We have not yet achieved health for all. Health disparities continue to widen in countries at all income levels. The social margins team with individuals and populations excluded from economic productivity and good health based on their position in the social hierarchy and processes that assign privilege and disadvantage based on race, ethnicity, caste, sex, gender, sexual orientation, education, income, geography, and other characteristics. Social epidemiology and global public health have an opportunity to hasten social change by embracing intersectional complexities innovating our current research methods, and conducting research that facilitates social change. We must also recruit a new generation of public health researchers who represent multiple intersecting identities and encourage them to think critically and creatively about what our current research methods miss.

The health of Indigenous peoples

Papaarangi Reid, Donna Cormack, Sarah-Jane Paine, Rhys Jones, Elana Curtis, and Matire Harwood

Defining Indigenous

The United Nations (UN) reports there are more than 370 million Indigenous peoples worldwide, residing in around 90 countries (UN Permanent Forum on Indigenous Issues (UNPFII) 2009, p. 1), with greater numbers in the Africa, Asia, and South America regions. These population statistics are fraught with significant challenges in how Indigenous peoples are defined, whether Indigenous peoples are recognized in all nation states, and data completeness and quality (Ohenjo et al. 2006; Gracey and King 2009; Davis 2016).

Defining the term 'Indigenous peoples' is contested and while it is often taken as an umbrella for other names such as Aboriginal, Native, First Nations, tribal peoples or original inhabitants (Gracey and King 2009), these terms are not universal and may fail to acknowledge the many and varied histories of coloniality across different continents in different eras (Ohenjo et al. 2006; Mohindra 2017). In discussing the challenges of defining Indigenous peoples, the UNPFII notes:

> Today, the prevailing view is that a single formal universal definition of the term is unnecessary for the recognition and protection of the rights of indigenous peoples, and will fail to capture the diversity, range and complexity of the situations of indigenous peoples throughout the world. (2015, p. 6)

The UN reiterates the importance of self-identification in recognition that some states may deny the existence of Indigenous peoples, and suggests that on an individual level:

> . . . an Indigenous person who self-identifies with an Indigenous population (group consciousness) and is recognised and accepted as one of its members (acceptance by group), which in turn reserves the sovereign right and power to decide who belongs without external interference. (UNPFII 2015, p. 4)

Despite the fundamental right for Indigenous peoples to be recognized, some states refuse to do so (Ohenjo et al. 2006), choosing instead to describe peoples as being marginalized by geographic, socioeconomic, linguistic or lifestyle factors (UNPFII 2015). Defining who is Indigenous is central to claiming Indigenous identity, history and rights and is also fundamental to 'being counted' within nation states. Reluctance to acknowledge Indigenous peoples amplifies challenges with data completeness and quality.

'Counting' Indigenous peoples in data

Indigenous peoples are often undercounted, miscounted, or not counted in state data systems (Anderson et al. 2016; Axelsson et al. 2016a; Davis 2016). In many jurisdictions, data for Indigenous peoples are not collected, not reported, or aggregated into broader groups, limiting visibility for Indigenous communities within the data. The ability to count, in a practical and technical sense, is deeply connected to the right to be counted as Indigenous peoples and nations (Robson and Reid 2001) and affirmed in human rights frameworks and conventions, including the United Nations Declaration on the Rights of Indigenous Peoples (UNDRIP) (UN 2007). Appropriate data collection and disaggregated data for Indigenous populations is an 'urgent priority' (UNPFII 2004).

Variable availability and quality of data across Indigenous populations also impacts on understanding the complex inequities in Indigenous health globally. Available data are not always relevant for Indigenous peoples' own priorities (Walter 2018), and limited by a focus on narrow biomedical measures rather than Indigenous conceptualizations of health and well-being (UNPFII 2009; Walker et al. 2017). This limits the ability to explore questions of importance to our own Indigenous communities, or to hold states to account for their failures to recognize Indigenous rights and to eliminate inequities.

The state of health of Indigenous peoples

UNDRIP reaffirms Indigenous rights, including the right to be actively involved in the planning, development, and implementation of health services and programmes, the right to traditional medicines and health practices and the right to equal health within the country of residence (UN 2007; UNPFII 2013; Axelsson et al. 2016b).

In contrast to this clear articulation of rights, and corresponding obligations for states to ensure the realization of these rights, many Indigenous peoples experience stark inequities in health, reflected in lower life expectancy, increased mortality and morbidity, and disproportionate numbers living with disability relative to other populations (Anderson et al. 2006; Ohenjo et al. 2006; UNPFII 2013; Axelsson et al. 2016b; Mohindra 2017). These outcomes are heavily influenced by the environments in which we live, including unequal access to conditions that are important for good health, such as safe water, secure and nutritious food, sanitation, and other social determinants of health (UNPFII 2013). Indigenous peoples experience multiple obstacles to healthcare, as well as discriminatory, inequitable, and culturally incompetent care (Allan and Smylie 2015; UNPFII 2015). Further threats to the health of Indigenous peoples include the ongoing impacts from the destruction of Indigenous systems and institutions, natural environments, and the effects of climate change (Gracey and King 2009; UNPFII 2013).

While there are publications describing important health issues across Indigenous communities, comprehensive health outcomes data, and peer-reviewed studies of Indigenous health at the state level predominantly focus on high-income countries, especially Australia, Canada, New Zealand, and the United States (Anderson et al. 2016; Axelsson et al. 2016a), with less research published for low- and middle-income countries (Mohindra 2017). Challenges also arise from international comparisons between Indigenous peoples that may not account for variations in territorial histories, social, political, and economic arrangements, and risk focusing attention on whose health status is worst among Indigenous communities. However, international comparisons can be useful in representing the international failure of many nation states to realise Indigenous peoples' rights to health. Mindful of these challenges, this section summarizes key health measures and outcomes for Indigenous peoples globally.

Stark, inequitable health outcomes for Indigenous peoples have been documented globally (e.g. Montenegro and Stephens 2006; Ohenjo et al. 2006; Hayman et al. 2015). An international collaboration recently published the most comprehensive review on Indigenous health to date, drawing on data from 28 populations in 23 countries, covering around 154 million Indigenous peoples globally (Anderson et al. 2016). The review confirmed previous work, documenting poorer outcomes for Indigenous peoples globally when compared with non-Indigenous populations, sustained across many health and social outcomes (Anderson et al. 2016). The review also identified variations in the magnitude of inequities between countries. Worse outcomes for Indigenous were typical but not universal, with some instances identified where there were no differences or, very rarely, better outcomes for Indigenous communities (Anderson et al. 2016). For example, data on Life-Expectancy-at-Birth (LEaB), covering 18 Indigenous populations from 14 countries, showed generally lower LEaB for Indigenous peoples. Inequities between Indigenous and non-Indigenous peoples varied from extreme inequities in some populations of 10 years or more, to eight Indigenous populations with gaps between 5 and 10 years, with the remaining countries having differences of two years or less, except for Sami in Sweden where the difference was not statistically significant (Anderson et al. 2016).

The review also reported that the health of Indigenous mothers and infants generally echoed socioeconomic conditions of their communities. In general, infant mortality rates were lower (less than 50/1,000 live births) in higher income countries than in lower income countries (more than 50/1,000 live births). In almost all populations where data were available, Indigenous infant mortality rates were higher than for non-Indigenous peoples with particularly high ratios in some countries (Anderson et al. 2016).

Maternal deaths should be infrequent and reflect the availability, accessibility, affordability, and safety of local health services. Data was unavailable or unstable for many nations in the review but consistent disparities in maternal deaths were noted in Australia, New Zealand, Panama, and Columbia (Anderson et al. 2016). The receipt of lower levels of maternity services by Indigenous mothers has been reported elsewhere (Rumbold et al. 2011; Paulino et al. 2019). In some nation states, Indigenous women in remote communities have to relocate to give birth

(UNPFII 2015), which may leave them without social support in health services that may be culturally unsafe.

Indigenous peoples continue to be disproportionately impacted by infectious diseases with mortality and morbidity generally reported to be higher, especially for HIV/AIDS, tuberculosis, malaria, syphilis, viral hepatitis, and rheumatic fever (Montenegro and Stephens 2006; Gracey and King 2009; UNPFII 2009; Russell et al. 2019). Infectious diseases have a significant impact, especially in lower income countries, among marginalized communities living in poverty, and where the disease or its risk factors are stigmatized. Indigenous health inequities for rheumatic fever exist in both developing (Steer et al. 2002) and wealthy countries (Carapetis et al. 2005; Abouzeid et al. 2019). Indigenous children in high-income countries also experience inequitably high rates of respiratory disease (Chang et al. 2009). The socioeconomic and health disadvantage common among Indigenous communities drives much of these inequities (UNPFII 2009, 2015), which are further exacerbated by inequitable health service access and care (Baker et al. 2012).

Non-communicable diseases (NCDs) are now deeply problematic for Indigenous peoples. NCDs account for significant mortality and morbidity globally (di Cesare et al. 2013), contributing to both health inequities within nations (di Cesare et al. 2013) and to the well-being and economic security of Indigenous communities (NCD Alliance 2012). The four most common NCDs are cardiovascular diseases, cancers, diabetes, and chronic respiratory diseases (WHO 2013), contributing significantly to inequities in life expectancy between Indigenous and non-Indigenous peoples. Cardiovascular disease (CVD) is the leading cause of mortality for most Indigenous peoples. Deaths from ischaemic heart disease, twice those of non-Indigenous peoples (Ministry of Health 2011; Espey et al. 2014), account for more than half of CVD deaths, followed by stroke, heart failure (Woods et al. 2012) and rheumatic heart disease (RHD) (Watkins et al. 2017). CVD inequities are evident between Indigenous and non-Indigenous peoples in age of onset and the underlying cause of the heart disease. For example, RHD causing heart failure is more common in young Indigenous Australians and Africans; hypertensive and ischaemic heart failure is more common in older non-Indigenous people (Bukhman and Ochieng 2017).

Cancer is underemphasized as a health issue for Indigenous peoples, particularly in low income countries, possibly due to overwhelming rates of

infectious diseases. Cancers have a broad range of risk factors including infections (e.g. Hepatitis B and C, HPV, HIV, and *Helicobacter pylori*), metabolic conditions, diet, and exposure to toxins and carcinogens (WHO 2019). The relative frequency of exposure to these factors has led to variation in the types of cancer impacting Indigenous peoples in different regions (Moore et al. 2014). However, the risk of dying from all cancers is significantly higher for Indigenous peoples in general (Cunningham et al. 2008; Parkin et al. 2008; Ministry of Health 2015). Timely access to cancer screening, diagnostic and treatment services (Moore et al. 2014) by Indigenous peoples show consistent inequities in regions where measured (UNPFII 2015).

Respiratory conditions, including chronic obstructive pulmonary disease (COPD) and asthma, are also common causes of mortality, morbidity, and hospitalizations for Indigenous peoples. Asthma is the second leading cause of hospitalization among Indigenous Australians and death rates are 3.2 times higher (NCD Alliance 2012). COPD hospitalization and mortality rates for Indigenous peoples are higher in most higher income nations (Australian Institute of Health and Welfare 2014; Gershon et al. 2014; Ministry of Health 2015) with differences in exposure to tobacco and environmental pollution, differences in disease management, and differential access to health services, explaining most of these inequities (NCD Alliance 2012; Chang et al. 2014). While allergic disorders are rare in traditional rural settlements, urbanization, and the concurrent move to overcrowded living conditions and increased exposure to environmental pollutants has seen increased rates for Indigenous communities (Mbugi and Chilongola 2010).

Disorders of nutrition, including undernutrition, malnutrition, and overnutrition, are also important. Anderson et al. (2016) note that child malnutrition is still a significant issue for Indigenous peoples, reporting higher levels of childhood malnutrition with stunting among Indigenous peoples residing in a number of nation states in South America. Rates of obesity among children and adults are increasing, including among those populations where childhood malnutrition is still disproportionately high (Anderson et al. 2016).

Type 2 diabetes is currently estimated to affect more than 50% of Indigenous adults aged over 35 years, with incidence rates climbing (NCD Alliance 2012). Indigenous peoples experience disproportionate rates of

diabetic complications including renal failure, lower extremity amputations, eye disease and macrovascular outcomes (Naqshbandi et al. 2008). While the high incidence of end-stage renal failure among Indigenous peoples is reported in major population centres across Oceania, Indigenous peoples receive fewer kidney transplants than non-Indigenous peoples and many experience geographic and economic difficulties accessing optimal treatments (Weil and Nelson 2006).

Diabetes inequities exist across the life course. For example, gestational diabetes mellitus (GDM) incidence rates among Native American (7.9%), Canadian First Nations (11.5%), Australian Aboriginal (8.4%), and Māori in New Zealand (6%) are higher than those for non-Indigenous women of those respective countries and the total international incidence (2–5%) (Lawrence et al. 2008; Porter et al. 2012; Jowitt 2016). GDM is a risk factor for the development of NCDs in the lifetime of both mothers (Nolan 2011) and their offspring (O'Reilly 2014). Despite suggestions that this might be a driver for the high prevalence of intergenerational diabetes (Osgood et al. 2011) and other NCDs in Indigenous peoples, screening for and management of GDM among Indigenous women is currently inadequate (McGrath et al. 2007; Daly et al. 2017). It is critical to acknowledge the lived context of Indigenous peoples who often have been excluded from traditional territories and food sources and reside in obesogenic environments and situations of food insecurity (Gracey and King 2009).

Finally, mental well-being is a global health priority for Indigenous peoples (Pan American Health Organization (PAHO) 2018). Mental health conditions are 'a complex challenge because of increased visibility, pervasive structural stigma, outdated practices and organizational fragmentation' (PAHO 2018, p. 2). Mortality data underestimate the importance of these conditions on the well-being and livelihoods of individuals and their families. In 2015, it was estimated that globally NCDs accounted for around 60% of Disability-Adjusted Life Years, of which mental, neurological., substance-use disorders, and self-harm (MNSS) accounted for 12% (PAHO 2018).

The legacies of colonization, dispossession, marginalization, systematic discrimination, and denial of Indigenous rights are linked to disproportionately high rates of stress and mental distress, highlighting the downstream impacts of these trauma on a number of parameters of Indigenous well-being. Anderson et al. (2016) note that the lack of

morbidity data for Indigenous peoples, including data on mental health conditions, was a key issue especially for countries outside of North America and Oceania, limiting the ability to fully explore the impacts of mental illness on Indigenous well-being.

Mental health conditions are disproportionately prevalent among young Indigenous peoples (WHO 2014). Suicide is a leading cause of death in young Indigenous peoples, particularly in Australia, Brazil, New Zealand, Taiwan, and circumpolar countries (Patel et al. 2007; WHO 2014). Indigenous youth are more likely to be exposed to risk factors for mental illness such as growing up in poverty, adverse conditions such as scarcity of food, poor nutrition, violence and aggressions, inadequate education, substance abuse and sexual and reproductive health challenges (Patel et al. 2007).

NCDs are clearly a challenge for Indigenous peoples and one that needs Indigenous voice, active participation, and leadership. Despite these inequities, international efforts to prevent and control NCDs have been slow to ensure Indigenous participation. Leaders in Indigenous health remain frustrated by this and note that working with Indigenous peoples is critical to ensure a reduction in NCD risk factors and NCD burden, and to avoid increasing inequity (NCD Alliance 2012; Finlay and Armstrong 2018).

Inequities have also been documented in both intentional and unintentional injury among Indigenous peoples, with higher rates of death, morbidity and disability reported by a number of countries illustrating differential exposure to violence and conflict (Montenegro and Stephens 2006), differential access to safe living and working conditions, and appropriate injury prevention strategies (Berger 2002).

Access to, and quality of, healthcare is an issue for Indigenous peoples globally (Montenegro and Stephens 2006; Ohenjo et al. 2006; UNPFII 2015). For some Indigenous peoples, healthcare is inaccessible for geographic and financial reasons, or because of discrimination (Montenegro and Stephens 2006; Ohenjo et al. 2006). In addition, many countries have healthcare systems that privilege non-Indigenous approaches to health and well-being, and marginalize Indigenous ways of healing, including denying access to traditional medicines. The decentring of Indigenous health knowledges and practices, coupled with discrimination, means that even where care is available, Indigenous peoples often experience culturally inappropriate or unsafe services.

The representation and framing of Indigenous health

Alongside the urgent need for improved data for Indigenous peoples, Indigenous scholars are concerned with the ways in which Indigenous peoples are represented in health research and statistics (Walter 2016, 2018). Representations of Indigenous health, often controlled by non-Indigenous peoples, invoke deficit, racialized narratives that contrast sharply with Indigenous narratives (Walter 2016). Moreover, data available to describe the health of Indigenous peoples often do not reflect historical and embodied contexts and circumstances, nor contemporary lived realities. In many states, non-Indigenous models of health are dominant in health systems (UNPFII 2015) and data, displacing Indigenous approaches to health and well-being.

Indigenous models of health recognize the interdependence of peoples, the connections between peoples and environments, and the importance of balance (Bird 2002; Smylie and Anderson 2006; Kaholokula et al. 2009; UNPFII 2009), and take into account how histories fundamentally shape social, cultural, political, legal, and economic institutions in societies, with flow on effects for social categorization and hierarchies such as socioeconomic status, and exposure to health-protective or health-damaging factors for individuals and communities (Walters et al. 2011). Current inequities in health are understood to be intimately linked to colonialism and racism, and the disruption to connections between people and environments from forced removal from lands, dispossession or destruction of territories and resources and environmental degradation and pollution (UNPFII 2009). The disruption of connection parallels a disruption to Indigenous systems of knowledge, ways of being, social institutions and processes of intergenerational transmission, and is understood as a root cause of current health inequities (Bird 2002; King et al. 2009; Wirihana and Smith 2014). Increasingly, Indigenous models of health are also articulating historical trauma and its intergenerational transmission, as a fundamental determinant of health for Indigenous peoples (Walter et al. 2011; Paradies 2016).

Interventions for equity in Indigenous health

Given the complex and self-replicating processes that contribute to the health inequity experienced by Indigenous peoples, effective interventions need to be comprehensive, connected, long-term, tailored, and responsive to change. The following are a range of important considerations for progress towards health equity for Indigenous peoples.

Self-determination

Self-determination is an essential component of Indigenous health development. It is affirmed as a prerequisite for the protection, promotion, exercise, and enjoyment of all other human rights and fundamental freedoms (UNPFII 2009). It is a pre-existing human right and is not dependent on the views of, or permission from, nation states (UNPFII 2009). Self-determination is intimately linked to a peoples' democratic entitlement and thus underpins the integrity of all relationships between Indigenous peoples and respective nation states. UNDRIP reaffirms Indigenous rights to self-determination, active participation in decision-making and the need of states to 'obtain free, prior and informed consent' before adopting and implementing legislative or administrative measures that may affect Indigenous peoples (UN 2007). Self-determination also applies to the right of Indigenous peoples to determine the structure and form of health systems and institutions in our territories.

Decolonisation of Indigenous knowledge and knowledge production

Human rights and fundamental freedoms detailed in international rights instruments do not always fully align with Indigenous worldviews. Indigenous values have greater focus on collective rather than individual rights, and these being balanced against responsibilities (UNPFII 2009). Further, Indigenous values including respect, cooperation, reciprocity, spirituality, deference to elders, and the importance of language and traditions are not captured. Most Indigenous peoples acknowledge the life force of all things, animate and inanimate and see as limited, international rights instruments that only acknowledge humans.

Royal (2009) promotes that the central tenet of indigeneity is an active and ongoing kin-based relationship between humankind and the natural

environment, noting that this is not about claiming resources but rather an affirmation that the earth is truly our mother. This alters relational dynamics between humans and the natural environment from one permitting extractive activities that degrade and endanger to one where humans are expected to respect and protect the environment. These worldviews are supported by Indigenous knowledge systems that are neither static nor finite, but have been undermined by processes of colonisation.

Indigenous knowledges form an essential part of the diverse knowledge systems on earth and are critical for important health challenges. UNDRIP specifically notes the right to protect Indigenous knowledges and manifestations of these knowledges including human and genetic resources, while also acknowledging rights to supporting customary processes, philosophies, and relationships.

Interventions on oppressive pathways

Acknowledge historical trauma, promote healing, and prevention

Historically, Indigenous peoples have survived horrific traumatic events, including genocides, ethnocides (destruction of cultures, languages, and ways of living), epistemicides (destruction of traditional knowledges and ways of knowing), and ecocides (destruction of environments including food sources) (Walters et al. 2011; Walters 2016). For many, these events have continued into recent history (forced adoptions or removal of children to boarding schools, long-term poverty, and discrimination) and the present (deforestation of tribal territories, pollution of waterways, continuous racialized microaggressions). Indigenous scientists are seeking to understand the role of historical trauma, and how contexts, processes and outcomes become embodied and contribute to patterns of illness among Indigenous peoples and subsequent health inequities (Walters et al. 2011).

Two growing bodies of evidence are important. First is the evidence that traumatic events are important in the life course by negatively and directly affecting the health of individuals and communities, especially if events are repeated (Walters et al. 2011). The second body of evidence demonstrates that significant trauma can have an intergenerational effect. These effects are mediated by both epigenetic pathways, affecting the way in which genes are regulated and expressed, as well as physiological mechanisms, usually mediated by stress hormones and metabolic or immune responses. It is

thought these mechanisms contribute to the disparate rates of diseases among Indigenous peoples including metabolic diseases, cardiovascular diseases as well as stress and coping disorders such as depression, anxiety, and substance abuse (Walters et al. 2011).

While the theory and evidence relating to historic trauma is still evolving, especially methodological issues (Walters et al. 2011), the complexities of the relationships become obvious. These complexities demand sophisticated research and we ought to rise to this challenge rather than dismiss the role of historic trauma in Indigenous health status.

While Indigenous peoples continue to exhibit courageous resilience in the face of these traumas, healing will require a dual focus. First, eliminating exposure to further stressors that could become embodied, such as poor nutrition, especially during pregnancy and childhood, poverty, lower quality services especially in education, health, justice, and welfare services, exposure to racisms, and higher levels of violence and loss. Second, Indigenous peoples must be permitted to heal and restore from these traumas. Some authors have noted the importance of traditional knowledge and practices to support this healing and how culture can be medicine (Walters et al. 2011, 2020).

Acknowledge racism, and intervene to mitigate and eliminate

Indigenous communities and scholars note the role of racism as a fundamental determinant of Indigenous health (Paradies et al. 2008; Allan and Smylie 2015; Paradies 2016; 2018). As a system of oppression, racism shapes health for Indigenous peoples through its structuring of histories as well as social, cultural, political, and economic institutions. Racism also operates through racially discriminatory practices at the level of individuals, intersecting with other oppressive systems to negatively influence health across the life course and intergenerationally (Paradies 2016).

Interventions are necessary to eliminate racism at interpersonal and structural levels, including action to address the role of racialized beliefs and assumptions among health providers in shaping interactions with patients and influencing clinical decision-making and healthcare outcomes (Paradies et al. 2013; Fitzgerald and Hurst 2017). There is an urgent need for the fundamental role of racism to Indigenous health to be acknowledged as a global public health issue, and for nation states to combat racism against Indigenous peoples within the health sector and more broadly in

society. Further, whether or not there are health impacts, Indigenous peoples have a right to freedom from all forms of discrimination (Paradies 2018).

Acknowledge and address health system bias, make (health) systems culturally safe

Although Indigenous peoples have long identified relationships between imposed colonial health systems and healthcare delivery, and health outcomes, these relationships have been underexamined in health research generally (Smedley et al. 2003), and for Indigenous peoples specifically (Paradies 2018). Acknowledgement of the contingent and culturally-embedded nature of health systems demands critical reflection on how organizational structures, policies, environments, practices, and provider behaviours reproduce and maintain colonial logics and power structures.

Cultural competency and cultural safety are proposed as possible interventions to eliminate ethnic health inequities. In some countries, they have been incorporated into regulatory and legislative frameworks governing healthcare workers (Bacal et al. 2006). However there are important differences in definitions of these terms, how they are interpreted, incorporated into practice, and what these interventions are hoping to achieve. While cultural competency interventions often focus on teaching healthcare workers awareness of Indigenous languages, cultures, and practices, these teachings do not address the fundamental causes of inequities and risk promoting stereotypes and therefore undermine the decolonizing and transformative work necessary to address biases (Truong et al. 2014).

Interventions are necessary that ensure health professionals develop a critical consciousness about historic processes and how they play out in contemporary practice today. Cultural safety was articulated by Dr Irihapeti Ramsden who insisted health workers reflect on their privilege and power within the health system and use it to eliminate injustice and inequity (Papps and Ramsden 1996). Cultural safety insists health workers reflect on themselves as power bearers and on their ‘own culture’ and ask what we need to change in our practice to achieve equitable outcomes for all patients. Ramsden’s work contributed to the current standards of critical self-reflection and reflective practice in the training of healthcare providers.

The importance of health systems where healthcare, interventions and policy are grounded in Indigenous culture and knowledge systems has been

acknowledged (Walters et al. 2020). There are many examples where Indigenous knowledge and healing practices have been incorporated into current health systems, and have contributed significantly to what is now called Westernized medicine (Oguamanum 2004; Maskarinec et al. 2014; Baddock et al. 2017). However, this incorporation can be problematic and damaging where it is extractive, performative, or tokenistic. While culturally grounded health services have been posited as a response to inequities in healthcare access and quality, they should be more rightly understood as a fundamental right of Indigenous peoples to have access to health services, interventions, and systems that are based on Indigenous knowledge and worldviews, and are designed and controlled by Indigenous peoples.

Build an Indigenous health workforce

A health workforce that reflects the community it will serve is a critical component of high quality and equitable healthcare (Betancourt et al. 2003; Lancet 2016). Indigenous health workforce development contributes both to Indigenous development and reducing ethnic inequities in health (Curtis 2016) and aligns with international workforce initiatives. There is evidence that if patients and healthcare workers are of the same ethnicity, described as ethnic or racial concordance (Burgess et al. 2004), interactions are marked by better communication, shared decision-making, improved respect, affiliation, and trust (Cooper et al. 2006), greater satisfaction with the care received and less likelihood of the patient perceiving racism in the interaction (LaVeist and Nutu-Jeter 2002).

Indigenous health workforce development also increases the potential for cultural competency of both health workers and health systems (Betancourt et al. 2005) as it requires healthcare providers to critically reflect on their own culture and biases and the impact these have on clinical interactions and health service delivery (Kumagai and Lypson 2009). Becoming an Indigenous health professional is also generally associated with improved financial independence (Curtis 2016), community respect and support, positive role modelling and intergenerational effects, access to health expertise and better system navigation (Ratima et al. 2007). Seeing Indigenous peoples as health professionals, as opposed to recipients of care, helps challenge colonial stereotypes and increases the potential for positive

collegial interactions which may in turn reduce implicit bias among non-Indigenous health workers (van Ryn et al. 2015).

Some countries are investing in Indigenous health workforce development and their experience has reinforced the need to adopt a 'whole pathway' approach that includes recognition of socioeconomic, cultural, and geographical barriers to accessing quality education at all levels, appropriate careers advice, and comprehensive academic, pastoral. and cultural support within tertiary contexts (Curtis et al. 2014).

Mitigate biases in research

Research is the process of knowledge production but knowledge, who is knowledgeable and knowledge creation are all situated—politically, economically, socially, culturally, and historically. Smith (2012) writes that many Indigenous peoples consider 'research' a dirty word. This references the alignment of research with colonization and its processes of appropriation and claiming. Colonization included the brutal suppression of Indigenous cultures, languages, customs, traditional knowledges and ways of knowing, and in this process, colonizers rebranded themselves as discoverers and authorities of Indigenous lives.

Colonial processes sought to replace what Indigenous peoples know with a belief in a single Euro-centric knowledge system. Imperialism now seeks to govern the way we think about knowledge, controlling what questions we ask, what we see and what we know (Smith 2012). Research is thus understood as a mechanism for establishing and maintaining power and control as part of the colonial project. Even supposedly 'objective' scientific methods can produce evidence that supports racist beliefs and further marginalizes Indigenous peoples (Te Rōpū Rangahau Hauora a Eru Pōmare 2002; Reid et al. 2017).

Indigenous researchers are increasingly rejecting approaches that seek to further entrench colonialism, deny the Indigenous experience, and reaffirm discriminatory views about Indigenous peoples. Further, Indigenous academics have been active in challenging Euro-centric research, revitalizing Indigenous research methodologies and supporting research institutions to do more for Indigenous peoples and communities (Smith 2012). However, it is necessary for all researchers, research organisations, and funding authorities to reject research projects and processes that fail to respect Indigenous knowledges, histories, ambitions, stories, voices, data,

bodies, genes, and rights (Reid et al. 2017; Walker et al. 2017). UNDRIP affirms the rights of Indigenous peoples to maintain, control, and protect traditional knowledges, develop, and incorporate traditional knowledges into our contemporary practices, advance new practices, and create new Indigenous knowledges.

Identify and mitigate future external risks to inequity

Climate change is the greatest threat to global health for the twenty-first century (Costello et al. 2009) working through multiple pathways both direct and indirect (Smith et al. 2014). Climate change acts as a threat multiplier, amplifying the health effects on structurally oppressed communities (Watts et al. 2018), with marginalized populations who already experience poorer health facing disproportionate risk (Levy and Patz 2015; Woodward and Porter 2016; Paavola 2017). Those who have contributed least to global greenhouse gas emissions (e.g. those in developing countries, low-lying island nations, and Indigenous peoples) will be hit first and worst.

Indigenous peoples are also more likely to depend on natural ecosystems for daily living and economic well-being. In addition, the capacity to respond and adapt to climate change is restricted by conditions of greater socioeconomic deprivation, ongoing social marginalization, and exclusion from political processes and structures (Ramos-Castillo et al. 2017).

Actions to tackle climate change could negatively impact Indigenous health and equity (Walpole et al. 2009; Robbins 2015) and further undermine Indigenous rights (Jones et al. 2014). However, climate action is also an opportunity for health development (Watts et al. 2015) and reducing health inequity. Despite the central importance of climate change to Indigenous well-being, international decision-making bodies and processes have not centralized Indigenous voices (Nilsson 2008).

Indigenous peoples have affirmed the pivotal importance of Indigenous ways of knowing and being to climate action. Whyte (2016) has shown that Indigenous cultural and political systems have in-built flexibility that allows societies to constantly adapt to environmental changes. The International Indigenous Peoples' Forum on Climate Change ((IIPFCC) 2012), stated, 'we reiterate the need for recognition of our traditional knowledge, which we have sustainably used and practised for generations; and the need to

integrate such knowledge in global, national, and subnational efforts. This knowledge is our vital contribution to climate change adaptation and mitigation' (p. 1).

To Indigenous peoples, climate change represents an extension and intensification of colonialism (Whyte 2017). Activities and industries that are major producers of greenhouse gas emissions have depended on the dispossession and appropriation of Indigenous lands and resources (Cameron 2012). Indeed, the values, systems, structures, and processes foundational in the colonization of Indigenous peoples also underpin the environmental changes that threaten local and global ecosystems (Wood 2015). That these same systems are being relied on provide solutions for the climate crisis is of concern to Indigenous peoples, as these systems have historically been tightly bound to philosophies that see the planet in extractive and exploitative ways (Jones 2019).

Indigenous worldviews, especially relationality with the natural environment, challenge systems where human rights dominate. The time has arrived to mitigate unprecedented damage to our planet and solutions based on Indigenous sciences provide balance to current debate, processes, and interventions.

Conclusion

Describing the health of Indigenous peoples has many challenges including definitions, enumeration, and analysis. Making sense of health data is also challenging as we seek to recognize the complex, layered, and multifactorial influences that play out through time and across geographies for Indigenous peoples. This chapter canvasses the inequitable health outcomes for Indigenous peoples globally, shaped by shared experiences of dispossession and oppression, and the significant and ongoing health impacts resulting from differential exposure to social, political, economic, and cultural determinants of health, particularly colonialism and racism. These data also speak to the ongoing resistance of Indigenous peoples, and aspirations for the recognition of our rights and restoration of relationships with our territories, environments, and relations. The state of Indigenous health challenges us to have a critical view of colonial histories and how these have become embedded in our lives. We also recognize the potential

of Indigenous knowledge systems, ontologies, and values to drive positive health and well-being into the future.

Introduction

The health of people with disabilities has, until recently, been largely ignored by public health researchers, practitioners, and policymakers. We argue this is because public health largely concentrates on the prevention of disability and conceives of disability as a health deficit. This chapter will show why the health of people with disabilities is a significant public health issue that requires urgent attention.

People with disabilities are a substantial minority of the world's population. Approximately 15% of the world's population has a disability; that's over one billion people. Globally, people with disabilities are one of the most disadvantaged populations. They are more likely to have low levels of education, be unemployed, socially excluded, live in poverty, experience homelessness, and live in poor-quality housing (OECD 2010; WHO 2011). These disadvantaged circumstances impact on their physical and mental health. In many countries, in part due to their exclusion from public health and broader society, people with disabilities smoke at higher levels than their peers without disabilities (Courtney-Long et al. 2014; Australian Institute of Health and Welfare 2016b), are more likely to be overweight and physically inactive (Neter et al. 2011; Kim et al. 2015; Australian Institute of Health and Welfare 2016b).

People with disabilities are also more likely to experience discrimination, bullying, and physical and sexual violence (Hughes et al. 2012; Krnjacki et

al. 2016; Krnjacki et al. 2017; Pinquart 2017). This is further compounded by difficulty accessing quality health promotion and care. Remedying the disadvantage, discrimination, violence, risky health behaviours and poor access to healthcare and disability services people with disabilities experience will lead to improvements in their health. This means that much of the poorer health of people with disabilities is avoidable rather than a consequence of their underlying impairment.

In this chapter, we describe how disability is conceptualized and measured; what is known about the prevalence of disability internationally; the health outcomes for people with disabilities and the impact of the social determinants of health. We also discuss some of the extant literature on improving health outcomes for people with disabilities. The chapter concludes with a call for people with disabilities to be a priority population for public health and outlines an agenda for future public health research, policy, and practice.

Evolving conceptualizations of disability

Disability is a complex and contested concept. The United Nations Convention on the Rights of Persons with Disabilities (CRPD) describes disability as resulting from:

> *'the interaction between persons with impairments and attitudinal and environmental barriers that hinders their full and effective participation in society on an equal basis with others.'* (United Nations 2006, Article 1)

The importance of this definition is that it distinguishes between an impairment, such as paraplegia or vision loss, and barriers to participation such as discrimination, physical inaccessibility, and limited employment opportunities. The disability is not solely caused by an impairment *per se* but rather by the presence of the impairment and other characteristics of society that prevent, or make it difficult for, people with disabilities to participate in key life domains, attain their rights, and realize their aspirations.

The CRPD is the first human rights treaty to specifically define the rights of people with disabilities and outline state obligations to promote, protect and uphold these rights (United Nations 2006; Keogh and Down 2014). Among these rights is the recognition that people with disabilities have the

right ‘to the enjoyment of the highest attainable standard of health without discrimination on the basis of disability’ (United Nations 2006, Article 25).

Conceptualization of disability within public health

Public health researchers, practitioners, and policymakers have traditionally focused on the prevention of disability and ill-health through policy and programmes which reduce the risk of acquiring disability. Examples include seatbelts and speed limits to reduce road accident injuries, immunization, and smoking taxation. Prevention of injury and ill-health, alongside promoting health and well-being is central to public health and should remain so. Like the rest of the population, people with disabilities can benefit from such public health interventions. However, in most public health programmes disability is considered a ‘failure’ of public health. Further, interventions which work among the general population are often assumed to apply to and be effective for people with disabilities. This is despite limited evidence or knowledge on appropriate research designs which could measure the benefit of mainstream public health interventions for people with disabilities (Berghs et al. 2016).

Antiquated assumptions that conceptualize disability as a burden or deficit can reinforce this exclusion from public health. Burden of disease studies for example position disability as a health deficit. This means that years lived with disability are valued far less than years lived without disability. This positioning assumes that people with disabilities cannot be healthy, and, when used for resource allocation or cost-effectiveness analyses, emphasizes that the lives of people with disabilities are less effective at the outset (Arnesen and Nord 1999). Effectively, this means that an intervention targeted at women with disabilities such as mammographic screening would be considered less cost-effective than in the general population because their lives are assigned lesser value.

Addressing health deficits and disability aligns broadly with what is often referred to as the medical model of disability. The literature distinguishes between the medical (or individual) model of disability and the social model. Proponents of the social model portray the ‘medical model’ as conceiving of disability as a deficit in individual bodies that is addressed through prevention, medical treatments and, preferably, cured (Oliver 1981; 1990; 1996a; b). The social model, positioned as a radical departure from this

approach, identifies physical, social, cultural, and economic barriers that are disabling. The social model draws attention to the ways in which governments, organizations, workplaces, and communities can respond to overcome barriers to an individual's participation in society.

The social model has been important politically and widely embraced by advocacy groups as it calls government and societies to account and has helped pave the way towards the formal recognition of the rights of people with disabilities as articulated in the CRPD. Others have drawn attention to the shortcomings of both models, pointing out that while the social model is an important counterpoint to the medical model, it ignores the fact that individual bodies have limitations, experience pain, fatigue and that can indeed impact on participation (Shakespeare 2014).

The International Classification for Functioning, Disability, and Health

The International Classification for Functioning, Disability, and Health (ICF), developed by the World Health Organization (WHO 2002), is one of the most widely used frameworks for conceptualizing disability. The framework is illustrated in Figure 10.7.1. This framework is designed to guide measurement, research, service delivery, and policy development. It distinguishes between functional limitations related to an impairment affecting body functions and structures (e.g. loss of arm function), activity (e.g. execution of a task or action such as dressing) and participation in life (e.g. employment).

The ICF emphasizes that acting on the impairment through medical treatment alone is not sufficient. Society can reduce activity restrictions through technologies and other adaptions (e.g. screen readers, wheelchairs, hearing loops) and reducing participation restrictions (e.g. by reducing discrimination, referred to as environmental factors in the ICF). These domains are classified as bodily, individual, and societal perspectives in the ICF, respectively. In the ICF the 'functioning' refers to all body functions, activities, and participation, while disability is an umbrella term for impairments, activity limitations, and participation restrictions. The ICF also lists environmental (e.g. discrimination, policies) and personal (e.g. age) factors that interact with all these components.

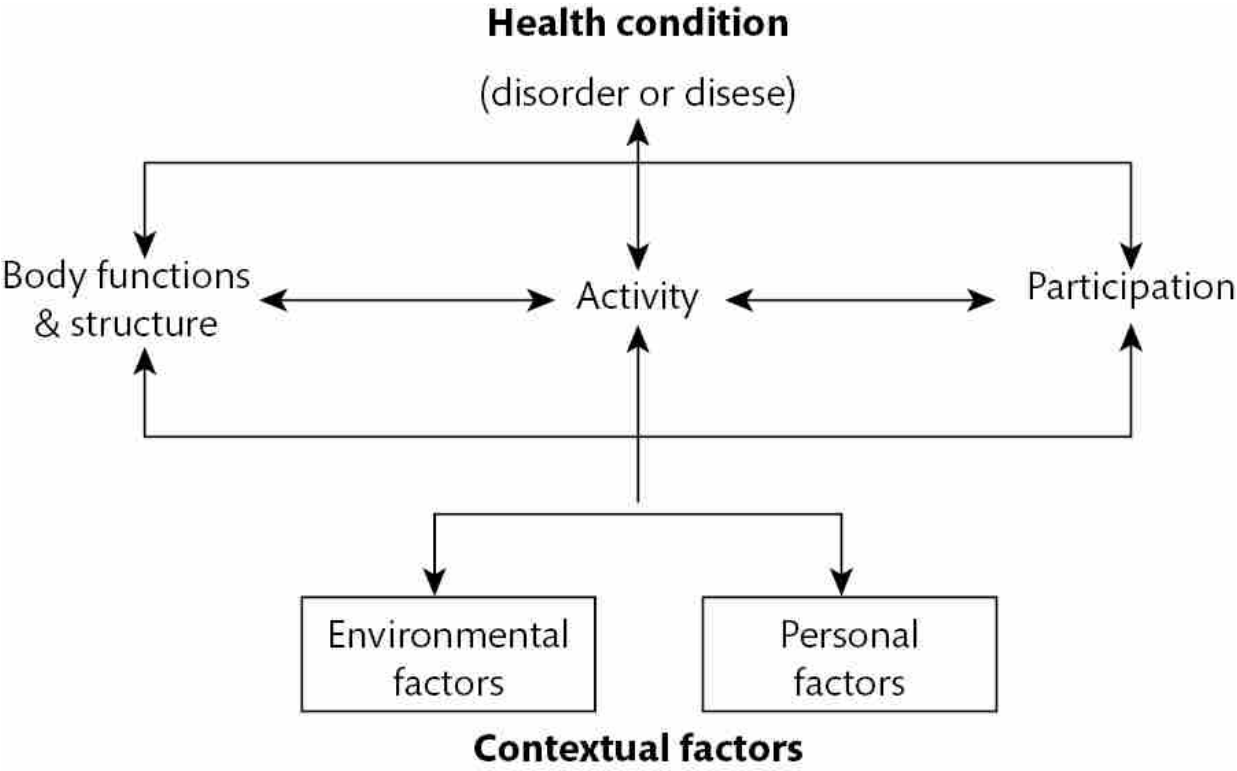

Fig. 10.7.1 Disability framework for the International Classification for Functioning.
WHO (2002) Towards a common language for functioning, disability, and health: The international classification of functioning, disability and health. Geneva: World Health Organization. p.9).

