by Mr. Bill Wilson and Dr. Bob Smith in 1935.[58] Other adaptations of self-help groups and fellowships have emerged since then including Narcotics Anonymous, Al-Anon, Gamblers Anonymous, Debtors Anonymous, and so on. Other self-help groups such as Refuge Recovery, Life Ring, Women for Sobriety, and Smart Recovery have also gained traction.

With COVID-19, many self-help groups had to switch to an online mode to connect with their patrons.[59] For some with difficulty accessing video visits, this posed a new challenge. For others who could access groups, this provided new opportunities to find connections across the globe. For those with changing shift work, this increased their access to groups in different time zones, depending on when they were working that day. Interestingly, on analyzing attendance to online support groups, it was found that participants were more likely to attend if they followed more than one type of mutual support group.[60]

Outside of more traditional alcoholics anonymous type groups, applications, and online access are sometimes the only way to get peer support for more unique issues such as pornography addiction, gaming addiction, excessive Internet use, or disordered eating in early recovery.

With the COVID-19 pandemic emergency coming to an end, many of the groups have gone back to in-person care. However virtual access remains an attractive option for many. As a result, groups such as Alcoholics Anonymous now generally have online meetings available as a default. In some regions, these meetings can take on a "hop on/hop off" continuous meeting available online 24 hours a day and seven days a week. This has provided significant support to patients at a vulnerable period in their lives.

SMART Recovery, which is a cognitive behavioral therapy-based approach to managing substance use disorder, launched a SMART Track app that showed some promise.[61] People are also likely to use the internet consistently to find meetings for Alcoholics Anonymous even if they may have spotty access to smartphones.[26]

103.5 EFFECTIVENESS OF APPS: DO THEY WORK?

It is simple to say we have apps available, but it is not guaranteed that patients use them, nor (even if usage occurs) is it clear how effective they can be. Several papers in the literature look at how to evaluate applications, examining adherence, usability, and other clinical outcomes to help our patients with their substance use issues. App evaluations in their nascency were based on a Likert Scale between "Strongly Agree" to "Strongly Disagree" (Sr et al., 2015). Then came a tool for rating engagement, functionality, aesthetics, and information, which was applicable to a few apps called the mobile app rating scale or MARS.[62] In a 2019 study, most apps had a low MARS score.[63]

103.6 CONCERNS AROUND HARMFUL INFORMATION AVAILABLE ONLINE

People with substance use disorders can use internet forums, social media, and other applications to access information that worsens their use. A study of Twitter messages or tweets in 2017 found that about 49% of the tweets around opioids were for procuring illicit sources of drug use[64] In a study by Tofighi et al. reviewing apps to help treatment of addiction, they, in fact, found the converse, apps had features that would exacerbate use, such as a forum where people offered to sell drugs, features like binge drinking games, or advice to decrease the smell of alcohol.[63] Some apps also promoted increased smoking, cannabis use, or alcohol use. The app stores exercise vigilance and delete more harmful apps when detected. Recovery apps may also lack the required level of privacy protection to offer care for substance use disorders and may not be HIPAA compliant (Health Insurance Portability and Accountability Act).

It is common knowledge that on the web, information is available for addiction harm as well as treatment and does not need to be elaborated here.

103.7 LIFESTYLE AND SLEEP APPLICATIONS

Globally, about 80% of youth do not meet the recommendations of one hour of moderate to vigorous physical activity a day.[65] To encourage more physical activity in youth, apps can employ features such as notifications and rewards. A recent systematic literature review showed apps that focus on clear design, community involvement, and gamification had a higher chance of eliciting engagement and increasing physical activity in children aged four to 18 years.[65]

Sleep issues are widespread across the world, especially among smartphone users.[66,67] A Japanese app "Nenne Navi" when assigned to caregivers of young children showed benefits in decreasing sleep latency.[68]

CBT for insomnia (CBT-I) based interventions are perhaps the most famous for helping with sleep issues and may be superior to patient education alone.[69] The CBT-I Coach app from the United States Veterans Administration is available for free and has shown benefits in improving sleep for veterans with experience in combat zones.[70] Though these apps are not specific to patients with history of a substance use disorder, they can serve as effective free tools for increasing sleep.

The Calm app as well as CBT apps mentioned before also typically have an option for sleep coaching or meditation exercises that may be helpful.

103.8 RELEVANCE TO LIFESTYLE MEDICINE PRACTITIONERS.

As we inevitably create more seductive electronic and chemical addictions, we will inevitably create more useful electronic and chemical tools to combat those addictions. Lifestyle medicine practitioners should remain vigilant throughout their careers for such threats and opportunities, as they are likely to be among the most rapidly evolving variables in our practices.

Also, our patients can have a family member struggling with substance use, or personal health goals for which they need the help of such digital interventions, particularly for setting limits around alcohol, smoking, or cannabis.

Sleep, mindfulness, meditation, and mood meditation apps can speak to the other pillars of lifestyle medicine. Also, the less time we spend on our devices, the more we get to build social connections, which is an important domain of lifestyle medicine.

103.9 CONCLUSIONS

Digital approaches to increasing access to care for patients with addiction are continuously being developed and improved. After the COVID-19 pandemic, the frequency of use of telemedicine services increased, and there has been a surge of apps built for the management of addictive problems. At the same time, with increased access to technology such as wearables, contactless monitoring, tracking, machine learning, and in the future, artificial intelligence, we are likely to see an increase in the use of smartphone-based applications in healthcare, including in the care of patients with substance use disorders. This opens novel avenues for screening, diagnosis, treatment intervention, harm reduction, and monitoring for patients.

Outside the box of smartphone applications, there are also newer ways of asynchronous learning, such as audiobooks and podcasts, that can be used by clinicians as well as clients.

Great strides have occurred in using applications for psychotherapy and mindfulness, with many insurance providers approving access to digital therapeutics, text coaches, and other modalities.

CLINICAL APPLICATIONS

Accessing medical care:

- Several telemedicine startups provide easy access to medications for substance use disorders and patients can sign up using commercial insurance plans or cash-pay.
- Since the COVID-19 pandemic, most health systems have robust telemedicine options.

Accessing psychotherapy:

- Several companies now offer telehealth-only options for psychotherapy and may be contracted with insurance providers. This can make evening and weekend therapy options available for patients. There are specific therapy teaching-based applications such as myStrength that can be prescribed for patients for a set amount of time. Recently, artificial intelligence bot-based chat applications (such as Woebot) have also become available.

Accessing self-help groups:

- Applications have been developed for easier access to self-help groups such as Alcoholics Anonymous, Narcotics Anonymous, SMART Recovery, and others. They can also provide counting for sober days and easy access to online meetings.

Health education information:

- Websites such as "Kick it California" have been developed for easy access to information about smoking or vaping. Other portals where patients can seek information or access to free telephonic coaching for help with substance use issues are also available.

Prescription digital therapeutics:

- This is a new area of application development, in which notable are the reSET and reSET-O applications to be used in conjunction with medical care for substance or opioid use disorders to deliver contingency management options. These may be covered by insurance.

Lifestyle intervention applications:

- Well-rounded care for patients with substance use is essential. Text-based or chat options are available for coaching around distress tolerance and coping skills.
- Sleep applications such as CBT-I and mindfulness applications such as Calm and Headspace can help patients center on their wellness.

Lifestyle Medicine in Geriatrics

Taylor & Francis
Taylor & Francis Group
http://taylorandfrancis.com

104 How Geriatrics Principles and Paradigms Can Inform Lifestyle Medicine Practice

Jennifer D. Muniak, MD

KEY POINTS

- Geriatrics and lifestyle medicine have philosophical overlap, in that geriatricians strive for our patients to age in a healthful way, minimizing disability and premature death that is often dictated by lifestyle factors over time.
- Lifestyle medicine, as an emerging field, can benefit from the cognitive frameworks, strategies, and treatment modalities embedded in the related and more established field of geriatrics, building on previous work that made the case for geriatricians to embrace facets of lifestyle medicine.

104.1 EMBRACING COMPLEXITY AND NUANCE

Geriatricians will often joke that "if you've seen one geriatric patient, you've seen one geriatric patient". Older adult patients come into our offices not only with a chief medical concern; that concern is a metaphorical iceberg, embedded in a unique compilation of:

- Other chronic medical issues
- Structure of living arrangement (home, community, transport)
- Caregiver and social supports
- Financial resources
- Coping strategies
- Beliefs about illness and treatment efficacy
- Mental health issues

These overlapping factors to consider in the care of every older adult can seem overwhelming—many of them exist outside the reach of the prescription pad and are often rooted in the past, personal circumstances, and surrounding social, economic, and political structures (i.e., social determinants of health). Yet our training in geriatrics calls us to embrace the complexity and nuance of every patient story, producing a "complexivist" mindset, as dubbed by esteemed geriatricians Fried and Hall in a 2008 editorial.[1] They posit that geriatricians have "the cognitive skills to analyze complex health issues and establish priorities consistent with patient goals and knowledge of models of care delivery".

Case example: A geriatrician is seeing an older adult patient for a routine clinic visit who has advanced coronary artery disease, severe generalized anxiety, food insecurity, and vision impairment. Properly managing this patient will require the practitioner to consider several parallel processes: the state of each problem in isolation, the direction and velocity of that problem's change, how various problems interact with each other, and how they interact with the patient's unique set of resources and values to ameliorate them. Perhaps the most important is to connect with the patient about their perceptions of the problems and understand what is the highest priority to them.

"Complexivist thinking" (i.e., carefully holding all the interconnected facets of a patient's story in one's mind with reference to the whole) is a necessary core skill when making a diagnosis or treatment recommendation for an older adult patient. This way of thinking is contrasted to a "reductionist" model, whereby complex problems can be explained algorithmically by a collection of simpler processes. At times, reductionist thinking is necessary and appropriate, such as when a discrete problem has an equally discrete solution; but the human body rarely functions in this way, particularly when we allow ourselves the wide-angle lens of the entire biopsychosocial nature of a patient's life. Often, the application of reductionist principles in clinical medicine (e.g., making a diagnosis off a single blood test, clinical guideline, or collection of vital signs) is a cognitive shortcut that can miss crucial details and cause harm to the patient.

The field of lifestyle medicine, in a manner very similar to geriatrics, confronts complex problems that fail reductionist thinking. Practitioners need to bravely wade through the ever-changing biopsychosocial fabric of a patient's history in order to reach them and provide counsel. Only when all the relevant domains are identified and processed, will the practitioner start to have an impact.

Case example: an LM practitioner is meeting a new patient who wants to lose weight. The patient has a strong family history of obesity and has a 20-plus-year history of dieting with transiently successful 5% weight loss followed by regaining back to baseline. They have an emotionally demanding job as an ER nurse with irregular work hours and frequently will have two to three glasses of wine after

DOI: 10.1201/9781003227793-122

work to unwind. They have poor social support and low feelings of competence to make change.

This patient will clearly require a holistic approach that addresses many layers of their lifestyle that are intertwined. Even digging below the chief complaint of "losing weight" could take some time: Why? Why now? Is this internally motivated? Externally? Both?

104.2 STRUCTURING THOUGHTS USING DATA-DRIVEN FRAMEWORKS

In 2016, the John A. Hartford Foundation and the Institute for Healthcare Improvement among others, came together to find a different overarching approach to the care of older adults. They realized that healthcare structures were inherently dangerous to older adult patients and that with an aging population, healthcare systems needed to rapidly adopt best practices for the care of older patients on a *consistent* basis—every older adult, at every touch point in the healthcare system. What emerged was the framework of Age-Friendly Health System (AFHS).

The framers of the AFHS understood the inherently complex and unique needs of older adult patients, as alluded to in Section 104.1. Additionally, each healthcare system has a unique culture, resources, leadership, and patient needs. Therefore, the framework needed to be flexible and easy to adapt to different clinical environments. Given this, the model focuses on major domains of care relevant to older adults and is known as the "4Ms Framework".[2]

- What Matters: Know and align care with each older adult's specific health outcome goals and care preferences, including, but not limited to, end-of-life care, and across settings of care.
- Medication: If medication is necessary, use age-friendly medication that does not interfere with What Matters to the older adult, Mobility, or Mentation across settings of care.
- Mentation: Prevent, identify, treat, and manage dementia, depression, and delirium across settings of care.
- Mobility: Ensure that older adults move safely every day in order to maintain function and do What Matters.

104.2.1 Other Uses of the Model

The 4Ms are intended to anchor the health system in best practices while still allowing for individualization based on the unique needs of the setting. While this model is rooted in quality improvement practices, clinicians, health researchers, and clinical educators have found other uses for this model, including but not limited to the framing of:

- Clinical notes (i.e., Assessment and Plan organized by the 4Ms)
- An individual didactic presentation or entire curriculum
- A research question and/or results

Each of these uses serves as a cognitive frame that encapsulates and organizes the inherent complexity and nuance of caring for older adults in a way that does not over-simplify (such as with a reductionist model).

Lifestyle medicine can similarly benefit from cognitive models that help organize the complex, multi-faceted information that comes with the territory. The six pillars of lifestyle medicine are a similarly flexible and comprehensive framework[3] to help anchor the cognitive process of a lifestyle medicine practitioner.

- Healthful eating
- Physical activity
- Stress management
- Relationships
- Sleep
- Substance use

As with the AFHS's 4M framework, the six pillars have the potential to be used in a variety of contexts within the field of lifestyle medicine: clinical work, health education (for patients and trainees), and research.

104.3 FOCUS ON PERSON-CENTERED CARE

In 2015, a team from the American Geriatrics Society collaborated to produce an evidence-based definition of person-centered care as well as its essential elements.[4] Their definition consisted of the following:

> "Person-centered care" means that individuals' values and preferences are elicited and once expressed, guide all aspects of their health care, supporting their realistic health and life goals. Person-centered care is achieved through a dynamic relationship among individuals, others who are important to them, and all relevant providers. This collaboration informs decision-making to the extent that the individual desires.

The panel went on to frame critical elements necessary to realizing this definition:

- *An individualized, goal-oriented care plan based on the person's preferences*
  Creating such a plan is the foundation of person-centered care, and first requires a thorough medical, functional, and social assessment. Understanding where one is in the present is critical to understanding where they can and want to go.
- *Ongoing review of the person's goals and care plan*
  Reassessing the care plan on a regular basis is critical to determining its effectiveness and continued alignment with the patient's goals, particularly as the patient experiences changes in their medical, functional, psychological, or social status.
- *Care supported by an interprofessional team in which the person is an integral team member*

The team must be flexible in composition and adaptable to changes in the person's health status, circumstances, and care goals.

- *One primary or lead point of contact on the healthcare team*
  Having one care provider who serves as a point of contact for the person and everyone involved in their care eases communication and facilitates continuity of care and transitions across care settings.
- *Active coordination among all healthcare and supportive service providers*
  Coordination among all providers assures that all services continue as seamlessly as possible, particularly when the person moves from one site of care (or residence) to another. The primary point of contact referenced above facilitates this.
- *Continual information sharing and integrated communication*
  Communication and information sharing may be accomplished through mechanisms such as the electronic health record and enhanced by careful listening and open communication between the person and everyone involved in their care.
- *Education and training for providers and, when appropriate, the person and those important to the person*
  Including the principles of person-centered care in the education and training of all healthcare providers contributes to their understanding of and commitment to providing person-centered care, including consistent recognition and maintenance of the person's autonomy. Health education of people receiving care and those important to them supports informed decision-making and self-determination.
- *Performance measurement and quality improvement using feedback from the person and caregivers*

  Measurable outcomes should focus on the successful implementation of care plans, evidence that the person's goals are being met, and evidence that efforts are being made to minimize difficulties during transitions between healthcare providers and across care settings.