Measurement of disability

A recent scoping review of research using the ICF found that the ICF has been widely adopted in research and has led to better quality statistics on disability. Of particular note is the important role the ICF has played in monitoring community-based rehabilitation in low-resource settings and its use in policy and programme design and evaluation (e.g. education and social policy). Many countries have used the ICF in new surveys of disability, in particular conceptualizing the activity and participation domains of functioning. However, the authors of the review note that environmental factors have not been well conceptualized or measured (Madden and Bundy 2019).

Despite the widespread acceptance of ICF as a useful model for the collection of data on disability, it has been operationalized in many different

ways, resulting in challenges in the interpretation of disability statistics (Madans et al. 2015; Sabariego et al. 2015). For example, at an international level the Washington Group has developed a short and extended set of questions that can be used in censuses and surveys (see http://www.washingtongroup-disability.com/about/) (Madans et al. 2011; Madans and Loeb 2013). Over 30 countries have used the short set in their census, with the questions now globally endorsed for use in monitoring the Sustainable Development Goals. In parallel, the WHO developed the 'Model Disability Survey' (MDS). The MDS is considered a very comprehensive survey with approximately 320 questions and has been piloted in a small number of countries to allow for a more in-depth understanding of disability (WHO 2017a).

At a country level, a number of countries have developed instruments that broadly capture functioning in an ICF framework. For example, Ireland has developed a National Disability Survey which captures all elements of the ICF, including environmental factors which affect functioning, such as attitudes and flexible working arrangements (Kostanjsek et al. 2013). In Australia, the Australian Bureau of Statistics conducts a comprehensive survey of disability every three years—the Survey of Disability, Ageing, and Carers. This survey includes over 150 questions and provides a comprehensive picture of all aspects of the ICF. They have also produced a short module on disability which is used in a number of other surveys they administer (Harper 2010).

Prevalence of disability

Comparisons of different surveys designed to collect disability prevalence reveal markedly different prevalence estimates and have demonstrated that the concordance between surveys is poor (Mont 2007). For example, in Australia the prevalence of disability from the Survey of Disability, Ageing, and Carers was 18.3% compared to 6.7% when disability was measured using the Washington Group questions (Australian Bureau of Statistics 2016b). A Norwegian study investigated the prevalence of disability and the concordance based on eight different instruments applied to the same sample. They found that prevalence varied between 10 and 25% with instruments with more questions tending to yield higher estimates (Molden and Tossebro 2010).

The varying prevalence estimates, and the lack of comparability between the different instruments used to measure disability, presents major challenges for monitoring and evaluation. There is a need for methodological research that seeks to harmonize the different approaches so that disability is consistently captured.

Figure 10.7.2 shows the prevalence of disability across a selected range of countries that have measured disability using census or survey data. As discussed earlier, the Survey of Disability, and Carers in Australia yields a high prevalence of 18.5%. However, many other countries did not use such a comprehensive set of questions and prevalence was less than 2% in Togo, Iran, Philippines, and Nepal. These low prevalence estimates were ascertained through a single question on the country's census, which asked if the respondent or a person in the household had a disability, however the exact question varied between countries. For example, in Iran the respondent to the census was asked '*Is there anybody in the household with at least one of the following disabilities?*' with nine different disability types to select from. In Togo the respondent was asked for each household member '*Does [person] have a handicap?'* Until more consistent approaches to disability measurement are applied across countries it will be very difficult to make meaningful comparisons between countries.

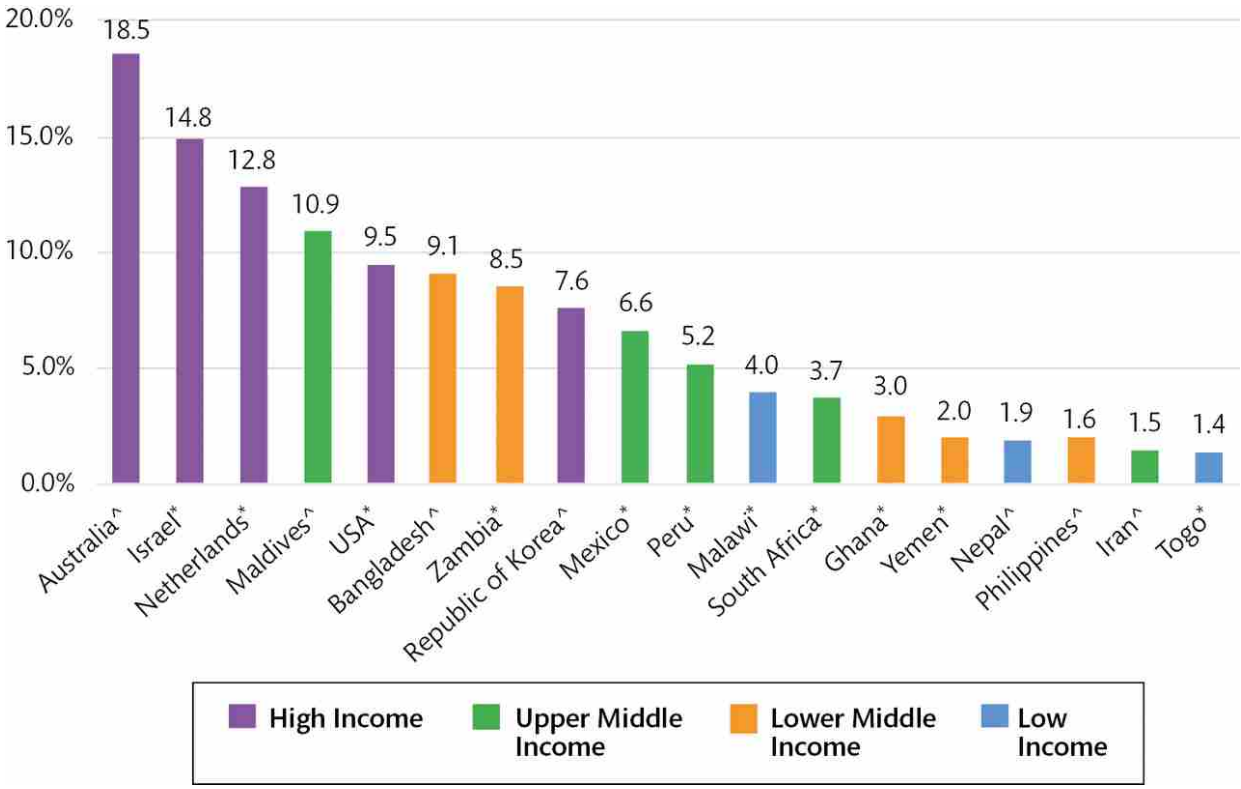

Fig. 10.7.2 International prevalence of disability across selected countries.

The health of people with disabilities

People with disabilities generally experience poorer physical and mental health outcomes and have a higher prevalence of health conditions than the general population. People with disabilities are often at higher risk of experiencing secondary health conditions, compounding existing health conditions and disability, as well as increasing the likelihood of experiencing comorbidities such as diabetes and other non-communicable diseases (WHO 2011).

While it is clear that people with disabilities experience poorer physical and mental health outcomes compared to people without disabilities, there is uncertainty as to the true prevalence of health conditions among people with disabilities due to poor-quality research and data. For example, a systematic review on the prevalence of diabetes among people with intellectual disabilities found that the prevalence ranged from 0.4% to 25% across studies from Europe, North America, New Zealand, Australia, China, and

Hong Kong (MacRae et al. 2015). Similarly, a systematic review of mental health conditions among people with intellectual disabilities found the prevalence ranged from between 14% to 75%, again underscoring the challenges in ascertaining true and comparable prevalence estimates (Buckles et al. 2013).

Despite concerns regarding prevalence measurement of particular conditions, people with disabilities consistently report poorer self-rated health and increased psychological distress. Over half of adults with severe or profound disabilities in Australia reported fair or poor health, compared to only 6% of people without disabilities. Prevalence of psychological distress was also elevated in this group, with 34% experiencing high or very high distress. Only 5% of the population without disabilities experience such high levels of distress, clearly indicating a disparity in mental health (Australian Institute of Health and Welfare 2016b). These findings were replicated in the United States, as researchers found the number of conditions people experienced was directly associated with increased feelings of psychological distress (Okoro et al. 2014). While these perceptions of health and well-being are important in their own right, poor psychological well-being is associated with a higher prevalence of physical health conditions among people with disabilities, such as coronary heart disease, diabetes, and hypertension (Okoro et al. 2014).

Health outcomes are also related to health seeking behaviour, which in turn is influenced by disability. In a population-based case-control study in Cameroon and India, people with disabilities were significantly more likely to report significant health problems compared to people without disabilities, yet delayed seeking healthcare. The researchers found that awareness of and access to rehabilitation services were extremely low among people with disabilities (Mactaggart et al. 2016).

Health outcomes among specific groups of people with disabilities

Health outcomes within population of people with disabilities can vary however, with some population groups experiencing poorer health outcomes than others, depending on the type of disability, severity of disability, and geographic and cultural context. Adults with severe or profound disabilities in Australia for example are over three times as likely to have three or more

health conditions, such as back problems, arthritis, and cardiovascular disease, as compared to people without disabilities (Australian Institute of Health and Welfare 2016b). Individuals with particular disability types, such as autism spectrum disorder (ASD), or intellectual disability, have also been shown to have poorer physical health outcomes relative to the general population. A review of international literature found people with ASD had elevated levels of cardiovascular risk factors and more multimorbidities compared to people without ASD (Cashin et al. 2018).

People with intellectual disabilities in Scotland were also more likely to have poorer physical health outcomes, with only 39% of individuals reporting no physical health conditions. Overall, people with intellectual disabilities had a higher prevalence of 14 conditions, such as epilepsy, visual impairment, and hearing loss, in comparison with the general population (Cooper et al. 2015). These comorbidities are likely to become even more prevalent as individuals with disabilities age, as shown by research from the Netherlands wherein 80% of adults with intellectual disabilities over the age of 50 reported two or more physical health conditions, compared to 56% of community-dwelling older adults without disabilities (Hermans and Evenhuis 2014).

As highlighted by a national survey of psychosis in Australia, people with psychosocial disabilities experience higher risk of diabetes, metabolic disorders, heart disease, and obesity. They also have a significantly elevated mortality rate from all these conditions, compared with the general population. Their health outcomes are also impacted upon by the side effects of medication, as well as higher prevalence of drug and alcohol misuse which may aggravate mental health conditions (Morgan et al. 2012; National Mental Health Consumer and Carer Forum 2011; Simonsen et al. 2013). Compounding this is the insufficient resourcing of most mental health systems, and the fact that health practitioners do not always have the skills or resources to address the co-occurring health needs of people with disabilities.

Not only are people with psychosocial disabilities more likely to experience the ill-effects of co-occurring health conditions, but people with other types of disabilities are disproportionately impacted by certain co-occurring mental health conditions. Approximately 40% of mothers with disabilities in the United States for example, experienced depression prior to their pregnancy, and nearly one-third of women with disabilities reported

symptoms of post-partum depression following birth, compared to 16% of women without disabilities (Mitra et al. 2015). Adults with intellectual disabilities in Scotland have a sevenfold increase in the odds of schizophrenia and are twice as likely to have anxiety. Fifteen percent of people with intellectual disabilities were found to have depression, compared to 10% of the general population (Cooper et al. 2015). More generally, half of people with severe or profound disabilities in Australia had at least one mental health condition, compared to 8% of individuals without disability or restrictive long-term health conditions (Australian Institute of Health and Welfare 2016b).

Increased likelihood of engaging in risky health behaviours

People with disabilities are more likely to engage in some risky health behaviours, which in turn, contribute to poor health outcomes. Important health behaviours impacting people with disabilities include tobacco use, alcohol and substance misuse, and physical inactivity.

Smoking

Internationally, people with disabilities have higher rates of tobacco use compared to the general population. Across all disability types in the United States, 40% of men and 38% of women with disabilities aged 18–49 were regular smokers, while only 21% of adults without disabilities smoked regularly (Courtney-Long et al. 2014). Patterns are similar in Australia, where 30% of adults with severe or profound disabilities smoke; twice that of the general population (Australian Institute of Health and Welfare 2016b). People with disabilities are also less likely to report trying to quit smoking. In the Republic of Korea for example, 55% of adults without disabilities who smoked regularly made a past-year quit attempt, while only 45% of individuals with disabilities did (Lee et al. 2014b). Less than 20% of people with mobility impairments in the United States attempted to quit in the last year, compared to 27% in the general population (Borrelli et al. 2014).

Alcohol use

By contrast, people with disabilities appear to consume less alcohol than the general population (Glazier and Kling 2013; Pinquart and Pfeiffer 2015;

Australian Institute of Health and Welfare 2016b; Mitra et al. 2016). However, people with disabilities have an increased use of other substances. In the United States, the prevalence of any substance misuse in the past month, including prescription or illicit drugs, binge alcohol, or habitual cigarette smoking, is 40% for people with disabilities, and 34% for people without disabilities.

Substance misuse

Individual with disabilities in the United States have higher odds for using substances such as heroin, oxycodone, sedatives, and methamphetamine (Glazier and Kling 2013). Research into substance misuse has been less indicative for people with specific disability types, such as intellectual disabilities. While evidence from the United States suggests the overall prevalence of substance misuse is low among people with intellectual disabilities, the risk of developing a substance-related problem is comparatively high (Carroll Chapman 2013). As lower cognitive function is associated with increased drop-out from treatment (Brorson et al. 2013), issues relating to substance abuse may be particularly challenging to measure and treat among people with intellectual disabilities, as well as other disability groups.

When asked about substance misuse and treatment, people with physical disabilities in the United States were less likely to have received helpful treatment for substance misuse issues, with 50% reporting useful treatment compared to 57% of the general population (Anderson et al. 2014).

Physical inactivity

Participation in physical activity is an additional key concern for people with disabilities, as many individuals have very limited support or opportunity to engage in physical activity. Across all people 15–64 years with severe or profound disabilities in Australia for example, 46% reported no past-year physical activity. By comparison, 31% of people without disability reported no physical exercise (Australian Institute of Health and Welfare 2016b). Similarly, 30% of adults with disabilities 20 years and older in the Republic of Korea did not participate in physical activity within the last year (Kim et al. 2015). Rates of physical activity are especially poor for people with particular types of disability, such as people with intellectual disabilities.

Only 9% of adults with intellectual disabilities met minimum physical activity guidelines, according to a recent systematic review (Dairo et al. 2016). This pattern extends to children with disabilities, who also have lower rates of physical activity. For example, 70% of children with disabilities in the Netherlands did not participate in organized sports, and 80% played sports either not at all, or for less than 1 hour per week (Neter et al. 2011).

Disability and the social determinants of health

So why are the health behaviours and outcomes of people with disabilities so much poorer than people without disabilities? This can be answered in part by exploring the social determinants of health for people with disabilities. As discussed, disability is not simply the result of a particular impairment or condition. Rather, the experience of disability is largely determined by society and the environment. The social determinants of health reflect this by illuminating external factors which impact the circumstances, opportunities, and perception of a particular person (Emerson et al. 2011). Social determinants, such as violence, poverty, education and employment, and stigma and discrimination are crucial in understanding the experiences and health outcomes of people with disabilities.

It is likewise imperative to understand the processes by which people with disabilities are excluded from health systems, including public health, to the detriment of their health, well-being, and disability. International research continues to highlight that people with disabilities experience ongoing inequalities in relation to socioeconomic status, employment, educational attainments, lack of access to accessible and appropriate housing and surrounding environments, and restricted access to services (Groce et al. 2011; WHO 2011; Byrne 2018). These inequalities play a major role in influencing health behaviours and outcomes for people with disabilities.

Emerson et al. (2011) offer a useful explanation of how the relationship between disability and the social determinants of health are often established at an early age and differ across the life course. For young children, the most relevant social determinants often relate to ‘material and psychosocial’ hazards (e.g. poor housing, poor diet, economic insecurity, family violence, stressful life events, lack of supportive relationships with adults). As children age, these social determinants may be exacerbated by the costs of caring for a child with disabilities. Adults with disabilities face exclusion

from the labour force which may exacerbate existing social and economic challenges. While the mechanisms for these associations are not fully understood, it is clear that children and adults with disabilities are at increased risk of exposure to poorer living and working conditions and greater economic insecurity, which are associated with poorer health outcomes (Emerson et al. 2011).

Poverty and disability

Globally, people with disabilities are more likely to live in poverty compared to people without disabilities, and the situation appears to be worsening. In the United States, the overall poverty rate has increased for all individuals, but most dramatically for people with disabilities. Twenty-five per cent of people with disabilities were in poverty in 1981, rising to 32% in 2014 (Brucker and Houtenville 2015).

The link between poverty and disability is also evident in low and middle-income countries (LMICs), where a systematic review found over 80% of included studies identified a positive relationship between disability and poverty. Notably, the severity of disability was associated with the severity of economic poverty. The authors found the observed relationship remained despite adjustment for age, gender, area of residence, and education. This trend was consistent throughout regions across the globe, impairment types, study designs, and age groups (Banks et al. 2017).

Poverty among people with disabilities in LMICs has persisted despite many countries making gains in addressing poverty more broadly. In Cambodia for example, the country has made significant progress in addressing poverty through sustained economic growth and the implementation of social protection programmes. Poverty rates have declined over the past decade from estimates of 47% of the population in 2007, to current estimates of 13.5% (National Institute of Statistics et al. 2015; World Bank 2018a; b). However, reductions in poverty are not equal across households with and without family members with disabilities.

This situation was highlighted in a study analysing the Cambodian Socio-Economic Survey data from 2009 to 2014 (National Institute of Statistics et al. 2015). Analysis found that the poverty rate among households with members with disabilities was 18%, compared to 13.6% for households without any members with disabilities. When the cost of disability incurred

by households was included in the analysis, the poverty rate for households with a member with disabilities increased to 34%. An additional 17% of household income was required in order to achieve the same standard of living as similar households without disabilities (Palmer et al. 2016). The limited household resources of families who have a family member with a disability make it more difficult to meet the costs of accessing services, such as health and education (UNESCAP 2015).

Poverty, health, and disability are clearly inter-related. In the UK, it has been found that the greater risk of exposure to socioeconomic disadvantage may constitute 20–50% of the risk of decreased physical and mental health among children with intellectual disabilities (Emerson et al. 2011). Similarly, a cross-sectional survey of English men and women with mild and moderate intellectual disabilities found that self-rated health was strongly associated with material hardship, with individuals who had experienced material hardship in the past year more likely to report 'not good health' (Emerson and Hatton 2008). Most high income countries have income support for people with disability who are unable to work however many low-to-middle-income countries do not have such a safety net putting people with disability at even higher risk of poverty and ill-health (WHO 2011).

Access to nutrition

People with disabilities, especially children, experience poorer nutritional status than people without disabilities. Malnutrition and disability are intimately linked—with malnutrition contributing to the risk of impairment, and children with disabilities thought to be more at risk of experiencing malnutrition. The risk of malnutrition is often assumed to be linked to difficulty with feeding, or that children with disabilities are more likely to be unwell which impacts on their ability to eat. While these are important factors, a study conducted in Kenya in 2013 found malnutrition was also related to neglect, lack of awareness of the need for greater nutritional intake that some children with disabilities have, and intentional underfeeding (Groce et al. 2014; International Centre for Evidence in Disability et al. 2014). Identifying malnutrition in children with disabilities can also be challenging given certain impairments may impact on physical growth. As such it can be difficult to accurately use traditional malnutrition assessments such as measuring the mid-upper arm circumference. This may hinder the

identification of malnutrition among children with disabilities and reduce the likelihood of timely and adequate treatment for malnutrition.

Possible outcomes of poor diet and malnutrition include poorer health outcomes, missing or delay in developmental milestones, acquiring avoidable secondary conditions, stunting and wasting, and preventable death (Groce et al. 2014; International Centre for Evidence in Disability et al. 2014). Researchers in Iran found that more than 40% of girls and boys with disabilities assessed were underweight, while stunting was present in 42% of children with disabilities in the study. Notably, only 6% of children without disabilities were underweight. Further, 90% of the children with disabilities did not receive adequate vitamins and minerals, such as iron and calcium (Neyestani et al. 2010). In the Netherlands, children with disabilities were less likely to have breakfast, and were four and a half times less likely to eat fruit on all weekdays (Neter et al. 2011). Children with intellectual disabilities in France were also found to have poorer diets, with nearly half consuming soft drinks with meals at school, compared to only a quarter of students without disabilities (Mikulovic et al. 2011). Young people with intellectual disabilities in Taiwan also had a poorer diet, eating fewer fresh fruits and vegetables than their peers without disabilities (Yen and Lin 2010).

Poorer diet and lower rates of physical activity contribute to the higher prevalence of obesity and being overweight observed among adults and children with disabilities, particularly in high income countries. Forty-five per cent (45%) of adults with upper or lower limb disabilities in the Republic of Korea for example are reported to be obese (Oh et al. 2012), and nearly 80% of adults aged 18–65 with intellectual disabilities in the United States are reported to be overweight or obese (Barnes et al. 2013). Among school children in Northern Ireland, 33% of students with intellectual disabilities were overweight or obese, compared to 24% of their peers without disabilities (Slevin et al. 2014). In the Netherlands, 31% of children with disabilities were overweight, compared to 10% of children without disabilities. The difference in the prevalence of obesity was likewise striking, as 11% of children with disabilities were obese, compared to only 2% of children without disabilities (Neter et al. 2011).

Exclusion from education and work

People with disabilities in both LMICs and high-income countries (HICs) experience many barriers to education and to gaining and maintaining work (Saleh and Bruyere 2018). In relation to education, these inequalities arise due to negative attitudes or low expectations of the benefits of education for children with disabilities, the absence of necessary adjustments and accommodations, and limited access to inclusive education. In terms of employment, low expectations about the capacity of people with disabilities within the workplace, restricted access to important career development opportunities such as training and skills development, insufficient support to gain and maintain work, and precarious engagement with labour market (e.g. underemployment, insecure employment, exploitation) are major barriers (Saleh and Bruyere 2018).

People with disabilities in Guatemala for example, expressed their frustration at the unattainability of education, a result of poverty, social invisibility and stigma, and structural barriers to access. Lack of education was perceived as a primary barrier to alleviating poverty (Grech 2014). Alternatively, evidence from Nepal, Bangladesh, Cambodia, and the Philippines suggest that longer years of education significantly increase the opportunity for people with disabilities to get a job and engage in full time, white collar jobs, reducing the risk of poverty, improving participation and access to better health (Lamichhane 2015).

From the employment statistics of people with disabilities in the United States, it is clear that barriers to employment are still present. Full time, full year employment for people with disabilities has decreased markedly over time, from 12% in 1981 to less than 6% in 2014. For those employed, median earnings are $10,000 USD less for people with disabilities (Brucker and Houtenville 2015).

Similarly, of the 18.3% or 4.2 million Australians living with disabilities, only 53.4% are currently in the labour force (e.g. employed or looking for work). This is compared to 83.2% of Australians without disabilities. The unemployment rate for Australians with disabilities is 10%, nearly double the rate of that for Australians without disabilities (5.3%) (Australian Bureau of Statistics 2016a). Stigma and discrimination are recognized as one of the major barriers to improving employment outcomes for Australians with disabilities (Australian Human Rights Commission 2016). When people with disabilities are employed, they are often in insecure work, have poorer working conditions, less perceived fairness of pay and are more likely to be

underemployed (LaMontagne et al. 2016; Milner et al. 2015; Milner et al. 2017).

Likewise in the UK, adults with intellectual disabilities are more likely to be in non-standard employment and experience job insecurity. They are also more likely to transition into economic inactivity from standard employment (Emerson et al. 2018). Stigma and structural barriers also constituted major barriers to employment in Brazil. People with disabilities who did gain employment were typically paid less and given less skilled work, as their abilities were persistently doubted (Toldra and Santos 2013).

Additionally, people with disabilities struggle to enter the workplace, as shown by a study of young people with disabilities in Canada. Overwhelmingly, young people with disabilities had significantly poorer work and job search experiences. Eighty-three per cent of young people with learning or memory impairments were refused an interview, and 63% of young adults with mobility impairments were denied workplace accommodations. 77% of young people with learning or memory impairments reported discrimination at work due to their disability (Lindsay 2011).

Using longitudinal data from the US, the authors found that a third of young people with ASD had attended college (34.7%) and just over half had been in paid employment within the first 6 years after high school (55.1%). Over half of youth with ASD who had left high school in the past two years had no participation in employment or education. The authors found that young people with ASD had the lowest rate of employment participation and the highest rates of no participation as compared to young people with other disabilities (Shattuck et al. 2012).

Housing and the surrounding environment

Accessible, affordable, and secure housing are key determinants of health (Australian Institute of Health and Welfare 2016a). Conversely, reduced access to safe and accessible housing disproportionately impacts on the social and health outcomes of people with disabilities (Beer and Faulkner 2009). Researchers from Victoria, Australia found that people with disabilities were substantially less likely to own a home and were much more likely to experience housing stress and live in rental accommodation than the general public. People with disabilities may be additionally

hampered in their access to safe and accessible housing due to restrictions imposed by availability of transportation systems and access to services. Housing that is safe, accessible, and close to transportation and services may require people with disabilities to move away from family and friends, thereby leading to isolation from support networks (Beer and Faulkner 2009).

Community living is known to be essential for social inclusion and a key element of quality of life. Deinstitutionalisation has continued to occur in most countries, but this has not been sufficiently replaced with resources to support independent living within the community for people with disabilities. As such, adequate housing within the community remains out of reach for many people with disabilities, particularly for people with intellectual and psychosocial disabilities (Siska et al. 2018).

The surrounding environment to where people live and work is also important. A qualitative survey of adults with a variety of different disabilities and functional limitations in the US analysed the environmental factors influencing participation at the individual community, and societal levels. The eight major categories of factors were: built environment, natural environment, transportation, assistive technology, IT access, social support and societal attitudes, systems and policies, and economic environment. Particularly poignant was one participant's description of the immense process and organization that facilitates participation, wherein having physical access (such as a ramp) is not enough when one must consider the weather, if the personal assistant will come, if sidewalks and ramps are clear outdoors, and if transportation will arrive. This work highlights the interconnected nature of environmental barriers on health and participation. Individuals expressed a desire to work but were concerned that they would lose their disability pension, and if they lost their job, they would have no income at all. Individuals discussed challenges with negative, disabling societal attitudes, and of the importance of social facilitators such as a supportive family. The researchers emphasize that barriers can, and must, be addressed at the societal, community, and individual levels in order to positively influence participation (Hammel et al. 2015).

Violence

Globally, people with disabilities are disproportionately affected by violence. Despite this, violence prevention and response programmes all too often have neglected the needs or excluded people with disabilities, or do not understand how to accommodate or respond to the people with disabilities who have experienced violence (Devine et al. 2017). Twenty-eight per cent of people with disabilities in the United States have experienced intimate partner violence (Mitra and Mouradian 2014), and evidence from a systematic review of violence found people with disabilities were 50% more likely to experience violence compared to people without disabilities (Hughes et al. 2012). One-quarter of people with mental illness have experienced recent physical, sexual, or intimate partner violence (Hughes et al. 2012).

Women with disabilities are particularly at risk. In Australia, women with disabilities have a twofold increase in the odds of experiencing physical violence, intimate partner violence, emotional abuse, and stalking and harassment compared to women without disabilities (Krnjacki et al. 2016). In the United States, women with disabilities were fourfold as likely to experience rape and threefold as likely to experience other sexual violence as compared to women without disabilities (Breiding and Armour 2015).

Violence against people with disabilities is similarly prevalent in lower income countries. Eighty-four per cent of women with disabilities involved in a survey of disability and violence in Bangladesh had experienced at least one act of violence or abuse (Hasan et al. 2014). These experiences were echoed in Nepal and Cambodia, where nearly 60% of women with disabilities had ever experienced violence (Astbury and Walji 2014; Puri et al. 2015). Despite the alarmingly high prevalence of violence towards people with disabilities, especially women, a recent evaluation of interventions found that there is currently no clear evidence on the type of approaches that work to reduce violence (Mikton et al. 2014).

Stigma and discrimination

Stigma and discrimination play a key role in all the barriers encountered by people with disabilities. The negative attitudes of society at large exclude people with disabilities from education, employment, and healthcare, as shown throughout this chapter. Stigma deprives people with disabilities of their independence and rights, as discussed by individuals in a study from

Croatia, who typically have little say in their education, employment, or sexual and reproductive health (Buljevac et al. 2012). Negative attitudes have also been found to be the major barrier for people with disabilities in the Philippines to participate in work, community meetings and social activities (Marella et al. 2016). Stigma also contributes to neglect and exclusion, such as in the Solomon Islands, where children with disabilities are seen as a punishment for violating a taboo (Gartrell et al. 2018).

Stigma and exclusion trap people with disabilities in poverty (Grech 2014; Trani et al. 2015). For example, a study on people with severe mental illness in India highlights this 'negative feedback loop' wherein individuals with severe mental illness face stigma, especially for individuals from lower castes. This stigma, combined with the educational and employment limitations imposed on people from lower castes, feeds persistent poverty, decreases social involvement and self-esteem, and poses additional responsibilities on carers, further contributing to stigma and discrimination (Trani et al. 2015).

In summary, while public health action is needed across a multitude of health-related areas, eliminating the disparities in the social determinants and resultant health of people with disabilities can only be done through addressing stigma, prejudice, and discrimination and the subsequent exclusion experienced by people with disabilities.

Inclusion of people with disabilities within public health

The number of people living with disabilities is likely to increase in both LMIC and HIC over time due to communicable and non-communicable diseases; road traffic accidents and injuries; longer life expectancies/ageing; conflict; natural disasters; and growing socioeconomic inequities experienced in many countries (Marmot et al. 2010; WHO 2011; Mannan and MacLachlan 2013; Krahn et al. 2015; Durham et al. 2016). Exclusion from public health interventions, combined with the greater unmet health needs and barriers to health services of an increasing number of people with disabilities, will lead to poorer health outcomes at an individual and population level (Durham et al. 2016; Marella et al. 2016). This highlights the urgent need for public health and health systems more broadly to ensure people with disabilities are better included in and benefit from all aspects of public health.

This will require both disability-specific initiatives and disability-inclusive programmes. Disability-specific initiatives are designed to target people with disabilities directly, for example capacity development for people with disabilities to better understand the risks of certain health behaviours, promoting access to physical activity and recreation for people with disabilities, or, providing outreach screening programmes for people with disabilities who are not able to travel to health services. Disability-inclusive programmes are mainstream activities designed to ensure that they are accessible to people with disabilities and that they benefit people with and without disabilities equally (Kleinitz et al. 2011; Piatta and Guy 2010). Examples include health promotion messaging designed to include representation of people with disabilities which is accessible in a range of communication formats (e.g. Braille, easy-to-understand) (Piatta and Guy 2010; Kleinitz et al. 2011). Even with appropriate messaging, people with disabilities may experience additional barriers to making healthy choices due to issues such as mobility (e.g. unable to access parks, public transport, shops), difficulty to reading information (e.g. food labels) due to vision or cognitive impairments and community attitudes towards people with disabilities accessing resources in their community.

It also requires barriers to all aspects of public health and health systems experienced by people with disabilities to be identified and addressed. The section to follow focuses on key components of public health, outlining some of the barriers experienced by people with disabilities, as well as examples of how these barriers can be addressed.

Health promotion and prevention

Disease prevention, including screening for cancer and immunization, are crucial components of primary healthcare for all people. However, people with disabilities do not always receive disease prevention services to the same extent individuals without disabilities do. Access to disease prevention, especially screening, is often difficult, particularly for women with disabilities. Costs for screening may not be available through universal healthcare and costs may be prohibitive. Women with disabilities frequently report that medical professionals do not understand their disabilities, putting women in a position where they must explain themselves and advocate for their own care (Ramjan et al. 2016). Disability-specific information is

typically unavailable for screening processes, (Angus et al. 2012) and most healthcare providers report they need substantial additional training in order to provide adequate preventive care for people with disabilities (Merten et al. 2015).

Data from a national health survey in the United States revealed that women with disabilities are less likely to be up-to-date with cervical and breast cancer screening. Only two-thirds of women with mobility impairments were estimated to have received a Pap test within the previous three years, and 61% of women with cognitive limitations received a mammogram within the last two years. By comparison, 81% of women without disabilities had an up-to-date Pap test, and 73% had had a recent mammogram (Steele et al. 2017). Women in the United States with more complex, and more severe, disabilities are consistently less likely to be up-to-date with cancer screening (Horner-Johnson et al. 2014).

While breast and cervical cancer screening rates among women with disabilities are still lower than those of women without disabilities, there is some evidence for the effectiveness of educational programmes in increasing cancer screening rates among women with disabilities. *Women Be Healthy 2*, an educational programme about mammography and Pap tests, was appropriate for women with disabilities as materials were created to be hands-on, multimodal, and accessible to people with low literacy (Swaine et al. 2014). Similarly, a DVD about mammography preparedness for women with intellectual disabilities starred an actress with intellectual disability confidently navigating her first mammography appointment (Greenwood et al. 2014). Both programmes showed increases in cancer screening knowledge among participants. Despite small sample sizes, these programmes suggest that appropriate educational and support resources can help women with disabilities increase their knowledge of, and ability to access, cancer screening. For another example of disability-inclusive screening programmes, see the Case Study 10.7.1 next.

Encouraging research from the United States on colorectal cancer screening suggests similar rates of testing between people with and without disabilities, and that where disparities exist, people with disabilities are actually screened more (Iezzoni et al. 2016). While the exact explanation for good uptake of colorectal cancer screening among people with disabilities are unclear, increased contact with physicians, who may follow-up to ensure screening is completed, may be an important driver of this trend.

CASE STUDY 10.7.1 Just checking: increasing cancer screening for people with disabilities

While people with disabilities have generally lower cancer screening rates, the literature indicates mixed outcomes regarding immunization rates. Older people with disabilities in the United States were more likely to have received a flu vaccine in the past year and a pneumonia vaccine than their peers without disabilities (Pharr and Bungum 2012). Researchers in remote Ecuador found that children with disabilities were immunized at rates comparable with their siblings without disability, highlighting the effectiveness of the national immunization programme and importance of positive cultural attitudes towards disability (Groce et al. 2007). The relative ease of giving vaccinations, which typically do not require special equipment, may positively influence vaccination rates. However, some groups of people with disabilities, such as individuals with intellectual disabilities, may have vaccination rates lower than the general population. Data from Taiwan has shown that teenagers with intellectual disabilities were vaccinated against Hepatitis B at lower rates than the general population (Yen and Lin 2011). Young people with intellectual disabilities in Taiwan were also less likely to have received a flu vaccine than older people and very young children, although individuals with moderate and severe intellectual disabilities were more likely to have received the vaccine than individuals with mild intellectual disabilities (Yen et al. 2012; CDC 2010 cited in Yen et al. 2012). This suggests that although regular contact with the medical system may positively influence vaccination rates, people with disabilities do not consistently receive the same level of immunization as the general population.

Despite these factors, people with disabilities may be less likely to receive vaccinations associated with sensitive issues, such as sex and sexuality. Providers of the human papilloma virus (HPV) vaccination in the United States reported the main reason children with disabilities were not vaccinated was due to parental refusal (Cody and Lerand 2013). As such, immunization rates may differ between people with and without disabilities depending on the acceptability of particular vaccinations and (mis)perceptions about the relevance for people with disabilities. Identifying barriers to HPV vaccination among people with disabilities is critical and strategies to improve uptake of HPV need to be developed.

Health promotion is an area which requires significant new research and investment to improve diet, increase physical activity and reduce smoking rates. Despite the higher prevalence of smoking among people with disabilities, there are few programmes and little literature on successful tobacco cessation approaches and programmes, contributing to the decreased rate of quit attempts by people with disabilities. It is clear, however, that people with disabilities have a desire to quit: nearly 90% of people with mobility impairments in a study from the United States planned to quit within six months (Borrelli et al. 2013).

Some initial evidence from small tobacco cessation programmes in the United States emphasizes the importance of tailoring programmes to people with disabilities, through disability-specific examples and discussion of disability-relevant issues, such as the interaction between nicotine replacement therapy and medication (Pomeranz 2014; King et al. 2016). While these suggestions provide a foundation for creating effective cessation programmes, it is obvious people with disabilities are underserved in this area.

A recent review of intervention research focused on improving physical activity levels found that research in this area is increasing. Interventions were predominantly individually focused on behaviour change with mean incorporating technologies (e.g. information and interactive technologies). Most studies showed positive outcomes however 60% of studies were of groups were multiple sclerosis (41%), stroke (15%), and spinal cord injury (12%) limiting the generalisability of findings (Lai et al. 2017). Further research is needed with people with other types of disability.

Research should also concentrate on how population-based interventions in the general population can be adapted to be more appropriate and relevant to people with disability.

Access to health services

Access to healthcare services is a substantial issue for people with disabilities across the globe. The poorer physical and mental health outcomes of people with disabilities, as well as poorer health behaviours and discrepancies in disease prevention services, are related to barriers to health services. While the experiences and health of people with disabilities may vary widely across countries, issues of transport, lack and/or inaccessible health facilities and equipment (including toilets), discrimination by health workers, and cost of services and travelling to services are routinely reported as major barriers. Similarly, lack of knowledge on when, where and how to access health services, and inaccessible information and health messaging compound these barriers (MacLachlan et al. 2011; Kleinitz et al. 2012; Van Rooy et al. 2012; Vaughan et al. 2016).

Research from various contexts demonstrates these barriers. Nearly 15% of people with disabilities in the Republic of Korea for example reported difficulty accessing healthcare in the preceding year, with approximately 60% citing cost as their primary barrier to care (Lee et al. 2014a). Qualitative work in Namibia found cost was also a significant barrier to care for people with disabilities, although interviewees cited transport as the main barrier. Nearly 90% of respondents with disabilities reported walking, sometimes hours, to healthcare centres due to prohibitively expensive transport fees. For those who were able to reach the clinics, additional obstacles to care included language differences, a shortage of healthcare workers, and inaccessible facilities (Van Rooy et al. 2012).

Further qualitative work in Sudan, Namibia, Malawi, and South Africa reinforced these barriers, and respondents discussed problems with inaccessible equipment and poor availability of services (Eide et al. 2015). Children with disabilities and their parent carers in rural and remote Australia reported similar challenges in accessibility of health services due to long travel times and lack of services (Dew et al. 2013).

In addition to these barriers to general medical care, individuals often face further difficulties to effective sexual and reproductive care. Often policies and strategies do not recognize the unique needs of males and females with

disabilities and community perceptions may hold that people with disabilities are asexual or hypersexual. In Ghana, men and women with disabilities are typically grouped together as a homogenous group, despite differences in needs. The use of derogatory language, like 'idiot', when describing men and women with disabilities was found to further contribute to stigma and control over their sexual and reproductive health needs (Mprah et al. 2014).

Stigmatizing attitudes may also prohibit people with disabilities from having access to information about sexual health and reproduction, as was reported by people with physical disabilities in Vietnam (Nguyen et al. 2018). These negative attitudes, and the ubiquitous belief that sexuality and reproduction are taboo for people with disabilities can be further seen in a study of access to services in Uganda. Women with disabilities reported extreme stigma surrounding their pregnancy and sexuality due to their disabilities. Male partners with disabilities described total exclusion from the pregnancy and childbirth, as they were offered no assistance to reach antenatal and birthing wards on upper floors of the hospital (Ahumuza et al. 2014).