Importantly, the panel also explored common barriers to the implementation of person-centered care at both the level of health systems and individual healthcare practitioners:

- *Inconsistent terminology*
  (e.g., "goals" vs. "preferences" vs. "values")
- *Traditional approaches to clinical practice*
  That is, established professionals can have embedded habits and philosophies of care that are difficult to change.
- *Physician workload is already high*
  A high workload limits the cognitive flexibility needed for person-centered care. This is perhaps ameliorated by the use of an interprofessional team.
- *Misaligned incentives*
  Teams that practice person-centered care may not be the beneficiaries of eventual cost savings and may be financially punished for the time and labor associated with pursuing this type of care.
- *Identifying appropriate indicators*
  Currently, it is difficult to measure success in providing person-centered care.
- *Provider concerns for risk and safety*
  When patient-centered care yields decisions that the healthcare team disagrees with and/or puts the patient at risk for death/disability, there are often ethical and medical-legal challenges to the delivery of person-centered care.
- *Lack of advance care planning*
  Older adults with cognitive impairment will often struggle to make their preferences known and therefore cannot fully engage in a shared decision-making model.
- *Lack of payment structures that span healthcare and community-based organizations*
  That is, the current healthcare system is fragmented, often failing to promote coordinated, comprehensive care for support and community-based resources that frail older adults need.
- *Lack of continuity in health records*
  That is, coordinated, comprehensive care of an interprofessional team is threatened when records are not easily accessed between health systems.

The above outline of person-centered care, while often difficult to achieve, is perhaps a critical component to the cognitive and philosophical outlook of those of us practicing geriatrics or lifestyle medicine, given our patients' complex and nuanced needs. Additional, practical applications of person-centered care to consider:

104.3.1 Health Optimization Looks Different for Different Patients, at Different Times

Geriatricians are well-versed in meeting patients where they are, optimizing based on the context and patient values. For example, a patient in a long-term nursing home unit will typically have a care plan that is palliative in nature, with the primary goals reflecting the desire to avoid pain and other symptoms and avoid unwanted interventions at the end of life. This is in contrast to a patient who might reside in a post-acute rehabilitation unit, typically a community-dwelling older adult recently hospitalized for an acute illness complicated by a functional setback and requiring intensive physical and occupational therapy. The strategy is restorative in nature with the goal being to return home and resume previously enjoyed activities.

These juxtaposed examples reveal that while strategies and goals for geriatric patients may differ based on patient circumstances, the same fundamental skillset from a thoughtful practitioner has a positive impact on both.

In a similar fashion, practitioners in lifestyle medicine need to have a flexible approach and individualized goals for patients based on their unique set of circumstances and values. One patient may need lifestyle medicine to get off medications for hypertension and diabetes and avoid downstream events of these diseases. Another patient may benefit from lifestyle medicine to avoid or delay needing any medications for hypertension and diabetes.

104.3.2 Motivation Looks Different for Different Patients, at Different Times

Attitudes around one's own health often shift throughout the lifespan, alongside motivations to make health changes. In both geriatrics and lifestyle medicine, it is essential that practitioners tap into a patient's intrinsic motivation for meeting their goals, given that sustainable, positive changes are most often dependent on the patient (± caregivers) implementing treatment recommendations.

Adolescents and young adults are more typically motivated by social acceptance and physical appearance, whereas those in middle age can be more interested in role-modeling for their children and staving off the chronic diseases (with associated burdens) that they are witnessing in their parents. Older adults may want to preserve independence or avoid future negative experiences through secondary prevention (e.g., "How do I not have another heart attack, doctor?"). By tuning in to an individual's motivational state and their readiness for change, a practitioner can more adeptly guide them in the direction of specific health behaviors.

Low motivational states are common during relapses in health goals, which are unfortunately a frequent occurrence in geriatrics and lifestyle medicine; further, these states can compound if the patient is prone to perfectionism, shame, self-doubt, or binary thinking. In these times, practitioners would be wise to avoid these psychological trappings ourselves (difficult though that may be) and instead provide empathy and validation of feelings, making space for ultimately picking up the pieces and recalibrating a path forward.

104.3.3 Triage and Make Trade-Offs

Geriatricians are well-versed in the need to triage patient health goals and carefully weigh the pros and cons of every decision we make, given the inherent medical complexity of our population in combination with reduced tolerance of most interventions; in short, we are usually looking for the path of "least potential for harm", aware that treating one problem may, in fact, make another worse. Though other patient populations may be more physiologically robust than older adults, all health practitioners would be wise to have a similar philosophy of "triage and trade-off". Particularly when it comes to lifestyle medicine interventions, patients have a limited cognitive and psychological bandwidth for behavior change that is not always appreciable (particularly when enthusiasm for change is high in the initial stages). Attempting too drastic of a change or too many changes simultaneously will set the patient up for relapse, shame, and a reluctance to re-engage. There is always a trade-off when making a change. It may not be obvious at the forefront, but it is wise to move cautiously alongside the patient in whatever field we are practicing so that we can notice and adapt to any unintended consequences that may arise.

104.4 INFLUENCE OF ENVIRONMENTAL AND STRUCTURAL FORCES UPON HEALTH OUTCOMES

> You do not rise to the level of your goals. You fall to the level of your systems.
>
> **~James Clear**

Most clinicians implicitly focus their attention on disease determinants that are rooted in pathophysiology and are directly observable during the visit by way of history, physical exam, and chart data. Especially with high patient volumes, there is little time to think about much else than these "proximal" determinants. In contrast to these, "Distal" causes of disease are rooted in systems and the environment and have traditionally been left to those in public health. Esteemed physician and medical anthropologist Paul Farmer bridged this divide in his own career, treating patients with HIV and other diseases in places such as Haiti. He became intimately familiar with systemic forces that create barriers to care for populations and can exert harm through "structural violence" that is embedded in social, economic, and political systems.[5] He called on the medical community to embrace the structural, distal causes of disease, integrating these into our care for patients in our offices.

As a group, older adults are vulnerable to poor health, elder abuse, neglect, and isolation in the absence of supportive structures. This is particularly true for those with high levels of frailty, cognitive impairment, and/or functional impairment. Whether it be a family unit, residential facility, community partner, or day program, high-functioning supports are often essential to older adults being safe and getting to experience what matters most to them. Because of this, geriatricians spend a significant amount of time during their training to understand the different resources available to older adults, how different resources interface with each other, and how to recommend the right support to the right individual. On the other hand, there is a nuanced and necessary skillset required to notice a problematic or frankly unsafe environment for older adults and disentangle them as necessary.

One exemplary care model for older adults that emphasizes infrastructure is the Program of All-Inclusive Care for the Elderly (PACE). Utilizing payments from Medicare and Medicaid, PACE provides comprehensive medical care, day programs, and social events to patients in the program. This is all done while keeping patients in their homes, although they meet the criteria for nursing home admission. PACE has positive patient satisfaction, reduces institutional care rates, controls utilization of medical services, and has cost savings to the Medicare and Medicaid programs.[6]

PACE may owe its success, in part, to its structural design. With medical care and day programming happening in the same building, there's a seamless transition from a card game to a medical checkup. Medical transportation from the patient's home to the PACE site is provided in most cases, eliminating the multitude of reasons an individual's transportation might fail them and inhibit their participation in the program. In general, individuals are going to be more successful at achieving goals when their environment is aligned with these goals. All environments encourage and discourage individual choices based on their make-up. Those who are intentional about good health outcomes will "bake in" mechanisms to decrease the energy expenditure at critical health choice points (i.e., make the healthy choice the easy choice). Unfortunately, the majority of health systems have not been as carefully curated as PACE; in fact, one could argue that mainstream healthcare is harmful to older adults and other vulnerable populations, encouraging poor outcomes by virtue of the barriers encountered by patients at every touchpoint to receive quality, affordable medical care.

All of the aforementioned six pillars of lifestyle medicine have heavy interaction with the individual's environment; therefore, optimizing those pillars will first require an assessment of how well the environment is set up to help the individual meet those goals. How well is someone going to sleep (realistically) if they are not using their CPAP for obstructive sleep apnea, if they watch TV before bed, and have an irregular sleep-wake cycle due to shift work? How well is someone going to consistently abide by a whole food, plant-based diet when the family meal pattern is based on processed animal foods?