Pregnant women in higher income countries, such as the United States, still face humiliation and embarrassment in the doctor's office, such as when being transferred to inaccessible equipment, such as examination tables that cannot be adjusted for height (Iezzoni et al. 2015). For a case study on an effective sexual and reproductive health programme for women with disabilities, please refer to Case Study 10.7.2.

CASE STUDY 10.7.2 Promoting inclusive public health programmes

Women with Disability taking Action on REproductive and sexual health—W-DARE project

Compounding disability and gender based discrimination often mean that women with disabilities experience exclusion from the socioeconomic and political lives of their communities. Similarly, women with disabilities face barriers to accessing public health programmes such as health information, screening, prevention, and care services, as well as violence prevention and response programmes. As a result, women with disabilities experience poorer health outcomes across their life cycle when compared to women without disabilities, including in relation to sexual and reproductive health (SRH) and violence (MacLachlan and Swartz 2009; Lee et al. 2015; Vaughan et al. 2015; Marella et al. 2016; Vaughan et al. 2016; Devine et al. 2017).

Limited data, particularly from LMIC, on the prevalence of disability and the lived experience of women with disabilities in relation to their health and access to programmes, also makes it difficult

to plan and resource disability-inclusive public health programmes. The W-DARE project in the Philippines is one of the few examples of inclusive action research that has been undertaken to increase demand for and supply of quality SRH services and information for women with disabilities.

W-DARE was a 3-year project conducted by the University of Melbourne in Australia and De La Salle University in the Philippines, in collaboration with the Likhaan Center for Women's Health; Center for Women's Studies Foundation at the University of the Philippines; and two national disabled people's organizations (DPOs)—WOWLEAP (Women with disabilities Leap social and economic progress) and PARE (Persons with disability Advocating for Rights and Empowerment). Women with disabilities were resourced as co-researchers across the project, ensuring their lived experience informed the design, implementation, and evaluation of the project (Vaughan et al. 2015).

Key findings from phase one of the research highlighted women with disabilities reported poorer well-being when compared to women without disabilities, and were more likely to report reduced access to health services, work, education, and social activities. Barriers to inclusion reported included cost of services, lack of information about services, and difficulty getting to health facilities. Levels of SRH knowledge were generally low, especially among women who are Deaf or hard of hearing and women with intellectual disabilities. Specific barriers to SRH services reported by women with disabilities included discrimination; limited capacity of service providers; inaccessible transport; economic barriers; and difficulty accessing sign language interpreters. Reports of violence and abuse against women with disabilities were common. What was also evident was the resilience of many of the women with disabilities interviewed.

In response, the W-DARE team developed and implemented a number of interventions aimed at promoting access to quality SRH programmes. Demand side interventions included peer-facilitated Participatory Action Groups for women with disabilities to enhance knowledge and demand for SRH services and develop networks of peer support. Supply side interventions included workshops for service providers to increase awareness of the needs and rights of women with disabilities; collaboration with the Department of Health to increase disability inclusion in primary healthcare settings; project partner exchange visits to share experiences of disability inclusiveness within local health and development programmes; and, working with violence prevention and response services to strengthen disability inclusion including through referral practices. Recognition that sustained change requires a major shift in society's perception of disability, led to the production of a number of social media videos of women with disabilities talking about their lives and their rights.

The W-DARE interventions led to positive outcomes for women with disabilities and highlighted that increased access to information on rights and disability inclusion for both women with disabilities and service providers; enhanced social networks and opportunities for social inclusion for women with disabilities; and consumer participation in the design of more inclusive health services, are essential for upholding the right to SRH for women with disabilities.

For the W-DARE project to have a sustained impact however, it is vital address systemic barriers to participation in all other life domains experienced by women with disabilities such as education, employment and general health programmes are addressed This will require governments, service providers, DPOs, public health and development programmers to work collaboratively with women with disabilities to identify context-specific barriers and solutions to promote inclusion of people with disabilities within their communities.

Health-related rehabilitation

While not relevant for all people with disabilities, health-related rehabilitation is not only an important right articulated in the CRPD, but recognized as a key component of Primary Health Care and a critical part of

the broader health system (Pryor et al. 2017; Bezmez et al. 2018). However, many people with disabilities, particularly those living in LMICs, have limited access to health-related rehabilitation services, resulting in unmet health and rehabilitation needs, reduced social and economic participation, and reduced quality of life (Gargett et al. 2016; Pryor et al. 2017; WHO 2017b).

Similar to broader health services, individual level barriers to rehabilitation services in LMICs include difficulty travelling long distances to services when roads and transport are often inaccessible or unaffordable and services are mainly located in urban areas, such as was identified by Gargett et al. in their review of rehabilitation workforce needs in the Pacific (Gargett et al. 2016); the prohibitive cost of rehabilitation services and assistive devices as identified by Palmer et al. in their study of the economic challenges experienced by people with disabilities in Vietnam (Palmer et al. 2015); and lack of knowledge on when, where, and how to access rehabilitation services, such as highlighted by Mactaggart in their study of access to health and rehabilitation services in Cameroon and India (Mactaggart et al. 2016).

At a systems level, access to rehabilitation is hampered by the neglect of rehabilitation within broader health systems strengthening efforts (Pryor et al. 2017); lack of rehabilitation specialists within an already limited pool of health workers who can respond to the rehabilitation needs of people with disabilities (Gargett et al. 2016); limited inclusion of measures of disability and rehabilitation within Health information Systems in many low- and middle-income countries (McPherson et al. 2017); and extensive gaps within referral processes across and within health systems (WHO 2017b).

As like all public health interventions that aim to improve the capacity to meet the needs of people with disabilities, health-related rehabilitation services need to actively and respectfully involve people with disabilities in all aspects of decision making and service delivery; and, ensure a holistic understanding of rehabilitation that responds to the complex needs of individuals (Bezmez et al. 2018).

Health information systems and data transparency for monitoring and evaluation

There is still a need for greater context-specific information on the lived experience of people with disabilities in relation to their health and inclusion within the public health sphere (Vaughan et al. 2016). Very few health systems in LMIC and HIC collect information on people with disabilities and their access to health. For example, a study of health information systems in Lao found indicators related to disability or functioning were not included, and overall health data was often incomplete, inaccurate or poorly used (Durham et al. 2016). This makes it difficult to monitor progress in access or health outcomes. Enhancing the focus on disability within public health could provide an opportunity to strengthen health information systems (Durham et al. 2016).

Similar to the issue of measurement of disability more broadly, this requires an accepted definition of disability and standard measure of disability that health information systems can readily and affordably adopt. As highlighted earlier, better disability measures within population and health surveys are also required to better monitor health behaviours, health outcomes, access to health and impact of disability on other key domains such as education and employment (Durham et al. 2016). In Australia the Australian Institute of Health and Welfare have developed a set of questions that can be routinely implemented in administrative data (such as primary care and hospitals). It is hoped in the future that the implementation of these questions will enable enhanced monitoring and evaluation of health service use for people with disabilities (Australian Institute of Health and Welfare 2016c).

Disability services and supports

Disability services and supports (both within and external to health systems) for people with disabilities are critical for health and well-being. Services and supports include personal assistance with self-care (e.g. dressing, eating, showering) as well as support to participate in the community and paid and unpaid work. Access to therapeutic supports such as speech therapy is also critical to enabling people with disabilities to attain their potential. Basic supports such as hearing aids and wheelchairs are also critical for full participation in society. New technologies such as robots (van den Heuvel et al. 2017), IT assisted technologies including smartphone apps (Mavrou et al. 2017), and technological innovation in assisted and augmented

communication (Miksztai-Rethey and Farago 2018) hold considerable promise for improving participation and access to health. In all settings, including education, workplaces, and health services, reasonable adjustments and accommodations are critical to enable people with disabilities to access and participate. This can range from ramps and lifts to improve the physical accessibility, to flexible working conditions, such as working from home. Further, ensuring the development, implementation and monitoring of workplace disability strategies (including mental health) will not only promote healthier workplaces, but will promote better understanding of the importance of inclusion (International Labour Office et al. 2014).

Internationally, disability services are often underfunded and poorly resourced with considerable inequities in access to services. Approaches to the funding and delivery of services vary widely. Given the barriers that many people with disabilities experience in accessing mainstream services, one of the most important approaches to improving health and social outcomes in LMIC is community-based rehabilitation (CBR). CBR is a multisectoral approach to improve the equalization of opportunities for, and social inclusion of, persons with disabilities. CBR is implemented through the combined efforts of people with disabilities, their families and communities, and relevant government and non-government health, education, vocational, social, and other sectors (WHO 2010).

In Cambodia for example, a number of non-government organizations have been working with communities in rural and remote areas to improve understanding of disability, promote early identification, and, develop locally based approaches to support people with disabilities and their families to address impairment related conditions (i.e. through training families on appropriate rehabilitation techniques and exercises that they can do with their family members with disabilities), and, working with local authorities and other stakeholders to promote community inclusion (i.e. promoting access to local schools). The government of Cambodia has been working with these organizations to develop National CBR guidelines. As with many countries of all income levels, sustainable financial and human resources is an ongoing challenge (Bailey and Nguon 2014).

A review of disability services in Australia by the Productivity Commission found that services were ‘inequitable, underfunded, fragmented, and inefficient and give people with disabilities little choice’. The Commission recommended a doubling of funding and significant

changes to how services were provided (Productivity Commission 2011). This led to the introduction of the National Disability Insurance Scheme which provides individuals with disability-individual budgets and they can purchase the services and support they need. See Case Study 10.7.3.

CASE STUDY 10.7.3 Australia's National Disability Insurance Schemes

Prior to the introduction of the National Disability Insurance Scheme (NDIS) in Australia, the disability services were delivered by state and territory government and access, quality and coverage varied significantly between states. Funding was provided by the federal government to the states and territories to fund disability services but the delivery of services was a state or territory responsibility. This meant that service access varied according to what state people lived in and whether they lived in cities or rural and remote areas and there was no guarantee of long-term security of funding. People also had little choice of the services they were provided.

The Productivity Commission of Australia was tasked with reviewing the current disability service system and to consider alternative models of delivery. In particular they considered the implementation of personalized budgets, such as introduced in the United Kingdom, where people with disabilities and their families and carers are provided with individual budgets, depending on their particular support needs, to buy the services and supports they need (Needham and Dickinson 2017). The Commission also recommended the adoption of an insurance approach whereby people with disability are assured of funding to cover the lifetime costs of their disability. The Productivity Commission recommended the implementation of the National Disability Insurance Scheme and a doubling of funding to the disability service sector (Productivity Commission 2011).

The Productivity Commission recommended that the NDIS include three tiers of support.

Tier 1 provides insurance (i.e. guaranteed support) for all Australians who acquire a significant disability. Tier 1 was also designed to promote opportunities for people with disability to participate in the community.

Tier 2 included anyone with a disability and their primary carers (estimated by the Productivity Commission at around 4.8 million people). Tier 2 involves working with mainstream services, provided information and referral services.

Tier 3 involves the provision of long-term care and support, through individualized funding packages, to people with a significant and ongoing disability and who were less than 65 years of age and Australian citizens or residents. At the time of Commission's report this was estimated be around 410,000 people, about ten percent of the disabled population. To be eligible for Tier 3 support the disability needs to be permanent as well as associated with 'significantly reduced functioning in self-care, communication, mobility or self-management and require significant ongoing support' and/or be assessed as belonging to a group 'for whom there was good evidence that [early] intervention would be safe, significantly improve outcomes and would be cost-effective'. To be eligible for packages individuals are assessed to identify their goals and needs, are provided with certainty of funding based on needed and have choice over the services and supports they purchase (Productivity Commission 2011). The services and support were to be provided by a range of not-for-profit, governmental, and private organizations.

The NDIS reform received strong support from both major political parties as well as State and Territory governments. It was implemented in four trial sites across Australia from 1 July 2013, with

another three sites commencing on 1 July 2014. It began full roll-out across Australian in July 2016 with full roll-out due to be completed in 2019/2020 (Buckmaster and Clark 2018).

The NDIS is the largest social policy reform implemented in Australia since the introduction of Medicare—the universal health scheme. It has faced a number of significant implementation issues including clarity around eligibility for individualized services and supports particularly for people with psychosocial disabilities, ICT issues, lack of services for people with disabilities to choose from ('market failure'), problems with the processes of planning with participants and difficulties faced by individual's navigating the complexities of the new system. There are also concerns related to the different capacities of individuals to negotiate and navigate such a complex system resulting in significant inequities in funding packages (Carey et al. 2017). A further tension is in the role of governments from 'light touch' 'market regulation', where government identifies fraudulent practices and sets some minimum standards, to 'market stewardship', where government plays an active role in supporting innovation, stimulating markets particularly where there are shortages, and ensuring equity and choice and control. While it is clear that there are gaps in the NDIS in terms of access to services for people with different types of disability or people regional and remote Australia, partly driven by lack of financial sustainability, the role of government in supporting markets to develop in these areas is underdeveloped with the potential for considerable inequities to arise (Carey et al. 2017; Carey et al. 2018).

The initial evaluation of the scheme showed that participants were generally satisfied (Mavromaras et al. 2018) however it will be many years before we know just how well Australia's bold reforms in the funding and delivery of disability services delivers on its aspirations.

Public health research and disability

To date, research on the health of people with disabilities has been sparse, however it is clear that public health research could do much to advance the evidence-base about the health of people with disabilities as well as identify evidence-based interventions and strategies to improve their health. For example, public health researchers could advance the measurement and reporting of disability-related information, the development of interventions and programmes to address health disadvantage (e.g. targeted tobacco cessation programmes) and policy analysis. Importantly this research needs to be conducted from multiple disciplinary perspectives and employ both qualitative and quantitative methods. It is also critical that people with disabilities are central to all research conducted and at the core of solutions to problems identified. Best practice in this area involves co-design of research projects where people with disabilities are appropriately resourced to conduct the research.

The W-DARE project, presented earlier, is an example of co-designed research. As such, women with disabilities were resourced as co-researchers to work alongside researchers without disabilities at all stages of the project. This included initial two-way capacity development, design and

implementation of all stages of the research, ongoing training of health workers and other women with disabilities on attaining the rights to sexual and reproductive health, analysis of data, and presentation of findings. Not only did this ensure the research benefit from insider knowledge of the lived experience of women with disabilities in the Philippines, but it also demonstrated the capabilities of women with disabilities as central to research that is about them (Vaughan et al. 2015).

The Centre for Research Excellence in Disability and Health is example of a multidisciplinary programme of research on the health of people with disabilities that draws on the disability sector to drive its research priorities and dissemination activities. See Case Study 10.7.4.

CASE STUDY 10.7.4 National Health and Medical Research Council, Centre for Research Excellence in Disability and Health

The Centre of Research Excellence (CRE) in Disability and Health ((http://credh.org.au/) is funded by Australia's National Health and Medical Research Council. It is a world first; it aims to gather the evidence needed to guide social and health policy reform in Australia.

The CRE brings together an interdisciplinary group of researchers with stakeholders from the health and disability sectors, state and federal governments, and disability consumer representative groups—who are embedded in the research design and development. In collaboration with people with disabilities, service providers, non-government organizations and other stakeholders, the CRE will identify *the key and emerging issues affecting Australians with disabilities*. The research is designed to respond to the priorities identified by stakeholders in the disability sector.

The research involves four work programmes:

1. Mapping the spatial distribution of social, economic, and health inequities between people with and without disabilities
2. The application of cutting-edge epidemiological methods to establish the main social determinants of health of people with disability
3. The construction of the first ever cost-effectiveness model to estimate the health impacts and value for money of policy interventions for people with disabilities
4. An innovative policy lab where stakeholders are embedded in the research process where they are interviewed throughout the life of the CRE, given the opportunity to reflect on others' input and respond to the findings of the other three work programmes.

The CRE-DH is also engaged in developing a skilled research workforce in disability and health by training new early-career researchers and PhD students as well as building the research capacity of academics and policymakers across sectors to respond to the pressing problem of people with disabilities' poor health.

Conclusion and ways forward

In this chapter we have shown that while the evidence-base on the health of people with disability is incomplete, there is enough evidence to conclude that people with disabilities have poorer mental and physical health, on average, than non-disabled people. These poorer health outcomes are in part due to the underlying health conditions but are also a result of socioeconomic disadvantage, higher levels of health damaging behaviours, poorly targeted health promotion, and preventive healthcare, lack of access to quality health, disability and rehabilitation services, and higher exposure to discrimination, stigma, and violence.

Turning around the health disadvantage for people with disabilities requires population-based and targeted approaches that address the specific circumstances of people with disabilities. As one of the leading researchers into the social determinants of health highlights: '*To reduce the steepness of the social gradient in health, actions must be universal, but with a scale and intensity that is proportionate to the level of disadvantage.*' (Marmot et al. 2010). It can therefore be argued that people with disabilities have a greater need for all public health functions (e.g. immunizations, support for healthy behaviours) and it is time for public health researchers, policymakers and practitioners to address the exclusion of people with disabilities within public health and the broader health system (United Nations 2006; WHO 2011; Mannan and MacLachlan 2013; Krahn et al. 2015).

Public health approaches to improving the health of people with disabilities requires a social determinants approach to primary prevention, health promotion and support for healthy lifestyles, through to care and rehabilitation for those who experience health conditions and/or disability. Public health approaches must also consider social protection and welfare programmes which aim to reduce poverty and more effective interventions that promote the social and economic participation of people with disabilities (Skempes and Bickenbach 2015; Carey 2016).

Health and rehabilitation system strengthening is required to improve health outcomes of people with disabilities. Systems strengthening must have good governance; coherent and explicit policies which articulate and resource for targeted programmes for people with disabilities; appropriate resourcing to implement inclusive policies and programmes; better coordination of care and referral process throughout health and rehabilitation

systems; reduce the current gap in public health human resources for health that can support coordination of care as well as provide services that meet the needs of people with disabilities (Krahn et al. 2015; Mannan and MacLachlan 2013; McVeigh et al. 2016).

Essential to all of these processes is greater recognition that people with disabilities have the same (and often additional) health needs and rights as people without disabilities. The right to health is enshrined in the CRPD (United Nations 2006). A critical illustration of why this right and all other intangible rights of people with disabilities required its' own UN convention, is the fact that people with disabilities were excluded from international action, including public health action, in response to the Millennium Development Goals. With significant advocacy by and with people with disabilities and their representative organizations, the inclusion or people with disabilities is clearly articulated in the Global Goals for Sustainable Development 2015–2030 (SDGs) (Marella et al. 2016).

Global commitment to the CRPD, the SDGs, as well as platforms such as the WHO Alma-Ata Primary Health Care Principles (WHO 1978), mandates public health practitioners, researchers, and policymakers in all countries to ensure people with disabilities are both meaningfully included and benefit in all aspects of public health. This will require more inclusive approaches to address existing barriers to inclusion within mainstream public health policy and programming (i.e. health promotion messaging, disease outbreak and disaster responses), as well as disability-specific actions (i.e. promotion and resourcing of CBR in low- and middle-income countries (United Nations 2006; WHO 2011; MacLachlan et al. 2012; MacLachlan and Mannan 2014; Krahn et al. 2015).

We have described how the measurement of disability and the quality of information collected on disability is poor. There is an urgent need for better context-specific information and data on the lived experience of people with disabilities in relation to their health and inclusion within the public health sphere (Vaughan et al. 2016). Improved context-specific disability data collection and disaggregation including within Health Information Systems is critical to monitor progress towards inclusion, as well as identify barriers to improving health outcomes for people with disabilities (Durham et al. 2016). This includes identifying gaps in knowledge, practices, and attitudes of public health practitioners to improve their capacity for inclusion, alongside strategies to enhance the knowledge and capacity of people with

disabilities to improve their access to public health programmes (Mannan and MacLachlan 2013; Krahn et al. 2015; Vaughan et al. 2016).

Meaningful leadership and participation of people with disabilities in policy development is needed so that policy is responsive to the needs of people with disability (Love et al. 2018). Furthermore, we need to ensure that people with disabilities are supported to understand their rights to health, as well as provided with information, resources, and support to access public health programmes (Devine et al. 2017). In terms of research, we need to build the capacity of people with disabilities to take leaderships roles in public health research and ensure that all research projects are responsive to the priorities of people with disabilities.

Public health has much to contribute to alleviating the health disadvantage that people with disabilities face. To do this, public health needs to move beyond understanding disability as a health deficit and take a social determinants approach to the health of people with disability. Reducing disability-related health inequalities requires addressing the root causes of poor health including social determinants such as poverty and discrimination. Doing so would enable public health to more truly achieve its goals of promoting the health of *all* individuals and their communities.

Health of older people

Samir K. Sinha and Brittany Ellis

Introduction to health of older people

This chapter considers the phenomenon of population ageing, the unique health needs of older people, and specific approaches to providing health and social care for them. Ageing reflects biological, psychological, and social processes that occur across the life course, and at individual rates. Indeed, these processes are associated with ageing, but are not synonymous with chronological age. They vary between individuals according to many factors such as gender, ethnic background, lifestyle, socioeconomic, geographic location, and historical factors. This helps to explain why certain countries or populations are ageing faster than others.

How ‘old age’ has been defined continues to vary across settings, over time, and from person to person. In the past, the United Nations (UN) and other international agencies used 60 years or older (60+) to define ‘the elderly’, but more recently there has been a growing consensus that 65+, or even older ages, should be used in general to describe this segment of the population, while recognizing that disadvantaged populations may experience processes associated with ageing earlier.

While the process of ageing is universal, it is considered by many to be anything but uniform. Indeed, regardless of any current chronologically based descriptions, it is clear that people over 65 years of age are not one homogenous group and that there exists a great variance of experience, capacity, and health status between individuals at any age. As people age, some will age well and with little disability for significant periods of their later years while others may experience most of their later years as living with increasing frailty and a higher degree of dependence. It is essential to recognize this heterogeneity in defining the health and social needs of our ageing populations, designing and evaluating interventions, and planning for the future for this rapidly growing and increasingly diverse segment of our populations.

Demographic projections related to population ageing

The age of the world's population is rapidly increasing both structurally and numerically, and by 2050 the number of people aged 60 years or older worldwide is expected to exceed the number of people aged 15 years or younger. In 2019, there were an estimated 694 million people who were aged 65 years or older worldwide, representing 9% of the total population. This population is projected to number an estimated 1.55 billion persons, representing 15.9% of the total population in 2050 (UN DESA 2019).

Population ageing, which refers to an increasing median age, is occurring. In 2015, the median age of the world's population was estimated to be 30 years. The country with the youngest population by median age was Niger (14 years), and the countries with the oldest populations by median age were Germany, Italy, and Japan (46 years). By 2050, it is anticipated that the world median age will increase to 36 years, with Taiwan and the Republic of Korea projected to both reach a median age of 54 years (UN DESA 2017).

While much attention is focused around population ageing in high-income countries, this phenomenon is currently occurring far more rapidly in lower-income countries. Indeed, between 2017 and 2050, the number of older adults in high-income countries is expected to increase by 38%, which is much less than the expected 260% increase for lower-income countries (UN DESA 2017). In general, the more developed a country is, the more likely it is that population ageing will occur within an affluent environment, with higher levels of overall health and social care resources and infrastructure being available to support this phenomenon. However, in developing countries, ageing can still occur successfully even in the context of the emerging burden of chronic diseases, industrialization, and changing living patterns.

Figures 10.8.1 and 10.8.2 illustrate the global phenomenon of population ageing at the country level in the year 2020 and again in 2050. As can be appreciated across these two figures, a significant number of more developed and developing countries will be experiencing major demographic shifts over the coming decades with older people representing greater proportions of their ageing populations.

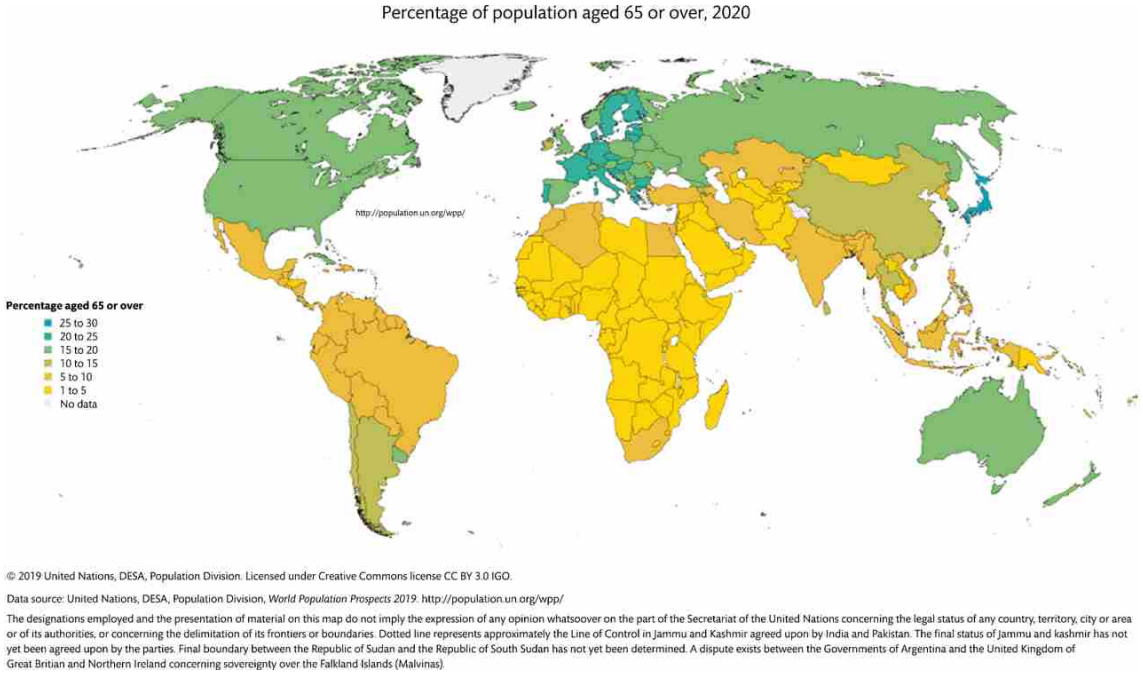

Fig. 10.8.1 Percentage of population aged 65 or over in 2020.

Determinants of population ageing

The achievement of population ageing can be considered a major success story, having come largely as a result of gains in infant and child survival, and, more recently, to gains in life expectancy at older ages accompanied by reductions in fertility.

The earliest observed influence on population ageing occurred in Europe as a result of declines in fertility and childhood mortality which began in the nineteenth century and accelerated in the twentieth century initially due to improved living conditions and sanitation, and then to better nutrition, immunizations, and antibiotics. From the middle of the twentieth century, reductions in deaths from heart disease, stroke and cancer have further significantly extended adult life expectancy, primarily in developed countries.

In developing countries, fertility and mortality rates have also fallen, but to a lesser degree than among their more developed counterparts. The adoption of modern health practices, including successful infant and child health programmes, are probably most responsible for the rapid rates of mortality decline achieved at younger ages. As a result, globally, over two-thirds of adults over the age of 60

years are now living in developing or low- and middle-income regions (UN DESA 2017).

The dramatic declines in fertility being witnessed throughout the world have mainly been attributed to urbanization, industrialization, and social mobility which have all had an influence on family structures. In addition, the 'emancipation' of women resulting in their greater chances for education, later age of marriage, and access to contraception have all contributed as well (Kinsella and He 2009). China's one-child policy, introduced in 1979, also had a dramatic impact on fertility rates in that country which fell from 4.77 between 1970 and 1975 to 1.51 between 1995 and 2000 only increasing slightly to 1.60 in between 2010 and 2015—further contributing to its more accelerated rate of population ageing (UN DESA 2017a).

Currently, close to half of the world's people live in a region in which fertility rates are below what is considered the population replacement level of there being at least 2.1 children per woman (UN DESA 2019). Currently, the country with the highest fertility rate is Niger (7.2) and the lowest is Taiwan (1.2) while fertility rates are considered to be below replacement levels in North America (1.9), Europe (1.6), and many countries in Latin America, Asia and the Caribbean (UN DESA 2017a).

As fertility rates decline, life expectancy begins to have a greater impact on the rate of population ageing. While human life expectancy has increased dramatically over the twentieth century and the beginning of this century, new data is starting to show a deceleration and even more recently a demonstrable decline in life expectancy in some developed countries like Canada, the United States, and the United Kingdom. For example, in 2016 the average life expectancy in the United States of America reportedly decreased for a second year in a row, driven largely by a 50% gradual rise since 2005 in what are being coined 'deaths of despair'—the combined deaths from suicide, alcohol and drug use (Radley et al. 2018). Nevertheless, current conventional thinking predicts that our actual potential life-span as humans remains at around 120 years, with centenarians—those living to ages greater than 100 years—still representing the fastest growing age group in many developed countries.

In some populations, including Canada and the United States, international migration has also had a role in changing age (and gender) distributions, with large influxes of relatively young immigrants helping to influence population ageing rates. In the case of many of these countries, progressive immigration policies have been developed to help partially address the issue of declining fertility and population ageing rates. Furthermore, dramatic shifts have been seen in some nations as social and political conflicts have led to significant emigration. Nowhere was this more recently evident than in Syria where death and emigration have led to a population decrease by over three million people or roughly 20% of the country's population between 2010 and 2019 (UN DESA 2019). However, in most countries,

migration has had less of an overall impact than changing fertility and mortality rates.

Specific factors that further influence population ageing

Ageing and gender

Women have always tended to live longer than men, and globally, with the exception of Mali and Swaziland, this continues to be the case with the current average life expectancy of women 75.0 years and men 70.2 years (UN DESA 2019). The reasons behind this difference in life expectancy between men and women is complex and likely results from an interplay between differences in attitudes, social roles, biological risks, and particular behaviours including the higher incidence of alcohol and drug use and smoking in men, leading to their higher rates of accidents, violence, and cardiovascular disease. Many theories behind biological risk differences exist, however, all lack firm evidence. They include more active female immune functioning, the protective effect of oestrogen, compensatory effects of the second X chromosome, and the influence of oxidative stress (Austad 2006). Regardless, as a result of their tendency to live longer, women are more likely to experience a greater burden of the disease and disability associated with advanced age.

While conditions that affect people at older ages are similar among men and women (except for breast cancer and reproductive cancers), there are specific gender differences in the incidence of these conditions and their peak age of onset. For instance, men experience their peak incidence of coronary artery disease earlier than women. Lung cancer is more common among men who have long had higher rates of smoking, although lung cancer has now become the second most common cancer among women, reflecting their increasing smoking rates. Also, while there are few differences noted on self-rated health, older women have higher rates of reported functional disability than men, likely due to the higher prevalence of arthritis, asthma, depression, anxiety, and cognitive impairment that occur among women as they age.

Women continue to also be at increased risk of violence and abuse, both as children and adults, and these acts, which come in a variety of forms from domestic and sexual violence, to human trafficking, honour crimes and female genital mutilation, are associated with an increased incidence of anxiety, depression and post-traumatic stress disorder (Oram et al. 2017) and risk of premature death. It has been further argued that research in this area continues to be flawed as it often reports issues in a gender-neutral fashion, not recognizing the important differences

between men and women, while regularly excluding important variables such as intimate partner violence (Howard et al. 2017).

Gender differences in terms of evolving social roles and human rights will continue to have significant effects on current and future experiences of ageing for women as well. For example, during the life course women are still more likely to be excluded from schooling, receive lower quantities of nutritious food, have no control over household decisions, and receive no health insurance from an employer. Their greater longevity also means that they are more likely to experience the death of their spouse and to spend a greater proportion of their later years widowed, very often with an accompanying loss of social status and reduced economic circumstances. The highest levels of widowhood (above 40% among women aged 60–64) are found in some sub-Saharan countries that have experienced political unrest or high prevalence rates of HIV (UN DESA 2015). Furthermore, in parts of Africa, widowed women have no rights to own their late husband's land, which often leaves them in poverty. Older women are also especially vulnerable in the event of crises such as war, natural disaster, and famine, partly because they generally control fewer economic resources than older men, and also because much of the care of children and other vulnerable people tends to fall on older women.

Finally, historically, clinical research, including disease modelling, management, and pharmacologic treatment, has been conducted in predominantly younger male populations and had its findings generalized to women and older people. For example, despite the facts that women are twice as likely to live with two or more chronic diseases when over 80 years old, and that heart disease kills more women than men, protocols for diagnosing and treating heart disease have been largely based upon research with middle-aged, white, male patients with only 27% of participants being female (Kim et al. 2008). As a result, women tend to be diagnosed later with more advanced disease and have poorer treatment outcomes.

Ageing among ethnic minorities and indigenous peoples

With increasing numbers of immigrants reaching old age in their host countries, racial and ethnic minorities are now beginning to constitute the fastest growing segment of the older populations within many Western countries (Zubair and Norris 2015). These demographic changes will continue to have important implications, especially since morbidity and mortality rates among older populations have also been shown to be unevenly distributed across racial and ethnic groups. In the United Kingdom, for example, data from the Black and Minority Ethnic Elders Study demonstrated that older adults from ethnic minority groups, particularly those of African/Caribbean or South Asian ethnicity, were more likely to report worse health outcomes than the white ethnic majority population (PRIAE Policy

Research Institute on Ageing and Ethnicity 2005). Many older people in these ethnic groups are first-generation immigrants and may have encountered particular issues as they age that relate to migration stress, their reasons for having had to leave their country of birth, and having to cope with language limitations and the separation from family members and networks in their country of origin.

Noted differences for older ethnic minority populations in general have also been extended to physiological ageing, access to social and healthcare services, income and educational levels, health habits, disease prevalence, progression, and response to treatment. Similar disparities among health and disease in older people in ethnic minority groups are evident in both the Netherlands (Denktaş et al. 2009) and the US (Federal Interagency Forum on Aging-Related Studies 2016). Despite these recurrent findings, there remains a lack of understanding as to the exact causes of these differences as, historically, 'minority' ethnic groups have been excluded from studies or their heterogeneity diminished through being classified occasionally as part of broader 'non-majority' ethnic groups.

Other research has demonstrated that minority ethnic communities sometimes have little confidence that mainstream services will meet their diverse cultural, linguistic, or religious needs and uncertainty around what services exist and how to access them. The challenge of having public sector providers assuming, often incorrectly, that minority ethnic communities have strong community/family support networks that they can rely upon is an additional barrier towards accessing the care and support needed (PRIAE 2005).

Significant health disparities also exist among indigenous minority groups throughout the world especially where their continued lower socioeconomic status, as compared to the majority non-indigenous population, and persisting effects of colonialism, remain two of the key drivers of their disparities. Their achievement of a poorer overall health status has been linked to being disproportionately plagued by factors like poverty, malnutrition, inadequate housing, and overcrowding. This in turn has been exacerbated by the transition from a traditional to more modern lifestyle, systemic racism, and discrimination, and has led to high rates of chronic diseases including diabetes, cardiovascular disease, obesity, and mental health disorders and functional limitations at an earlier age than the general population.

Access to care issues for indigenous populations has been associated with a significant health divide especially characterized by a decreased life expectancy of between 5 and 10 years compared to the general population in Canada (Statistics Canada 2005) and of similar ranges in both New Zealand and Australia (Australian Bureau of Statistics (ABS) 2011; Phillips et al. 2017). Nevertheless, while the life expectancy gap is expected to continue to shrink over time in Canada, the numbers of older indigenous people greater than 65 years of age is expected to triple over the next two decades, compared to only a doubling of this age cohort for the overall population (Government of Canada 2009). Indeed, shifting demographics, coupled

with the more vulnerable health status of older indigenous peoples, will demand that their needs are responded to with increasingly culturally safe and appropriate health interventions to further address and reduce health disparities.

Ageing among LGBTQ peoples

While between an estimated five to ten per cent of the population identifies as being lesbian, gay, bisexual, transgender or queer (LGBTQ), many may have lived a portion or their entire lives, to varying degrees, in hostile environments, prior to experiencing more inclusive modern-day standards. For some, this could result in feelings of great stigma and shame that continue to shape their lives, often requiring them to keep their sexual orientation hidden as a strategy for survival. In part due to their increased experiences of victimization and discrimination, individuals who identify as LGBTQ often face greater health disparities than those who do not. Older LGBTQ persons are more likely to live in poverty and may also have fewer future caregiver options as they are more likely to live alone, are less likely to have children or grandchildren (Barker et al. 2006), or they may remain isolated from their families of origin. Furthermore, current or past negative experiences with health, social, and community care professionals may also lead to hesitation on the part of older LGBTQ adults to seek appropriate supportive services, leaving some with specific healthcare needs that also go largely unrecognized by healthcare professionals (Brotman and Ryan 2008).

There are certain medical issues that require particular attention in LGBTQ older adults such as regular screening for HIV and other sexually transmitted infections among gay and bisexual men; greater risks of cardiovascular disease due to higher rates of obesity and metabolic syndrome, smoking, and alcohol use for lesbian and bisexual women (Valanis et al. 2000); and a higher prevalence of psychological disorders and distress overall (Mays and Cochran 2001). This latter issue is particularly important as experiencing social stressors such as prejudice, stigmatization, violence, and internalized homophobia over long periods of time can result in higher risks of depression, suicide, risky behaviour, and substance abuse for LGBTQ older adults. These disparities will likely continue as they age, but it is unclear if these disparities will increase, remain stable, or decrease with time. Further recognition of these challenges and work in this area is needed.

Ageing in rural areas

In 2010 the World Health Organization (WHO) recognized that, for the first time in history, the majority of the world's population were now living in urban settings. As early as 1960 it was estimated that 66% of the global population lived rurally, but this has been steadily declining to 45% by 2018 (UN DESA 2018). Rapid

urbanization has led to difficulties in providing appropriate urban infrastructure as many urban centres struggle to manage issues related to pollution, sanitation, transportation, and the provision of health and education. Health challenges with rapid urbanization have included increases in rates of non-communicable diseases (cardiovascular disease, diabetes, cancers, and chronic respiratory disease), violence, physical inactivity, substance abuse, and communicable diseases.

The shift of younger generations to urban environments principally to find work, coupled with the greater movement of some older people into rural areas in retirement, has led to unusually high levels of population ageing in rural regions. Further, living in rural areas has been associated with greater economic hardship, less access to basic health and social services and quality housing, and higher commodity prices (Phillipson and Scharf 2005). Although older people in rural settings might report higher levels of social cohesion, they may live more undersupported lives as their younger family members, who previously may have acted naturally as unpaid caregivers for them, migrate to urban areas in search of greater economic opportunities.

Demographic and epidemiological transitions

Population ageing and changes in mortality and life expectancy have also been accompanied by changes in patterns of prevalent and incident diseases. Omran (1971) described the epidemiological transitions we have been experiencing over time as (i) the age of pestilence and famine; (ii) the age of receding pandemics; and (iii) the age of degenerative and man-made diseases. These transitions have been witnessed at an accelerated rate in rapidly developing countries like Brazil, China, and India, as they have experienced substantial changes in economic development, increasing urbanization, and changes in the health status of their citizens resulting in rapid population ageing.

Globally, non-communicable diseases, particularly cardiovascular diseases and cancers, now represent the current leading causes of morbidity and mortality with prevailing risk factors for developing these conditions including an unhealthy diet, physical inactivity, obesity, hypertension, and tobacco use (Li et al. 2012). Even though the proportion of later-life fatalities caused by heart disease, strokes, and cancer significantly fell over the last 25 years, this decrease was partially offset by a concurrent increase in the number of deaths attributable to other chronic non-communicable diseases, such as diabetes, chronic lung disease, renal disease, and dementia (Table 10.8.1).

Table 10.8.1 Ten leading causes of death of those aged 60 years or over globally, by sex, 2016

	Males			Females		
	Cause of death	**Deaths (thousands)**	**%**	**Cause of death**	**Deaths (thousands)**	**%**
1	Ischaemic heart disease	3,545,283	20.1	Ischaemic heart disease	3,708,354	21.1
2	Stroke	2,440,336	13.9	Stroke	2,828,193	16.2
3	COPD[i]	1,575,380	9.0	COPDi	1,311,550	7.5
4	Lung cancer[ii]	919,887	5.2	Alzheimer disease[iii]	972,608	5.6
5	Lower respiratory infections	823,234	4.7	Lower respiratory infections	911,094	5.2
6	Diabetes mellitus	558,075	3.2	Diabetes mellitus	700,998	4.0

Nevertheless, stark differences in mortality causes in older people between developed and developing regions do remain. For example, in higher-income countries over 90% of deaths among people aged 60 years or over are due to non-communicable diseases, whereas in lower-income countries almost 20% of deaths in this age group are still due to communicable diseases. Many rapidly ageing lower-income countries are also still experiencing high overall levels of communicable diseases including childhood infections and HIV/AIDS (WHO 2011).