We know from Dan Buettner's work in blue zones of healthy aging (Loma Linda, USA; Nicoya, Costa Rica; Sardinia, Italy; Ikaria, Greece; and Okinawa, Japan) that "9 evidence-based common denominators" of health behavior, present in the environments, appear to slow the aging process and promote healthful longevity:[7]

- Move naturally. Aim for consistent activity throughout the day.
- Purpose. Have a reason to wake up in the morning.
- Downshift. Stress may be unavoidable, but blue zones residents have regular means of self-care.
- The 80% rule. Otherwise put, mindful consumption of food and drink, without trying to be full at the end of the meal. This can mean the difference between weight maintenance and gain.
- Plant slant. Beans, including fava, black, soy, and lentils, are the cornerstone of most centenarian diets. Meat is consumed less often, and by subsets of the Adventists in Loma Linda, not at all.
- Wine @ 5. People in all blue zones (except Adventists) drink alcohol moderately and regularly.
- Belong. Most interviewed centenarians had an active faith community. Denomination did not seem to matter.
- Loved ones first. Successful centenarians in the blue zones put their families first, meaning keeping aging parents and grandparents nearby or in the home, committing to a life partner, and investing in their children with time and love.
- Right tribe. Having a social circle is important for many health outcomes, including longevity. Health behaviors are contagious!

In contrast to the blue zones, most of our environments (inclusive of home, work, and family) are not aligned with the six pillars, ranging from a little to a lot depending on a myriad of circumstances. Perhaps then, one of the precursors of making individual lifestyle medicine changes in the office should be addressing those aspects of the environment that are least conducive to the patient achieving their lifestyle goals.

Structural problems are most effectively addressed with structural solutions, yet much can be achieved by the individual motivated and adequately empowered to make changes to their environments and systems in a skillful way. Examples of practical environmental alterations for lifestyle could include:

- Taking the TV out of the bedroom.
- Having a set day and time to prepare a grocery list and shop. Negotiate meal choices outside of being hungry or short on time.
- Carving out time for exercise or social connection by putting a regular placeholder in the calendar.
- Joining a gym, sports team, or support group that has regular meetings with like-minded individuals.
- Keeping "triggering substances" out of the home (e.g., ice cream, alcohol).

In addition to adding structures conducive to health, gently exploring a shift away from less helpful structures may be needed. Here, empathy is paramount for the practitioner, given that even highly problematic environments are benefiting the patient in some meaningful way (or else they would not be there). Acknowledging this and exploring all the ways in which the patient may be actually benefiting from the problematic environment can be helpful unto itself: identification will help the patient consider meeting those needs in other ways that are more aligned with their overall goals and values.

Personal relationships often prove to be misaligned with the patient's health goals, and yet making changes in this domain can prove to be a difficult dilemma for patients and their practitioners, given what we know about the positive value of social connections[8]. Therefore, breaking away from a tribe (even in the name of one's health) can be incredibly painful, difficult, and potentially harmful to health from a social isolation standpoint. Perhaps then, in the event a patient is so motivated to make a change toward a more health-driven social network, a more gradual migration will be advisable.

104.5 LOW-TECH AND HIGH-TOUCH MODALITIES

Empathy, presence, and skillful words are among the oldest and most sacred modalities used in healing professions. Even in modern times, these attributes are often the backbone of skillful, patient-centered care. The opposite of these—"high-tech, low-touch" modalities—are omnipresent in the press and indeed can have immense benefit to patients when chosen thoughtfully. Geriatricians are often wary of adding on layers of riskier treatments for the following reasons:

- *High toxicity.* As people age, they have a higher inherent risk of medication toxicity compared with their younger counterparts.
- *Interactions and side effects.* Older patients are prone to polypharmacy, which can increase the risk of medication interactions and side effects.
- *Complexity and decreased adherence.* As the number of concurrent treatments increases, costs, complexity, and the likelihood of patients being overwhelmed will typically rise. As a result, adherence to the regimen may go down.
- *Prescribing cascade.* With every medication or intervention, there is a risk of side effects that are often difficult to differentiate from new problems; thus, patients are at risk of having a second medication prescribed to treat a side effect of the first.

While younger, healthier patients may not be as vulnerable to the above risks of medications and other risky therapies (especially in combination), they too may pay a price, and practitioners would be wise to consider low-tech, high-touch in at least augmenting the care for younger patients. Examples of such low-tech, high-touch modalities include therapies: physical, occupational, speech, cognitive behavioral, and psychodynamic; support groups, dietary coaching, and nursing care. Many of these modalities cross disciplines and are highly relevant for those practicing lifestyle medicine. They are lower risk for the patient and may be more effective for long-term positive impact, particularly when the patient is an active participant, has a therapeutic bond with the professional, and can apply skills gained during a session at other points in the future.

These modalities can be difficult for some patients to accept or stick with. Relevant patient factors may include self-efficacy beliefs, degree of cognitive impairment, depressive disorders, beliefs about time to benefit, or affordability/access to the service. Factors negatively affecting the uptake of the modality on the practitioner or systems front include low quality of the personnel, lack of availability of the service on a consistent basis, and lack of access/affordability.

Practitioners in lifestyle medicine have a particular challenge in advocating for low-touch, high-tech modalities: new lifestyle treatments are exploding onto the market at a rapid pace. Most are highly advertised, make wild claims about efficacy, and have scant if any evidence base. The lure of a "quick fix" to deep-rooted lifestyle problems can be strong for patients, and therefore it can be an uphill battle to convince them otherwise. Aspects of motivational interviewing may be helpful here, helping draw out prior experiences with "quick fix" modalities and the eventual impact.[2]

CLINICAL APPLICATIONS

- Geriatric healthcare providers are "complexivist" thinkers by nature, trained to integrate multiple layers of patient factors in making diagnostic and treatment decisions. Lifestyle medicine confronts similarly complex problems and practitioners can benefit from this way of thinking.
- Problems rooted in lifestyle medicine and geriatrics are not conducive to "reductionist" thinking, which often oversimplifies problems, and can lead to diagnostic and therapeutic errors, as well as low patient satisfaction. Given the inherent complexity of care involved with patients in the fields of geriatrics and lifestyle medicine, it is useful to have cognitive frameworks that are flexible and identify key domains of care, without oversimplifying.
- The Age-Friendly Health System 4M framework and the six pillars of lifestyle medicine are examples of such models for geriatrics and lifestyle medicine, respectively, which (because of their flexibility) can be applied by practitioners to a variety of contexts, such as clinical notes, patient and trainee curriculum, and research.
- Person-centered care is a critical philosophical and cognitive approach for practitioners in geriatrics and lifestyle medicine. Critical components of patient-centered care include having an interprofessional team with coordinated communication; frequent reassessment of the care plan based on the patient's goals/preferences/health status; ongoing data collection; and quality improvement; and attunement to individual variations in health optimization, patient motivation, and the need to make trade-offs.
- The fields of geriatrics and lifestyle medicine are inextricably linked to the environment

and structures. The ability of these structures to encourage healthful behavior will have an immense impact on the overall trajectory of the individual within that environment, and clinicians need to be aware of their patients' various environmental forces. Patients can often make changes to the structures in their own lives, setting themselves up for health-promoting behaviors.

- Low-tech, high-touch approaches to treatment often form the backbone of geriatric care models and are appropriate interventions to consider for lifestyle medicine patients as well, given the potential for long-term benefits and low toxicity.

105 Addressing Physical Function, Sarcopenia, and Frailty through Lifestyle Medicine

Hillary B Spangler, MD, David H. Lynch, MBBS, and John A Batsis, MD, AGSF

KEY POINTS

- Healthy aging is essential for maintaining mobility in older adults, which fosters an ability to maintain independence.
- The natural aging process places older adults at risk for poor mobility due to sarcopenia and frailty development.
- Nutrition and exercise interventions show promise for primary and secondary prevention of sarcopenia and frailty.
- While specific nutrients like omega-3 fatty acids, vitamin D, and protein may positively impact muscle mass and strength, dietary patterns like the Mediterranean diet may be most impactful for treatment and prevention.
- Exercise regimens should include both aerobic and resistance exercises that target older adults' activities of daily living.
- Future research needs to focus on the interplay between dietary patterns, protein supplementation, and mixed exercise routines and their impact on sarcopenia and frailty prevention and treatment to optimize healthy aging and mobility preservation.

105.1 INTRODUCTION

Preservation of physical function is a priority for older adults as it allows them to maintain independence and prevent sarcopenia and frailty. Physical independence is a key driver of overall quality of life.[1] As defined by the European Working Group on Sarcopenia in Older People, sarcopenia is the gradual loss of muscle mass, strength, and physical function.[2] Sarcopenia is a main contributor to the frailty syndrome, defined as the presence of three or more of the following components: slow gait speed, lower grip strength, low physical activity, self-reported exhaustion, and unintentional weight loss.[3] Frailty syndrome is the result of complex interactions between aging at the cellular level and the downstream impacts on muscle physiology (sarcopenia) and physical function (Figure 105.1).[4]

The progression of sarcopenia and frailty increases the risk of multimorbidity, institutionalization, and adverse health outcomes in older adults.[5,6] The negative impacts of this cycle emphasize the need for both primary and secondary prevention strategies for sarcopenia and frailty to encourage healthy aging, as defined by a recent American Geriatrics Society statement.[7] As frailty has a spectrum of phenotypes (e.g., robust, pre-frail, and frail), individualized interventions are likely needed to prevent its development or progression.[8] This need for individualization is further highlighted by older adults with both obesity and sarcopenia (i.e., "sarcopenic obesity"), where there is a need to balance weight loss and maintenance of "healthy" muscle physiology.[9,10] This chapter will discuss various approaches to the primary and secondary prevention of sarcopenia and frailty (and their overlaps) via nutrition and exercise interventions and identify areas of needed exploration.

105.2 NUTRITION

Appropriate nutrition is imperative for preventing sarcopenia and frailty and maintaining physical function throughout the lifespan. The Dietary Guidelines for Americans 2020–2025 suggest that females and males over 60 should consume 1600–2200 calories and 2000–2600 calories per day, respectively.[11] Table 105.1 highlights the composition of a typical 2000-calorie diet. However, older adults are at risk for poor nutritional intake due to factors associated with aging, such as decreased appetite (e.g., "anorexia of aging"), a blunted olfactory system, various medications, and earlier satiety due to slowing neuronal conduction.[12] Poor oral health is also a driver of inadequate intake, supported by the inverse relationship between the number of posterior teeth and consumption of a nutritionally complete diet.[13] For instance, participants with poor oral health in the National Health and Nutrition Examination Survey III lacked vitamins A and C, carotene, folate, and fiber in their diets. Furthermore, poor dietary intake is associated with chronic diseases, increasing the risk of sarcopenia and frailty. As a result, these components must be adequately addressed across the lifespan to improve the physical

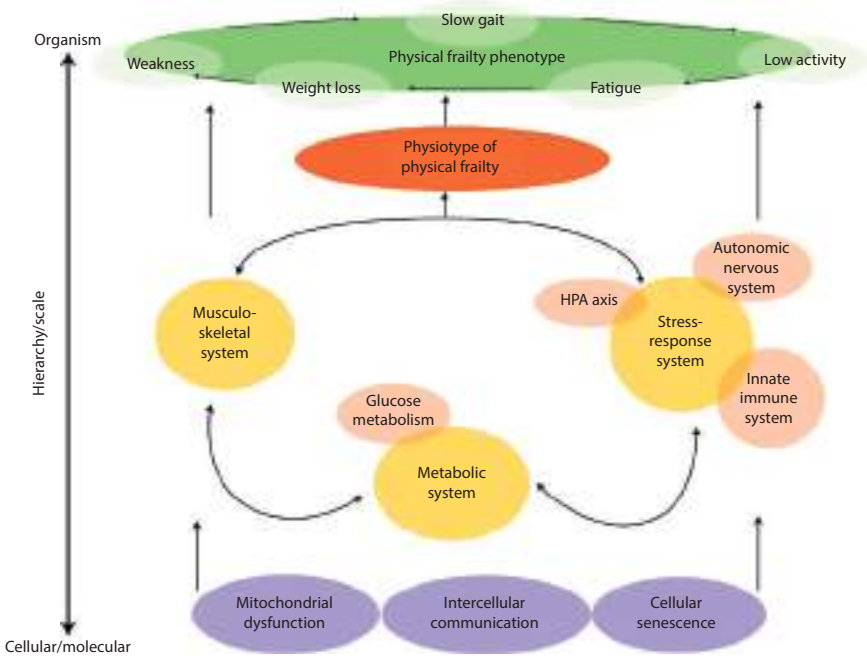

FIGURE 105.1 "A hierarchical, multiscale representation of the physiological dysregulation and likely biological drivers of physical frailty. The schema depicts the clinical syndrome of physical frailty as an emergent property, at the highest level of the hierarchy, underlain by physiological modules (systems) at a smaller scale and cellular/molecular modules (systems) at an even smaller scale. The musculoskeletal system, stress-response system, and metabolic system circles represent the three major physiological modules (systems) with the most evidence of interactions and the most evidence of a relationship with frailty. The glucose metabolism, HPA axis, autonomic nervous system, and innate immune system ovals represent submodules (subsystems) within these three larger modules. Stressors from age-related biological changes at the cellular/molecular scale, represented in the ovals with mitochondrial dysfunction, intercellular communication, and cellular senescence, likely underlie dysregulation of the physiological modules represented above, which also interact with each other. The aggregate physiotype of dysregulation (the oval containing physiotype of physical frailty) is associated with both the phenotype of physical frailty, in the top oval, and the vulnerability associated with its state" (reproduced with permission from Fried et al., The physical frailty syndrome as a transition from homeostatic symphony to cacophony. *Nat Aging*. 2021;1(1):36-46. doi:10.1038/s43587-020-00017-z).

function of older adults. Because nutritionally rich diets are important over time, we will explore certain macronutrients, micronutrients, dietary supplements, and dietary patterns as primary and secondary prevention interventions for sarcopenia and frailty.[7,11,12]

105.2.1 Protein

The Recommended Dietary Allowance of protein for adults over 18 years of age is 0.8 g/kg/day.[11] Slightly higher amounts of 1–1.2 g/kg/day and 1.2–1.5 g/kg/day are recommended by the European Society for Clinical Nutrition and Metabolism for healthy and malnourished older adults, respectively, in attempts to mitigate protein loss.[14] However, older adults are often not meeting their daily recommended dietary allowance of protein. Approximately 30% of men and 50% of women ages 71 and older do not meet their daily recommended amount.[11] Deficiencies in protein intake can lead to a metabolic deficit, leading to subsequent muscle atrophy and loss of strength.[15]

The association between protein intake and sarcopenia development is typically assessed by muscle mass or extrapolated from physical function outcomes. Lower (<0.8 g/kg/day versus >1.2 g/kg/day) protein intake was associated with loss of lean muscle mass and a higher odds ratio (2.56, 95% CI 1.01–6.50) of unhealthy weight loss in community-dwelling older adults in a longitudinal cohort study, after adjusting for caloric intake and other factors.[16] Additionally, higher protein intake was associated with a smaller reduction in grip strength for community-dwelling adults ages 60 and older in the Framingham Offspring cohort, gaining 0.52% to 0.60% strength per year.[17] Protein intake has a similar impact on the risk of frailty development. A systematic review by Lorenzo-López et al. showed that higher amounts of dietary protein (1 g/kg/day) were associated with less risk of frailty development in community-dwelling older adults.[18] Additionally, there was no significant difference based on the source of the protein (e.g., single amino acid versus whole food source). However, more recent data suggests that diets higher in plant-based protein may protect against frailty, with higher intakes of plant protein being associated with lower frailty risk (p-trend < 0.0001).[19]