Variations in life expectancy

While mortality rates tend to increase at older ages, in recent decades they have slowed at all ages. Life expectancy is defined as the average number of additional years of life that a person at a given age could expect to live, providing age-specific mortality levels remain constant. Table 10.8.2 shows life expectancy at age 60 for males and females in different regions of the world. In 2015, a woman in Africa who had already lived to 60 years could expect to live to 77.5 years, while one in Oceania could expect to live to 85.4 years. Similar differences are reflected in male life expectancy at age 60.

Table 10.8.2 Life expectancy at age 60, by sex, for the world and regions, 1950–1955, 2010–2015, and 2045–2050

	Females					Males				
	Life expectancy at age years (years)					Life expectancy at age years (years)				
	1950–1955	2010–2015	2045–2050	Change between 1950–1955 and 2010–2015 years	Change between 2010–2015 and 2045–2050 years	1950–1955	2010–2015	2045–2050	Change between 1950–1955 and 2010–2015 years	Change between 2010–2015 and 2045–2050 years

Inequalities in life expectancy exist between countries and regions, and between different population groups within countries. Between-country reductions were largely achieved between 1950 and 1990 due to improved access to safe water and sanitation, childhood immunization, improved childhood nutrition, and declining fertility (Hosseinpoor et al. 2012). However, large inequalities in life expectancy still remain, with life expectancy remaining low at 63 years across lower-income countries (UN DESA Population Division 2017a).

Within-country differences in life expectancy have been further observed according to gender, socioeconomic status, and other factors. A major study of 1.7 million people across seven countries compared the impact of low socioeconomic status with other major risk factors on health, such as physical inactivity, smoking, diabetes, high blood pressure, obesity, and high alcohol intake. It found that when compared with their wealthier counterparts, people with low socioeconomic status were almost 1.5 times (46%) more likely to die before they were 85 years old—estimating that low socioeconomic status was associated with a reduced life expectancy of 2.1 years, similar to being inactive (2.4 years) and more impactful than respectively having high blood pressure, obesity and high alcohol consumption (1.6, 0.7, and 0.5 years) (Stringhini et al. 2017).

Healthy life expectancy

As well as adding years to life, it is also important to add life to years. Healthy life expectancy (or health-adjusted life expectancy (HALE)) estimates life expectancy, but with an adjustment for time spent living with a disability and/or other impairment to good health. Within the context of population ageing, age-associated limitations in performing everyday activities can have substantive effects on healthcare utilization. Healthy life expectancy estimations can therefore help answer questions raised regarding whether extra years of life achieved are being spent in poor or good health and their resulting associated impact around the demand for health and social care services.

The level of inequalities in both life and healthy life expectancies that can exist across a region is well studied. One study looking at these two data points across 25 countries in the European Union observed a greater variation in healthy life expectancy than for life expectancy. It found that, on average, a 50-year-old man could expect to live until 67.3 years free of activity limitations, and a woman to 68.1 years with observed variations in healthy life expectancy ranging from a low of 9.1 to a high of 23.6 years, respectively, for men in Estonia and Denmark. Higher healthy life expectancies were associated with higher gross domestic product, lower unemployment, and with life-long learning (Jagger et al. 2008).

When healthy life expectancy increases relative to life expectancy, then people will spend a greater proportion of their life in good health and a ‘compression of

morbidity' will be experienced (Fries et al. 1989). If people live longer due to a reduction in fatal illness, but with an increase in disability due to chronic or degenerative diseases, then there will be 'expansion of morbidity' experienced. A third scenario, that of 'dynamic equilibrium', could, for example, occur if the population prevalence of some chronic diseases increases with ageing, but the progression of some degenerative diseases reduces.

While the achievement of a compression of morbidity may be prevailing in some populations, data to test this hypothesis are difficult to find and hard to interpret. Very few countries are capable of making reliable assessments over time, between geographic regions or socioeconomic groups. In some settings, there is evidence that the prevalence of disability at older ages may be decreasing, but other studies are finding an increase in disability. For example, a study which assessed disability trends in 12 Organization for Economic Cooperation and Development (OECD) countries among individuals aged 65 years and over, reported mixed results (Lafortune et al. 2007). Disability declined among elderly people in five out of the 12 countries (Denmark, Finland, the Netherlands, the United States, and Italy). At the same time, three countries demonstrated increased rates of severe disability (Belgium, Sweden, and Japan), indicating that increased longevity can still lead to increased numbers of older people in poor health and in need of long-term care.

If a widespread compression of morbidity is to occur at a population level, greater health promotion and risk reduction activities will be needed for groups that have high levels of health risks. For example, preventing smoking is likely to result not only in more years of life, but also more years in good health. However, even if preventive activities were highly successful in reducing or postponing disability, it is expected that increasing numbers of people living to very old ages would mean that there will also be greater numbers of people eventually living with disabling conditions. At a population level, even if a compression of morbidity dominates, there will still be an increasing need for health and other forms of care as the population ages.

Differential, usual, and successful ageing

Ageing is believed to be a slow, continuous process. Therefore, some of its effects can be observed only when they have progressed sufficiently to induce identifiable alterations that can be validated by available testing methods. An illustrative example is atherosclerosis, the consequences of which manifest during middle and older ages even though an atherosclerotic lesion may start early in life. Whatever organ or tissue is considered, timetables of ageing represent an approximation, as the onset of ageing cannot be pin-pointed precisely by a specific physiological sign.

While a number of functions undoubtedly decline as we age, the extreme heterogeneity of an overall achieved functional status, even in the oldest cohorts, supports the view that ageing must be evaluated on an individual basis. In addition to genetic makeup, an older individual's health and social status, economic, and environmental conditions all contribute to how they age. Ageing processes have thus been distinguished across three distinct categories: categories (1) 'disease/disabled', characterized by the presence of pathology, disability, or both; (2) 'usual' (normal) ageing, characterized by the absence of overt pathology but the presence of functional declines; and (3) 'successful' ageing, characterized by few or none of the physiological losses seen in the usual ageing group. This concept of differential ageing is based on (1) the substantial heterogeneity that exists among older individuals; (2) the common observation that ageing is not a uniform or inevitable process of disease or disability; (3) the persistence of 'plasticity' well into advanced age, that is, a continuing capacity for adaptive and compensatory rehabilitation; and (4) the identification of predictors of various patterns of ageing, especially factors that contribute to more successful trajectories of ageing (Seeman 1994).

Extrinsic factors appear to also play an important role in age-associated functional decline. In one study, factors promoting the maintenance or improvement of functioning included younger age, higher income, higher education, high cognitive performance, being Caucasian, being of lower body weight, maintaining good lung function, living without diabetes or hypertension, participating in exercise, and receiving emotional support (Seeman 1994). Other correlates of improved survival at later ages even among those with chronic conditions were the absence of smoking, regular participation in physical activities, and the maintenance of a strong social network (Rizzuto et al. 2012). Taking all such factors into account, the prospects for avoidance, or eventual reversal, of functional loss with age are vastly improved, while the risks of adverse consequences are reduced (Rowe and Kahn 1987). Furthermore, it is increasingly appreciated that interventions may be beneficial at all ages provided they are customized to the individual. Indeed, physical exercise, dietary, surgical, and pharmacological interventions have proved successful in enhancing health even at older ages and thus should never be restricted on the basis of age alone. Our growing ability to identify those factors that can maximize health and physiological competence can support an overall enhancement of an older person's quality of life, a reduction in their burden of disease and disability, while decreasing the potential need for healthcare resources.

Societal perceptions of ageing

Images and stereotypes related to ageing

‘Ageism’ was defined in 1969 by US gerontologist Robert Butler as a combination of prejudicial attitudes towards ageing and older people, discriminatory practices against older people, and institutional practices and policies that perpetuate older age stereotypes (Butler 1969). A report by the American Association of Retired Persons (AARP) concluded that many Americans had misconceptions about ageing and older people, including that they are senile, asexual, and miserable (Abramson and Silverstein 2006). Although some changes have occurred for the better in terms of depictions of ageing, older adults are still generally viewed less favourably than the young.

Older people’s own perceptions of ageing

The Growing Old in America report (Taylor et al. 2009) explored ‘markers of old age’. The study reported that ‘turning 85’ was the most commonly endorsed marker of what it meant to be old, with the second and third markers being ‘can’t live independently’ and ‘can’t drive a car’, respectively. Other markers included ‘has trouble walking up stairs’, ‘retires from work’, and ‘has grey hair’. The English Longitudinal Study of Ageing found that self-assessed health was strongly related to how old individuals felt, with study participants often reporting being in better health and feeling younger than their actual age (Demakakos et al. 2007).

Interviews with older adults in Australia demonstrated the wide acceptance of ageist stereotypes. Participants aged 65 and 89 years described oldness as ‘not trying, withdrawn, isolated, irritating, self-oriented, living outside the mainstream, unattractive, uninteresting, frail, senile, silly, over the hill, narrow-minded, a burden, lonely, vulnerable, dowdy, and unproductive’ (Minichiello et al. 2000). Such ‘internalized ageism’ can, however, be dangerous in that older adults may, as a result, experience worse functional health and even a reduced will to live. Levy et al. (2002) found that older individuals who held more positive self-perceptions of ageing (measured over 20 years earlier) tended to live 7.5 years longer than individuals with less positive self-perceptions of ageing. This advantage remained after accounting for age, gender, socioeconomic status, feeling lonely, and level of functional health. Within the context of Western societies, where older age is portrayed more negatively, while the post-war ‘baby boomers’ are said to be challenging old age stereotypes, there still remains a high level of diversity in the health and social circumstances of these birth cohorts.

Evolving concepts of later-life productivity and social contribution

With a societal emphasis pointed towards the anticipated demands that the ageing population will make, the significant value of the contributions older people make through continued paid employment, but also as unpaid caregivers, volunteers, and mentors are easily overlooked. Indeed, the way in which population ageing is evolving and being experienced is helping to challenge well-established concepts. The '*old-age dependency ratio*', for example, is a common demographic metric which compares the ratio of the economically 'dependent' part of the population, or those 65 years or older, with those who are 20–64 years old, who are considered to be working age and therefore economically 'active'. The metric, while providing some utility, is increasingly leading to erroneous conclusions as it specifically underestimates the contributions of individuals over the age of 65 years where increasing numbers of older people are remaining in paid employment, or still acting as significant economic contributors through their spending, while also neglecting to consider that not all persons of traditional working ages are active in the labour force, with some being economically dependent. The concept also negates the value of the contributions older people who perform unpaid work, including organized volunteer positions, child-minding, and unpaid caregiving activities, all of which have significant overall economic and societal benefits and implications. Several alternative measures are now being proposed to better account for the growing diversity of capacities and dependencies across age (UN DESA 2017a).

Ageing-related concepts in health

Multimorbidity and polypharmacy

The prevalence of diseases and morbidity among older people has increased over time, partly due to the improved and earlier diagnosis of diseases such as hypertension, diabetes, and dementia, but also due to the rise of disabling non-fatal chronic conditions such as arthritis.

Multimorbidity is commonly defined as the co-occurrence of two or more chronic conditions whose prevalence increases with age and negatively associated with many important health outcomes such as increased health service utilization and decreased life expectancy. It also profoundly affects an individual's overall well-being, quality of life, and ability to function normally. Patients with multimorbidity further struggle to manage the associated polypharmacy and medication burden of having to take the multiple medications prescribed to them, leading to difficulties with treatment adherence and a worsened quality of life.

Despite the increasing numbers of individuals living with multimorbidity, clinical practice guidelines and care delivery models are still primarily built around

the management of single diseases rather than the interplay between them. Thus approaches to the care and treatment need to shift to become more relevant to the actual needs and preferences of patients with multimorbidity, which will require complex treatment decisions to be made sometimes in the absence of high-quality or direct evidence.

While medications can be beneficial in the management of specific health problems, they also have the potential to cause serious adverse effects. Older people have a reduced volume of distribution for drugs, and slower rates of drug metabolism and elimination, and so are more vulnerable to overdosing or the side effects of certain medications that can make them less appropriate to prescribe in older adults. Furthermore, polypharmacy increases the risk of adverse drug reactions or related events including hospitalization and death.

In high-income countries like Sweden a recent study reported a prevalence of polypharmacy of 44.0% (5+ medications), and excessive polypharmacy (10+ medications) of 11.7% among older adults (Morin et al. 2017); while another study from Canada noted that nearly 40% of older adults were currently taking one inappropriate medication while 12% were taking multiple inappropriate medications (CIHI 2014). Adverse drug reactions have been associated with around 30% of the hospital admissions among older people and it is estimated that up to half these adverse reactions could have been prevented (Simonson and Feinberg 2005). With the support of medication reviews that promote more appropriate prescribing and even de-prescribing that is aligned with an older person's actual treatment objectives and preferences, increased compliance with an overall treatment regimen could likely be achieved, accompanied by a concomitant decrease in the risk and occurrence of adverse events and their associated morbidity and mortality.

Disability and function

As people age they are more likely to experience challenges with their ability to function, which can impact their capacity to mobilize, stay socially engaged, and live independently. Activities of daily living (ADLs) and instrumental activities of daily living (IADLs) are two classes of functional measures that have been developed, based on an individual's ability to perform specific tasks, and are widely utilized to describe one's capacity for independent living. ADL tasks refer to those that are required to carry out basic self-care activities, such as transferring out of a bed or a chair, walking, toileting, bathing, dressing, and eating, while IADL tasks refer to those that are required to maintain an independent household, such as doing light housework, preparing meals, using the telephone, shopping for personal items, managing money, and getting around the community.

ADL dependency is less common than IADL dependency, and in one survey of community-dwelling population, 85 years of age and older, only 16% reported requiring help with one ADL, 10% with two or three ADLs, and 9% with four or more ADLs, while just under half reported needing help in performing one or more IADLs (Kane et al. 2003). The monitoring of an individual's IADL and ADL performance, which generally demands a combination of both cognitive and physical abilities, has also become a useful way to measure and monitor disease severity, progression of certain neurodegenerative conditions such as dementia, and in certain cases recovery as well such as after a stroke.

Finally, the WHO estimates that approximately 33% of adults over 65 years of age have a disabling hearing impairment, while 81% of the world's visually impaired people are aged 50 years and above (WHO 2019). Both hearing and visual impairments can impact a person's ability to function independently, and can also negatively affect their economic opportunities, quality of life, mental health, physical health, and mortality risk. Furthermore, the burden associated with dual sensory impairment, which is prevalent in between 5 and 20% of people over the age of 70 years, is likely more profound (Brennan and Bally 2007).

Frailty

Frailty is a term that is increasingly being used to describe older people who are at risk of poor outcomes due to their diminished adaptive reserve and resiliency. Fried et al. (2001) developed an operational definition of frailty—a 'frailty phenotype' that includes decreased resiliency and reserve, cycles of decline across multiple systems, negative energy balance, sarcopenia, and decreased strength and exercise tolerance. Another common way to define frailty, uses the concept of a 'frailty index' to include the accumulation of a broader range of limitations and deficits that accumulate exponentially with age and corresponds with an increasing level of vulnerability to stressors (Rockwood and Mitnisky 2011). While frailty is not age specific, it more commonly occurs with increasing age. Furthermore, at any given age, women on average compared to men have been found to be living with more deficits than do men. However, women appear to tolerate their deficits better than men, and appear to have a lower risk of adverse outcomes in association with higher frailty index scores.

Increasingly, frailty is becoming recognized as an important risk factor for increased morbidity and mortality across a range of clinical settings. From emergency departments, to inpatient medical and surgical stays, increasing frailty has been associated with an increased risk of experiencing falls, disability, hospitalization, the need for long-term care and mortality (Clegg et al. 2013). However, more work needs to be done to develop better ways to more easily

measure and detect frailty and determine the levels at which certain therapies or interventions may or may not be useful in an individual's care.

Healthcare for older people

As ageing populations carry the greatest overall burden of illness and disability, healthcare planners are often challenged by concerns about increasing demands and rising costs of health and social care in the face of population ageing. Older adults visit doctors more often, use more medications, have more admissions to hospital, tend to have longer stays in hospital and pose the most complex diagnostic and therapeutic problems, but also have the potential to benefit the most from the provision of appropriate and timely health and social care. As greater consideration is given about how and for whom treatment interventions should be extended to mitigate morbidity and mortality within older populations, overcoming ageism around treating illness at later ages will be just as important.

For many, health concerns and symptoms in the elderly are overlooked or dismissed as part of the normal ageing process and thus may go underdiagnosed and undertreated. While healthcare professionals do not necessarily intend to behave in a discriminatory fashion, it is clear that a lack of skills and confidence in working with older people can lead to behaviour which may be perceived as discriminatory. Furthermore, denying access to services on the basis of age alone is becoming increasingly recognized as not being acceptable. Decisions about treatment and healthcare should always be made on the basis of a patient's health needs, the overall health status of the individual, their own wishes and aspirations and, where appropriate, those of their caregivers, and the patient's ability to benefit.

Increasingly, strategies that can both promote healthy ageing, prevent, and treat functional decline and enable people to more successfully manage and live with their chronic health conditions and functional impairments are becoming recognized and understood. These can both improve an older person's longevity and their overall quality of life and help them compensate for functional impairments, maintain their independence, and prevent future complications. Furthermore, as the health needs of older people living with multimorbidity can be particularly complex to manage, their care should be approached when possible from a multidisciplinary perspective and include them and their families and caregivers as partners in their own health management to enable the delivery of more efficient and effective care.

Health promotion activities to support healthy ageing

A useful framework for promoting healthy ageing has been described in three stages by Kalache and Kickbusch (1997). The *first* is increasing capacity for health in early life and includes good maternal nutrition, and optimizing the development of vital organs such as brain, muscle, bone, and blood vessels during childhood and early adulthood to build resources that may affect later capacity (such as increasing peak bone density to protect against osteoporosis). The *second* stage occurs in adult life and involves strategies to reduce damage (such as avoiding smoking), to protect against damage (such as eating a balanced diet) or to prevent loss through lack of use (such as with regular physical activity). The *third* stage is in late life and involves the continued primary prevention and minimizing the secondary progression of disease and disability, protecting against increased environmental demands or stresses, and compensating for lost capacity. Examples of these approaches in health promotion include routine immunization, exercise and strength training and rehabilitation when necessary, maintaining and strengthening social supports, correction of deficits in vision and hearing, making modifications to domestic and outdoor environments to enable more independent living and trying to address as possible important social determinants of health such as poverty.

Indeed, several key health behaviours are associated with diseases that are common in older age and thus suggest a primary preventive approach is likely to be the most effective way to reduce their incidence. A common example of this is the prevention of smoking which is linked to cardiovascular and respiratory diseases, many cancers, and ultimately a decreased life expectancy. While older people may find it difficult to maintain high levels of exercise, regular physical activity is strongly associated with lower rates of obesity, cardiovascular disease, diabetes, depression, and osteoporosis, and an increased life expectancy in many observational studies. Observational studies also suggest an association between good nutrition and better health at older ages (Tucker et al. 2005) as well as the importance of staying socially connected with others and an increased life expectancy (Rizzuto et al. 2012)

Much of the evidence for promoting vaccinations among older adults comes from observational studies and may reflect other differences between vaccinated and non-vaccinated groups. As the ageing process is associated with immunosenescence and subsequently an increased risk of infection, as well as diminished response to vaccination, the value of still promoting vaccinations in later life becomes apparent. Accordingly, it is currently recommended that in addition to updating routine vaccinations that may have been missed in earlier life, routine vaccinations for all older people over 65 years should include: influenza, pneumococcal, shingles (zoster) and tetanus, diphtheria, and pertussis (TdaP of Td) (CDC 2019).

It is a common assumption that prevention in general—and screening in particular—is always in the patient's best interest. In young healthy populations,

benefits of early cancer detection and treatment are considered to outweigh its harms. In older populations, mortality benefits may be less pronounced, as the screening tests themselves may pose a greater threat to one's health, while the presence of comorbidities may make treatment options untenable (Eckstrom et al. 2013). Furthermore, older adults are often underrepresented in both cancer screening and treatment trials, making recommendations around either, especially older adults with multimorbidity, functional impairments, and shorter life expectancy more difficult.

Currently in the US routine screening for cervical and breast cancers in women is still recommended for those up to the age of 65 and 74 years, respectively; screening for colorectal cancer is recommended for all adults over the age of 50 and up to the age of 75 years depending on the person's health and comorbidities; meanwhile, in men 70 years and older there remains insufficient evidence to support prostate cancer screening using the prostate-specific antigen (PSA) test (US Preventive Services Task Force 2019). In any case appropriate testing should occur for appropriate symptomology in line with an individual's overall goals of care.

Specific conditions predominantly affecting older people

A number of conditions affect older people with greater frequency and impact than those who are younger. This includes dementias, falls and osteoporosis, incontinence, frailty, and loneliness, as well as elder abuse. Further, older adults are also at risk of diseases that affect all populations, including mental health conditions such as depression and anxiety. The unique manifestations and impact of these conditions in older people has long been neglected in research, and it is increasingly evident that such issues impact the lives of older people in significant ways.

Dementia

The growing global prevalence of dementia is partially the result of population ageing, combined with improving awareness and diagnosis of the disease. With the greatest risk factor for developing dementia, with Alzheimer's disease being the most common form, being age, women remain more likely to develop dementia than men, due to their greater longevity. It is currently estimated that there are more than 50 million people currently living with dementia worldwide, and that this figure will reach 131.5 million in 2050 (Alzheimer's Disease International 2019).

Advances in the prevention and management of cardiovascular diseases over the past few decades, and improvements in educational attainment, has likely contributed to a lower current prevalence of vascular and some others forms of dementia (Livingston et al. 2017). While there currently exists no cure for

dementias, key reasons to support early diagnosis include the ability to provide pharmacological and social interventions that can help manage the manifestations of dementia, and better support for involved caregivers and individuals with dementia to live with as much independence as possible.

Falls and osteoporosis

Falls are a common and major cause of disability in older adults, with both the risk of falls and the risk of injury from falls increasing with both age and frailty. Approximately 30% of community-dwelling older adults report sustaining a fall on an annual basis, while between 5 and 10% of falls result in serious injuries such as osteoporosis-related fractures (Gillespie et al. 2012). Falls are often attributed to a complex interaction of risk factors that include chronic and acute illnesses, mobility or balance issues, medications, and cognitive impairment. Falls are also a growing concern because injuries from falls can threaten an older person's mobility, independence, and confidence. A number of interventions have been shown to reduce the risk of falls, including health/environment risk factor screening/intervention programmes, muscle strengthening, and balance retraining, and home hazard assessment and modification (Gillespie et al. 2012). Furthermore, the increased recognition of osteoporosis as a preventable and treatable disease common in older men but especially older women would aid in the dissemination of proven medical therapies that could significantly reduce a person's future risk of sustain a fragility fracture.

Incontinence

While urinary and faecal incontinence are not diseases of older age *per se*, the likelihood of having these conditions significantly increases with age, especially in older adults. The prevalence of any degree of urinary incontinence in older adults is reported to be as high as 5.4% for men and 29% for women (Herschorn et al. 2008), while the overall prevalence of faecal incontinence is 15.3% (Whitehead et al. 2009). Incontinence impacts all parts of a person's, and by extension, their caregiver's life, including staying active and socially engaged, and can lead to increased social isolation, depression, physical deconditioning, falls, fractures, and skin breakdown. Despite the high prevalence of these issues, older adults often do not seek treatment due to embarrassment and social stigma, or because they assume this is a normal aspect of ageing, and left untreated, incontinence can worsen over time. Educating both the public and professionals on how to engage more around this issue will allow more persons with these issues to be supported.

Elder abuse and neglect

Elder abuse is defined as ‘a single, or repeated act, or lack of appropriate action, occurring within any relationship where there is an expectation of trust which causes harm or distress to an older person’ (WHO/INPEA 2002). It can take various forms: physical, verbal, psychological/emotional, sexual, and financial, and also reflect intentional or unintentional neglect, as well as self-neglect. The self-reported global annual prevalence rate of elder abuse in 2015 was found to be 15.7% affecting an estimated 140 million older people (Yon et al. 2017). Psychological and financial abuse were the most commonly reported forms (11.6% and 6.8%, respectively), with neglect, physical, and sexual abuse representing 4.2, 2.6, and 0.9% of cases (Yon et al. 2017).

The most likely persons to commit elder abuse are family members and friends which creates especially complex situations when an older person is also dependent on their abuser for having their living or care needs met. With population ageing, the likelihood exists that elder abuse will increase unless it is more comprehensively recognized and addressed, especially when it can result in higher rates of depression, anxiety, hospitalization, nursing home placement, and mortality (Lachs and Pillemer 2015).

Depression and anxiety

The WHO estimates 15% of people over the age of 60 live with mental health conditions such as depression and anxiety (WHO 2017), which in older people can present atypically and is likely under-recognized. There are a number of reasons to expect why people may experience poorer mental health in later life, including the presence of more potential psychosocial stressors such as financial stress, social isolation, a lack of social support and losses, as well as the increasing likelihood with age of experiencing chronic illnesses, multimorbidity, and living with frailty. It is worthwhile, to screen for depression and anxiety, as there are many effective non-pharmacological and pharmacological treatments.

Models of care to support older people

Primary care for older people

It is essential that the evolving needs of older people are reflected in the routine provision of primary care by ensuring its practitioners are appropriately trained to have a solid understanding of normal ageing as well as the common problems and issues including those that can present more atypically in older adults. In addition to becoming more aware of effective disease prevention interventions,

understanding the importance of screening for and how to manage common geriatric issues like dementia, falls, osteoporosis, incontinence, constipation, frailty, multimorbidity, and polypharmacy, will be essential towards the provision of effective primary care of older people. Indeed, the reality is that when older persons with complex needs are paired with the inadequate provision of primary care, this tends to lead to more physician visits, more prescribed medications, more visits to emergency departments, more hospital admissions, and worse overall outcomes (Nie et al. 2008.).

Traditional clinic-based primary care models will also need to adapt to better support older adults with more complex health and social needs to receive ongoing care by the same providers and where possible with an interprofessional team-based approach to care. The advent of primary care models like the 'patient-centred medical home' as well as the provision of 'house calls' are becoming increasingly recognized as a cost-effective alternative way of providing primary care for patients for whom this form of care is a necessity rather than a convenience that can not only improve healthcare experiences and outcomes but also their overall healthcare costs (Stall et al. 2014). Lastly, the advent of new technologies that support remote patient monitoring and the provision of 'virtual' care using various technologies is also gaining prominence as a way to better deliver care to frail older populations who are unable to access conventional models of care.

Specialty care for older adults

In more developed nations the medical specialities of geriatric medicine and psychiatry have emerged to meet the changing needs of particularly frail older adults across the continuum of care. These fields' increasing expertise lay in their ability to understand the differences between normal and abnormal ageing and how typical ways of approaching the care of older persons may need to be further adapted to achieve the most optimal outcome. The value of a Comprehensive Geriatrics Assessment (CGA), the main skilled activity geriatricians provide has also become well-established as a highly effective way to minimize overall functional decline, help older adult remain living in the community rather than in an institution and improve an older person's chance of survival and overall quality of life (Ellis et al. 2017).

Despite their growing perceived value as specialist providers, even in most developed countries an extreme shortages of geriatricians still exist. In Canada for example, while older Canadians began to outnumber younger Canadians in 2016, there are currently nine times the number of as paediatricians as there are geriatricians. As the specialties of geriatric medicine and psychiatry gain more traction and support for their growth, other medical subspecialty areas of care are quickly emerging like geriatric cardiology, surgery, oncology, and emergency

medicine. Furthermore, the advent of specialist gerontological nurses, social workers, therapists, and pharmacists is also occurring as well in order to fill the rapidly growing need for more specialist expertise in the care of older adults.

Long-term institutional and community-based care

Many older persons as they age will require some form of long-term care during the course of their life. A common approach until recently to address the growing need for long-term care associated with population ageing in middle and high incomes countries was to prioritize the provision of long-term care in more institutional-based residential care settings like nursing homes as opposed to through the provision of more home and community care. While there will always remain a role for the provision for some long-term care in institutional settings, technological advances to better support home diagnosis, treatment, and monitoring is enabling a much broader range of care to be provided in one's home. In high-income countries, as a result of evolving societal preferences and the realization that community-based care can be far more cost-effective that institutional-based care, there is a trend towards care being increasingly provided in community settings. In many countries, a growing shortage of available paid long-term care providers and available family caregivers is placing additional demands on other health services such as acute care hospitals when inadequate long-term care capacity exists. As a result, more funding is being prioritized to better support the development and provision of more cost-effective and sustainable home and community-based long-term care.

Acute care for older people

Older adults compared to the rest of the population, not only use hospital services more often, but also on a more urgent and critical basis and are at least twice as likely as younger populations to be admitted to the hospital with acute presentations (Keim and Sanders 2004). While older adults represent the greatest users of hospital services overall, a number of longitudinal studies have consistently demonstrated that only a small proportion of older adults are actually high users of hospital services. Furthermore, three factors appear to characterize these high users: multimorbidity, having pre-existing functional impairments that make one more dependent, and being socially frail in having inadequate social and community supports at home (Wolinsky et al. 1995).

In recognizing that typical older patients that present to hospitals are characterized with more complex and often inter-related health and social care issues, compared to younger patients, we can appreciate that the management of their acute care needs often necessitate a different overall approach. Indeed, frail

older adults have been found to be at greater risk of experiencing functional decline, delirium, longer lengths of stay, and a greater risk of becoming institutionalized or dying during or after a hospitalization. In response, the Acute Care for Elders (ACE) model of care has emerged as a response designed to improve functional outcomes and to improve the processes for the care of older patients. This model emphasizes: an environment of care designed to promote improved function for older patients; an interdisciplinary team that works together to identify/address the vulnerabilities of older patients; nursing care plans to for the prevention of disability; early planning to help prepare the patient to return home; and a review of medical care to prevent iatrogenic illness (Malone et al. 2015). Implementing specific models and point-of-care interventions and practices that encompass ACE principles in locations such as the emergency department, inpatient, transitional, outpatient, prehospital, or community settings can improve overall outcomes and reduce lengths of stay, admissions, readmissions, and inappropriate resource use (Sinha et al. 2018).

A growing interest in helping frail older patients to minimize their need to receive acute care in hospitals has led to the emergence of more proactive prehospital models of care such as ‘community paramedicine’ that have been shown to meaningfully reduce emergency calls and in turn emergency department visits and hospitalizations (Verma et al. 2017) or alternative delivery models of acute care such as ‘hospital at home’ can result in less clinical complications such as hospital-acquired infections, delirium and functional decline, lower mortality rates, and for less overall costs (Shepperd and Iliffe 2005). These two examples represent just some of the emerging acute care models that could allow both more and less developed countries with their growing and evolving acute care systems to re-think their traditional acute care approaches in order to promote the achievement of better outcomes through the better use of limited healthcare resources.

Rehabilitative care and reablement services

The loss of one’s functional abilities can represent the largest threat to an older individual’s independence which can often necessitate increased support to maintain one’s overall capacity for independent living. Although care that prioritizes ‘early mobilization’, can mitigate some degree of the functional loss that is commonly associated with episodes of acute or chronic illness, some frail older patients will inevitably suffer from a loss of function to such a degree that, without restorative interventions, they may not be able to return to their previous level of functional independence. Therefore, having timely access to targeted and appropriate preventive, and restorative care services is critical to minimizing the frequency and extent of functional loss experienced by at-risk older adults.

Traditionally, individuals needing more intensive rehabilitation could only receive it in hospitals or other institutional settings, but more recently community-based rehabilitation options like geriatric day hospitals, in-home and community-based therapy options including exercise and falls prevention programmes are being developed and demonstrating their ability to better prevent and manage function decline. Furthermore, the provision of traditional home care services for those with functional limitations is increasingly being delivered using a 'reablement' approach that recognizes the 'resiliency' of many and enables them re-learn or develop new skills to once again complete their functional tasks independently. Not only does this approach further enable ageing-in-place, but it has appropriately reduced the need for ongoing long-term care services and their associated costs (Tessier et al. 2016).

The growing importance of unpaid caregivers and social support

Within the context of ageing populations, the role of unpaid caregivers is paramount, but often still remains socially and politically invisible. In Canada, for example, half of all Canadians aged 15 and over have provided care to a family member or friend, at some point in their lives (Sinha 2013). The contributions of unpaid caregivers represent an important component of many national economies. In the United States, the provision of unpaid care has an estimated annual economic value of $470 billion, which in the same year was more than six times the total amount spent on paid home care and health services (Reinhard et al. 2015).

With current societal, political, and economic imperatives encouraging a shift away from institutional care and towards 'care at or closer to home' there exists an assumption that in addition to having enough accessible and affordable housing and community-based healthcare providers, families and friends will be willing and able to continue to provide a substantial level of unpaid care. However in many countries, as their overall populations age, their population of potential unpaid caregivers is predicted to shrink. What is further complicating matters is that constantly shifting economic opportunities and the growing ease of mobility is contributing to the growing distance between family members and lessening their potential to be family caregivers.

While both caregivers and care recipients generally regard home-based care as preferable to institutionalization, caregiving can be physically, emotionally, and financially taxing. Legg et al. (2013) reported an association between provision of care and self-reported poor health of caregivers, that also increased with the amount of care being provided. Women, who tend to spend more of their time than others providing unpaid care, are also more likely to feel the financial effects of caregiving, contributing to higher rates of later-life poverty.

The tradition of being able to rely on family support to care for older people is changing in many countries as a result of changing economic and political conditions, the increased participation of women in paid work, and the impact of certain diseases. Economic development, urbanization, and internal and international migration, leading to demographic transitions and changing social norms are all significantly impacting on the traditional provision of intergenerational support. In what some view as an extreme response to this challenge, a new Chinese 'Elderly Rights Law' was instituted in 2013 requiring grown children to provide physical and emotional care for their elderly parents, including a requirement to visit their parents regularly and look after them financially, or face fines or jail sentences. HIV/AIDS has so significantly affected middle-aged populations in many regions that it has left both older people and children without support and further led to the care of orphaned children being undertaken by their grandparents.

There is a growing recognition that caregivers must ideally be able to access training, services, and financial supports to enable and encourage them to take on and maintain caregiving roles that enables the delivery of more personalized care and enable lower health system expenditures. The UK, New Zealand, and Australia have all implemented national strategies to better support caregivers, which include information services, financial supports, community supports, legislation to allow caregivers to request flexibility in the workplace, and working with employers to show the financial and organizational benefits of better supporting caregivers in the workplace. Indeed, recognizing the important role of unpaid caregivers, and ensuring that their evolving needs are taken into account in planning and allocating resources will be needed to enable the care of ageing populations.

Age-friendly cities and communities

The WHO over the past decade has been actively promoting the creation of age-friendly cities and communities to promote a more thoughtful approach that could promote the health and well-being of people of all ages across the life course. An age-friendly community is defined as one that recognizes the great diversity among older persons, promotes their inclusion and contributions in all areas of community life, respects their decisions and lifestyle choices, and anticipates and responds flexibly to ageing-related needs and preferences (WHO 2007). Through its work, the WHO has identified eight domains of community life that influence the quality of life and health of older persons and people of all ages: respect and social inclusion; social participation, communication, and information; civic participation and employment; outdoor spaces and buildings; transportation, housing, and community support and health services. The consideration of these eight domains

into the design and development of communities, has supported the needed transformation of communities into age-friendly ones that encourage active and healthy ageing by optimizing opportunities for health, participation, and security.

The development of the WHO *Global Network for Age-friendly Cities and Communities* was recently identified as one of its ten priorities to enable healthy ageing. It currently has over 500 member cities and communities across 37 countries. Among communities that have taken part in age-friendly community development activities at various levels, many have learned to assess their level of 'age-friendliness', how to integrate ageing perspectives into urban planning efforts, and how to create age-friendly environments that consider not only design and physical features, but also infrastructure, policies, and service provision. Further increased concern towards ensuring older people have appropriate and affordable housing and transport options and that pedestrian safety and safety from violence and crime are better addressed will ensure that the social involvement and the health and well-being of older people can be better supported.

Public health implications of population ageing

As seen in this chapter, population ageing is a major global phenomenon that will continue to have a major impact on disease and disability patterns and on the use of health and social services. A coordinated and appropriate public health response, therefore, is essential if this phenomenon is to translate into an opportunity for longevity and healthy ageing, rather than a threat to global health and resources.

Public health is important in monitoring trends and transitions in risk factors, disease, and disability, encouraging effective health promotion practices that promote healthy ageing, and in setting policy for equitable and efficient use of healthcare resources for this growing population that requires different and more customized approaches to their care. The fact that vaccinations rates among the elderly lag far behind those of children speaks to just some of the significant public health gaps that currently exist. For example, no country other than South Korea has achieved the WHO-recommended target influenza vaccination rate of 75% for older adults (National Institute on Ageing 2018).

Health promotion to support healthy ageing begins in early life and continues throughout the life course to the oldest ages. As noted earlier, exercise, not smoking and maintaining strong social networks can allow older adults to live significantly longer that others who do not engage in these practices. Increasingly, it is also becoming recognized that dementia is not an inevitable consequence of ageing and that nine potentially modifiable health and lifestyle factors from different phases of life that, if eliminated, might prevent the development of dementias (Livingston et

al. 2017). Much more knowledge is needed as to how we can optimize the conditions and experiences of ageing.

Finally, better acknowledgement and recognition of the continued contributions made by older people themselves, as well as unpaid caregivers, to their families and communities and national economies is also of fundamental importance in addressing ageism and better meeting the challenges of an ageing population and their associated health needs.

Summary

Ageing is universal, unavoidable, and not uniform.

Population ageing is occurring at far greater rates in low-and middle-income countries than in high-income countries, and is placing considerable strains on health and social care sectors in varying ways.

Increased longevity has not been experienced uniformly across socioeconomic and ethno-cultural groups or in different countries.

Severe disability is becoming less common in successive cohorts of older people indicating that a compression of morbidity and disability is occurring, although not with certainty in a growing number of cases.

Advances in healthcare for older people have more recently had dramatic effects in improving survival and reducing disability associated with the inevitable increases in chronic diseases at older ages, but has also allowed the emergence of new chronic diseases like Alzheimer's and other related and incurable dementias that now appears to be emerging as one of the greatest global challenges for health and social care in the twenty-first century.

Families and increasingly friends in all countries are increasingly providing a major part of the care needed by older people—as unpaid caregivers—but do require more knowledge and support of formal health and social services.

Public health has major roles in surveillance, disease prevention and the promotion of healthy ageing, and in the development of health and social services for older people.

Forced migrants and other displaced populations

Catherine R. Bateman Steel and Anthony B. Zwi

Introduction to forced migrants and other displaced populations

Migration and displacement have always been features of human life but the intensification of globalization, and increased ease of travel and interconnectedness, has seen the effects of displacement reaching far beyond the immediate contexts in which they occur. Forced migration is displacement that involves coercion and the implication that those involved have moved against their will. The previous few decades with the end of the cold war, rapid globalization, increasing inequality between and within nations, ongoing wars, and conflict (United Nations High Commissioner for Refugees (UNHCR) 2006), have created a landscape where forced migration affects all populations to some extent, whether as displaced or as hosts to the displaced. Health professionals will undoubtedly be confronted with the effects of forced migration and called upon to engage in responses for those affected regardless of where they practice. This chapter aims to provide a global overview of forced migration and the public health challenges facing populations forced to move from their usual homes, in order to assist the public health professional in framing their own responses. It begins by presenting a brief history of forced migration and the legal definition of ‘refugee’. We describe the emergence of categories of forced migrants that do not meet the legal definition of ‘refugee’, describe how these groups are treated by states, and the implications for people’s lives and health. The chapter then explores the social and political factors that have influenced the treatment of refugees by states. We lay out some of the major health issues that refugees face in both developing and developed countries. The wide variety of actors involved in both protecting forced migrants and providing

health services is presented, along with a discussion of the contextual conditions that have an impact, often detrimental, on the health of forced migrants. As well as describing the structural factors that create and limit health outcomes, this analysis seeks to highlight the agency and voice of forced migrants, exploring the importance of understanding and projecting these, and of appreciating the rationales for how forced migrants may act in the often chaotic situations in which they find themselves. We consider how interactions with other actors, within the complex social, political, and legal context of forced migration, may lead to seemingly unhealthy choices, and at times, barriers to engaging with services. Yet, forced migrants make choices, when possible, seeking to protect their well-being and fight for better, and healthier, outcomes.