Given the significant overlap in the pathophysiology of sarcopenia and frailty (e.g., muscle weakness leading to decreased strength and worse physical outcomes), recommended secondary prevention interventions are similar and

TABLE 105.1
Recommended Dietary Intake for Adults Aged Older than 50 Years of Age

Macronutrients	
Protein	10–32% of daily kcal (56 g)
Carbohydrate	45–65% of daily kcal (130 g)
Fiber	28 g
Added sugars	<10% of daily kcal
Total lipids	20–35% of daily kcal
Saturated fatty acids	<10% of daily kcal
Micronutrients	
Vitamin A	900 µg
Vitamin C	90 mg
Vitamin D	600 IU
Vitamin K	120 µg
Vitamin B_6	1.7 mg
Vitamin B_{12}	2.4 µg
Thiamine	1.2 mg
Riboflavin	1.3 mg
Niacin	16 mg
Choline	550 mg
Folate	400 µg

Recommended macronutrient and micronutrient components of a typical 2000-calorie diet for adults 51 years of age and older adapted from the 2020–2025 Dietary Guidelines for Americans.

include protein supplementation and exercise.[20] In a randomized controlled trial including pre-frail and frail older adults in Korea, 1.5 g/kg/day of whey protein supplementation led to increased appendicular skeletal mass, skeletal mass index, and gait speed when compared with 0.8-, 1.0-, and 1.2 g/kg/day supplementation amounts.[21] However, a systematic review by Cruz-Jentoft et al. yielded inconsistent results for sole protein supplementation in individuals with frailty.[22] Physical performance improved, but there was no change in muscle strength or muscle mass. The inconsistency in strength and muscle mass improvement is further supported by a randomized controlled trial where no differences in muscle mass or improvement in physical function occurred after non-protein malnourished, sedentary older men received protein supplements and testosterone injections.[23] The reasons for the negative trial were unclear as protein supplementation was ideal body weight-based; however, program adherence was self-reported, potentially confounding results.

Pairing exercise (combined [aerobic and resistance] or resistance exercises) with protein supplementation may amplify the impact of supplementation on improving muscle mass, strength, and frailty indices. In a meta-analysis by Liao et al., more significant improvements in lean body mass (standard mean difference [SMD] 0.52; $p < 0.00001$), leg strength (SMD 0.37; $p < 0.00001$), and frailty status (odds ratio 2.77; $p = 0.006$) occurred when protein supplementation (4.1–40.8 g/day) was coupled with combined or resistance exercises in community-dwelling and institutionalized frail older adults.[20] However, 40 mg daily whey supplementation paired with three times weekly resistance exercise did not lead to any statistically significant improvements in lean body mass or strength in a randomized controlled trial for older adults with mobility limitations.[24] The inconsistencies in muscle mass and physical function outcomes after protein supplementation emphasize the need for identifying which older adults will benefit from supplementation, the role of augmentation with exercise, and the appropriate supplement agent.

Branched-chain amino acid protein supplements, particularly leucine, stimulate muscle protein synthesis in older adults.[25] Leucine is found in various plant- and animal-based sources (e.g., whey). In a meta-analysis, leucine supplementation was associated with increased muscle protein synthesis when compared to controls (SMD 1.08, $p < 0.001$), making it an amino acid of interest for primary and secondary prevention.[26] There was an association between lower serum levels of branched-chain amino acids with lower skeletal muscle index and grip strength in a cross-sectional study of Norwegian adults ≥70 years.[27] Additionally, there was no defined plasma level of amino acids to identify sarcopenia and or set as a maintenance goal. Institutionalized older adults in Spain had improvements in walking time ($p = 0.011$) and muscle mass index ($p = 0.08$) with 6 g/day of leucine for 13 weeks.[28] For the supplementation amount, the PROT-AGE consensus committee recommends 2.5–2.8 g of leucine of the 25–30 g of protein consumed at each meal for healthy adults.[14] This is higher than younger adults due to the increased daily recommendation of 1.0–1.2 g/day of protein for older adults.

Both animal and plant-based protein supplement sources show promise for increasing muscle mass, with less being known about plant-based sources.[29] However, additional evaluations need to determine if plant-based or animal-based supplementation is superior for increasing muscle mass when paired with exercise and the recommended 1–1.2 g/kg/day of protein per meal. Overall, dietary protein content is important throughout the lifespan, particularly for individuals with sarcopenia and frailty, as it is required to maintain and stimulate muscle development. Additional studies are needed to individualize dietary protein amounts and types for primary and secondary prevention of sarcopenia and frailty, particularly when coupled with exercise for secondary prevention.

105.2.2 Carbohydrate

The primary energy source of an individual's diet is carbohydrates. The body uses simple sugar for energy by metabolizing simple sugars or breaking down oligosaccharides and polysaccharides. The Dietary Guidelines for Americans recommend older adults consume 45–65% of their total daily calories as carbohydrates (Table 105.1).[11] A meta-analysis examining carbohydrate intake of adults aged 45–65 years over a 25-year follow-up period demonstrated

a strong association with lower mortality in persons with a daily carbohydrate intake of ~50–55%.[30] A U-shaped curve represented the relationship between carbohydrate intake and mortality for low (<40% of daily dietary calories, pooled hazard ratio 1.20, 95% CI 1.09–1.32) and high (>70% of daily dietary calories, pooled hazard ratio 1.23, CI 1.11–1.36) carbohydrate consumption. In a cross-sectional, population-based study, dietary patterns including complex carbohydrates had lower odds of sarcopenia (odds ratio 0.25; 95% CI 0.10–0.63) and lower odds of decreased gait speed (odds ratio: 0.46; 95% CI 0.22–0.96).[31] However, future studies are needed to examine the impact of individual macronutrients, such as carbohydrates, on the risk of sarcopenia development.

105.2.3 Fat

Like protein and carbohydrates, dietary fats contribute to the energy content of the diet. Fats are the most calorie-dense at 9 kcal/g, comprising 20–35% of total daily calories (Table 105.1).[11] Dietary fats are important across the lifespan to promote cell function and the absorption of fat-soluble vitamins (A, D, E, K). Public health efforts encourage the incorporation of polyunsaturated fats versus saturated fats in the diet due to less risk of developing chronic diseases (e.g., cardiovascular disease and cancer) with diets higher in polyunsaturated fats.[32] Diets higher in saturated fats may drive the development of sarcopenia secondary to muscle inflammation and oxidative stress and are associated with an increased risk of frailty development.[33] A cross-sectional study by Montiel-Rojas et al. observed a lower risk of developing sarcopenia risk factors if polyunsaturated fats replaced saturated fats in older adult dietary patterns (β coefficient =-0.152, 95%CI −0.253, −0.051, p = 0.003).[34] However, the substitution of saturated fats with monounsaturated fats in the diet did not yield a statistically significant risk reduction of older adults developing sarcopenia risk factors. Polyunsaturated fats such as omega-3s have anti-inflammatory qualities that may have important implications for sarcopenia and frailty prevention through supplementation and dietary patterns.