Causes of displacement

The global context

Forced migration reached record levels in 2011 with more people becoming refugees in that year than in any year since the start of the new millennium. Humanitarian crises in countries such as Sudan, Libya, Somalia, and Côte d'Ivoire, as well as ongoing instability in Afghanistan and Iraq among others, contributed to a staggering 4.3 million people being newly displaced from their homes (UNHCR 2011). While war, violence, and natural disaster are major contributors, and the causes most commonly associated with forced migration, it is important to consider the broader global dynamics that shape and create the forced migration situation.

Globalization, inequality, and perceptions of crisis

Forced migration cannot be fully understood without considering the global context and the shifting global forces that shape the form and patterns of migration. Globalization and its role in shaping the dynamics of forced migration need to be considered. Although globalization is a contested concept with disputed definitions, most people accept it as a global process of integration which affects sociocultural, economic, and political domains (see Chapter 1.5). The increased ease of travel, and the cultural interconnectedness that projects visions of opportunities in distant lands,

provides a context which may facilitate migration among those with powerful forces driving them from their homes.

The economic implications of the globalized landscape are also worthy of mention in any analysis of forced migration. There is a polarized debate over the effects of globalization on human development and health. Some commentators argue, like Feachem (2001), that the forces of economic globalization may be beneficial to the poor, increasing wealth and therefore health; while others (Baum 2001; MacDonald 2007) highlight the poor health situation in many developing countries and the vast inequities present, and suggest that globalization plays a part in generating these conditions by creating an uneven playing field and weighting the economic benefits towards those that already have power and wealth. They argue that globalization cannot be separated from economic policies that serve the interests of the wealthy, reinforcing or exacerbating inequalities, fuelling conflicts, and contributing to public health crises in developing countries. This analysis suggests that the only way to improve health is to seriously restructure the dominant international financial institutions. Taking the middle ground, Lee (2004) suggests that rigorous, ongoing analysis is required to assess the positive and negative impacts on health within the overall conceptual domain of globalization. Zwi and Alvarez-Castillo (2003) argue that globalization has often led to poor health outcomes for vast populations and that this in turn is responsible for fuelling forced migration. Regardless of our standpoint on globalization, what it is, how it impacts on health, and its influence, what is clear is that global inequities exist and are dramatic, the impact of such inequities cannot be ignored as major contributors to forced migration, whether or not associated with violence.

Castles (2004) provides an analysis that calls for careful examination of the global context when describing forced migration dynamics. He argues that the current perception of a global ‘asylum crisis’ should be seen more as a crisis of North–South relationships, within which ‘asylum’ is but one aspect. The current picture of forced migration, he argues, is a result of disparities between ‘North’ and ‘South’. Although the North–South conceptualization does not perhaps accurately represent the divisions we see today, we can see the dynamics he describes as ‘North–South’ as being between the wealthy and less-wealthy nations. While disparities exist and people search for a better life, or simply for survival, forced migration will continue. The disparity is also reflected in how the effects of forced

migration are absorbed globally, further deepening the crisis in North–South relations. He shows that while there has repeatedly been a perception of impending asylum crises ever since the 1800s, which largely do not fully emerge as feared, there are some new features. He cites the increase in endemic violence and human rights violations as a feature that has increased the volume of forced migration in recent times. Castles (2004) shows, however, that for the North, there is no significant economic or social crisis resulting from forced migration and contrary to popular belief, the North has not had to absorb large influxes of people. The situation is nonetheless construed by those in the North as a crisis because it highlights the 'erosion of nation-state sovereignty'. The South, however, has absorbed the vast majority of forced migrants from neighbouring countries (Allotey and Reidpath 2003). This combined with increasingly restrictive policies of wealthy countries that seek to limit refugee absorption from the South, leads to a tension in North–South relations, and opens space for people smuggling and trafficking, further threatening the sense of control over borders that the North is seeking to maintain, and therefore deepening the sense of crisis perceived by the North. Hence the burden has been left largely with the South, while in the North, incomplete pictures of fear that exclude vulnerable people have been painted and promoted (Grove and Zwi 2006). In their review of globalization, forced migration, and health, Zwi and Alvarez-Castillo (2003) suggest that public health professionals have a responsibility to examine the context and whole picture, and in so doing, to break down these 'incomplete pictures of fear' and advocate for a more humane globalization that has a chance of decreasing the poor health outcomes associated with forced migration.

Immediate drivers of displacement

There is general agreement on the range of factors that contribute to displacement and forced migration. However, the importance of particular factors, and the linkages between them, varies in different contexts. Identification of specific causes has implications for both the states involved and the migrants themselves, given that the perceived cause of displacement has an impact on the international response, the level of funding support provided, and the attitudes of host populations to those seeking protection. The health consequences of forced migration will be shaped by not only the

causes of displacement, but also by the perceptions of all actors regarding these causes and their relationship to them. In this respect, the terms and context within which forced migrants are described and 'presented' greatly affects the societal response and opportunities, or constraints, operating.

Forced migration has traditionally been associated with war and violence. The conception of a refugee as defined by the United Nations (UN) Convention, fleeing from persecution to a place of safety in another country, was clear-cut and well understood. As Moore and Shellman (2004) describe, the central model was one of:

Violence in = Forced migration out.

However, while the main causes of involuntary displacement remain armed conflict, repression, and war, other factors such as natural disasters and development projects are also important, as are the more complex set of economic, social, and political circumstances that may lead to trafficking and people smuggling.

Martin (2002) focuses attention on natural and man-made disasters and border changes leading to statelessness, as factors which lead to forced migration, alongside the well-recognized factors related to persecution, human rights violations, repression, and conflict. Environmental factors, such as rising sea levels and extreme weather conditions, are also increasingly recognized as important. Some argue that these causes may, over time, supersede conflict as a primary cause of forced migration (Myers and Kent 1995). Resource constraints, including depleted access to land and water, and conflict over precious minerals, are likely to become increasingly important, especially as the global population increases from around 6 billion people at present to nearly 9 billion by 2050.

While all these factors are important, quantifying their effects is difficult. Data are available regarding numbers of 'Convention' refugees (see 'Categories of forced migrants' section) and also, more recently, regarding internally displaced persons (IDPs). These data may give some indication of the level of displacement produced by conflicts and violence, alongside immediate natural disasters such as tsunamis and earthquakes. However, more insidious environmental and economic effects are far harder to quantify.

The increased complexity of recent times in describing and understanding factors that cause displacement raise new concerns that go beyond the simple 'violence migration' model therefore calls for new approaches. Major

challenges include an increased focus on economic migrants and those who are forced to move as a result of environmental and climate changes; there is also a rise in ‘mixed migration’, a term which recognizes that many migrants fall somewhere on the spectrum between forced and voluntary migration and are hard to categorize as one or the other.

Particularly important is a call for a shift in policies of protection for host countries to developing policies which address the root causes within countries from which people are forced to migrate; and a growing recognition that understanding causes may allow predictions of impending displacement as well as the identification of the means to avert large-scale displacement. Some analyses continue to support the primacy of violent conflict, or threat of conflict as the major predictor of populations leaving their homes. Moore and Shellman (2004) analysed a global sample of 40 countries and using a model that incorporated a wide range of indicators (government threat, dissident threat, government-dissent interaction, ethnic or non-ethnic civil wars, war on territory, income opportunity, political freedom and the rule of law, and cultural and family ties), they found that the first three were the primary determinants of forced migration flows. These were more important than other factors such as size of economy or type of political institution. Apodaca (1998) analysed a variety of models developed to predict forced migration and concluded that human rights violations are one of the most important predictors.

Economic migration has often been portrayed in the media as freely chosen migration that should not confer a responsibility to protect on accepting states. However, analysts such as Castles (2003) argue that forced migration is linked to economic migration and that the two are ‘closely related (and indeed often indistinguishable) forms of expression of global inequalities and societal crises’. These inequities have intensified since the end of the cold war. He argues that studies of the causes of forced migration have neglected the overarching economic and social structures which should be seen in relation to ‘US political and military domination, economic globalization, North–South inequality and transnationalism’ (Castles 2003).

Debates regarding causes of displacement have particular salience in relation to the protection offered to forced migrants. As subsequent sections of this chapter describe, the nature and extent of protection is often determined by perceived cause. Therefore, understanding these debates is

crucial as they may have effects on what and how protection, if any, is offered to forced migrant populations.

Categories of forced migrants

Definitions of forced migration have been debated for more than 50 years, dating back to the first UN Convention on Refugees in 1951. The legal framework that emerged under the Convention centred on ‘refugees’ as a specially defined group and is based upon the 1951 Convention and a subsequent 1967 protocol. According to these, a refugee is a person who:

> owing to a well-founded fear of being persecuted for reasons of race, religion, nationality membership of a particular social group, or political opinion, is outside the country of his nationality, and is unable to or, owing to such fear, is unwilling to avail himself of the protection of that country. (UNHCR 2009)

This definition has been modified by regional instruments in Africa and Latin America, as described in a later section. The International Association for the Study of Forced Migration (IASFM), however, defines forced migration much more widely as:

> a general term that refers to the movements of refugees and internally displaced people (those displaced by conflicts) as well as people displaced by natural or environmental disasters, chemical or nuclear disasters, famine, or development projects. (Forced Migration Online 2008)

This definition encompasses a wide range of forced migrants, and these can be distinguished into several distinct groups (Table 10.9.1).

The definitions of other forced migrant groups, and their sources, are outlined in the following subsections. They highlight the increased attention devoted to describing, as well as defining, the many forms of forced migration that exist. The discourse and narratives presented have a marked impact on how people see, and respond to, those forced to leave their usual homes and livelihoods.

Internally displaced persons

Unlike refugees, there is no legal definition of an IDP. It is generally accepted that if a person meets the definition of a refugee, but their

displacement does not take them across an international border, then they are internally displaced. The Secretary General of the UN has appointed a representative to deal with IDPs and the Office of the United Nations High Commissioner for Human Rights (OHCHR) has produced a set of Guiding Principles to address the specific needs of IDPs who are described as:

> persons or groups of persons who have been forced or obliged to flee or to leave their homes or places of habitual residence, in particular as a result of, or in order to avoid the effects of, armed conflict, situations of generalized violence, violations of human rights or natural or human-made disasters, and who have not crossed an internationally recognized State border. (Deng 1998)

Asylum seekers

Asylum seekers are those who are fleeing persecution and are seeking refugee status in another country. According to the UNHCR, an asylum seeker is:

> Someone who has made a claim that he or she is a refugee, and is waiting for that claim to be accepted or rejected. The term contains no presumption either way—it simply describes the fact that someone has lodged the claim. Some asylum seekers will be judged to be refugees and others will not. (UNHCR 2009)

The application referred to relates to being recognized under the 1951 Convention as a refugee and therefore being entitled to the protection and support stipulated by the Convention. They may or may not arrive in a country with authorization, nevertheless, they have a legal right to claim asylum and are therefore not ‘illegal’.

Trafficked persons

The 2003 Protocol to Prevent, Suppress and Punish Trafficking in Persons, especially women and children, describes trafficking as:

> recruitment, transportation, transfer, harbouring, or receipt of persons, by means of the threat or use of force or other forms of coercion, of abduction, of fraud, of deception, of the abuse of power or of a position of vulnerability or of the giving or receiving of payments or benefits to achieve the consent of a person having control over another person, for the purpose of exploitation. Exploitation shall include, at a minimum, the exploitation of the prostitution of others or other forms of sexual exploitation, forced labour or services, slavery or practices similar to slavery, servitude or the removal of organs. (UN 2003, Resolution 25)

Table 10.9.1 Categories of forced migrants

Refugee	A person who 'owing to a well-founded fear of being persecuted for reasons of race, religion, nationality, membership of a particular social group, or political opinion, is outside the country of his nationality, and is unable to or, owing to such fear, is unwilling to avail himself of the protection of that country' (UNHCR 2009)
Internally displaced persons	'Persons or groups of persons who have been forced or obliged to flee or to leave their homes' (Deng 1998). Or places of habitual residence, in particular as a result of, or in order to, avoid the effects of armed conflict, situations of generalized violence, violations of human rights or natural or human-made disasters, and who have not crossed an internationally recognized state border
Asylum seeker	'Someone who has made a claim that he or she is a refugee, and is waiting for that claim to be accepted or rejected. The term contains no presumption either way—it simply describes the fact that someone has lodged the claim. Some asylum seekers will be judged to be refugees and others will not' (UNHCR 2009)
Trafficking in persons	'Recruitment, transportation, transfer, harbouring or receipt of persons, by means of the threat or use of force or other forms of coercion, of abduction, of fraud, of deception, of the abuse of power or of a position of vulnerability or of the giving or receiving of payments or benefits to achieve the consent of a person having control over another person, for the purpose of exploitation' (United Nations 2003)
Smuggling in persons	'The procurement, in order to obtain, directly or indirectly, a financial or other material benefit, of illegal entry of a person into a state, party of which the person is not a national or permanent resident' (United Nations 2000) [Article 3 (a)]
Environmentally displaced person	'A person displaced owing to environmental causes, notably land loss and degradation, and natural disaster' (Deng 1998)
Development displacees	'People who are compelled to move as a result of policies and projects implemented to supposedly enhance "development" ' (Forced Migration Online 2008)

Smuggled persons

Smuggling of aliens or 'illegal migrant smuggling' is defined by the UN 2000 Protocol Against Smuggling of Migrants by Land, Sea and Air, which supplemented the UN Convention Against Transnational Organized Crime, to mean:

> the procurement, in order to obtain, directly or indirectly, a financial or other material benefit, of illegal entry of a person into a state, party of which the person is not a national or permanent resident. (UN 2000, Article 3(a))

Environmentally displaced persons

The Organisation for Economic Cooperation and Development's online *Glossary of Statistical Terms* describes an environmental refugee as 'a person displaced owing to environmental causes, notably land loss and degradation, and natural disaster' (United Nations 1997). However, the term was first described by El-Hinnawi (1985), a researcher from the United Nations Environment Programme (UNEP) in 1985, who defined environmental refugees as:

> those people who have been forced to leave their traditional habitat, temporarily or permanently, because of a marked environmental disruption (natural and/or triggered by people) that jeopardized their existence and/or seriously affected the quality of their life.

'Environmental disruption' in this definition is taken to mean any physical, chemical, and/or biological changes in the ecosystem (or resource base) that render it, temporarily or permanently, unsuitable to support human life. The validity of the term 'environmental refugees' has been debated greatly since that time. Actors emerge from a realm of perspectives including

environmentalists, economists, and refugee advocates, each with a different interpretation of the term. Some prefer to use the term ‘environmental migrant’ or ‘environmental displacee’; different terms establish different implications for both the individuals and states involved.

Development displacees

There is no legal definition for development displacees; however, Forced Migration Online suggests they are:

> people who are compelled to move as a result of policies and projects implemented to supposedly enhance ‘development’. These include large-scale infrastructure projects such as dams, roads, ports, airports; urban clearance initiatives; mining and deforestation; and the introduction of conservation parks/reserves and biosphere projects. Affected people usually remain within the borders of their country. People displaced in this way are sometimes also referred to as ‘oustees’, ‘involuntarily displaced’ or ‘involuntarily resettled’. (Forced Migration Online 2008)

Interestingly, large-scale agricultural projects do not seem to be specifically mentioned.

Forced migration statistics

Assessing the volume of global flows of forced migrants is valuable in identifying trends and the patterns of distribution with respect to where the burden for providing assistance and care lies. In specific countries and contexts, where people are forced to migrate from their place of origin, the first step in addressing public health and other more general concerns is often to define the size of the population at risk. Donors, governments, aid agencies, and community organizations require basic demographic and related data to inform planning and service delivery. The collection of data is complicated and surrounded by controversy, having the potential to immediately reframe what looks like a technical issue into a political one.

The two main sources of statistics on forced migrants are the United Nations High Commissioner for Refugees (UNHCR) and the US Committee for Refugees and Immigrants (USCRI). These organizations produce differing estimates for different types of forced migrants in different geographical contexts. The logistic difficulties of collecting reliable data from shifting forced migrant populations leaves space for political interests

to enter, and seek to shape, the field. This is compounded by disagreement over definitions of forced migrants and which groups to include in which categories, as mentioned earlier, with significant implications for the rights and entitlements of such groups, as well as for who bears the responsibilities for addressing their needs. Despite contested data, available sources provide valuable information on trends and distribution.

UNHCR forced migration statistics

The UNHCR provides data based on 'persons of concern', an increasingly wide-ranging term. 'Persons of concern' includes refugees (as defined by the 1951 Convention or the 1969 Organization of African Unity (OAU) Convention); persons granted complementary protection (alternative forms of protection for those that fall outside of the terms of the 1951 Convention) and those with forms of temporary protection; asylum seekers who in the year of data collection are still pending a final decision on an application for protection; stateless persons; refugees who returned to their country of origin in the year of data collection; and IDPs (see Table 10.9.2). For the purposes of UNHCR the latter are limited to conflict-generated IDPs to whom UNHCR protection or assistance is extended, but does not include all IDPs.

UNHCR reported that in 2011 the number of forcibly displaced persons exceeded 42 million for the fifth consecutive year (UNHCR 2011). This figure included refugees, IDPs, and asylum seekers. It was estimated that 4.3 million people were newly displaced in 2011 due to conflict or persecution, with 800,000 of these displaced across international borders. This was a 20% increase since 2010 of new displacement. There was also an increase of 700,000 in refugees and IDPs protected by the UNHCR and 7.1 million, three-quarters of the UNHCR refugee population, were reported to be in a protracted refugee situation. Developing countries hosted four-fifths of the world's refugees (UNHCR 2011). The countries of origin for refugees are shown in Figure 10.9.1. Afghanistan produced the greatest number of refugees followed by Iraq and Somalia. UNHCR statistics demonstrate that the majority of refugees remain within their region of origin. Pakistan was the country that hosted the most refugees in 2011, followed by Iran and Syria. Almost half of the world's refugees falling under the UNHCR mandate were hosted in countries with a GDP per capita of less than $3,000.

Table 10.9.2 Persons of concern to United Nations High Commissioner for Refugees (UNHCR 2011)

	2011
Newly displaced	4.3 million
Refugees	10.4 million
IDPs	15.5 million
Asylum seekers	876,100
Stateless	12 million
Resettlement	79,800[a]
Unaccompanied children	17,700
Protected by UNHCR	25.9 million[b]
Forcibly displaced people worldwide	42.5 million

[a] Resettlement—with or without UNHCR assistance—by 22 countries.

[b] Protected by UNHCR—refugees and IDPs.

Source: data from United Nations High Commissioner for Refugees (UNHCR), A Year of Crises: *UNHCR Global Trends 2011*, UNHCR, Geneva, Switzerland, Copyright © UNHCR 2012, available from http://www.unhcr.org/4fd6f87f9.html.

It is important to note that Palestinian refugees falling under the mandate of the United Nations Relief and Works Agency for Palestinian Refugees in the Near East (UNRWA) are not included in the UNHCR refugee figures, but are included in the 42 million forced migrants. The Palestinian community has been one of the largest groups of refugees that has remained without being fully resettled or absorbed into host nations; a reflection of how community members on the ground suffer while local, national, regional, and global powers resolve, or fail to resolve, higher-level strategic and political issues.

Given the importance of these numbers, they are invariably contested and debated; with key actors seeking to shape what data are collected and presented, who are counted, and what the implications are for future activities. Indeed each ‘player’ in the system, whether they be a UN or non-

governmental agency, a recipient or state of origin, a local community or professional group, and many others, has their own rationale for inflating or deflating the numbers of people whether they be refugees or IDPs, in or outside of camps, dependant or free of other major influences.

Internally displaced persons

The global number of IDPs at the end of 2011 was estimated by the UNHCR to be 26.4 million, with 15.5 million benefiting from UNHCR assistance. The figure for 2011 was the second highest on record, according to the UNHCR this was partly due to displacement from Afghanistan, Côte d'Ivoire, Libya, South Sudan, Sudan, and Yemen (UNHCR 2011). Figure 10.9.2 shows the distribution of IDPs globally.

Asylum seekers

In 2011, 876,100 applications for asylum or refugee status were submitted to UNHCR offices or governments. One-tenth of all these applications were registered in South Africa, making it the top asylum destination by a clear margin, more than half these claims were from Zimbabwean nationals. The United States was the next highest receiver of asylum applications with almost half coming from China, Mexico, and El Salvador. The UNHCR noted significant differences between countries in recognition rates suggesting differences in how asylum seekers are treated. For example, between eight European countries the recognition rate for Afghan asylum seekers ranged from 3 to 33% (UNHCR 2011).

Legal framework

Refugees

The 1951 Convention, which forms the basis of all international refugee law, was drafted in the aftermath of the Second World War in response to the large numbers of displaced people caused by the war. The Convention included restrictions on who would be classified as a ‘refugee’ based on geographical and temporal factors that were specific to the European context. As a result, the 1967 Protocol relating to the Status of Refugees was adopted which removed these restrictions and allowed for more general application of the Convention. The Convention and Protocol laid out not only the definition of a refugee but also the scope of protection to which refugees were entitled. The most fundamental of these is *non-refoulement*, the right to remain rather than be returned to a place where their lives or freedoms would be at risk. Debate has raged over the continuing relevance of the Convention definition, given that it excludes large numbers of people in need of international protection, notably IDPs and those that have

migrated as a result of generalized (as opposed to individualized) violence, civil war, and widespread human rights abuses.

Africa and Latin America responded to the limitations of the Convention and Protocol by adopting their own regional laws and standards. The Organization of African Unity (OAU) (now known as the African Union) adopted the 1967 Convention Governing the Specific Aspects of Refugee Problems in Africa (Barnett 2002). This is the only legally binding regional instrument and has a refugee definition similar to that of the Convention but includes those who flee due to 'external aggression, occupation, foreign domination or events seriously disturbing public order in either part or the whole of his country of origin or nationality' (OAU 1969).

In Latin America, the Cartagena Declaration, adopted in 1984, included a definition of refugee similar to that of the OAU Convention but which also included reference to 'massive violation of human rights' (Regional Refugee Instruments & Related 1984). The latter is not legally binding but has been adopted by many states and incorporated into some national legislation in the region.

Persons who have participated in war crimes and violations of humanitarian and human rights law, including the crime of terrorism, are specifically excluded from the Convention and cannot be recognized as refugees.

The UNHCR has been given a mandate to provide international protection to refugees and seek permanent solutions to their problems through its Statute, adopted by the UN General Assembly (UNGA) in December 1950. Over the years, the UNGA has allowed UNHCR to extend its responsibilities and is increasingly focused not only on refugee protection but also on managing refugees in the field.

Internally displaced persons

While IDPs do not have the same legal framework of protection, they have become included in the UNHCR's 'people of concern' and are therefore often covered by its mandate. The United Nations Office for Coordination of Humanitarian Affairs (OCHA) has produced a set of Guiding Principles to address the specific needs of IDPs (Deng 1998). The guidelines identify rights and guarantees that should be afforded to IDPs although they are not legally binding.

Asylum seekers

The Declaration of Territorial Asylum (DTA) adopted by the UNGA in 1967 is based on article 14 of the Universal Declaration of Human Rights, which declares that ‘everyone has the right to seek and to enjoy in other countries asylum from persecution’. The principles of the DTA are that all states recognize asylum granted by one State, that states themselves evaluate the grounds for asylum, and that no one seeking asylum should be rejected at borders or if already within a country should not be compulsorily returned to any state in which they may be subject to persecution. Exceptions can only be made in situations of national security or for asylum seekers that have committed a crime against humanity, against peace, or a war crime.

Asylum may be granted by states on the basis of the 1951 Refugee Convention, in which an individual has been deemed a 'refugee' as defined by the Convention. However, given the restrictions of this definition and the increasing numbers of people who are seeking protection but do not fit the Convention definition, alternative forms of protection have developed. Often termed 'complementary' or 'subsidiary' protection, McAdam (2006) describes the plethora of alternative forms of protection for 'non-Convention refugees' that previously had been treated much the same as Convention refugees by states.

'Non-convention' refugees, such as those fleeing widespread violence rather than targeted individual persecution, have to look to instruments of human rights law, rather than refugee law, for protection. However, human rights instruments do not attach the same clear rights and standards as the Refugee Convention and it has also been argued that human rights law can be weak on implementation (McAdam 2006). This has led many to argue that complementary protection is a lesser form of protection, and there is a danger of states using these forms of protection to decrease the numbers of Convention refugees and therefore their level of commitment. Debate continues as to whether expanding the current Convention definition, or expanding systems of complementary protection, will weaken or broaden protection to those seeking asylum.

Trafficking and smuggled persons

Although the reasons for a person to be trafficked or smuggled are very similar, international agreements and national laws treat them quite differently. Unlike trafficking, which may occur internally in a country, smuggling always involves the illegal crossing of an international boundary. Smuggling is seen as a crime against a *state* whereas trafficking is a crime against an *individual*. Consequently persons that are trafficked or smuggled are likely to be treated quite differently. The UN Convention on Trafficking mandates states to consider granting victims permanent or temporary resident status, whereas the Smuggling of Migrants Protocol calls on states to facilitate the return of smuggled persons to the country from which they came.

Environmental and developmental displacees

The concept of environmental refugees or displacees is particularly contentious and the subject of much current debate. There is little agreement on whether environmental factors can be seen as primary causes of displacement and equally no consensus on a definition for those displaced from their homes by these factors. As a result the legal protection available is marginal. The current legal regime has no specific mandate to protect environmental displacees, if they are displaced across international borders; however, 'natural or human-made disasters' are covered by the Guiding Principles on Internal Displacement (Deng 1998). These place the primary duty for protection with the national authority; however, no duty is placed on other states to recognize the need for protection. A growing body of opinion has begun calling for a system of global governance that recognizes environmental factors as a cause of displacement and for the displacees to be protected under international law (Courtland Robinson 2003; Biermann and Boas 2007).

Similarly, developmental displacees do not have frameworks of protection of their own but are covered by the Guiding Principles on Internal Displacement. There is a need to recognize the needs of this group and for research on displacement not to fall into a dichotomy that separates conflict-related displacement from development-related displacement (Cernea 2007).

Evolving rights of protection

Protection based on a definition of refugees fleeing from the effects of violent conflict has been the prevailing paradigm, and while the centrality of conflict-related displacement has been debated, conflict and violence clearly remain significant causes of forced migration and suffering. Analysis reflecting the increasingly complex drivers of forced migration, including economic and environmental concerns, while vital, should be careful not to compromise existing rights of protection. These rights of protection, based on conflict as the central tenet, should not be further eroded by the recognition that there are other causes of forced migration that need to be seriously considered.

Public health situation of forced migrants

Forced migrants live in a range of different social, political, and geographical conditions. They may form distinct populations or be dispersed among host populations; they may be displaced within their own country, to a nearby or distant country of asylum; and may dwell anywhere from a developing country experiencing conflict, to a more peaceful but poverty-stricken developing country, to a wealthy developed nation. The health of each forced migrant population, and each individual within the group, will be shaped by these factors, as well as their prior health and social condition, the journeys they have had to take, the stability and security present in their new environments, the social structures within which they live, and the access they have to services and social support.

Gushulak and MacPherson (2000) describe migration health in terms of 'three distinct but interdependent undertakings: The pre-departure phase, the migratory journey itself, and the arrival at destination', each of which influences health. Factors such as social networks, assets, language, knowledge, information or access to services, food security issues, poor shelter, sanitation, and availability of safe water will influence health outcomes.

In this section we describe the major health challenges facing forced migrant populations. This is followed by an overview of the public health responses and an indication of where more detailed technical advice may be found.

Refugees in developing countries

Developing countries continue to absorb the vast majority of forced migrants, in particular as developed nations have become more restrictive. Within developing countries, people who are forcibly displaced either within or across borders may find themselves in a variety of possible contexts, settling short or long term either in a camp situation or dispersed within a host population. Each presents threats and opportunities.

The type of settlement formed has implications for health and well-being. The typical refugee camp setting has presented a range of problems, although improvements in public health knowledge and experience, and informing policy and practice with evidence, have led to better outcomes.

The impact of forced migration falls heavily on developing nations, and within these countries, on host populations. This is particularly so where

forced migrants reside in non-camp situations.

Camps and non-camp settlements

Camps, while constructed with the intention of providing protection, safety, and access to services, may also pose risks. Poorly planned refugee settlements may have inadequate infrastructure, may pose risks to safety, or set up new inequalities. The combination of overcrowding, poor hygiene and sanitation, lack of water, poor nutrition, and inadequate shelter provides conditions for spread of many diseases, particularly communicable disease. Refugees may arrive in a poor condition, suffering from malnutrition, and with poor immunity, reflecting limited access to immunization services. Disrupted social structures decrease the capacity to deal with sickness. Communicable disease spreads quickly and may be particularly severe. Psychological distress is also a major issue due to the insecure, restricted environment and lack of resources.

Debates over the utility of camps are highlighted by Harrell-Bond (2000) who argues that as a concept they have failed. Originally based on modernization theory, the premise was that camp settlements would become new agricultural centres and eventually be integrated with host populations to the benefit of all. However, this was abandoned as the theory became discredited and was replaced by a view that refugees should be seen as temporary. Harrell-Bond suggests that those in camps are in ‘prison-like’ settlements with poor conditions, increased vulnerability to disease, and often poor nutrition. She also argues that camps do not help host populations, as large sums of money are diverted to camps which may be demolished if refugees do move on, as well as diverting scarce human and material resources from the host population. She suggests that it would be far more appropriate and cheaper to help integrate refugees into host populations and invest in the country and strengthening existing social structures, as a whole.

In many situations of forced migration, for example, when the Kosovar Albanians fled from Kosovo over the border into Albania, integration with host populations there was the norm. Following political instability and violence in Timor-Leste in 2006, 4 years after independence, makeshift camps were established within Dili, the capital city, for IDPs, while many also fled and were integrated with host communities in the districts. The

latter necessarily absorbed a portion of the social and economic costs associated with accommodating those who fled.

However, Salama et al. (2004) show that, despite the problems associated with camps, there are also benefits. The increased knowledge base and coordination of humanitarian interventions have led to improvements in health, with better nutrition, sanitation, and health services. The burden of ill health may shift from displaced populations who are relatively well serviced, especially if they cross international borders and become refugees, relative to host populations and IDPs whose needs may be greater and who have less access to assistance.

Mortality

Crude mortality rates (CMRs) are often used as an indicator of the immediate impact of complex emergencies. Toole and Waldman (1990) proposed a definition of the acute phase of a complex emergency as greater than one death per 10,000 people per day, based on a doubling of the baseline mortality rate in sub-Saharan African countries. Surveillance systems to monitor the impact of emergencies have been established in the past 15 years based on this definition. In recent decades, it has not been unusual to see CMRs in refugee populations of 30 times the baseline in the country of origin (Toole and Waldman 1997); some of the highest recorded were among Rwandan refugees who flooded into North Kivu in 1994 where average CMRs were 20–35 deaths per 10,000 (Salama et al. 2004). In refugee camps, CMRs of 2 per 10,000 are now rarely seen; however, the situation in non-camp situations has deteriorated (Salama et al. 2004). Refugees are usually at greatest risk in early days of displacement, with mortality rates subsequently diminishing. The highest risk group is young children with most deaths occurring in the under-5 age group, demonstrated dramatically in one Somali camp in which 70% of children under 5 appear to have died over an 8-month period (Moore et al. 1993; Toole and Waldman 1997).

Causes of death

The main causes of death in developing country refugee situations are similar to those of developing country populations in general. The most

common causes of death in Africa are diarrhoeal disease, measles, acute respiratory infections, and malaria (where endemic), exacerbated by a high prevalence of acute malnutrition (Toole and Waldman 1997). These diseases typically account for the vast majority of reported deaths in refugee populations, at times up to 95% thereof. This is in contrast to European countries affected by war, where the most common causes of death are injuries, as well as communicable diseases, neonatal problems, and nutritional deficiencies. Recent analyses suggest that chronic diseases require attention, given the ageing population, and violence, instability, and forced migration in populations in which communicable diseases have been relatively well controlled and chronic diseases have emerged as problems (Chan and Sondorp 2007).

The conditions affecting refugees may have been brought with them from the country of origin, may be acquired in the host country (with refugees susceptible due to lack of sufficient immunity), or may result from the camp conditions themselves.

Diarrhoeal disease

Possibly the greatest threat to life among refugees is diarrhoeal disease. The main pathogens of concern are usually cholera and shigella. In some refugee camps, more than 40% of deaths in the acute phase of an emergency can be attributed to diarrhoeal disease, and over 80% of these deaths are in children under the age of 2 years (Salama et al. 2004). Outbreaks are exacerbated by factors such as the sharing and contamination of water sources and food, the scarcity of soap, and inadequate sanitation.

Among Rwandan refugees in camps in North Kivu, 85% of the 50,000 deaths among the 800,000 people that flooded into the area in early July 1994 were caused by diarrhoea, with 40% from shigella dysentery and 60% from cholera (Salama et al. 2004). The primary drinking source, which was lake water, became rapidly contaminated, and as water was also scarce, infection spread swiftly through the refugees. Deaths in Goma were associated with a number of preventable causes (Siddique et al. 1995). Among Kurdish refugees, 70% of deaths were a result of diarrhoea (Toole and Waldman 1997). In the elderly and young children, dysentery case-fatality rates can be as high as 10%. Important public health interventions include the need to supply sufficient water, control excreta and hygiene, and

increase public awareness of basic rules of hygiene. Evidence-informed case management is necessary to avoid unnecessary deaths.

Measles

Another of the most feared diseases in camps is measles—a particularly large problem in refugee situations in the 1970s and 1980s until it was recognized that vaccination should be accorded priority. The risk of death from measles is exacerbated in the presence of malnutrition, a common occurrence among refugee populations, as are secondary complications. Globally, measles kills hundreds of thousands of people each year. In 2000 there were 562,000 measles deaths but with improved surveillance and vaccination rates this was reduced to 122,000 deaths in 2012 (WHO 2014). While it is less of a problem in previously well-vaccinated populations, in developing countries, measles death rates can range from 1 to 5%, and in refugee settings among malnourished children, the death rate may reach 10–30%.

In 1985, 53 and 42% of refugee deaths in eastern Sudan and Somalia, respectively, were caused by measles (Salama et al. 2004). The situation has improved in refugee camps due to mass vaccination, but IDPs still suffer as they have less access to vaccinations and, since 1990, it is more common to find high rates of measles in IDPs than in refugees. Measles is included in the Expanded Programme on Immunization but there is often low coverage in young children especially where human resources for health are limited or conflict affects normal service delivery. Increasing attention is being devoted to ensuring that services can continue to be supplied in fragile states.

Malaria

In areas where malaria is endemic, it can cause high rates of mortality and morbidity among refugees. This is particularly the case when people are displaced from an area of low endemicity to one of high endemicity. Drug resistance also plays a large part with chloroquine resistance and more recent resistance to fansidar reported in Rwandan refugees in Zaire. Local communities in low endemic areas may be placed at risk by refugees arriving from high endemic areas, especially if local conditions favour the mosquito. In Africa, 30% of annual malarial deaths occur in complex

emergency settings. This is because in complex emergencies (CEs) overcrowding increases the frequency of bites and also delays intervention thereby increasing the time that the parasite is in the blood (Salama et al. 2004). An example is Burundi which had a major epidemic in 2000–2001 when the population of 7 million reported 2.8 million cases of malaria, the war in 1993 caused control efforts to break down, populations were moving, and there was widespread resistance to chloroquine.

Acute respiratory infections

Refugee camp conditions facilitate the spread of acute respiratory infections (ARIs) and rank among the leading causes of death in displaced populations. The lack of shelter, overcrowding with poor ventilation, and exposure that characterize the refugee existence contribute to the susceptibility to ARIs with poor outcomes. Young children are particularly affected. In Kabul, in 1993, 30% of under-5 deaths and 23% of deaths in displaced persons were a result of ARIs (Salama et al. 2004). Vaccinations against malaria, diphtheria, and pertussis have led to decreased mortality from ARIs. It is not just that these pathogens cause ARIs but they also render hosts less able to defend themselves from bacterial infection.

Tuberculosis

Tuberculosis (TB) is becoming increasingly important in CEs and situations of forced migration—in part as a result of disrupted therapy (Connolly et al. 2004). TB can become a major problem, leading to a large numbers of deaths. Poor nutrition and overcrowding exacerbate the risk of TB, as may underlying HIV in some populations. A recent study of instability and internal displacement in Timor-Leste revealed a number of problems in maintaining continuity of treatment for those with TB. As a result, many may have incomplete or inadequate treatment.

Meningococcal disease

Meningococcal disease is a potentially major problem for refugees when they are in overcrowded settlements in an endemic area, such as the 'meningitis belt' of sub-Saharan Africa that stretches from Senegal to Ethiopia. In Africa, a threshold incidence of 15 cases per 100,000 population per week is used to define the presence of an 'epidemic'. In CEs, large epidemics have also been reported outside the traditional malaria belt. The Democratic Republic of the Congo had six epidemics in 6 months in 2002 and epidemics have also occurred in Uganda, Rwanda, and Tanzania (Salama et al. 2004). Immunization has proved to be an effective control measure but is only effective in epidemics, routine immunization is not effective as the current vaccines only produce immunity for 3–5 years and may not be used in children under 2 years. Therefore, the World Health Organization (WHO) only recommends mass immunization in areas where epidemic proportions have been reached, and they estimate that this can reduce deaths by up to 70%.

Hepatitis

Outbreaks of hepatitis E have occurred in African refugee camps. It is transmitted by the entero-faecal route, and therefore water supplies are often involved. Case-fatality rates vary from 1–4% but there have been particularly high attack rates and case-fatality rates (up to 20%) reported among pregnant women. The high level of previous exposure to hepatitis A and B in developing countries makes it likely that any hepatitis epidemic with high attack rates in adults is likely to be caused by hepatitis E.

HIV/AIDS and other sexually transmitted infections

The pattern of HIV/AIDS and sexually transmitted infections (STIs) among refugee populations in developing countries will depend on many factors, including the level of infection prior to displacement (Dualeh and Shears 2002). Speigel (2004), working at the UNHCR, has highlighted the key preventive and other responses to HIV/AIDS. Conflict situations and camp conditions have often been thought to exacerbate the spread of STIs, due to breakdown of social structures, behavioural change, sexual violence, and lack of access to services and testing (Zwi and Cabral 1991). However,

Speigel (2004) describes other factors inherent in refugee situations that may retard the spread of these diseases, such as decreased mobility, and the possibility of a host country having increased services in comparison to the country from which people have fled. He argues that each situation should be examined independently and that the spread of STIs is most likely to be determined by the complex interactions between a number of groups: refugees and their hosts, the original conflict-affected population, IDP populations in the country of origin, and host communities in country of origin. He argues for public health responses to be broad and focus not only on camps but the entire situation, including host populations.

Other communicable diseases

Outbreaks of other less common communicable diseases have been reported in some refugee camps, as highlighted by Dualeh and Shears (2002). Typhoid fever is endemic in many tropical areas and may occur sporadically in refugee situations. Leishmaniasis and trypanosomiasis have also been reported in epidemic proportions among displaced populations in Uganda and Sudan. Viral haemorrhagic fevers occur in selected areas and may place refugee communities at risk. Rift Valley fever has been documented among Somali refugees in Kenya, yellow fever occurred among displaced populations from Ethiopia to Sudan, and dengue fever affects refugees in endemic areas of South East Asia.

Connolly et al. (2004) provide an excellent overview of the literature on communicable diseases and CEs.

Malnutrition—protein energy deficiencies

Moderate to severe acute malnutrition is a common occurrence in refugee settings. Children are particularly affected, with some deteriorating in terms of nutritional status after arrival in camps, due to inadequate nutrition or diarrhoeal disease. Surveys undertaken between 1988 and 1995 documented a range of 11–81% of children under 5 years suffering acute malnutrition in conflict-affected populations (Toole and Waldman 1990). Acute malnutrition can be both the cause and effect of other illnesses, and contributes to mortality both directly and indirectly. Malnutrition and measles are

particularly linked with malnutrition exacerbating measles, and measles itself contributing to high malnutrition rates in those that survive it (Toole and Waldman 1990). This ‘synergistic relationship’ that malnutrition has with communicable disease requires an integrated response aimed at improving nutrition combined with efforts to improve public health services.

Micronutrient deficiencies

As a result of inadequate food rations micronutrient deficiencies occur frequently in refugee populations. The most common diseases seen are iron and vitamin A deficiencies but other diseases include scurvy (vitamin C deficiency), pellagra (niacin and/or tryptophan deficiency), and beriberi (thiamine deficiency). As Prinzo and Benoist (2002) discuss, the solutions are not simple and each setting may require a different approach, including providing fortified blended cereal and finding ways to exchange rations for locally produced fresh fruit and vegetables.

Food and nutritional interventions need to be responsive to cultural as well as economic issues.

Reproductive health

The reproductive health needs of refugees have gained recognition since the mid-1990s. The burden is undeniably greater for women as a result of insecurity in their social situations and gender-based violence. Women lack basic necessities such as sanitary napkins and condoms, and pregnancy itself can be a serious health threat in settings in which services are lacking or overwhelmed (Krause et al. 2000). Referral services are often non-existent and birthing or abortion may be undertaken in unsafe situations. Women may have no, or limited, access or means to carry out family planning, rape and sexual coercion are typically increased, and there may be pressures on women to rebuild the population. Female genital mutilation may occur and STIs, including HIV, may be relatively common (Krause et al. 2000). A particularly important set of risks relate to sexual and other forms of gender-based violence, common in all societies and increased where societal norms are less able to be enforced or reinforced, and in which men with guns can demand whatever they like in return for precious resources such as safety,

food, and onward passage. Intense efforts have focused on improving all aspects of reproductive health for women affected by CEs and forced migration—and a Minimum Initial Services Package has been produced to address these needs. A study by Hynes et al. (2002) showed that due to the strength of the response there have actually now been better reproductive health outcomes in refugee camps than in host population or origin countries. However, the lessons learned require expansion across settings.

Mental health and psychosocial needs

Mental health problems are recognized as an important source of morbidity globally (Prince et al. 2007) and are likely to be even greater among displaced populations. Epidemiological assessments have documented high rates of mental illness in these populations. Studies have tended to focus on trauma-related conditions, although low prevalence conditions such as psychosis have also proven significant in post-conflict and refugee settings. There is much debate about the validity of Western-derived measurement and about the trauma focus, with further development of relevant culturally valid ways to measure psychiatric morbidity still required. Despite the measurement debate, there is clearly a substantial burden of mental distress in these settings, and support for vulnerable people is vital in situations of social breakdown, especially where usual systems of social support and healing are disrupted (Silove et al. 2000a). It may be of value to identify and respond to the needs of three different groups of people who experience psychosocial and mental distress in these situations: those who are mentally ill, who need treatment; those who have had particularly horrific experiences and need care and support in order to recover; and what tends to be the majority who need a more stable social and political environment in which they can resume their normal day-to-day activities necessary to promote mental health.

Internally displaced persons

While IDPs in developing countries have very similar health problems to refugees, they also have particular vulnerabilities. Some of these result from falling through gaps in a system geared to protect a particular group of forced migrants (i.e. ‘Convention refugees’). Particularly in developing

countries, but also in more developed states, the limited data available suggest higher morbidity and mortality in IDPs compared with refugees (Salama et al. 2001). With limited protection granted by the international community, the responsibility for protection and assistance often lies with their own governments. Yet, it is these governments themselves that have often contributed to the displacement experienced. Governments may not even officially recognize the existence of IDPs for fear of international scrutiny or interference. A growing number of countries have developed laws and policies to govern responses to IDP populations but not all make concerted attempts to implement these policies, and even when there is political will the states involved are often the poorest countries of the world, limiting their ability to respond. There is no mandated international body although UNHCR may include them among their persons of concern and they are increasingly supported by agencies which follow the UN's Guiding Principles on Internal Displacement (Deng 1998).

IDP populations rarely experience access to health services at the same standard as offered to other citizens and are likely to be markedly poorer than those available to refugees. Recent efforts to improve quality and responsiveness of interventions in humanitarian crises and CEs have contributed to better health outcomes. IDPs, however, have poor access to these improved systems of protection and assistance.

Collection of data is more difficult among IDP populations and relatively few studies focus specifically on IDPs. However, the IDP-specific health data that are available suggest that access to healthcare for IDPs is often extremely limited. Salama et al. (2001) show how some of highest mortality rates in humanitarian emergencies have been found in IDP populations; Sudan and Somali, for example, reached 8 per 10,000/day and 17 per 10,000/day respectively (Salama et al. 2001). In Ethiopia and the Democratic Republic of the Congo, delays in vaccinations led to measles outbreaks. In Ajiep (southern Sudan), severe acute malnutrition among IDPS reached 36% during a famine in 1998.

Although international humanitarian law applies to all civilians affected by armed conflict and therefore IDPs should be afforded the same protection and assistance as the un-displaced host population, there may be multiple reasons why IDPs face discrimination and therefore do not receive the help they need.

Even in developed countries IDPs may have poor health outcomes. They are often subject to the discrimination and exclusion experienced by their developing country counterparts. The Internal Displacement Monitoring Centre (IDMC) describes the situation for a number of IDP groups in developed nations:

> While IDPs in the Balkans generally have satisfactory access to water, sanitation and healthcare, they are more likely than the local population to suffer from trauma-related problems. Roma IDPs usually live in informal settlements with very poor sanitary conditions. IDPs in Azerbaijan and the Russian Federation access healthcare less easily than the local population in some areas, due to administrative inconsistencies, lack of healthcare facilities and the demand for informal payments for medical treatment. (IDMC 2008)

IDPs, whether in developing or developed countries, are clearly living with a higher burden of illness and mortality than many other forced migrant groups. Initiatives are emerging that aim to support this extremely vulnerable population, but they are yet to be supported by any legal framework.

Refugees and asylum seekers in developed countries

Refugees and asylum seekers often reach destinations in developed countries after long, precarious journeys. Prior to the journey, they will have faced many of the routine health problems that present themselves in disrupted developing country settings. The journey itself will have produced health challenges; people may have been detained at points along the way or experienced significant anxiety and distress through difficult and dangerous journeys and experiences. On arrival, the range of situations they find themselves in will further shape their health condition. Those who have applied for refugee status prior to arrival may have undergone health checks already in the country of origin, as is the practice of many developed countries; therefore, certain health conditions may have been picked up. Depending on the country they arrive in, they will then have a different range of options available to address their health problems. However, those applying for refugee status on arrival have an even more complicated journey; they may be detained for short or long periods, they may have extensive periods on temporary visas or they may find themselves living illegally without authorization from the host country. Typically asylum seekers are often isolated with difficulty in communication, in a situation of

poverty, discrimination, and a lack of social structure, causing many to suffer from trauma-related problems and many general health problems, exacerbated by poor provision of health information and barriers to accessing to services.

Biggs and Skull (2003) discuss the specific medical conditions that may be present among refugees in developed countries. These include communicable disease such as TB, HIV, STIs, hepatitis B and C, and parasitic diseases, all compounded by incomplete immunization. In addition, nutritional deficiencies (vitamin D in particular), mental health problems, and other non-communicable diseases such as diabetes and reproductive health issues are common.

Screening for health problems among newly 'arrived' refugees, or prior to arrival for those applying for refugee status overseas, is common practice. Biggs and Skull (2003) point out that there is little evidence demonstrating that screening has proved effective as many people have limited contact with services and many are lost to follow up. Refugees seeking asylum in the United States are screened before arrival to identify 'inadmissible conditions' such as HIV, TB, and leprosy. They may also be screened for diseases that are known to be prevalent and targets of public health intervention. For example, Somali refugees were mass treated for malaria and intestinal parasites. The types of health problems sought and treated in newly arrived immigrants also reflect particular areas of concern for asylum seekers, including infectious disease, gynaecological health (rape, genital surgery, STIs), and mental health (torture, trauma) (Adams et al. 2007).

Burnett and Peel (2001) evaluated the health needs of asylum seekers and refugees in Britain. They point out that these groups are subject to 'poverty, dependence, and lack of cohesive social support' as well as racial discrimination. They consider a range of studies examining the health status of refugees and found, for example, that 21% of migrants to Spain from sub-Saharan Africa were chronic carriers of hepatitis B, and 3.4% of refugees arriving in the United States in 1988 had TB. They highlight the lack of screening programmes available and how the focus has tended to be on protecting hosts rather than a responsibility to provide healthcare to all.

One specific refugee and asylum health condition that has been investigated somewhat more extensively than other health issues is mental health (see Chapter 8.7). Gerritsen et al. (2004) describe how early research focused on those who used services, or victims of trauma, followed by early

population-based studies in Western settings which have tended to focus on psychiatric disorders such as post-traumatic stress disorder (PTSD), anxiety, and depression. In a review of the literature, Fazel et al. (2005) show documented rates of PTSD of 4–70%, depression 3–88%, and anxiety 2–80%. Their meta-analysis suggests that one in ten refugees in Western countries have PTSD, one in 20 has major depression, and one in 25 has a generalized anxiety disorder. Although lower than some estimates, this is still ten times higher than rates of PTSD in the general population in the United States. Data for asylum seekers alone is sparse but there are reasons to believe they have even higher rates due to their vulnerability because of disruption, separation from family members, increased levels of torture and trauma, lack of language skills, and the often hostile reception from host population fuelled by media perceptions. The current trend towards detention, and temporary rather than permanent protection has added extra stress, as evidenced by studies of asylum seekers in detention centres and on temporary protection visas showing very high rates of mental illness (Silove et al. 2000b, 2007).

Problems that asylum seekers in particular face, rather than refugees, relate to issues of having a temporary and often contested legal status, and in some cases being considered illegal, with implications (real or perceived) for access to health services. Many countries such as the United Kingdom and Australia have fluctuating policies with regards to what asylum seekers, of differing categories, may be entitled to in terms of healthcare. This can act as a barrier to health for many asylum seekers. The increased use of detention for asylum seekers, while claims are processed, has been challenged heavily by health professionals as a result of evidence that it is detrimental to health. The other popular policy of extending only temporary protection to some asylum seekers, therefore also causing confusion with regards to health entitlements, and long-term insecurity with associated health risks, has also caused concern to health professionals (Silove et al. 2000b). Australia has passed legislation to allow off-shore processing for asylum seekers. A policy of this kind raises more complex questions in terms of entitlement and availability of healthcare. Health professionals have called for screening to ensure those with the most severe mental and physical health problems are identified and if necessary processed on the mainland.

Healthcare for asylum seekers may be difficult to access on many levels: policies of active deterrent of asylum seekers may mean they are not entitled

to care, or there may be lack of prioritizing refugees; health professionals often misunderstand what the policies are and may refuse to register asylum seekers, they also fear the burden of vulnerable groups; those that do offer treatment may lack understanding of the refugee health situation; temporary registration with GPs may be offered rather than permanent (limiting access to immunizations and screening); and language problems are also a great barrier, with many practitioners having inadequate access to interpreting services.

Harris and Telfer (2001) estimated that in 1999–2000 there were over 10,000 asylum seekers living in the community in Australia. Many had to survive for many months or years with no right to work and no medical cover through the national Medicare scheme, resulting in untreated medical conditions. A study in Sydney suggested that most presenting to an Asylum Seeker Centre providing health services had fairly serious psychological or physical symptoms. Some related to trauma and torture, others were infectious diseases, musculoskeletal complaints, and gynaecological problems. Up to 40% of the asylum seekers were denied Medicare. A few are picked up by the Asylum Seeker Assistance Scheme and the Red Cross assists others. Hospital fees are particularly high and case studies have shown that some people are denied hospital treatment until assurance of payment is provided.

Trafficked and smuggled people

People that are trafficked or smuggled are not an entirely distinct group from other types of forced migrants already described. Trafficked people have been coerced or tricked into allowing another person to organize their passage to another country; also smuggled across borders are those who ‘voluntarily’ migrate for a vast range of reasons but feel unable to do so through legal channels. Although these groups may appear distinct from refugee populations they may include Convention refugees and others whose circumstances are very close to those of refugees. Resorting to illegal and clandestine methods of migrating to another country, either through being coerced and misled or through having such limited choices as to choose this route, is often a result of many of the factors behind the forced migration of refugees and internally displaced people.

Gushulak and MacPherson (2000) describe some of the reasons why people may fall into a trafficking situation. Poverty, exposure to violence, restrictive barriers—for example, screening for certain diseases or security barriers, slow processing of routine immigration applications which may cause delay to family reunification—all may encourage people to take alternative routes—especially when traffickers may offer what appear to be attractive possibilities. They state that the reasons why someone is more likely to migrate through these illegal methods are also reasons that place a person at higher risk of having poor health prior to migration. The journeys faced by trafficked and smuggled people are often extremely precarious, with high levels of morbidity and mortality attached as a result: unseaworthy and overcrowded boats on long journeys, stowed in containers, attached to carriers, attempts to cross inhospitable land with extremes of temperature, drowning from swimming attempts, violence from traffickers, and illegal activities such as smuggling drugs with people. On arrival people are then subject to many of the difficulties already outlined that face asylum seekers. Some trafficked and smuggled people may seek asylum and depending on the policies of the countries may incur some health benefits; however, many will be forced into illegal employment and be either too scared to make or prevented from making an approach to health services. Disease prevention and control in this population will be extremely poor—leading to increased prevalence of disease in the trafficked community as a whole.

Busza et al. (2004) examine the need for careful understanding of trafficking situations and to unravel the local dynamics. They state that even when intermediaries are involved, and even when they are taking people into exploitative arenas such as sex work, these situations remain a complex mixture of voluntary and forced migration. While economic disadvantage may fuel the choice, there is still a choice being made in some contexts and organizations seeking to stem the flow or break up these systems may compromise the health or the individuals involved more than they help. Attempts to ‘save’ people may make them even more vulnerable—for example, the raiding of brothels and other such moves can force vulnerable people to go underground making engagement with health services difficult.

The health of trafficked and smuggled people is affected by the fact that they cannot easily be separated out from each other or from other types of ‘voluntary’ migration that are not truly voluntary but have strong forces pushing people on. The policies developed by states towards any of these

groups are likely to impact on the capacity of other groups to access healthcare. Displaced people are more vulnerable to trafficking and may in desperation turn to smugglers. This should be kept in mind by health professionals to avoid vulnerable people missing out on essential services and support.

Public health solutions and interventions

Forced migration clearly has major impacts on public health. Specific solutions and interventions need to be sensitive to culture and context, and include a critical assessment of the political dynamics that may affect how assistance is actually received and impacts on the lives of forced migrants. Harrell-Bond et al. (1992), the doyens of analysts examining forced migration, along with other key commentators such as Crisp (1999) and Bakewell (n.d.), demonstrate how resources to deal with forced migration are structured by broader ideological, political, and economic decisions. Harrell-Bond et al. (1992) argue that refugee camps and many of the structures and organizations set up are part of a system of control of those in need. She argues that the allocation of resources (whether aid, political or military resources) is a 'central component in an ideology of control'. The granting of aid often legitimizes a group and their struggles; politics influences the status and visibility accorded to different groups. Even where humanitarian and development assistance are well targeted at forced migrants in need, the impact of services, systems, and funds, may be both positive and negative. While the forced migrants in great need may be able to access resources, these are not distributed equitably, and local populations, which often bear the brunt of providing for such community members, frequently are marginalized and unable to access new resources or services.

A valuable compilation of insights (Essed et al. 2004) highlights how forced migrants interact with agencies and the implications for ethics, policies, and politics. A case study by Turner (2004) in the same volume, for example, demonstrates how UNHCR effectively displaces older men as providers in their families and in so doing creates new dependencies. UNHCR becomes 'a better husband'—at the same time undermining and transforming traditional household and family relationships. These political

complexities are vital to keep in mind when planning and implementing a public health response with vulnerable communities.

Key actors and organizations in refugee health

There is an extensive range of organizations involved in addressing forced migration. The UN has designated the UNHCR as the key multilateral agency for identifying and dealing with refugee issues. More recently, the mandate of UNHCR, as described earlier, has been extended to include other 'people of concern' including IDPs and asylum seekers. Other agencies with a specific mandate for dealing with forced migrants include the International Organization on Migration, the International Centre for Migration and Health, the American Refugee Committee International, the US Committee on Refugees, and the Global IDP Project.

A wide range of multilateral agencies including the WHO, UN Population Fund (UNFPA), UNICEF, International Committee of the Red Cross (ICRC), International Federation of Red Cross and Red Crescent Societies (IFRC), and UNAIDS has some concern with forced migrants. Key non-governmental organizations (NGOs) include Merlin, Médecins Sans Frontières (MSF), International Medical Corps (IMC), International Rescue Committee (IRC), OXFAM, Save the Children Fund, CARE, Caritas, CONCERN, and the Norwegian Refugee Council. Academic bodies include the Oxford University Refugee Studies Programme, the Centers for Disease Control and Prevention (CDC), and the Refugee Studies Programme in Cairo. A number of important journals, notably the *Journal of Refugee Studies*, *Disasters* and *Conflict and Health*, and the website of Forced Migration Online, provide avenues for academic debate.

Developing countries and complex emergency settings

The principles of public health and epidemiology only began to be systematically applied to complex emergency situations from the early 1970s (Salama et al. 2004). Since then, new academic and practitioner fields have developed, including emergency public health and public health nutrition. With the introduction of an indicator to measure the impact of a complex emergency through CMRs, alongside the development of simplified measurements of malnutrition, and threshold rates for epidemics,

it has become increasingly possible to draw meaningful inferences from data collected.

An understanding of the dynamics of disease and related mortality in CEs has grown, and practice improved on the basis of experience and research evidence. Guidelines and technical manuals have been produced and efforts enhanced to promote organizational learning and enhanced service delivery, building on a growing evidence base. The call for evidence with which to inform policy and practice (Banatvala and Zwi 2000) reinforced what was already happening in the field where practitioners and academics were drawing lessons from experiences and enhancing the quality of their responses.

Mortality rates are now much lower than previously seen, malnutrition is declining in many settings, and measles, a major killer in the past, is less catastrophic following efforts to ensure early immunization of children. Enhanced understanding of risks of communicable diseases has decreased risks, although failures to apply evidence, such as in Goma following the Rwandan genocide, still lead to tens of thousands of preventable deaths. Epidemics of some communicable diseases are better controlled and may be less serious and last for shorter periods given improved surveillance and earlier detection of outbreaks. The pattern seen is often similar to the baseline in developing countries, in terms of the major killers. However, the shift has been to seeing many of the highest mortality rates outside of camps, where the public health response has not been as well developed.

Toole and Waldman (1997) describe the need for primary, secondary, and tertiary prevention. In primary prevention, they argue that political and diplomatic mechanisms should be developed to prevent conflicts evolving to the point of mass displacement, and that epidemiology may be able to add value in studying some of the dynamics that indicate conflict developing on a large scale. Secondary prevention comprises early detection of population movements, contingency planning so that relevant actors are prepared for the scale and nature of likely public health crises, having well-trained personnel with knowledge and experience in dealing with the health problems associated with refugee situations and able to rapidly assess and intervene in partnership with local organizations, along with the capacity to monitor and evaluate programmes swiftly and effectively. Tertiary prevention involves channelling resources into combating the sources of morbidity and mortality already outlined. This involves providing shelter and protection, adequate

food rations, adequate clean water and sanitation facilities, programmes for preventing specific communicable diseases, preparing for epidemics, specific programmes such as maternal and child health or mental health, managing diarrhoeal disease, and setting up health information systems.

The social, cultural, and political challenges of instituting these levels of prevention, alongside the practical implications of working in such settings, are substantial. Salama et al. (2004) describe how the field has been growing over 30 years, with increasing attention by humanitarian actors since the 1990s to codify technical guidelines. In the early 1990s, there was a growing disappointment and recognition among the actors attempting to engage with these complexities, and provide emergency assistance to refugees, that the field was uncoordinated and lacking in technical direction. Research, adverse publicity, and heightened calls for accountability around standards of service delivery and to the supposed beneficiaries of humanitarian interventions, all pointed to the need for significant improvements.

Initiatives were beginning to emerge that were investigating ways to address these issues, but the field was ultimately galvanized by events in 1994 in Goma, Zaire. The unprecedented rapid influx of refugees and the resulting massive cholera epidemic, producing one of the highest mortality rates recorded, led to a serious reappraisal of humanitarian work in these settings. The Joint Evaluation of Emergency Assistance to Rwanda was an impressive, multiagency, multidonor-funded initiative, paving the way to a deep review of the humanitarian and relief field and the standards of care and conduct.

In terms of future public health directions, Salama et al. (2004) describe the need to move beyond the current refugee and IDP paradigms, as non-camp populations affected by conflict are now often greater in number and burden, and mechanisms to deliver services to such populations are less clear. There is a need for enhanced coverage in all settings of known effective public health interventions, and for the more upstream causes of CEs to be addressed. The technical needs identified include the development of more context-specific methods for assessing mortality rates as an indicator based on surrounding baseline CMRs, and considering which other indicators may point to a deteriorating situation such as fluctuations in disease incidence, levels of displacement, and decreasing food security. They suggest that implementation of control measures should be early, not when mortality and malnutrition are already high, and that while communicable

disease control should continue to be prioritized along with nutrition and food security, that enhanced efforts at addressing mental health, reproductive health, and neonatal health should also be incorporated. Important policy issues include better means of determining direction and coordination of public health interventions, early identification of a lead agency, and greater effort to support fledgling governments to take the lead with the support of a coherent international system. They suggest that the skills of relief workers should be strengthened and broadened to include knowledge of assessment and prevention of disease, monitoring and evaluation, and international systems, policies, and regulatory bodies.

Ensuring equity in the response and equity in access to services and resources made available remains a considerable and underemphasized challenge.

Developed countries

In developed countries, the complex political arena and the increasingly restrictive views of host populations towards asylum seekers and refugees complicates the task of addressing the public health of forced migrants. While an array of motivated and effective actors plays a number of different roles in this field, there are few central bodies charged with overseeing the public health of forced migrants as a whole. The policies of the host nations themselves are likely to shape the public health landscape and in situations where these policies seem to be detrimental to the health of this population, public health professionals may find themselves having to take increasingly political roles to fulfil their public health duties.

Advocacy groups and health professional organizations have set up refugee and asylum seeker health networks and centres through which to provide services and support and advocate for more inclusive social and health policies.

The Health of London Project established a health centre in 1999 to provide access to good-quality primary care for forced migrants. The service aims to provide a thorough initial health assessment, along with effective responses to issues such as mental health problems and communicable diseases. In Europe, Médecins du Monde, an NGO, has stepped in to provide care for groups with restricted access to healthcare, particularly failed asylum seekers.

The best way in which to organize healthcare for resettled refugees, and for asylum seekers, remains contentious. A key issue point of debate is whether they should be integrated within mainstream services, or offered separately through distinct services for these marginalized groups (Finney Lamb and Cunningham 2003). Such centres are often voluntarily run and unable to cover the full extent of need. Hull and Boomla (2006) discuss the implications of such NGO provision, including some of the unanticipated negative aspects.

Another potential theoretical divide that can emerge with health approaches to asylum seekers and refugees is that between public health and human rights frameworks. Governments are more responsive to public health arguments whereby health problems of forced migrant populations may be addressed for the benefit of the wider population, often highlighting the risk brought with incoming refugees and forced migrants of communicable diseases. However, these approaches focus more on protecting the host than the forced migrants' right to receive healthcare (Burnett and Peel 2001) and may reinforce discrimination and marginalization of the migrants who are seen as posing a risk to the general community and demanding excessive use of public services (Grove and Zwi 2006). Tarantola et al. (2008) argue for much closer links between public health, human rights, and development—all equally relevant to forced migration.

Hull and Boomla (2006) describe recent UK government proposals to deny general practitioners the discretion of registering overseas visitors including failed asylum seekers, and to provide care to them. They highlight the possibility that such a policy will inadvertently increase costs through more emergency admissions, and they stress that such a policy is a breach of human rights, ethically unsupportable, and may place clinicians in conflict with their professional duties.

Ashcroft (2005) describes the language of the UK and Australian governments as 'Orwellian' in an overview of their approaches to asylum seekers and health. In discussing the UK government's move to make failed asylum seekers pay for all non-emergency care, despite not having the right to work, he states that the treatment of asylum seekers is an ethical issue and that denial of medical treatment should not be used as a lever to exclude people or get them to leave the country. In some cases, the presence of HIV seropositivity has been used to exclude refugees from the opportunity to

resettle in a third country; this is of particular concern given the heightened risk of violence and infection that may characterize the lives of many refugees. Using this against such vulnerable community members is a double victimization.

As Silove et al. (2000b) stated:

> the medical profession has a legitimate role in commenting on the general and mental health risks of imposing restrictive and discriminatory measures on asylum seekers, especially when some of these administrative procedures threaten one of the fundamental principles underpinning the practice of medicine: primum non nocere [do no harm].

In response to current debates in Australia, the Australian Medical Association issued a position statement on the Health Care of Asylum Seekers and Refugees (Australian Medical Association 2011). This lays out not only the health vulnerabilities of these populations but also that medical practitioners should insist on the rights of their patients being respected and lays out certain competencies necessary for treating asylum seekers. These include identifying victims of torture, assessing and managing trauma, identifying suicide risk, and recognizing health conditions specific to these groups such as TB.

Further study is required to document the patterns of disease, the links to the asylum experience, and impact of policies, not only on forced migrant health but also the implications for host populations are required. Given the more restrictive policy environment, health professionals require a strong evidence base from which to lobby for improved access to services as a first step in improving the health of refugees and asylum seekers in developed countries.

Emerging issues for public health professionals

Many of the issues raised in earlier sections have a technical focus, even if their links with broader sociopolitical issues have been acknowledged. In this concluding section of the chapter, we highlight some of the many issues which challenge professionals and societies, not only on a technical level, but in terms of the values underpinning how we, individually and collectively, whether as citizens or professionals, see and respond to others, especially those who have been forced to flee.

This section seeks to highlight, briefly, a number of key themes: globalization and poverty, quality, and accountability, ethics, and researching with forced migrants, voice, visibility, and agency. They are central to understanding the context within which forced migration arises and health needs should be understood and addressed.

Globalization and poverty

There is increasing evidence of widening gaps in income and basic needs between the well-off and the impoverished in many settings. Labonte and Schrecker (2005) identify the key links between current patterns of globalization and the influence these have on the social determinants of health. The challenges are evident in the failure to address the Millennium Development Goal (MDG) targets, while extreme wealth continues to be generated and monopolized by small fractions of the world's population. Resource constraints are likely to increase; countries engaging actively with global economic and political opportunities may do well but not all their citizens will necessarily benefit.

Evidence of gaps is widespread; and it is apparent that the MDGs, a major driving force at present in international development, do not adequately address issues of equity (Attaran 2005). Such concerns are likely to be amplified in relation to especially vulnerable and socially excluded communities such as forced migrants, data on whom may be unavailable and systems of response to which will be fragmented, uncoordinated, and inadequately monitored. Colson (2007) argues cogently that much greater emphasis should be placed on understanding the 'factors that provide the impetus to leave' and not focusing only on the aftermath of such forced migrations.

Quality and accountability

A key challenge in engaging with situations of violence, social exclusion, and disempowerment is in ensuring that work undertaken to assist those affected does no harm, or at least strives to limit the potential harm and maximize the potential value. The international community, through the UN, other multilateral and bilateral agencies, and international NGOs, all ostensibly seek to assist those forced to flee or migrate.

One way in which evidence improvements are underway is in relation to enhancing and seeking to assure the quality of humanitarian and relief work. Major quality and accountability initiatives such as SPHERE, the Humanitarian Code of Conduct, the Humanitarian Accountability Partnership, and many others contribute to enhanced practice. There remains a need to facilitate self-reflection and open review, transparency of difficulties limitations and failures, and promotion and funding for the search to do better.

The vast majority of incentives currently in place, however, encourage the hiding, rather than the declaration, of weaknesses, so as to elicit the next tranche of funding. This is counterproductive when seeking to reflect and improve services and their responsiveness to need. New thinking is required: how do we develop systems of trust and collegiality, mutual support between affected communities, services providers, and agencies, to ensure that all incentives operate to maximize the gain for those at greatest risk?

New initiatives in the humanitarian and relief areas of activity seek to enhance practice and open out debate and public scrutiny. In so doing, weaknesses are identified, guidelines and lessons for better practice formulated, and processes which seek to engage and creatively respond to problems, developed. Taking forward such action requires promoting an ability to report and record limitations and inadequacies, and to carefully and systematically document strengths and limitations, weaknesses, and potentials, to address real problems. Services are never ideal and always have constraints and limits; it is crucial to establish ways of examining them such that opportunities to change, to experiment, to creatively engage with solving problems are established.

New and enhanced knowledge management systems would be most valuable if they assisted in finding innovative means of conceptualizing problems, sharing information and insights of what works in different contexts, and developing systems to ensure accountability to the intended beneficiaries, the forced migrants themselves.

Ethics and researching with forced migrants

Ethical issues require considerable attention especially given the power imbalances present and in relation to research. Forced migrants may be especially vulnerable and risk being abused, either through their stories and

survival strategies being exposed and used by their opponents to undermine them; the very practice of talking with an outsider or sharing information may heighten risk, vulnerability, and the attention of those seeking further to undermine and disempower. Real risks may result from security lapses, confidentiality lapses, exposure of coping strategies and adaptations; as well as stigma and reinforcement of difference and of 'otherness'.

A major challenge in research with refugees and other forced migrants is to assist them in documenting their experiences of forced migration (Mackenzie et al. 2007). In so doing, the locus of power in the research relationship has the potential to shift from the researcher him or herself, to the communities being researched. The project may shift from research *on* refugees to research *with* refugees and research *by* refugees for action and change.

While this may be conceptually and morally attractive, the practicalities of achieving this are impeded at multiple levels, not least of which is establishing a trusting relationship between the researcher and the communities with whom they research. Engaging with forced migrants is itself a major challenge: Such communities are often highly dependent on others, and may be reliant on outside agencies with expertise and resources and/or on local power-brokers in control of the basic necessities of life and survival—food, water, shelter, and security.

Zwi et al. (2006) have highlighted the importance of reconceptualizing such research to consider the potential to ensure benefit and reciprocity for the subjects of research and to shift the locus of decision-making in their direction. They offer a model to describe this process, while Mackenzie et al. (2007) present a case study of applying many of these considerations to work with forced migrants on the Thai–Burmese border. Of note is the transfer of power to community organizations, with women's groups from the Thai–Burmese border having control over the stories and narratives collected from them and academics being required to obtain permission from them to publish and distribute and write up such material.

Innovative approaches to research are emerging and warrant support. Youth-focused research highlights the importance of young people in exploring and documenting their own lives and experiences. Young people play a central role in refining and redefining the issues, identifying the challenges and the potential approaches to solving them through new models

of participatory action research. Such collaboration needs to build skills, resilience, and opportunities to shape the future.

Voice, visibility, and agency

There is increasing recognition of the importance of hearing from those most affected by any public health condition and ensuring that their voices are heard; empowering them to help shape the proposed solutions. Black (2003) emphasizes the importance of advocacy as a central component of work with marginalized and disempowered groups and reinforces the centrality of ensuring that the voices of those affected, and of the range of stakeholders engaged, is heard.

The voices of forced migrants may be silenced while those of powerful agencies and governments are privileged in shaping our understanding both of the problems and of the solutions which surround forced migration (Harrell-Bond and Voutira 2007). Power imbalances, vulnerability, and cultural and linguistic differences are among the many barriers to creating an environment in which refugees and IDPs are able to take an active part in shaping solutions. As with the youth, truly participatory models of action and research require sensitivity to the challenges of the context and understanding of the conditions that usually deny refugees a voice.

It is crucial that we hear the voices of those most affected by forced migration if we are to recognize the range of experiences, and the positive and negative change and transformation which results. As Eastmond (2007) states eloquently: ‘while transformation and change are part of the refugee experience, not all change is perceived as loss or defined as problematic or unwelcome by all individuals involved. Nor are refugees necessarily helpless victims, but rather likely to be people with agency and voice’ (p. 253). Learning and recognizing how agency, transformation, resilience, adaptation, and change are shaped, notably, but not only, in relation to gender and power, would not be possible without hearing from and learning with, those most affected.

Conclusion

Forced migrant populations frequently suffer vast health challenges. Their experiences need to be understood within the context of accelerating

globalization, with its positive and negative features transforming the lives of millions of people.

The role of public health professionals in working alongside forced migrants to bring about improvements in their health is demanding and complex. A comprehensive understanding of the dynamics of forced migration and sensitivity to the constraints placed on individuals and populations is vital to gain trust and provide opportunities for transforming health outcomes. Particularly, given the increasingly restrictive environments that forced migrants find themselves in, public health professionals can have a crucial role in advocating for forced migrant health, enabling forced migrants to speak and be heard, and to bring about improvements in their own health.

Improving knowledge and understanding is central to affirming the rights and the agency of those affected. Public health can play an important role, and indeed has done so, in improving technical quality of service delivery. Key gaps remain, however, in understanding, appreciating, and responding to the varied ways in which those forced to move seek to shape, transform, and better their own lives and experiences.

Prisoners

A wicked problem for public health

Tony G. Butler and Peter W. Schofield

Background

The relationship between incarceration and population and individual health outcomes is influenced by a vast array of contextual factors. Broad determinants include national or regional differences in criminal justice system policies and their application—which influence how many individuals are incarcerated—or in the nature of the healthcare system as it functions for the general public and in prison. At the level of the individual, factors such as pre-offending medical history, indigenous or minority status, gender, education and occupational status, financial resources, and family history may each influence the impact of criminal justice system interventions on health outcomes. Incarceration can be evaluated for its immediate impact on health (i.e. among prison inmates) as well as for the consequences for health upon release. Furthermore, from a public health perspective, it is appropriate to consider the health consequences of incarceration not only upon prisoners themselves, but on their family and friends. The challenge in confronting the health needs of those incarcerated indeed constitutes a ‘wicked problem’, embodying huge social complexities, including striking health inequities, for which optimal data are frequently lacking (Plamondon and Pemberton 2019).

Historical perspective on prison public health

Prison health reformers such as John Howard and Sir George Onesiphorous Paul in the 18th century recognized that infectious conditions could easily

spread from those detained in gaols to the wider community, with dire consequences (Howard 1973). The main point of contact between the incarcerated population and the community occurred when those in detention were brought up from the bowels of squalid prisons to attend court. Well-documented cases exist whereby infectious diseases spread from prison to the community during so-called assizes (courts set up by judges who travelled across various circuits in England and Wales). Notable outbreaks (dubbed ‘Black Assizes’), included the Oxford Black Assize outbreak of 1577 resulting in over 300 deaths. The Black Assize of Exeter 1586 was caused by the filthy condition of Exeter Prison situated underneath the court. By the time the assize occurred, some individuals had been in gaol for a long period; so weak and thin, they had to be carried into the courtroom and subsequently spread disease to the judges and locals in attendance, and infected the population of the Westcountry for many months after. Typhus, known as ‘gaol fever’, was responsible for these deaths.

In 1759, an English authority estimated that each year one-quarter of prisoners died from gaol fever and that ‘Imprisonment until the next term of court’ was often equivalent to a death sentence. This concept of prisons as a public health threat and the need for interventions to improve health is eloquently expressed by the eighteenth-century reformer and philanthropist, Sir George Onesiphorous Paul, who in 1784 stated that prison hygiene procedures were:

> ‘Not for the benefit of the prisoners but rather to increase the 'salutary humiliation' of prison life and to prevent the spread of epidemic disease beyond the prison walls and to the general citizenry’.

The spread of disease from prisons to the wider community can take place prior to release because of the substantial contact that occurs between prisoners and the general community during incarceration from legal interactions such as court appearances, via the vast number of prison guards, teachers, administrators, health staff, and welfare workers employed in prisons, and by relatives and friends during visits and day-release. All provide a potential bridge between prison and the community. Furthermore, the cycle of incarceration ensures that many individuals relentlessly cycle back and forth between prison and the community (Andolsek 1997).

This notion of the prison as an incubator of disease originates from these historic examples but persists today in the consciousness of prison public health officials. While ‘gaol fever’ is not the focus of concern, new threats

such as tuberculosis, influenza, Ebola, HIV, viral hepatitis, and COVID-19 have replaced it. A striking example of prisoners' health impacting on the general community occurred in the countries of the former Soviet Union around the turn of the twentieth century where the epidemic of tuberculosis (TB) among the prisoner population was linked to its re-emergence in the community (Farmer et al. 1999; Stern 1999, 2000; Kenyon 2009). In 1997, an amnesty of 40,000 prisoners occurred, of whom 4,000 were estimated to have TB with a further amnesty releasing up to 120,000 prisoners to relieve chronic prison overcrowding (Gentleman 2000). This example illustrates two salient factors in prisoner healthcare—the need to ensure that appropriate infection control measures are in place in prison during incarceration to prevent the spread of infection within the prisoner population, and secondly that prison health services should be aligned with those of the community to ensure the standard of healthcare in prison is the same as that afforded to those in the community. This latter point is referred to as the 'principle of equivalence' and is underpinned by the United Nations' Principles for the Treatment of Prisoners (United Nations 2015).

Prisoner populations: an international perspective

Offender populations, most notably prisoners, comprise some of the most stigmatized and socially excluded groups in society, and are characterized by extreme socioeconomic, health, and psychological disadvantage. Those exposed to the criminal justice system are typically poorly educated, unemployed, socially isolated, and financially dependent. Epidemiological surveys of prisoners consistently find high levels of physical and psychiatric ill health, exposure to communicable diseases such as bloodborne viruses and sexually transmissible infections, and engagement in health risk behaviours including tobacco use, violence, harmful alcohol consumption, and illicit drug use. It is unsurprising therefore that studies have found increased mortality compared with community peers, particularly in the areas of drug overdose and suicide (Kariminia et al. 2007a, 2007b). Over the past 15 years, numerous systematic reviews and meta-analyses have unambiguously highlighted the extreme health needs of the offender population across all health domains (Fazel and Baillargeon 2011; Dolan et al. 2016; Fazel and Seewald 2018). While this information provides an important platform for health policy formulation it does not supplant the

need for better, more effective interventions to prevent events such as suicide and drug overdose. Without question, enormous challenges face prison medical services and those involved in prison health provision and research with respect to prioritizing the use of limited resources.

Prisoner populations

Overall, the world's prisoner population increased in absolute terms between 2000 and 2015 to over 10 million (Coyle et al. 2016), this 20% increase in the world's total prison population is broadly in line with the increase in the overall population (18%) over this period (see Figs. 10.10.1 and 10.10.2 from Coyle et al. 2016). However, at regional level, the prisoner populations of the Americas, Asia and Oceania all outstripped natural population growth whereas in Africa and Europe the prisoner population grew at a lesser rate than the overall population. In percentage terms, Europe is the only region showing a trend towards decarceration.

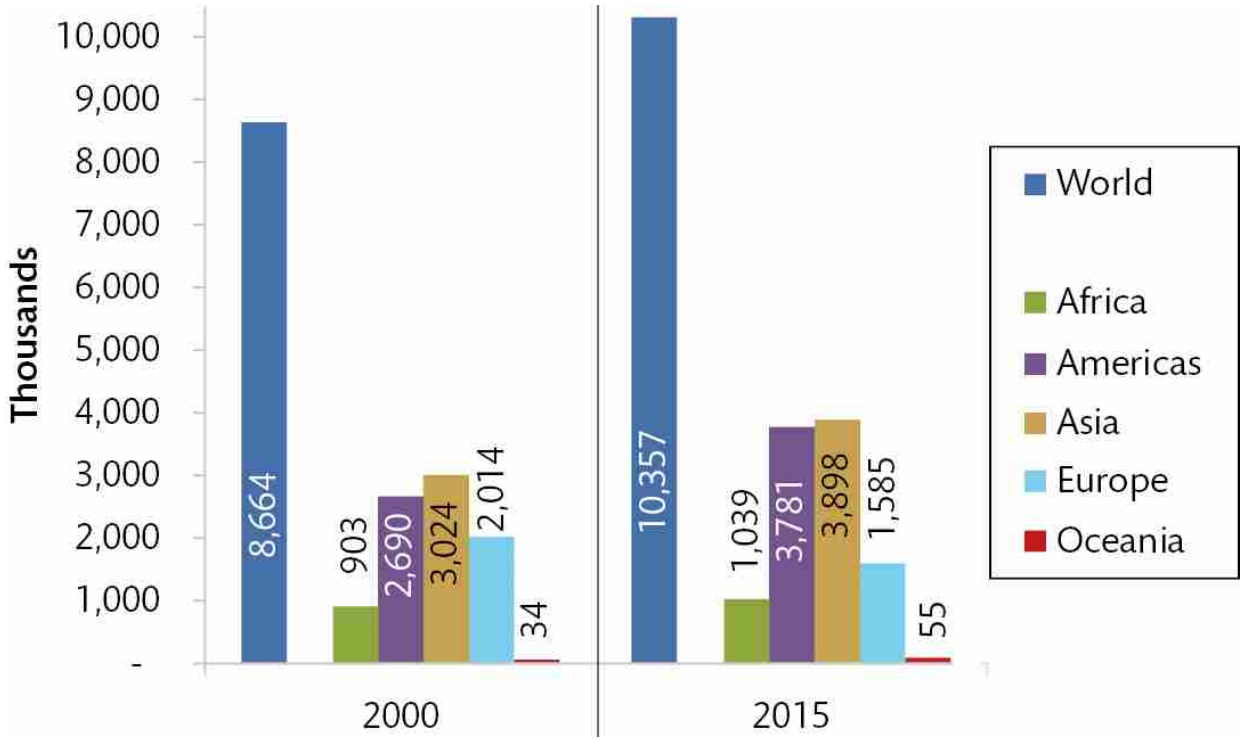

Fig. 10.10.1 Prison population totals, 2000 and 2015*: entire world and by region.