105.2.3.1 Omega-3s

Omega-3 polyunsaturated fatty acids have historically been a topic of discussion within the realm of cardiovascular event prevention, acting as both a pharmacological and dietary intervention. Omega-3 polyunsaturated fatty acids include α-linolenic acid (ALA), eicosapentaenoic acid (EPA), docosapentaenoic acid (DPA), and docosahexaenoic acid (DHA) and are anti-inflammatory in nature.[35] Omega-3s are found in fish, nuts, ground flax and chia seeds, and plant oils. Their anti-inflammatory activity is thought to be important for slowing muscular aging ("inflammaging"), which may be useful for both primary and secondary prevention of sarcopenia and frailty. Inflammatory markers of interest in sarcopenia and frailty include C-reactive protein, interleukin-6, and TNF-alpha.[36] In a longitudinal cohort study by Abbatecola et al., higher serum omega-3 levels were associated with better physical performance and less physical decline.[35] Similarly, in a longitudinal cohort study (5.2-year period), higher levels of ALA were associated with better knee extension in older adults (regression coefficient 5.97, 95% CI 1.17–10.8; p = 0.014).[37]

The anti-inflammatory impacts of omega-3s are inconsistent, which may be dependent on differing baseline interleukin-6 levels in older adults, as those with lower levels experienced less improvement in inflammation at similar omega-3 doses.[38] In a randomized controlled trial by Tan et al., longer duration (eight weeks versus four weeks) of omega-3 supplementation (1.5 g of EPA and 1.0 g of DHA) was associated with more successful lowering of interleukin-6, interleukin B, and TNFα levels in older adults (mean age 60.6 years) with at least one chronic venous leg ulcer.[39] These findings suggest that omega-3s may have the potential to mitigate inflammation and delay sarcopenia and frailty development. Tan et al. used higher EPA and DHA doses than in previous studies, which highlights the need for more randomized controlled trials focused on the impact of dosing on inflammation levels and physical performance outcomes, and including older adults with various chronic diseases as this may affect baseline inflammation levels.

Randomized controlled trials exploring the impact of omega-3 use coupled with exercise on muscle mass and function yielded inconsistent results. In the ENRGISE (Enabling Reduction of Low-Grade Inflammation in Seniors) trial, omega-3s did not reduce interleukin-6 levels or improve walking speed.[38] However, muscle thickness of the upper and lower extremities increased after 12 weeks of omega-3 supplementation (2 g) and three times weekly resistance training for men and women.[40] While omega-3 intervention is promising for the prevention and treatment of sarcopenia and frailty, more research is needed to identify the appropriate dose of omega-3s and exercise regimens to optimize their impact. Because dietary omega-3s are typically found in fatty fish and plant-based oils, the Mediterranean diet may be a tool for sarcopenia and frailty mitigation, which will be explored later in this chapter.

105.2.4 Micronutrients

Micronutrients are the vitamins and minerals in the foods we consume. Poor quality diets (e.g., those with limited sources of a variety of macronutrients, vitamins, and minerals) are associated with sarcopenia and frailty development.[31,41] The following section will discuss the role of micronutrients in sarcopenia and frailty prevention and treatment.

105.2.4.1 Vitamin D

Vitamin D 25(OH)D is of particular interest as vitamin D is a common supplement for osteoporosis prevention and previous observational studies suggest that vitamin D deficiency is associated with the development of sarcopenia and frailty.[42] Vitamin D acts on a cellular level at the

muscle, binding to the vitamin D receptor on the muscle and stimulating muscle growth.[43] In vivo, muscle vitamin D receptors decline with aging, leading to blunted muscle growth. Observational studies yielded inverse relationships between vitamin D, muscle mass, and strength and may predict physical decline in older adults.[44,45] In a longitudinal cohort study by Houston et al., healthy, community-dwelling older adults with a vitamin D level <20 ng/ml had worse performance on hand grip and Short Physical Performance Battery than those with a level ≥30 ng/ml at two- and four-year time points.[46] Similarly, older men in a five-year longitudinal study with 25(OH) vitamin D level <16 ng/ml and 1,25 vitamin D level <25.8 pg/ml had an odds ratio of sarcopenia of 2.53 (1.14–5.64; p = 0.02) and 2.67 (1.28–5.60; p = 0.01), respectively.[47] A randomized controlled trial by Cai et al. did not yield any clinically significant improvement in frailty status, of older adults with low vitamin D, with vitamin D supplementation (200, 1000, and 2000 IU doses) and had weak evidence for the benefits of the 4000 IU dose.[42] However, multiple randomized controlled trials support that vitamin D supplementation paired with protein (whey) supplementation may improve muscle mass in older adults.[46,48,49] Older adults with sarcopenia increased muscle mass and improved chair-to-stand performance with twice-daily whey, leucine, and vitamin D supplementation.[48]

105.2.4.2 Other Vitamins and Minerals

Sarcopenia is associated with low intake of vitamins C, D, E, and folate and low serum levels of vitamin E and carotenoids.[18] A sequential decrease in micronutrient levels has been associated with progression along the frailty spectrum, from robust to frail. A systematic review by van Dronkelaar found that sarcopenia was associated with low intake of magnesium (p = 0.015), selenium (p = 0.015), and phosphorous (p = 0.014), and calcium (highest versus lowest tertile of calcium intake OR 0.259; 95% CI 0.087–0.768, p < 0.01) intake was associated with increased muscle mass.[50] Magnesium supplementation was associated with better physical performance (handgrip change of 0.41 points, p = 0.03, chair stand change of 0.14 m/s p = 0.006, SBBP −1.31 seconds p = 0.0001) and increased muscle mass in healthy older women.

Various micronutrients also serve as antioxidants. Oxidative stress and inflammation are drivers of chronic disease with reactive oxygen species causing cellular death and clinical aging ("inflammaging").[51] Antioxidants mitigate inflammation by counteracting free radicals. Vitamins C and E are of interest in sarcopenia and frailty as vitamins C and E are associated with collagen development and muscle formation, respectively.[52] While some observational population studies suggest that vitamin C and E slow muscular aging, data is inconsistent for both primary and secondary prevention of sarcopenia and frailty.[53,54] Knowing micronutrient associations can help guide future sarcopenia and frailty screenings to include nutritional evaluations focused on particular micronutrients and direct future randomized control trials to focus on individualized dietary plans and patterns.

105.2.5 Dietary Patterns

Dietary patterns are of particular interest across the lifespan as healthy eating is important for healthy aging. Anti-inflammatory dietary patterns are associated with preserving physical function and slowing cognitive decline and include the Mediterranean and the Dietary Approaches to Stop Hypertension (DASH), which are diets rich in omega-3s and antioxidants.[55–58] The Mediterranean diet minimizes processed foods and encourages fruits, vegetables, potatoes, whole grains, beans, nuts, seeds, and extra virgin olive oil while including moderate amounts of lean poultry, fish, seafood, dairy, and eggs.[59] The DASH diet is rich in vegetables, fruits, and whole grains and low in saturated fat, sweetened beverages, foods with added sugar, and sodium.[60] The DASH diet also includes fat-free or low-fat dairy products, fish, poultry, beans, nuts, and vegetable oils. In this section, we will explore the Mediterranean and DASH diets as potential interventions for sarcopenia and frailty prevention and treatment.

105.2.5.1 Mediterranean Diet

The Mediterranean diet contains omega-3s and antioxidant micronutrients that may mitigate "inflammaging" and serve as primary and secondary prevention interventions for sarcopenia and frailty.[58] Omega-3s and antioxidants are often consumed in the form of seafood (15 ounces/week) and fruits (2.5 cups daily)/vegetables (2.5 cups daily), respectively.[59] Better Mediterranean diet adherence was associated with higher appendicular skeletal muscle mass and slowing muscular decline (e.g., less decline in gait speed and better lower limb performance).[55–58] In a cross-sectional and retrospective cohort study including older adults aged 59 to 73 years of age, each additional serving of fatty fish per week yielded improvements in grip strength for men (0.48 kg, 95% CI 0.24–0.72) and women (0.43 kg, 95% CI 0.13–0.74).[61] Similar trends were seen for frailty primary prevention in a systematic review and meta-analysis by Kojima et al., as better Mediterranean diet adherence was associated with a lower risk of frailty development.[62]

The Mediterranean diet may be a method of secondary prevention of sarcopenia and frailty through the anti-inflammatory and antioxidant properties of its food components. Despite these associations, there are no clearly defined mechanisms to specifically explain the observed benefits of the Mediterranean diet for sarcopenia and frailty but these may be related to the combination of nutrients. In areas of more Westernized diets and insufficient resources, Mediterranean diet adherence may be challenging, which will need to be taken into consideration in future research. Additionally, future research will need to explore the impact of the Mediterranean diet, and its components, as secondary prevention of sarcopenia and

frailty due to the paucity of current longitudinal data in older adults.