*Data are aggregated national prisoner population totals for the year 2000 or nearest available year. Figures for 2015 are based on World Prison Brief data as of November 2015 and vary as to the specific dates to which they refer. Source: data from Coyle A, Fair H, Jacobson J, Walmsley R. Imprisonment worldwide. The current situation and an alternative future. Policy Press, Bristol. 2016.

Source: data from Coyle A, Fair H, Jacobson J, Walmsley R. Imprisonment worldwide. The current situation and an alternative future. Policy Press, Bristol. 2016.

The United States of America (USA) is the world's largest incarcerator with over two million individuals currently behind bars (Drucker 2011). Although crime rates have fallen in recent times in many countries, the prisoner population has increased due to myriad changes in justice approaches such as: 'three strikes and you're out' (in some states in the USA), mandatory minimum prison terms, better police detection methods allowing cold-case prosecutions, commissions of inquiry into historic sexual abuse of those in care, and a trend towards bail refusal (in the case of Australia) (Coyle et al. 2016).

Internally, prisoner populations are far from static with significant prisoners movements occurring due to security reasons including splitting up gangs, for a prisoner's safety and protection, moving prisoners to and from courts, attending medical appointments either in the community or at other correctional facilities better equipped to address certain health problems, moving individuals closer to their family in the community, to attend

rehabilitation programmes at other sites, as a punishment by moving a prisoner to a facility with a harsher regime or different security classification, and moving closer to a city or town in anticipation of release.

While the static prisoner population represents a cross-sectional count on a census date, the throughput (or churn) of prisoners is large and significant. In the USA for example, the cross-sectional population is around 2 million, but an estimated 12 million individuals cycle through USA correctional facilities each year. Globally, while around 11 million individually are incarcerated at any one time, an estimated 30 million people are released from prisons annually (Coyle et al. 2016). By further example in New South Wales (Australia's most populous state and the jurisdiction with the highest prisoner population), the static population is around 13,000 with an estimated 180,000 prisoner movements per year. This presents challenges to prison health services in ensuring continuity of treatment within the prison system.

In Australia, the number of adult former prisoners returning to prison within two years of their release increased from 33% in 2000 to 51% in 2015 (Corrective Services 2016). Over two-thirds of state prisoners in the USA were arrested at least once within 3 years of their release in 2005 (Durose et al. 2014), and in the United Kingdom (UK) the re-offending rate is approximately 46% after 1 year of release from prison (Ministry of Justice 2016). These figures indicate the challenges faced by departments of corrective services in preventing recidivism suggesting the need for innovation and multipronged approaches involving a range of government agencies, including the health, welfare, and justice sectors.

Indigenous incarceration

Beyond the socioeconomic characteristics that define prisoner populations as over-representing the poor and disadvantaged, closer examination reveals that key ethnic groups are also over-represented in custodial settings. In the USA in 2017, Blacks represented 12% of the general adult population but 33% of the sentenced prisoner population while Whites accounted for 64% of adults in the community but 30% of prisoners (Bronson and Carson 2019). Expressed as a rate, there were 1,549 Black prisoners for every 100,000 Black adults but for Whites the rate is 272 per 100,000. Similarly, in the UK, 27% of prisoners identified as coming from an ethnic minority,

compared with 13% in the general population (Ministry of Justice 2019). Black or British Black people comprised 13% of the UK prisoner population (Ministry of Justice 2019) but approximately 3% of the UK general population (UK Office for National Statistics 2018).

Indigenous or first nations people have also been identified as over-represented in the prison systems of Canada, New Zealand, and Australia. In Canada, 'In 2016/2017, Aboriginal adults accounted for 28% of admissions to provincial/territorial correctional services and 27% for federal correctional services, while representing 4.1% of the Canadian adult population' (Malakieh 2018). While forming 12.5% of the general population aged 15 and over in New Zealand, 50% of prisoners identify as Māori, with Māori women accounting for 60% of the female prisoner population (New Zealand Department of Corrections 2007). In Australia, the pattern is similar with Aboriginal people comprising around 2% of the general population aged 18 years and over but 28% of the adult prisoner population (Australian Bureau of Statistics 2018). The overall crude incarceration rate in Australia is 164 per 100,000 but for Aboriginal people the rate is 2,481 per 100,000 (Australian Bureau of Statistics 2018). The rate varies considerably across Australia from 672 per 100,000 in Tasmania to 4,257 per 100,000 in Western Australia. It is believed that Australia has the highest incarceration rate of Aboriginal people in the world.

Explanations for these high rates among Aboriginal people include offence criminalization with Aboriginal people more likely to be imprisoned for certain, often petty, crimes than a non-Aboriginal person, poverty, unemployment, inadequate legal representation, a lack of diversionary options for Aboriginal people, intergenerational offending, and colonization and dispossession. A comprehensive set of recommendations from a socio-legal perspective have been developed by the Australian Law Reform Commission covering Justice Reinvestment, bail, sentencing, use of community-based sentences, mandatory sentencing, prison programmes and parole, access to justice, fines and driver licences, alcohol, police response, and child protection and adult incarceration (Australian Law Reform Commission 2017). All have been identified as important in issues in the overincarceration problem.

Why is the prisoner population so unhealthy?

Wilkinson and Pickett have drawn attention to a consistent, positive association of national or regional levels of inequality with poor health and adverse social outcomes (such as homicide or rates of incarceration) (Wilkinson and Pickett 2009) citing evidence for the potency—for its negative impact on those experiencing social inequality—of 'social evaluative stress' related to individuals' perceptions of their relatively lower positions within the social hierarchy. Chronic stress can have direct effects, mediated by the autonomic nervous and endocrine systems as well as, most importantly, the brain directly, such that early experiences and exposures become biologically embedded with lifelong consequences with respect to health, behaviour and resilience to future life challenges (see next).

Another influential theory, that of 'fundamental causes' posits that higher socioeconomic status (SES) is associated with better health because '*SES embodies an array of resources, such as money, knowledge, prestige, power, and beneficial social connections that protect health no matter what mechanism are relevant at any given time*' (Phelan et al. 2010). Thus, relative to those of higher SES, individuals with *less* privilege are less likely to be informed about health practices, less likely to adopt them, and to have poorer access to health or preventive healthcare leading to later detection and treatment of illness when it occurs. The fundamental theory has some explanatory relevance for the disproportionate rates of incarceration—representing an unwanted outcome through contact with the criminal justice system—among those least privileged in the community.

Finally, it is apposite to reference one of the most influential theories of crime causation, which considers low self-control as a fundamental mechanism and for which there is very considerable empirical support (Hirschi and Gottfredson 1995). The theory claims to explain more than just why individuals break the law. Poor self-control is suggested as a key cause of '*practically everything that (…) provides short-term benefit at the risk of long-term cost*' (Hirschi 2004). For this reason, gambling, smoking, heavy drinking, or misusing prescription medication—examples of conduct conceivable as analogous to crime—are part of the behavioural package that the theory seeks to explain (Moffitt et al. 2011; Wills and Stoolmiller 2002; Hirtenlehner 2019). Consistent with this theory, *incarcerated* populations display high rates of substance abuse, illnesses related to risky sexual practices, and traumatic brain injury related to other risk taking or impulsive behaviour. These theories each contribute a perspective on why offenders,

and the incarcerated in particular, are some of the most socially disadvantaged and unhealthy individuals in society.

Enormous advances in our understanding of how early life experiences may influence later life health and behaviour have come from the study of epigenetics (Moore 2015). The extent to which specific genes are accessible to the machinery by which they are transcribed (leading to protein synthesis and the attendant biological effects) can be significantly influenced by specific events or exposures, especially in early life. For example, epigenetic changes adjacent to the gene encoding the glucocorticoid receptor (GR) implicated in the hypothalamic–pituitary–adrenocortical (HPA) axis which plays a major role in the stress response have been shown to occur in the context of adverse exposures, leading to reductions in cortisol which have been shown to be associated with impaired stress response and poor self-regulation (Conradt 2017). Highlighting how early exposures of relevance may occur, in one study, intimate partner violence during pregnancy was shown to be associated with changes in the expression of the GR in the children born to that pregnancy (Radtke et al. 2011).

The data deriving from these sophisticated genetic techniques, together with that from structural and functional brain imaging which have demonstrated important adverse biological correlates of low SES and of criminality, serve to emphasize the importance of optimizing early childhood development and reducing toxic adversity as likely to be the most effective long-term measures to reduce the individual and social harms associated with offending behaviour, often the product of individuals exposed to early life disadvantages (Hackman et al. 2010; Lange et al. 2010; Lawson et al. 2013).

A snapshot of mental and physical ill health in prisoners

Prisoner populations are characterized by very high rates of mental morbidity and illness with rates of major mental illness such as psychosis and depression substantially exceeding community rates (Butler et al. 2006; Torrey et al. 2010; Fazel and Seewald 2018). Increased rates are seen also for post-traumatic stress disorder (PTSD), personality disorder, ADHD and substance abuse (Fazel and Seewald 2018). The evidence for major depression and psychotic illnesses is the strongest (Fazel et al. 2016; Fazel and Seewald 2018). Despite the high level of need, these disorders are

frequently underdiagnosed and poorly treated (Wilper et al. 2009). The extent to which, at the prisoner population level, incarceration itself is a cause of mental ill health is not clear but in some individuals it has an adverse impact with the development of depression with or without suicidality (Baillargeon et al. 2009; Mears and Cochran 2012).

Mental illness has been shown to be a risk factor for suicide, premature mortality on release from prison (Kariminia et al. 2007b) and recidivism (Baillargeon et al. 2009; Fazel and Yu 2011). Issues that naturally arise in relation to this high burden of psychiatric morbidity include its optimal and efficient detection, appropriate management, and its impact on the incarceration experience and on release (Wilper et al. 2009). Upon entry into prison, immediate risks related to existing psychiatric conditions include suicidality, the health consequences of withdrawal from substances (e.g. alcohol, amphetamine, or opiates), or the sudden discontinuation of medication for which adverse consequences might ensue (e.g. anticonvulsants, antidepressants, antipsychotics). Approaches to screening for significant mental illness vary considerably both within and between countries, but as with other illnesses, incarceration presents an opportunity to identify and treat mental illnesses that may have been either unrecognized or untreated previously. The stigma and practical adverse consequences in terms of securing employment, relationship/family breakdown, or resumption of addictive behaviours can make the post-release period particularly challenging psychologically.

Of the psychiatric illnesses prevalent among the incarcerated, there is evidence to suggest that depression and psychosis are risk factors for offending and that adequate treatment may reduce offending risk (Fazel et al. 2014; Albalawi et al. 2019). Substance abuse is also associated with an increased offending risk. The situation with respect to acquired brain injury, in many instances due to trauma, is complex. A consistent finding throughout the international literature is of a very high prevalence of self-reported traumatic brain injury (TBI) within populations of offenders and prisoners, ranging up to 85% of male prisoners in some studies (Schofield et al. 2006, 2011; Durand et al. 2017). The frontal lobes of the brain, important for regulating behaviour, are known to be especially susceptible to damage by trauma, and therefore the possibility that TBI may be causally implicated in subsequent offending behaviour arises. Several retrospective cohort studies using record linkage have identified an increased risk of offending

following a TBI (Fazel et al. 2011; Schofield et al. 2015); however a study in which non-head trauma cases served as controls failed to find evidence of offending risk associated with TBI, although in that study only mild TBI was evaluated (Kennedy et al. 2017). Indeed, many of the TBIs reported by offenders may be mild, following which the likelihood of significant brain damage impacting brain function is low. In some unknown proportion of offenders who report a TBI which preceded their offending, the TBI may have been a consequence of an underlying predisposition towards impulsive or risky behaviour (Schofield et al. 2019).

With respect to physical health, prisoners have a substantial excess of morbidity relative to the general community. One study from the USA, in which adjustment was made for age, gender, race, education, employment, the USA as birthplace, marital status, and alcohol consumption found elevated rates of hypertension, asthma, arthritis, cervical cancer, hepatitis but no increased odds of diabetes, angina, myocardial infarction and a lower odds of obesity (Binswanger et al. 2009).

For some individuals, incarceration may be associated with health benefits, related to the provision of increased access to healthcare compared with the community, abstinence from illicit drugs, alcohol and tobacco, and reduced risk of accidents or violence. The benefits may differ according to racial/ethnic group and by country (Fazel and Benning 2006; Kariminia et al. 2007a; Spaulding et al. 2011). Thus, in the USA, compared to community controls, African American (but not white) men were reported to have substantially reduced mortality for the period of time in prison although the effect largely disappeared when adjustment was made for the compassionate release of prisoners with terminal illnesses (Spaulding et al. 2011). By contrast, in the UK and France, in prison mortality was reduced overall among prisoners, although deaths by pneumonia and other infective illnesses were higher (Clavel et al. 1987). More consistent are the findings of increased mortality in the months after release from prison, related to factors including suicide, overdose either deliberate or unintentional, violence or liver disease (Kariminia et al. 2007b; Spaulding et al. 2011).

Drug use in prisoner populations

Alcohol and other drug (AoD) use is a defining characteristic of prisoner populations (Butler et al. 2006; Fazel et al. 2006), and the association

between AoD use and offending behaviour, including violent offending, is well established. In New South Wales, Australia, 60% of prisoners surveyed as part of the highly regarded New South Wales' Inmate Health Survey report they were drunk, 'high', or 'stoned' at the time of committing the offence for which they were currently imprisoned, most commonly on amphetamine or methamphetamine (49.1%), alcohol (43.8%), and cannabis (27.1%) (Justice Health & Forensic Mental Health Network 2015). Methamphetamine use in the 12 months prior to incarceration has now surpassed cannabis use in Australia (Butler and Simpson 2017).

Approximately half of all prisoners report histories of injecting drug use (Australian Institute of Health and Welfare 2015; Justice Health & Forensic Mental Health Network 2015; Butler and Simpson 2017). While most injecting drug users (IDUs) suspend this behaviour during incarceration, approximately half of IDU continue to do so during incarceration (Fetherston et al. 2013). Only a small proportion of individuals report commencing injecting drug use during imprisonment (Butler et al. 2003). Drug use in prison is fairly common with over half of participants (56%) reporting that drugs were either 'quite easy' or 'very easy' to obtain in NSW prisons (Justice Health & Forensic Mental Health Network 2015). Injecting drug use is the overwhelming risk factor associated with hepatitis C transmission (Luciani et al. 2014). However, in the prison context other risk behaviours implicated in the transmission of infectious diseases include: amateur tattooing, sharing barbering equipment, and blood-to-blood contact during fights (Luciani et al. 2014).

Problematic alcohol use receives far less attention than illicit drugs in the prison context, possibly due to its legal status, yet two-thirds of those reporting alcohol use in the 12 months prior to incarceration (67%) had consumed hazardous or harmful quantities of alcohol (Justice Health & Forensic Mental Health Network 2015). Despite the widespread and problematic use of alcohol among those in prison when in the community, a lack of evidence-based prison-based alcohol treatment programmes is apparent in the peer reviewed literature (de Andrade et al. 2018; Doyle et al. 2019). This is important given the link between substance use and re-offending and suggests a need for more prison-based drug treatment options for this population (de Andrade et al. 2018).

Apropos the high rates of drug use in this population, histories of injecting drug use, prison drug use, and also injecting drugs in prison, it is notable that

few jurisdictions internationally have allowed the provision of clean injecting equipment despite its proven effectiveness in reducing the spread of bloodborne viruses in the community (Stöver and Hariga 2016). Reasons for this include arguments that it will effectively arm prisoners with a weapon to be used against prison personnel. However, to our knowledge only one case of a prison officer being stabbed with a needle has been reported in the literature. This occurred in Australia and tragically resulted in the officer dying from AIDS. This incident has harmed efforts to consider the provision of clean injecting equipment both in Australia and beyond. This day is still remembered by custodial officers in New South Wales over 20 years since the incident occurred. It is also argued that introducing needle exchanges in prison would be viewed as condoning drug use and this should be avoided. Interestingly, similar arguments are used by opponents of condom provision to prisoners, i.e. if filled with liquid and frozen they can be used as a cudgel, and symbolically they are seen as condoning and promoting sex between prisoners (even providing sexual predators with protection from sexually transmissible infections). However, evidence suggests that condom introduction in the Australian context did not increase sex between prisoners but, when sex did occur, promoted safe sex between prisoners (Butler et al. 2013).

Smoking

Tobacco smoking is recognized as one of the deadliest health risk behaviours, responsible for killing up to half of its users and more than seven million deaths each year (WHO n.d.). More than six million of these deaths are the result of direct tobacco use while around 890,000 are the result of non-smokers being exposed to second-hand smoke (WHO n.d.). Successful public health campaigns have contributed to reducing daily smoking rates in the general population in many developed countries, but these reductions are generally not reflected among prisoners. For example, smoking rates fell from 19% in the general Australian population in 2001 to 12% in 2016 (Australian Institute of Health and Welfare n.d.) However, among prisoners, there has been no corresponding downward trend and the rate of current tobacco smoking has remained stubbornly high at around 84%. This is due to high rates of tobacco use in key marginalized groups who are over-

represented in prisoner populations—IDUs, those with mental illness, and Aboriginal people (in the case of Australia) (Baker et al. 2006).

The main response to tobacco control in prisons has been to ban smoking altogether (Spaulding et al. 2018). Whether this is in response to concerns for smokers' health or a fear of litigation by non-smoker prisoners and staff is unclear. While banning smoking undeniably improves air quality (Proescholdbell et al. 2008) and reduces the health risk posed to non-smokers, this measure is not without consequences such as the creation of another black market borne out of tobacco scarcity and the problems associated with this, and smoking other noxious substances as a substitute (Puljevic et al. 2018). The issue of smoking bans can present a dilemma for public health officials who by nature are opposed to tobacco smoking yet believe that the human rights of one of the most vulnerable groups in society ought to be respected. The effectiveness of smoking bans as a cessation strategy is questionable with several studies indicating that many of those released to freedom go on to relapse. One USA study found that 63% of former prisoners relapsed on their first day of release, 82% after 1 week, 86% after 4 weeks, and 97% had resumed smoking at 6 months (Lincoln et al. 2009). These figures illustrate several important points for those working in public health in prison and the extreme challenge posed by this population. Firstly, the scale of the problem is staggering with few, if any, other population group in the community having such high levels of tobacco smoking. Secondly, the high rates suggest an absence of appropriately tailored and effective interventions specific to the needs of this population to achieve sustained abstinence. Thirdly, going from total bans that promote drastically reduced tobacco smoking during incarceration to almost all relapsing after fairly short periods in the community suggests existing interventions are ineffective for this population or don't reach them, or that continuity of care is lacking with respect to health promotion activities aimed at tobacco smoking in the transition from prison to the community.

Women prisoners

The number of women and girls in prison worldwide has been reported to have increased by 53% since 2000, against a global population growth (from 2000 to mid-2016) of 21% (ICPR 2017). Consistent with the situation in other countries, in Australia women represent a substantially smaller

proportion of the total prisoner population than men (9% vs. 91% in Australia), but there was an 85% increase in women prison numbers between 2008 and 2018 (*vs.* 55% in men) (Australian Bureau of Statistics 2018). The increase has been particularly marked among Aboriginal women with a 117% increase between 2008 and 2018 (versus a 74% increase in non-Aboriginal women in Australia). Many of these women have endured significant abuse and trauma and much of their substance use, mental health issues, and violence likely has its origins in past traumatic events (Wilson et al. 2017). Higher levels of psychiatric morbidity and substance use are found among women prisoners relative to men (Fazel et al. 2016). In Australia, 2 in 5 (38%) women coming into prison reported they had children in the community who were dependent on them for their basic needs (Australian Institute of Health and Welfare 2015). The rate of women incarcerated for violence offences is increasing (Australian Bureau of Statistics 2018). Recognizing that '*women prisoners are one of the vulnerable groups that have specific needs and requirements*', and that prison system worldwide have been developed around men, in 2010 the 'United Nations Rules for the Treatment of Women Prisoners and Non-custodial Measures for Women Offenders'—the Bangkok Rules (UNODC 2010)—were passed by the UN. This resolution encourages member states '*to adopt legislation to establish alternatives to imprisonment and to give priority to the financing of such systems, as well as to the development of the mechanisms needed for their implementation*'.

Family members

There is a growing literature attesting to the adverse health effects of incarceration upon family members. Significant increases in the frequency of adverse physical and mental health problems, as well as increased mortality, have been found in the children of prisoners (Wildeman 2014; Wildeman et al. 2014; Wildeman and Wang 2017) and rates of obesity and cardiovascular disease may be elevated in women who have a family member incarcerated, even after controlling for socioeconomic status (Roettger and Boardman 2012; Lee et al. 2014). Because African Americans in the USA, and those of indigenous background in the USA and other countries, are far more likely to be imprisoned, the burden of such health consequences is more likely to affect women and children of the same racial or ethnic background,

compounding pre-existing levels of disadvantage. The impact on children of having a parent incarcerated can be extensive, prolonged, and insidious, including developmental problems affecting learning behaviour, and psychological issues (Lee et al. 2013).

The ageing offender

In the USA, the incarceration epidemic has been associated with a substantial increase within the prison system of older inmates, and other countries are experiencing similar developments, albeit in lower absolute numbers. In comparison with the non-offender population, related at least in part to the greater burden of chronic disease, prisoners as a group display features of accelerated ageing due to poor health, mental illness and lifestyle factors, including drug and alcohol misuse, and other social determinants such as trauma, homelessness and victimization (Angus 2015). In the USA, from 1996 to 2008, the number of older adults in jail who were aged 55 or older increased 278% compared to a 53% increase in the overall jail population. Data from Canada indicate that 25% of the federal prison population are aged 50+, a 50% increase over the preceding decade (Darrell and Beck 1997; Beck and Berzofsky 2010; OCI 2019).

Based on figures from the Australian Bureau of Statistics, the number of prisoners aged 65 years and over has increased by 348% between 2001 and 2017 (Ginnivan et al. 2018). The increase was over 700% in the case of women prisoners in the same age group. The World Health Organization (WHO) has recommended restructuring prisons to accommodate the environmental needs of elderly prisoners (WHO 2014). Recommended provisions include grip rails, seats in showers, bunk bed ladders, ramps and widened doorways to accommodate wheelchairs, and better access to bathroom facilities. The WHO has also urged institutions to adopt appropriate screening for conditions associated with ageing, such as sensory impairment, mobility problems and arthritis (WHO 2014).

The serious nature of some older prisoner’s crimes (e.g. historic sexual offences or murders) often precludes their diversion into the community, release at the end of their allotted sentence, or compassionate release on diagnosis of a terminal illness. Those released at the conclusion of their prison sentence face difficulties finding accommodation in aged care

facilities who are often reluctant or unable to accommodate ex-offenders, placing this group at an increased risk of homelessness.

In a recent USA study using the Montreal Cognitive Assessment (MoCA) to evaluate cognition, 70% of 310 individuals who had been incarcerated for at least 48 hours aged 55 years and older met criteria for cognitive impairment (defined by a MoCA score of <24) (Ahalt et al. 2018). Those scoring within this range were more likely to be non-white, report fair or poor health and, on six month follow-up, were more likely to make multiple visits to the emergency room and to be rearrested.

Some of the most difficult and controversial issues with respect to the application of criminal justice system procedures, including the appropriateness of incarceration, arise in relation to violent or other serious illegal acts by individuals who have sustained brain damage or disease affecting parts of the brain that mediate or regulate behaviour. Such individuals include those suffering from frontotemporal dementia (FTD), a condition associated specifically with behavioural dysregulation and loss of insight (Liljegren et al. 2015). The growing recognition that cognitive impairment, like psychiatric problems, when present in individuals who come to the attention of the criminal justice system, may better be managed through the health system than the criminal justice system has, in some settings, been reflected in changes in legislation. For example, in New South Wales, Australia, the Mental Health Act was recently changed to allow for the possible diversion of individuals with cognitive impairment away from courts and legal sanction to healthcare settings for further assessment and management. The operational consequences of such legislation, however, include practical challenges with respect to how best to screen for cognitive impairment. One distinct challenge relates to the fact that impairments of self-control and insight of major relevance to offending behaviour (so-called executive impairment), may not be accompanied by any formal test abnormalities but are typically detected based upon history from an informant.

Research challenges in the prison setting

An extensive literature describes the myriad health problems facing prisoners, but a dearth of evidence exists regarding interventions for this population. Information regarding health status is important but it needs to

be complemented by culturally sensitive treatments and interventions that are customized to this population and the unique environment. A search of PubMed in June 2019 covering the period 1980 to 2019 using the terms ‘prisoners’ + ‘randomized trial’ returned only 34 results while ‘prisoners’ + ‘review’ or ‘meta-analysis’ yields 1,641 results. The small number of randomized trials in this setting reflects the poor evidence base in this area and also the considerable challenges of undertaking research in the prison environment.

Difficulties undertaking research in the prison setting and challenges associated with the population may explain this trend towards descriptive rather than applied research and the employment of study designs such as randomized trials. Challenges include a protracted ethics approval processes and a culture among ethics committees of being overly protective of this population who they characterize as inherently vulnerable and incapable of providing informed consent. This perception of prisoners has likely been formed on the basis of well-documented abuses by researchers of this population in the past (Hornblum 1997). However, these are unlikely to apply today but nonetheless are still projected onto this population by zealous ethics committee members. As Beecher (1966) comments ‘*the harms that are apt to result from social scientific research are rarely of the same magnitude as those produced by research in the medical sciences, which have placed the lives of unwitting research subjects at risk by infecting them with dysentery and malaria and using them as guinea pigs for LSD research*’ (Beecher 1966).

Another challenge is a tendency for the prison system not to like being examined by an external organization, including researchers. Researchers cannot simply design a study and approach participants via telephone or methodologies that rely on direct recruitment or mail-out surveys as might occur in the community. Any of these research approaches in the correctional setting requires a rigorous ethics approval process which can sometimes take several years to reach a resolution. Even with ethics approval, site-specific concerns from local prison management may prevent the research from progressing should it be deemed disruptive to the smooth running of the prison.

Issues raised by ethics committees include whether or not prisoners should be paid for participation in research, and what form of payment (Moreno 2001). Payment is often cited by ethics committees as an inducement despite

its widespread use in the community to compensate research participants. However, as Moreno states ‘none of the landmark scandals that have marred the history of medical ethics— the concentration camp experiments, the radiation experiments, the Jewish Chronic Disease Hospital case, the Willowbrook hepatitis studies, the Tuskegee syphilis study—did financial inducement figure’ (Moreno 2001).

‘Vulnerability’ of prisoner research participants is also a widely used concept to stymie research but is often poorly articulated by ethics committees in adopting a protectionist view of this group. Fitness to provide fully informed consent is often raised as a concern. However, it is our experience across numerous surveys that most prisoners can comprehend the research being undertaken, the reason it is being conducted, and hence make an informed decision whether or not they wish to participate in a study. Recent work has established that prisoners feel insulted at the thought that a third party can decide on their behalf that they are incapable of making such a decision.

Numerous physical barriers exist in the prison setting which present a challenge to the conduct of research including: locked doors, X-ray scanners, biometric scanners, sniffer dogs, and a reliance on custodial officers to locate research participants. However, once inside the prison walls, prisoners are mostly willing to participate in research often for altruistic reasons of genuinely wanting to improve the lot of prisoners and as a form of civic duty (Lafferty et al. 2016). Response rates in the order of 80% are not uncommon in the prison setting if participants are approached with respect and the research is explained properly. Contrary to popular perception, prisoners are reliable survey respondents. We validated self-reports of TBI in a sample of 200 men and found we could locate evidence of the reported head injury in over 80% of cases using hospital medical records (Schofield et al. 2011).

Many individuals in prison have never been involved in surveys or invited to express opinions and often relish the opportunity to participate; they often report involvement in research as a cathartic experience. For many, involvement in research is often the first time they have ever told anyone about their background, upbringing, etc. and feel valued at being consulted. It is important that treatment pathways are put in place by researchers as part of a duty of care to participants including counselling for those who may be distressed, follow-up testing for bloodborne viruses and sexually

transmissible diseases, access to hepatitis treatments, vaccinations, and other forms of treatment and care.

The process whereby ethics committees make research on prisoners more difficult has been referred to as ‘ethics creep’ and results in research being hampered or even abandoned (Gill 2019). As Haggerty (2004) states ‘The range of potential research related harms envisioned by REBs at times seems to be limited only by the imagination of different reviewers’ (Haggerty 2004).

While we recognize the important and necessary role that ethics committees play, a more realistic approach should be adopted to facilitate a better understanding of the population they serve, and greater recognition be given to the positive benefits that can accrue from research in this field.

Cost of incarceration

Taken in its broader context, the vast sums of money spent on incarceration indirectly impact on public health as the criminal justice system absorbs funding that could otherwise be spent on health and education (Settumba et al. 2018). Justice Reinvestment is one approach that has been touted as a solution to this conundrum and posits that funding used for incarceration and running the justice apparatus might be better spent on programmes and infrastructure that keep people out of prison (Willis and Kapira 2018). Despite the enthusiasm of Justice Reinvestment advocates, the evidence base is small which could explain the lack of uptake by jurisdictions internationally.

Synergizing health services between prisons and the community is important to ensure continuity of healthcare on reception into prison and on release from prison into the community. The provision of health services to prisoners is most effective when it meets the same standards as those of the broader community in terms of both the scope of services provided and the standard of healthcare. During discussions on the provision of health services to prisoners in the UK, it was commented by the Inspectorate of Prisons for England and Wales that:

> Prisoners were members of the wider community before their reception into prison and their health care was the responsibility of the NHS (National Health Service); the vast majority will return to that community and to the NHS on release. It is illogical that, during the time they are prisoners, their health care is provided through separate channels. (Inspectorate of Prisons for England and Wales 1996)

Public health opportunity

Contact with the justice system via the police, courts, and prisons provides an important point of contact to connect and engage with this underserved population to identify health and social problems and initiate treatments to improve health, social, and justice outcomes. It has been suggested that imprisonment, while unfortunate, represents an important but largely overlooked public health opportunity to improve the health of this group (Glaser and Greifinger 1993). Evidence for this comes from studies showing that some prisoners are more likely to use health services when in prison than in the community (Butler and Milner 2003; Indig et al. 2009). Australia is unique in terms of having a national prisoner health data collection that collects indicators on various aspects of prisoner health and health service use on entry to prison, during incarceration, and at the time of release (Australian Institute of Health and Welfare 2015). Indicators from this survey show that almost all those entering prison received a health assessment, one-fifth referral to mental health services, few reporting needing to see a health professional but did not; almost all could see a health professional in prison if they wanted to; and eight out of ten prisoners reported their health either improved or stayed the same while in prison (Australian Institute of Health and Welfare 2015). See Table 10.10.1.

Table 10.10.1 Prison health indicators, Australia

Health indicator	Proportion
Proportion of prison dischargees who received a health assessment upon entry to prison.	92%
Proportion of prison entrants who, at reception, were referred to mental health services for observation and further assessment.	22%
Proportion of prison entrants who, in the last 12 months, consulted a medical professional for their own health within the community.	66%
Proportion of prison entrants who were in prison in the last 12 months and consulted a medical professional for their own health in prison.	57%
Proportion of prison entrants who, in the last 12 months, needed to consult with a health professional in the community but did not.	34%
Proportion of prison entrants who were in prison in the last 12 months and needed to consult with a health professional while in prison but did not.	15%
Proportion of prison dischargees who were tested for bloodborne viruses or a sexually transmissible infection.	69%
Proportion of prison dischargees who could easily see a medical professional (GP or nurse) in prison if they had a health problem.	91%
Proportion of prison dischargees who rated the healthcare they received in the prison clinic as excellent.	27%
Proportion of prison dischargees reporting that their physical health improved or stayed the same in prisons.	83%

Using the incarceration opportunity to tackle a major public health problem is currently being trialled in a world-first study in New South Wales (Australia) as part of efforts to eliminate hepatitis C (HCV). The Surveillance and Treatment of Prisoners with Hepatitis C (STOP-C) project aims to halt the transmission of HCV in prisons and hence the community when otherwise infected individuals are released from prison back to the community (Hajarizadeh et al. 2017). As the global burden of HCV infection continues to rise with an estimated 71 million people affected worldwide interventions that target hard-to-access populations are needed (The Polaris Observatory HCV Collaborators 2017). People who inject drugs represent

the core of the HCV epidemic in developed countries, accounting for most new (80%) and existing (60%) cases (Shepard et al. 2005). HCV is particularly prevalent among prisoners with around half reporting a history of injecting drug use and one-fifth exposed to hepatitis C (Sarah et al. 2013; Butler and Simpson 2017). Significant interest exists in whether treating those in prisons with HCV can impact on the wider HCV epidemic in Australia. The treatment-as-prevention approach adopted by the STOP-C trial comes from the HIV field where it has been shown that using antiretroviral therapy can prevent HIV transmission (Cohen et al. 2011). STOP-C leverages off the new treatments for HCV which have 90–95% cure rates, few side effects, and taken for only 8–12 weeks. If successful, the possibility exists to scale-up HCV treatment thus representing one of the first attempts to use the incarceration opportunity to impact on a major public health problem affecting the wider community. If successful, this approach could be adopted for other public health problems prevalent in this population.

International covenants and protections for prisoners' health

Numerous statements and covenants exist that *theoretically* protect the health of prisoners and those held in detention; many of these have an HIV prevention focus. The most famous is the United Nations' Standard Minimum Rules for the Treatment of Prisoners which was first adopted in 1955 and revised following consultation as the Nelson Mandela Rules in 2015 (United Nations 1955, 2015). While not legally binding, the Mandela Rules provide broad guidelines for best practice for citizens held in prisons and other forms of custody covering physical and mental health, disability, confidentiality of healthcare, accommodation, clothing, exercise, nutrition, etc. (United Nations 2015). Although not enforceable, they do provide principles against which countries can be judged in terms of their treatment of prisoners. Similarly, the Optional Protocol to the Convention against Torture (OPCAT) provides a framework under the United Nations' human rights system for oversight of places of detention and closed environments (United Nations 2002). It requires signatories to establish an independent national preventive mechanism to conduct inspections of all places of detention. As of June 2018, 88 countries have ratified the protocol (Wikipedia n.d.). However, three of the world's largest incarcerators—the

USA, Russia, and China—who together account for over 4 million prisoners—have not ratified the protocol. Brazil, the world's third largest incarcerator *has* signed the protocol.

Recent statements by the cities of San Francisco and London calling for public health approaches to be adopted to tackle incarceration (San Francisco) and violence (London) give rise to the view that traditional approaches to crime prevention have not been effective and new thinking is required to address these problems. In specifying how this approach might operate to fight violence, the public health approach is spelled out as one which:

takes a population approach, not one which just focuses on high risk individuals;
is preventive: by tackling 'upstream' risk factors, it aims to lessen 'downstream' consequences;
takes a system wide multiagency approach including involving business and volunteers;
takes brave decisions that require a long-term commitment;
recognizes the complexity of the issue, and seeks to build an evidence base that reflects that (Catch 22 2018).

While this [preventive] thinking is the bread and butter of public health, it represents an important conceptual shift in thinking in the fight against crime which has traditionally been downstream focused and tackled by justice agencies once contact with criminal justice system has occurred.

The public health approach to violence outlined here is important in highlighting the role of upstream factors in crime prevention which includes genetic and biological drivers of offending behaviour which to date have received little attention given the focus on sociological approaches. Traditional approaches to offending have often relied on sociological theories. Indeed, as Raine (2013) states in 'The Anatomy of Violence', '*The dominant model for understanding criminal behaviour has been, for most of the twentieth century, one built on social and sociological models. ….. sole reliance on these social perspectives is fundamentally flawed*' (Raine 2013).

The father of criminology, Cesare Lombroso, sought to identify criminal characteristics in physiognomy (Lombroso 2006). His work has long since been discredited, but advances in techniques such as brain imaging and genetics have resulted in a resurgence of interest into the biological

influences on offending. The emergent discipline of ‘biosocial criminology’ seeks to explain crime and antisocial behaviour by exploring both biological and environmental factors and their interactions (Beaver 2009).

Clearly, ‘brave decisions’ need to be made in addressing crime. Politicians frequently adhere to a perceived punitiveness on behalf of the community adopting a ‘tough on crime’ stance, driven by a populist press motivated by delivering sensationalist headlines to their readership. However, recent deliberative work that takes a more considered approach than that offered by snap opinion polls challenges this view of the community as punitive and driven by a desire for revenge and retribution. This important work, incorporating Citizens Juries and deliberative roundtables, suggests that the public, when provided with relevant information regarding the costs of incarceration and its limited deterrent and therapeutic qualities, favours the development and implementation of effective interventions to treat this population (Simpson et al. 2014). Public health can contribute to this area by promoting the use of rigorous research methodologies such as randomized control trials, cohort studies, case-control studies, and systematic reviews in the criminal justice area.

Multi-agency approaches will be required to tackle crime and hence reduce the numbers held in prison. This approach will necessarily have to harmonize biological and social factors for optimal success. To this end, the approaches of these two cities (San Francisco and London) is both refreshing and forward thinking.

Future challenges

Consistent with our intention of preserving relevance for an international readership, we recognize that prioritization, in terms of advancing health outcomes of individuals who come in contact with the criminal justice system will differ by country, or region. Thus, a major priority within the USA concerns the imperative to halt and reverse the epidemic of incarceration, particularly among Blacks (Drucker 2011). In relatively less developed regions, such as Latin America, improvement in the physical conditions of prisons and the better recognition and treatment of psychiatric conditions may be paramount. Setting region-specific considerations aside, we consider that the following challenges are likely to have broad relevance regardless of setting: creating and operating diversionary programmes,

reducing the impact of incarceration on families, dealing with cognitive impairment and other ageing-related illnesses, optimizing transition to the community and health maintenance on release from prison and, of crucial importance, more rigorous research as mentioned in the previous section (Adams 2018).

Prisons represent individual, societal, and institutional failures at multiple levels. They are costly and have limited efficacy in terms of their rehabilitative properties. To this end, they represent one of society's greatest challenges and one requiring a concerted effort by agencies spanning health, welfare, justice, law, and education. The prisoner population represents one of the most unhealthy in the community across all health metrics and one that presents numerous challenges, including the attitude of the community towards a group that has transgressed the rules of society. What has not occurred to date is the 'ownership' of this population by mainstream public health agencies, although recent moves have sought to remedy this, calling on public health professionals to apply the arsenal of methodologies and evidenced-based approaches to tackle offending behaviour. This will require a 'genes to gaol' approach that will not come quickly and will require effort, funding, innovation, and dedication.