105.2.5.2 DASH Diet

The DASH diet has similar components to the Mediterranean diet. However, it is based on a Westernized diet that contains more refined grains (six to eight servings/day) and red meat consumption (six one-ounce servings/day).[60] Additionally, there is a focus on limiting daily salt intake to less than 2300 mg. The DASH diet was initially developed to target hypertension and led to improvements in cardiovascular disease and diabetes.[63] Like the Mediterranean diet, its anti-inflammatory and antioxidant components make it a potential approach to sarcopenia and frailty mitigation.

While few studies or reviews explore the impact of the DASH diet on sarcopenia, Perry et al. conducted a randomized controlled trial including non-frail older adults (aged 65 to 84 years) with obesity (body mass index $\geq$ 30 kg/meters^2) that consumed the DASH diet (including lean red meat) with a caloric restriction of 1800 kilocalories a day.[63] At the end of the 12-week period, there was a 6.3% ($p < 0.001$) weight loss predominantly of fat mass. Total muscle mass was reduced, hand grip strength increased, and participants maintained the same level or improved performance on sit-to-stand and gait speed. These findings suggest that the DASH diet may be a primary prevention method for older adults with a body mass index $\geq$30 kg/meters^2. Due to the preservation of lean mass during weight loss with the DASH diet, this dietary pattern may benefit individuals with sarcopenic obesity, as a special balance is needed between weight loss and muscle preservation. Cross-sectional data for community-dwelling older adults suggests that DASH diet adherence is associated with a lower prevalence of frailty (OR 0.97, 95% CI 0.94–0.99); however, there are few randomized controlled trials exploring the DASH diet as a secondary prevention method for frailty.[64] Future efforts need to explore the impact of DASH diet adherence throughout the lifespan and its impact on functional measures and body composition in older adults.

A combination of the Mediterranean and DASH diets, the Mediterranean-DASH diet intervention for neurodegenerative delay (MIND), also shows promise for slowing cognitive decline, which is of additional interest in this age cohort.[50] While the Mediterranean and DASH diets show promise for sarcopenia and frailty prevention and mitigation, the optimal dietary pattern for the prevention of sarcopenia and frailty has not yet been determined. Therefore, future research needs to explore the impact of specific dietary patterns on both primary and secondary prevention of sarcopenia and frailty.

105.3 EXERCISE

Exercise is imperative for the preservation of and improvement in physical ability in individuals affected by sarcopenia and frailty. Exercise is critically important across the lifespan as a determinant of healthy aging as it is associated with better cardiovascular health, cognition, mood, maintenance of physical function, and prevention of physical decline.[65–67] Independence is a major component of older adults' quality of life, as poor physical status negatively impacts older-adult quality of life.[68] This section will explore various exercise types and their range of impact on sarcopenia and frailty prevention and treatment.

105.3.1 Exercise Approach for Sarcopenia and Frailty Prevention and Treatment

For primary and secondary prevention of sarcopenia and frailty, older adults should engage in resistance and aerobic exercises as they age.[69,70] Both resistance and aerobic exercise directly impact muscle physiology by promoting muscle protein synthesis and are associated with the maintenance of function and cognition.[71] Aerobic activities are important for achieving the stamina needed for resistance training but have little effect on strength.[72] Resistance exercises successfully counter muscle weakness by increasing muscle mass.[73,74] The Physical Activity Guidelines for Americans recommend 150 minutes of moderate-intensity exercise weekly with resistance exercise of all major muscle groups at least twice a week.[69] Exercise programs should include combined aerobic and resistance exercises that target older adults' daily activities, focusing on large muscle groups,[75] particularly the lower extremities, as the activities of daily living heavily rely on the lower extremities. This concept is supported by better chair stand performance by older adults who participated in exercise programs that included more squat repetitions.[76] Resistance exercise prescriptions should be progressive and with a goal at least twice per week, consistent with the Physical Activity Guidelines for Americans.[69,76]

The ideal exercise intensity is unknown for sarcopenia, but a spectrum of intensities shows improvement in strength. High-intensity (e.g., three times weekly for 1.5 hours) training with resistance training and supplementation with whey, vitamin D, and calcium (versus no intervention) led to improvement in total body fat (-1.76 ± 2.08 %, $p < 0.001$), thigh lean body mass (242 ± 231 g, $p < 0.001$), leg press amount (451 ± 223 N ($p < 0.001$), and decreased abdominal fat percentage (-2.27 ± 1.89%, $p < 0.001$) in older men with sarcopenia after a 36-week intervention when compared with controls.[77] While higher-intensity resistance exercises are associated with greater improvements in strength, low- to moderate-intensity resistance exercises still show clinically significant gains.[73,74] In a randomized controlled trial comparing low-intensity (training at 40% of the one repetition maximum) versus high-intensity (training at 70% of the one repetition maximum) resistance training, there were no statistically significant differences between groups for instrumental activities of daily living and routine activities of daily living.[74] Ideally, the individual should provide maximal effort at any resistance level with exercises that show muscle fatigue at the end of the session.[78] Gradual

increases in resistance and repetitions can be guided by the individual's fatigue level, with one to three sets of six to 12 repetitions being adequate for strength gain. Ideally, rest periods between exercises cater to the individual's preference, and exercise routines should not occur on consecutive days.[69,78]

Aerobic, resistance, and combined exercise programs have shown improvements in timed up and go ($p < 0.01$), gait speed ($p < 0.01$), skeletal muscle mass index ($p < 0.01$), and appendicular skeletal muscle ($p < 0.01$) in a systematic review and meta-analysis of adults over 65 years of age participating in a randomized controlled trials investigating the aforementioned exercise regimens.[79] The exercise regimens ranged from 30–60 minutes, one to seven times a week for 8–36 weeks. Similar effects were seen in a systematic review and meta-analysis by Lu et al., as individuals with sarcopenia participating in exercise interventions (mixed training, resistance training, and whole-body vibration therapy) performed better than controls for knee extension strength ($p < 0.00001$), timed get up and go times ($p < 0.00001$), and gait speed ($p < 0.0001$).[76] These findings highlight the impact of exercise on secondary prevention of frailty and sarcopenia and the role of a combination of aerobic and resistance exercises.

Strength and functional outcomes from resistance training vary between community-dwelling and hospitalized older adults, which may result from varied study protocols and individualized responses.[80] Sáez de Asteasu et al. stratified resistance exercise response by adverse responders, responders, and non-responders to intensive exercise (five to seven consecutive days, twice daily) versus routine care for hospitalized adults.[81] The presence of adverse and non-responders emphasizes the heterogeneity of responses to exercise interventions and the need for further exploration to develop individualized programs. These varying responses may also highlight the impact of sarcopenic obesity on response to exercise interventions. For instance, older women with sarcopenic obesity had blunted strength gains with chest press (12.9% versus 8.7%), biceps curl (11.3% versus 10.3%), and leg press (50.3% versus 40.5%) when compared with women with solely sarcopenia, proposing a need for individualized therapies for this group and/or a combination of diet and exercise interventions.[82]

Although less commonly prescribed exercise regimens, yoga and tai chi show promise as methods of both primary and secondary prevention of sarcopenia and frailty and are readily available in community-based settings. In a randomized controlled trial comparing physical measures between community-dwelling older adults randomized to a ten-month tai chi intervention versus health education, the tai chi group improved their appendicular skeletal muscle mass and gait speed.[83] However, there were no changes in grip strength. Despite no changes in grip strength, this study suggests that tai chi may be a tool for sarcopenia mitigation. In a prospective cohort study of older adults with frailty residing in Singapore, those performing tai chi more than once a week had better quality of life measures and were less likely to develop pre-frailty or frailty than those who only performed tai chi zero to one time per week.[84] Yoga has not been thoroughly studied in the older adult population. Because there is some literature to suggest that yoga decreases the inflammatory markers associated with muscle aging (e.g., C-reactive protein, interleukin-6), future studies should consider including yoga as an exercise intervention.[85]