Health needs assessment

Michael P. Kelly, Jane E. Powell, and Natalie Bartle

Introduction

The idea of health needs assessment is, on the face of it, straightforward—estimate the health needs of a population or subgroup in a population and organize services accordingly. The English National Institute for Health and Care Excellence (NICE n.d.) defines Heath Needs Assessment as ‘a systematic process used by NHS organizations and local authorities to assess the health problems facing a population. This includes determining whether certain groups appear more prone to illness than others and pinpointing any inequalities in terms of service provision. It results in an agreed list of priorities to improve healthcare in a particular area’ (NICE n.d.). In the United Kingdom health needs assessment has been used in a wide variety of settings. These have included Immigration Removal Centres (NHS England 2015), local NHS organizations (NHS Kent and Medway 2013); and by local authorities (Horsley and Hollingsworth 2014; Derby City Public Health—Knowledge, Intelligence and Strategic Planning Council 2017). In an uncomplicated world the assessment of health need and healthcare need should be a tool for tackling inequalities, a prerequisite for the allocation of resources and the first step in planning and evaluating care (Stevens and Raftery 1997). In practice however, measuring health needs is not straightforward. It raises difficult questions about healthcare, equity, equality, fairness, and justice (Gillam et al. 2012).

Needs assessment embraces a variety of methods and techniques to gather information about populations (Health Development Agency 2003). In the United Kingdom traditionally it has meant taking ‘a population-based, epidemiological and public health approach to the planning of health interventions’. That means using data about population patterns of health to

do rational planning in order to meet the particular needs of all, or parts, of the community, taking account of equity, efficiency, and affordability. In principle, this approach to needs assessment might be used as the basis for planning in any health system (Clarke et al. 2009). It aspires to 'maximize the appropriate delivery of effective health interventions or care …in an evidence-based way … [to] maximize equity' (Powell 2006).

Globally however, the term health needs assessment is more widely used and deployed to mean a range of different things. Sometimes the approach is highly specific focusing on particular risks or specific diseases (Cox et al. 2013; Cicero et al. 2014; Nacul et al. 2014; Allchorne and Green 2016). Sometimes it is aimed at special subgroups and populations (Ash and Mackereth 2013; Vyas et al. 2013) or for specific services (Ingold and Hicks 2015), and particular populations at particular points in the life course (Pretty 2014). In the United States its currency includes linkages to charity hospitals and the needs of disadvantaged groups who might be eligible to use the hospital facilities or to determine what sorts of services ought to be provided (Apatu et al. 2018; Van Gelderen et al. 2018). The US 2010 Patient Protection and Affordable Care Act created a new legal requirement for non-profit hospitals to conduct Community Health Needs Assessments (CHNA) every three years to maintain not-for-profit status with the Internal Revenue Service (Rosenbaum 2013; Fischer et al. 2018) and various techniques have been used to do this (Mathews et al. 2015; Pennel et al. 2015; Franz et al. 2017; Stone et al. 2018). Practice varies widely (Alfano-Sobsey et al. 2014; Becker 2015).

The website of the US Centers for Disease Control and Prevention (CDC) defines community health assessment as a systematic examination of the health status indicators for a given population that is used to identify key problems and assets in a community. The ultimate goal of this kind of community health assessment is to develop strategies to address the community's health needs and identified issues. A variety of tools and processes may be used according to CDC to conduct a community health assessment; the essential ingredients of which are community engagement and collaborative participation. https://www.cdc.gov/stltpublichealth/cha/plan.html. Health needs assessment has also been used in the United States in Medicaid enrolment (Leininger et al. 2014).

In disaster zones the term denotes ways of getting emergency provision to the population in the most acute of circumstances (Malilay et al. 2014; Hong et al. 2017) or assessing need after disaster has struck (Subaiya et al. 2014). There is no single method or methodology applied, and the term health needs assessment or just needs assessment has come to refer to any way of making an assessment of need.

The UK population-based, epidemiological approach to health needs assessment

We begin by focusing on the approach to needs assessment which originally drew heavily on epidemiology and health economics. In this view assessment of need must include an assessment of the effectiveness of interventions to meet identified health needs (Mooney 1992). The assumption is that the relative total need can be measured sufficiently by just a few factors such as mortality or morbidity rates. It emphasizes quantification and objective comparative measurement. This type of needs assessment is usually dependent on existing or available data, it seldom involves generating new information from primary research because this would be too expensive and take too long. Health needs assessment tends therefore to be based pragmatically on the routine data sources that are there already (Clarke et al. 2009).

There are a number of distinct steps. It begins with clear problem definition. To do this, two questions need to be considered. What do we want to find out about the population, and how can we go about finding it out? A series of further questions can then be asked to help clarify the process: why is this assessment needed now, who will be affected, what would the consequences be of doing nothing, how much time is available, how can the results and the recommendations be presented to maximal effect, are sufficient resources available, and how will the needs assessment be itself assessed and evaluated? (Clarke et al. 2009).

A detailed project plan identifying the component parts of the exercise should be prepared. Central to the exercise will be an epidemiological assessment, which will determine how many people in the population need care and at what level and what services are available for them. It is important to identify the denominator population, that is the total population

or relevant sub- population because otherwise it is very difficult to interpret prevalence (total number of cases) and incidence (new cases in a given time period) (Clarke et al. 2009). Collecting data like these tends to be more straightforward in developed countries. In less developed countries data systems tend not to be so reliable, although where data systems are less than optimal other options may be available (Bonnefoy et al. 2007).

Details of the structure of the population need to be built into needs assessment; the age, ethnic, occupational, and geographical contours of the local population and the patterns of health inequalities will be assessed and described (Kelly 2010a). The level and severity of the diseases of interest need to be examined at this stage too, along with an assessment of the prevalence of relevant risks—for example levels of smoking, physical activity, and alcohol consumption. In a population with a significant number of Afro Caribbean people an assessment of sickle cell disease might be a particular focus of interest, in a mining community chest disease might command attention. The absolute number of people suffering from the condition, and the degree of severity can then be calculated (Clarke et al. 2009). If assumptions have to be made in the absence of data and proxy variables are used, these must be made explicit.

The next stage is sometimes to develop an assessment of the clinical effectiveness of interventions for the condition or conditions of interest. There are a variety of ways of assessing effectiveness. However, if we are concerned to determine the clinical effectiveness of a medicine, or some other kind of intervention, we will get a more accurate assessment if we use evidence in which a control is used and potential biases are minimized. If this is so, we can be reasonably sure that the observed size of the effect is a consequence of the intervention not some other biasing factor. Some commentators suggest that using only evidence drawn from the top of the evidence hierarchy to assess clinical effectiveness is the way to do this (Clarke et al. 2009). The evidence hierarchy is a device which categorizes studies according to the methods they have used and the degree of bias which is associated with the methods. Randomized controlled trials (RCTs) and the meta analyses of such trials rest at the top of the hierarchy as these methods are deliberately designed to reduce bias and offer the greatest certainty that the observed relationship between the independent and the dependent variable is the consequence of that relationship, not some other factor.

It is possible to make an assessment of the effectiveness of interventions by examining clinical trial data for its quality or bias. So it would be quite appropriate, but very time consuming, for someone conducting a needs assessment, who is interested in the effectiveness of particular treatments, to examine RCT findings directly. An easier route is to use the evidence of effectiveness which has already been appraised for its quality in for example Cochrane reviews. These are produced by Cochrane (formerly the Cochrane Collaboration), a world-wide network of reviewers conducting quality appraisal of primary intervention studies. Alternatively, data examined by the National Institute for Health and Care Excellence (NICE) who conduct clinical and cost-effectiveness analyses of new technologies, treatment pathways, and preventive interventions in England can also be consulted. The assessment of effectiveness is based on a set of principles which collectively are known as health technology assessment (Kelly and Moore 2012).

After the effectiveness analysis is complete a synthesis of the evidence is then undertaken comprising the epidemiology in the local population, incidence and prevalence, underlying risk factors, treatments and interventions ranked according to effectiveness, along with evidence of cost-effectiveness and actual costs. These will, of necessity, be imprecise, but if assumptions are made explicit they will suffice as a starting point for needs assessment (Clarke et al. 2009).

Once data have been collected on the local population of interest, the next stage is to compare locally derived data with data from other places in a *comparative needs* assessment. This allows an appraisal of the degree to which local provision is consistent with what might be expected on the basis of the comparisons. This is sometimes difficult because rates of interventions vary both within and between countries, but the process is about putative differences between the observed and the expected values rather than exactness. It is important to consult with stakeholders at this point and genuine community participation is important. Rapid needs assessment may come into play where statistical and other data are unavailable (Clarke et al. 2009). All of this is brought together in a ‘case for change’ document which will outline what is in place, what ought to be done, what stakeholders believe should be done and what the community want done. Costed options are essential to inform redistribution of

resources. The final step is to act on the needs assessment and implement a plan.

Health systems are complex sociotechnical arrangements consisting of people, cultures and practices, organizational structures, equipment, and technologies. Health systems are constrained, because whatever the system, the resources to fund them are finite. Because of finite resources it is not possible to do everything, to fulfil every need or to adopt every new drug, procedure, or device. At the same time demand for health services rises because expectations of what medicine can achieve increase. People, especially in advanced societies, frequently think that they deserve or have some entitlement to—that they *need*—the best and most up to date medicines and procedures. The availability of a medicine therefore often creates the demand *and* the need for it—patients want it and doctors want to use it. All of this adds to the demands on the resources in the system.

Health systems have to adapt to constantly evolving inputs in the form of new medicines, medical technologies, and approaches to medical and surgical interventions. Decisions have to be made about the adoption and use of these new things. In addition, the health needs of populations are complex and change. For example, the age and ethnicity distributions of populations alter. Not only do populations change, but health systems themselves also evolve. Needs assessment, is one means of deciding how to allocate scarce resources to prioritize and tackle need in the face of these complexities. A needs assessment provides a basis for decision making, which will include local knowledge and understanding of the nature of communities, their sociodemographics, and physical environment. Health needs assessment consists of a range of techniques to assess and meet need in a rational and systematic way against this background of complex and changing systems, population diversity, evolution, and increasing expectations and demand. An understanding of the social environment and the social relationships within those environments is essential to successful implementation of needs assessment.

Later in this chapter we explore some of the difficulties attached to this approach. However, it is very important to remember that applying rational principles in this way arose from an understanding that the operation of an unmanaged system in which historical patterns of supply, the generosity of benefactors, the preference of medical practitioners to live in attractive areas, and their wish to provide services that were consistent with *their*

interests led to very unequal and inefficient distribution of resources. So whatever the imperfections of the approach just described, it was born out of a desire to do things better and more fairly.

Other techniques for doing needs assessment

Other techniques may be and have been used to assess need. It has been recommended in the United States in the context of the Affordable Care Act that community health assessments use such principles as: multisector collaborations that support shared ownership of all phases of community health improvement, including assessment, planning, investment, implementation, and evaluation; proactive, broad, and diverse community engagement to improve results; a definition of community that encompasses both a significant enough area to allow for population-wide interventions and measurable results, and includes a targeted focus to address disparities among subpopulations; maximum transparency to improve community engagement and accountability; the use of evidence-based interventions and encouragement of innovative practices with thorough evaluation to inform a continuous improvement process; and, use of the highest quality data pooled from, and shared among, diverse public and private sources (Rosenbaum 2013).

A very wide range of methods have been pressed into service in the United States. Becker notes that ‘Research designs vary across states and agencies, and little is known about the reliability or representativeness of results’ (Becker 2015, p. 15). Telephone and door to door surveys have been used to ascertain people’s self-reported health needs (Stone et al. 2018). Routine data and records (Alfano-Sobsey et al. 2014; Franz et al. 2017), community health partnerships and community surveys (Mathews et al. 2015), key informant interviews, focus groups, mixed methods designs (Becker 2015, p. 15) and opinion surveys (Alfano-Sobsey et al. 2014) have all been used.

Community participation and community engagement are particularly emphasized ‘community participation and mobilization in CHA processes includes the following: recognizing the community as a unit of identity; building on strengths and resources; facilitating collaborative partnerships; emphasizing locally relevant problems and an ecological perspective;

promoting power sharing, co-learning, and capacity building; improving cultural sensitivity, reliability, and validity through quality community participation; increasing community trust and ownership; developing community systems through a cyclical and interactive process' (Pennel et al. 2015, p. 104). Pennel et al. (2015) note that the following should be included 'gathering and analysing quantitative and qualitative data; using data to identify health issues; using broad social determinants of health to identify influences on health issues, including environment, behaviour, socioeconomics, and culture; identifying resources and resource gaps; identifying health disparities; engaging and mobilizing the community; organizing and sharing findings; setting health priorities; developing an action plan to address health priorities; implementing action plans; and providing opportunities for continual feedback with community members' (Pennel et al. 2015, p. 103). But they also note that this broad public health approach, may be at odds with the way that hospitals apply more biomedical principles.

In England, Joint Strategic Needs Assessment (JSNA) develops analysis and strategy for current and future health and care needs of local populations to inform and guide the planning and commissioning of health, well-being, and social care services within a local authority area. Health in All Policies (HiAP) aims to identify interactions between strategic targets, policies and strategies and population health and wellbeing (Public Health England and the Local Government Association 2016) utilizing 'Health Lens' assessment (Kickbusch et al. 2014). Health Lens Analysis has five essential elements that make the most of opportunities to implement 'Health for All' actions for potential population health impact and value. These are:

To engage in order to innovate and establish and maintain strong collaborative relationships across sectors and disciplines.
To determine agreed policy focus among stakeholders to achieve take-up, reach, and delivery of programmes and services. To gather evidence and data: to establish insight on population health need in the policy areas of focus. The use of insights and inference drawn from big, digital routine data sources within JSNA, is increasingly common.
To generate policy recommendations and a jointly owned final strategy report.
To navigate to help steer recommendations through the decision making process.
To evaluate to determine the effectiveness of the health lens.

Health economics and needs assessment

Over the last several decades, two important techniques have come into general use to assist the allocation of resources in the face of scarcity in health systems; health technology assessment which helps to assess effectiveness of interventions and cost utility analysis in health economics, to help assess cost-effectiveness (Kelly et al. 2010). We have already discussed health technology assessment previously in the context of assessments of effectiveness. We now turn our attention to the contribution of health economics.

As a starting point we look to utilitarianism—which is the ethical basis of the discipline of economics. Utilitarian ideas, theories and techniques are concerned with the common good or the greatest happiness of the greatest number (Bentham 1834). Utilitarianism in allocation of resources for the common good of society has much to commend it. But the tools and techniques do tend to favour the status quo. They do not challenge or on the whole try to amend existing resource allocations that might be considered to be unfair or unequal. Utilitarian tools and techniques if applied without critical reflection implicitly approve existing resource allocation and aim to improve social welfare starting from that point. They make what might be viewed as conservative changes to reallocate resources, so that at least one person is made better off and nobody else worse off (Pareto 1935).

Utilitarianism, or the greatest utility of the greatest number, is the ethic that continues to guide economic thinking, tools, and techniques and is also central to the ethic of health needs assessment. However, at the end of the nineteenth century, the future direction of economics as a discipline was influenced by the introduction into mainstream economic theories of mathematical thinking from the physical sciences and engineering.

Economics moved away from broad questions of how resources should best be applied for the good of society—a mix of value judgement on social welfare and observation of facts, to empirical testing of hypotheses using data. For example, economists became very interested in the relationship between unemployment and inflation and used empirical testing of data to test hypotheses about these variables.

A new more scientific language and a range of tools and techniques emerged from economic theories which tended to distance themselves from the messy details of complex human behaviour. The legacy of these changes still survives within economics. A quick perusal of the main economics journals today reveals numerous articles containing strings of equations to test hypotheses, as well as outlining the intricacies and new derivatives of different economic techniques and tools and how to apply them rigorously. In addition, the need within the economics discipline to find mathematical solutions to applied problems has guaranteed survival of the basic assumptions of the economic way of thinking, i.e. people, firms, and institutions are perfectly rational and behave predictably, as if, they have perfect information and control over environment and events. In economics, people are assumed to be equal and social/cultural and environmental/place variations between them are not acknowledged explicitly. So when health needs assessment is viewed as rational, this is the underlying rationality.

Health economics has developed particular techniques and tools, in particular the quality-adjusted life year (QALY) (Cohen and Henderson 1988). This technique is steeped in utilitarianism—allocating resources efficiently for the common good—in this instance fair allocation of health technologies and other interventions in the face of finite resources. Economic thinking is predicated on the notion that most resources are scarce and have limits, but demand on those resources is potentially infinite. This creates choice and opportunity cost meaning that once resources have been allocated and used, they cannot be reallocated and used again in

another way (Powell 2007). Health has been characterized as a multidimensional, dynamic concept subject to changing human expectations and revision over time (McGuire et al. 1988). The economics of health has therefore also developed over time to reflect these changes. Since the Second World War, successive generations of theorists have sought to embrace new ideas about health. For example, economic, social, and psychological aspects of health have been included to reflect changing expectations, the nature of health systems, stage of economic development and passing time (WHO 1947, 1948, 1958). From the late 1980s in developed countries, definitions of health broadened considerably to reflect the notion that wellbeing is inseparable from and crucial to health, and in turn, both are influenced by society as a whole (Bowling 2001).

Cost utility analysis and the QALY have been widely used around the world in the assessment of the cost-effectiveness of new drugs and of other types of clinical interventions. But it has proved less well suited to assessing preventive public health type interventions. The literature identifies a number of conceptual, methodological, and practical difficulties in evaluating the effectiveness and cost-effectiveness of primary prevention interventions (Lorgelly et al. 2010). There are difficulties of producing evidence of cost-effectiveness for public health guidance and methodological difficulties associated with applying health economic techniques to public health interventions (Kelly et al. 2005). These difficulties and issues spring from the focus on efficiency within economic evaluation techniques to the exclusion of the determinants of health and inequalities in health, which are central preoccupations in public health (Barendregt 2006). This is important because as we will show, health needs assessment is itself premised on principles of economic efficiency as well as the principle of equity. And so the same problem that applies to the application of simple cost utility analyses to preventive interventions also applies more broadly to health needs assessment.

Equity, efficiency, and health economics

Health systems may be characterized by the way they organize, finance, and deliver resources to attempt to balance competing health and well-being objectives. Equity in the distribution of resources is the main objective of a

health system where citizens have entitlement and equal access to the means of achieving good health and well-being according to health need. Efficiency in the allocation of resources—where the cost of good health and well-being is minimized and the benefits maximized—is often prioritized by governments over equity in order that the overall cost of a health system as a proportion of GDP, is controlled. Efficiency and equity are generally viewed as competing objectives that most health systems fail to reconcile because both objectives cannot be optimized at the same time—creating an equity-efficiency trade-off. This in turn raises concerns about social justice and generates philosophical arguments about where the balance between efficient resource allocation and equitable distribution of health resources to meet health need, should lie. Early forms of health needs assessment and similar approaches—social audit and rapid appraisal—attempted to establish the size of different health needs and to prioritize and allocate resources pro rata on that basis.

Health economic techniques and tools were directed at inefficiencies in the allocation of healthcare resources and ‘the need for healthcare’ defined as ‘capacity to benefit’ from healthcare became recognized as a key aspect of health status. As a consequence, the health intervention needed in any given circumstance is a function of factors such as the level of prevailing resources, the availability and effectiveness of health interventions, and the perspective and values of those making the assessment. Over time notions of health need have come to be defined as a result of momentum in economic discourse and debates and the development and proliferation of common currency quality of life measures that reflect the outcome and efficiency of interventions to improve health and well-being.

Health systems and the equity–efficiency trade-off

We next examine how economic conditions influence the inter-relationship between equity, efficiency, and cost, describing debates about resource allocation in Beveridge and Bismarckian health systems. These systems take their names respectively from William Beveridge whose report was used as the basis for the policies which helped establish the Welfare State in Britain in the 1940s (Ross 1952) and Prince Otto Von Bismarck who set up the first schemes of national insurance in Germany in the 1880s (Taylor

1955; Thomson 1957). We outline the ways theories of justice underpin equity-efficiency trade-offs, explaining the background to the emergence of new policy concepts and techniques of assessing, measuring, evaluating, and prioritizing efficient and equitable allocation of resources. The nature of the determinants of health and the role of physical and social environment in the improvement of community health outcomes are considered with respect to equity, need, and efficiency.

Healthcare is financed and provided free at the point of use by government through taxation in Beveridge-type health systems. Beveridge health systems differ from Bismarck-type systems in which healthcare is financed by multiple employer-based insurance schemes and taxation in which providers are privately rather than publicly owned. Both types of system however face the same problem of increasing demand in the face of finite resources to fund the systems. In recent decades, some reformers of health systems and health policies have attempted to create market incentives within the system to control overall healthcare expenditure, increase quality, bring down prices and increase choice (Bevan et al. 2010) —for example, providing a choice of provider for healthcare treatments and services as a way of taking some people off waiting lists. However, the economic and social trade-off is that this comes at a price—leaving those who cannot afford to move to languish on the longer waiting list.

Alternatively, other systems that prioritize access and give universal coverage to meet health need provide a narrower range of healthcare services because price signals to reallocate resources within the system are absent. An equity-efficiency trade-off occurs and this can create a dash from central decision making to localism where the allocation of resources is determined by local decision makers. Much of the tension in the balance between efficiency and equity, however, can be traced to expectations and changes over time in the common understanding of what constitutes good health and well-being in communities and countries. Inevitably, these understandings are related to stage of economic development, economic performance, and historical gross national product (GNP).

Some political and philosophical considerations.

At the heart of the approaches to needs assessment outlined so far is a relatively one dimensional idea of need. There is an altogether different approach in the philosophical literature which defines need as a dynamic, politically, and ideologically value-laden idea. In the political and philosophical view, one focus is *unmet* health needs in the form of morbidity in individuals and populations. It is argued that unmet need creates unfair deficits in the distribution of health and wellbeing among communities and populations—deficits that society should take steps to address. In this view, need is described as something that is likely to be dynamic over time as technologies, expectations, and availability of services change. Measurement of need will therefore vary in different contexts, such as, in the clinical setting and at the population level. Needs assessment planning would therefore involve considerations of allocative efficiency along with social values (McIntyre et al. 2009).

Unfortunately, morbidity turns out not to be a good guide to unmet need! We may posit that one person's need is greater than another's because there is a greater degree of morbidity—they are sicker. This in turn implies that one health state is more deserving than another because of the extent of the disease. It also assumes we can accurately measure the differences in disease states. This however may be a false premise because degrees of illness in a strictly biological or pathological sense, even if they can be measured accurately and meaningfully compared, tell us nothing about an individual's quality of life with different degrees of morbidity and therefore their needs in a social or psychological sense. Some people cope extremely well with illness and have a relatively good quality of life while others seem to be rendered incapable of normal social functioning with relatively minor ailments. The subjective experience of illness and an individual's response to it significantly affects their expression of need. It is difficult to measure need solely by assessing biological morbidity in any absolute sense (Anderson and Bury 1988).

There is a still more difficult issue relating to health differences in populations. All health systems, and by definition all health needs assessment, have to confront the systematic differences in the pattern of heath in populations. The health of individuals varies, and the health of groups of individuals also varies; so men and women, age groups, and ethnic groups show *average* differences in life expectancy and patterns of disease. The health of one country varies compared to other countries;

within countries there are differences between individuals and groups. These variations occur because of biological inheritance, because of differential exposure to factors which cause disease and because health services are not uniformly or equally spread between individuals and populations. In any case, individuals make widely different use of available services especially preventive ones. Some people die relatively young, while others live to a ripe old age. Some people live life with multiple health problems and disabilities, others lead lives of a good quality and die peacefully in their beds in their nineties. So as a starting point the demands placed on health systems of these different individuals and groups vary. If we are trying in some way to meet the health needs or demands of various individuals and populations on what basis should we do it?

The straightforward answer at the heart of most approaches to health needs assessment is that we should seek to measure the needs of individuals or populations and we should allocate provision to meet the need accordingly, as that would be the fairest way to do it. But that in turn raises several questions—how exactly would we measure need? Could we do so in a way that was accurate and precise and more importantly could we do it in a way that was fair? And fair exactly to whom? To the people in need or to the people who are not in need and whom we might call upon to fund the needs of others in greater need than them. But why should those not in need, subsidize those who are in need? Is that fair? The answer as to whether one thinks it is fair will be dictated by a political preference as well as general ideas about fairness which would in turn be influenced by other ideas about ethics, morality, duty, responsibility, and liberty for example. Is it fair to have one's income taken away to fund the needs of others? Not forgetting that some people's health needs are in part generated by the choices that they themselves have made in how they have lived their lives, whether they have chosen to smoke, to excessively consume alcohol and food and to take drugs or engage in sexual practices which might expose them to risk of infection. These people have health needs, but whose responsibility is it to meet those needs? Again the answer will be influenced by other value positions. It must also be acknowledged that in response to the international financial crisis of 2008 austerity policies have been pursued in many countries. Consequently, the recent economic environmental context is less likely to trigger positive change in population health impact and value through strategic needs assessment. In response to

austerity in England, local authorities have developed Sustainability and Transformation Plans (STPs) alongside JSNA. These aim to move resources from acute care to prevention by targeting those most in need.

Patterning of health differences

There is another very important dimension at play here which, we have not so far explored in detail; this is the *patterning* of health differences. This removes the discussion from the level of the individual to the level of the social or population. The differences in health experience and health outcomes, the differences in access to services, the differences in exposures to risk and the differences in activities which are health damaging are not distributed randomly or evenly in the population. Health experience and health outcomes are strongly patterned by social position. On whatever measure used to assess health be it mortality, morbidity or self-defined health, the measures follow a social gradient. Those who are better off *on average* enjoy better health, live longer, and make more use of available services. This applies under whatever arrangements for the funding of services operate.

It holds true in market systems like the United States, it holds true in social insurance systems as found in much of Western Europe and it holds true in societies where care is free at the point of use like the United Kingdom. This is called the health gradient—and is one of the most enduring and vexatious characteristics of contemporary health systems (Graham and Kelly 2004).

Comparative data for the United Kingdom and the United States illustrate the gradient. They show similar patterns of graded health differences measured by income for, among other things, self-assessed health, diabetes, heart disease, and lung disease (Banks et al. 2006). The gradient is described in many texts, reports, and papers (Bleich et al. 2012). The shape of the gradient varies; it tends to be steeper in societies with very heterogeneous populations and rather gentler in societies which are more socially homogeneous; but only by degree. Health differences linked to social position remain an enduring and structural feature of contemporary developed societies. In both developing and low income countries the same features of health inequities apply though the shape of the gradient tends to

be more curvilinear. In some developing and low income countries a small affluent elite enjoy good health outcomes and the majority of the population are in a less desirable situation (Bonnefoy et al. 2007).

In broad terms the state of the contemporary world is one where health differences, however measured, prevail across all societies and also between societies. There are absolute health differences between rich and poor societies and between rich and poor people and those not so poor, in all societies (Kelly and Doohan 2012). So here we encounter a major problem with the apparently rational calculus of health needs assessment. Whether health need is expressed in terms of health status or outcome, need (including subjective expression of need) varies systematically across the population and there are considerable health inequalities. It can be, and often is argued that the needs of the most or the relatively disadvantaged are paramount and therefore resources should be deployed in such a way that they meet those needs first. All that would remain to be done would be to find a technical solution to the measurement of need.

In addition to the health gradient there are two other ways of looking at health differences called health disadvantage and health gaps (Graham and Kelly 2004). Health disadvantage simply focuses on differences, acknowledging that there are differences between individuals, distinct segments of the population, or between societies. It is a descriptive and non-judgemental approach. The health gaps approach, in contrast, focuses on the differences between the worst off and everybody else, often inviting the conclusion that those who are not the worst off enjoy uniformly good health. The gap approach also invites the conclusion that this state of affairs is wrong or unfair.

A gap approach and a gradient approach lead to rather different solutions. Conceptually, narrowing health gaps look to actions which will improve the health of the poorest regardless of the rest of society. Such an approach would be one which achieved both an absolute and a relative improvement in the health of the poorest groups. The health gradient approach takes, as its starting point in contrast, the acknowledgement that the penalties of inequities in health affect the whole social hierarchy even though they increase from the top to the bottom.

Gaps and gradient approaches lead to quite different assessment of need and how to meet those needs. It may seem counterintuitive, but if policies or actions only attempt to target the needs of people at the bottom of the

social hierarchy, there will be little or no impact on health inequalities across the rest of society (Rose 1985, 1992). This is because inequities in health will still exist, the social determinants continue to exert their malign influence and the health needs of the majority of the population remain unattended to. The alternative approach advocated by the Marmot reviews for example and World Health Organization (WHO) (Bonnefoy et al. 2007) involves a consideration of the whole gradient in health inequities rather than only focusing on the health of the most disadvantaged. An effective policy in this regard is one that meets two criteria. It is associated with (a) improvements in health (or a positive change in its underlying determinants) for all socioeconomic groups up to the highest; and (b) a rate of improvement which increases at each step down the socioeconomic ladder. In other words, a differential rate of improvement is required: greatest for the poorest groups, with the rate of gain progressively decreasing for higher socioeconomic groups. It locates the causes of health inequity, not in the disadvantaged circumstances and health-damaging behaviours of the poorest groups, but in the systematic differences in life chances, living standards and lifestyles associated with people's unequal positions in the socioeconomic hierarchy (Graham 2004a, 2004b, 2006). The significant caveat is that where the health gap is both large and the population numbers in the extreme circumstances are high, a process of prioritizing action by beginning with the most disadvantaged would be the immediate concern.

From health inequality to health equity

The gradient leads to some other questions. Does it matter that there are patterns of inequalities in health? Why should we seek to remedy this state of affairs? Why use the instruments of health service provision to deal with this problem? Why conduct needs assessment to try to change the gradient? After all, all societies demonstrate a gradient to some extent. Even though health differences are clear, a case may be made that over the last century and a half, things have improved for nearly everyone—at least in the developed West. Rates of infant mortality are at an historic low and life expectancy has never been greater. Furthermore, while *average* patterns of morbidity and mortality in different social groups and populations may be

clear, there are wide variations between individuals. In short, not all well to do people live to a healthy ripe old age, and not everyone who is disadvantaged dies young. To be human is to know that we will eventually die and that the manner and timing of our death is in almost all circumstances beyond our control whether we are rich or poor. So is it the case that patterned average differences in *early* and largely *preventable* death and suffering are unfair and unjust just because they are theoretically preventable—particularly when there is no necessary inevitability that relatively disadvantaged people should die earlier than anyone else? There is no straightforward answer.

A number of writers have explored the theme of injustice in this context. The WHO has had a long-standing interest in the matter. The WHO's Commission on the Social Determinants of Health used a series of definitions to clarify things which were based on the work of Whitehead (Whitehead 1992; Whitehead and Dahlgren 2006) and Solar and Irwin (Solar and Irwin 2010). A distinction is made between health inequality and health inequity. Health inequality is defined as *health differences which are not avoidable or preventable, are not the consequence of human actions and activities, but are based on genetic or constitutional individual differences, age, or biological sex.* These are sometimes also referred to as variations (Kelly et al. 2007). Health inequity, in contrast, is defined as *unfair and avoidable or remediable differences*. Health equity in turn is defined as *the absence of unfair and avoidable or remediable differences in health among social groups* (Solar and Irwin 2010). The italics highlight the difference in definitions. It is particularly important to note that the difference in definition between inequity and inequality is not used universally and many writers and commentators employ the two terms as synonyms. Also the distinctions between individual differences which are based on human biology and differences arising from interaction between an organism and an external man-made hazard are in reality difficult to draw in anything other than an analytic sense. Empirically the divides are much fuzzier than these definitions suggest. However, as a way of beginning to find some clarity the distinction is helpful. Equity and inequity are not products of nature they are the products of human actions and, as they are socially, economically, and/or politically produced they are, theoretically at least, modifiable. The defining characteristics of equity are

fairness and justice; the defining characteristics of inequity are unfairness and injustice (Whitehead and Dahlgren 2006)

Fairness and unfairness can be conceptualized as absolutes; something or some state of affairs is either fair or unfair—it cannot be both at the same time. But thinking like this in absolute terms misses the point that fairness and unfairness are not properties, things, or states of affairs, but are about *relationships* between people. Fairness and unfairness arise as a consequence of the nature of the *relationships* between people and the ebb and flow of human affairs. So too justice is not a simple measure of equitable distribution of resources according to need, but is about the nature of relationships in society.

Justice may be understood in terms of the properties of people, their conduct, the rules that govern their affairs and the characteristics of institutions—an absolute definition The alternative is a *relational* concept of justice which concerns itself with the 'justness' of relations between people—X is unjust to Y (Pogge 2003). Such relations involve human agency, purpose, and motive. From a relational point of view justice should not be about fair distribution; it should be about seeking to identify the agents responsible for the social arrangements that determine the shape of human relationships (Pogge 2003).

Health equity may be conceptualised in distributional or relational terms in the same way that justice can be. The distributional approach is focused on the goal of equalizing good health across society—which is really the underlying value position of most health needs assessment and much of the discourse about health inequity. The relational view is about the balance between the harms inflicted and harms mitigated or prevented. In the relational view social institutions and those responsible for them should have more concern to prevent and mitigate those things they cause themselves and for which they are responsible, rather than those things which are outside of their control (Pogge 2003). So the real issue in relational terms, with which equity should be concerned, is not the fact that health is differentially distributed, but that social systems contribute to the differential distribution of health and disease. Poverty is the greatest contributor of all to ill health. Organizing economic arrangements so that they do not generate the conditions of poverty which generate ill health is thus, it may be argued, a moral duty. Therefore, focusing on assessing need without looking at the wider determinants of the causes of inequity in the

first place, is misguided. The global economic order is responsible for the generation of ill health and health inequities (Pogge 2003), and the social arrangements that have negative effects on health are unjust (Venkatapuram 2011).

In a celebrated paper called '*What is the point of equality*?' Anderson outlined a number of the problems associated with the distributional concept of equality. She warns against the notion that we can construct institutions to make them more equal and fairer, not least because this tends towards greater and greater state interference in the lives of the citizenry. She notes that one of the dangers associated with egalitarianism and the distributional approach is that it pushes the limits of the state further into the lives of ordinary people. This is a particular danger if states become concerned with equities of health rather than oppressions of the powerful against the powerless. In other words, focusing on rearranging healthcare resources to make the patterning of health more equitable is rather like moving deck chairs around on the deck of the Titanic after she hit the iceberg—largely irrelevant and pointless when the ship is sinking. 'Recent egalitarian writing has become dominated by the view that the fundamental aim of equality is to compensate people for undeserved bad luck—being born with poor native endowments, bad parents and disagreeable personalities, [and] suffering from accidents and illnesses' (Anderson 1999). This she says is not really the issue. We should instead be preoccupied with ending oppressive social relations rather than trying to ensure that everyone gets what they morally deserve. It is about creating a community in which people have equality in relationships with one another (Anderson 1999)—a community built on cooperation between members who see themselves as equals. She argues for democratic equality which means that all law abiding citizens are allowed effective access to the social conditions of their freedom. Anderson criticizes the view that the purpose of distributive justice is to compensate people for their misfortune. Her argument strikes at the heart of the idea that health inequities are simply unfair; her position is that while life may be unfair, bad luck is not at the heart of it—it is the relations between people and the way that they treat each other that is much more fundamental.

Anderson draws our attention to the fact that the concept of equality can mean a number of different things depending on the underlying political value position and the epistemological assumptions of the theory. So a

utilitarian seeking to maximize the greatest happiness of the greatest number would see things differently to a Marxist seeking absolute parity in access to wealth for example. She demonstrates that equality is a rationalist rather than an empiricist concept, meaning that the discourse about distributional equality and heath equity is premised on the manipulation of ideas and the contest between different ideas and political philosophies, rather than being something that can be demonstrated by empirical methods (Millican 2007). True, protagonists will appeal to empirical evidence about poverty and about wealth to justify their arguments, but in the end, much of the discussion about equality is grounded in ideal discussions of future desired states and institutions and the manipulation of ideas to justify that view, rather than the case being made that empirically things could be changed by doing x, y, or z. Where x, y, or z are suggested, they are selected on the basis of ideological preference, not empirical science.

Bernard Williams argued that the proper grounds for the distribution of healthcare are health need (Williams 1962). This he saw as a fundamental truth (Wolff 2007). Others have argued that this is not a fundamental truth at all. Nozick has suggested that the focus on need, common among egalitarian thinkers, is to define people quintessentially as consumers. The task then becomes one of finding the best way to ensure the fair distribution of available goods to consumers (Nozick 1974). The problem of course with this approach, is that this casts humanity into a fundamentally passive role and it doesn't consider individuals as active producers (Wolff 2007). Williams also argued that there is nothing about need itself intrinsically that should motivate action on equity (Williams 1962). What society decides to do for people, particularly in health need, depends upon a moral and ethical stance.

Another argument is that the goal of fair distribution should be treating the worst off as well as possible rather than flat equity (Wolff 2007). John Rawls argued that difference in the distribution of primary goods such as health is tolerable, so long as the welfare of the most disadvantaged is looked after (Rawls 1971). Dworkin takes this argument a stage further. He suggests that we need to determine why the worst off are in that position. Dworkin asserts that some may not be able to work because they are unable to find work; but others may decide they do not want to work. Dworkin also notes that some people's needs are greater than others (someone who is severely disabled has greater need than someone who is able bodied for

example—although as we noted earlier, this is a highly questionable first premise). But needs, Dworkin notes, are compounded by taste. Some people's needs are determined by expensive tastes say for drugs or wine or jewellery. Dworkin therefore distinguishes between brute bad luck and circumstance from optional bad luck involving some degree of culpability for being in need. For Dworkin, this distinction is all important, as it is his view that the state has a duty to deal with the former, but not the latter (Dworkin 2000).

Some further philosophical reflections

Health needs assessment is not value neutral it is premised on a number of philosophical and political concepts. It is helpful to explore the arguments relating to these ideas not least because although they are fundamental to health needs assessment the conventional literature about health needs assessment seldom considers the underlying assumptions and issues in detail. This is particularly so with respect to the central importance of utilitarianism and its contested place in the philosophical canon. The discussion is made all the more confusing because many of the relevant ideas like justice, equality, fairness and so on are in common as well as technical philosophical usage and the meanings attached to common sense understanding of the words and the technical vocabulary usage are seldom commensurate.

Another very intriguing characteristic of the literature—a literature after all which readily uses terms like justice, fairness, equality, is that with the exception of Sen (2009) (more of whom to follow) the origins of the arguments about justice and need are conducted almost entirely without reference to their antecedents in Christianity or the teachings of the other major world religions. The secular attempts to define the equal society, justice, and fairness struggle in this regard, to find a moral or ethical point of reference. The other very odd thing is that conventional political philosophy has, down the years, actually paid scant attention to health and health inequalities and issues of distribution of healthcare resources (Venkatapuram 2011).

At the heart of the debates about equity and health inequity in contemporary society is, as we saw earlier, social justice. Health inequities

are considered by many commentators to be unjust and unfair and this is advanced as a reason for allocating resources following needs assessment, more fairly. Just as utilitarianism is central to health needs assessment, it has also been central to theories of justice too viz. what produced the greatest happiness in the greatest number was considered to be socially just (Venkatapuram and Marmot 2009). This absolute or distributional approach to justice was based on a highly individualistic model and was premised in turn on the individual as the unit of analysis and not the alternative which is the relational conception of social life. The solution in the utilitarian view of the world is fair distribution and systems which can efficiently distribute resources, a principle at the very heart of health needs assessment. The utilitarian argument overlooks, by virtue of its basis in the maximization of utility, not only the fact that humans are motivated by a variety of things, not just maximizing utility, like love, social conflict, human venality, and sheer and utter evil, but also it doesn't seem to have a concept of the social (Etzioni 1988). In other words, individual utility maximizing motivated agents are the focus of the argument, not social relations between people. This individualistic approach chimes with medicine.

Medicine has as its principal focus, pathology in the individual human body. This means that, with only a few historical exceptions, the intellectual interests have been oriented to phenomena located in individual human bodies or minds with pathology measurable in ways that reflect the individual and individual variation from some notion of what is normal or healthy (Antonovsky 1985, 1987; Carter 2003). This approach received an enormous boost with the rise of germ theory and with the fantastic successes of the isolation of pathogenic microbes and then antibiotics to combat them (Kelly and Russo 2018). Of course medicine has other foci too; especially body systems, but the variables and phenomena of particular interests are individual. The pathogenic paradigm, in which the fundamental rationale is isolating the specific cause (pathogens) of specific outcomes (pathologies), reinforces the individualistic approach (Antonovsky 1987). Psychology has likewise made its main focus the individual so measures of intelligence, personality, quality of life, all reside in the individual or are characteristics or properties of individuals. The approach is about the degree to which things go wrong in individual bodies and minds and the preceding causes of the pathology. Need as an individual property is an obvious next step in this way of thinking.

Economics, and especially health economics has bought into this individualistic paradigm in a big way. The QALY and the application of cost utility analysis and health technology assessment are deeply infused with an individualistic orientation. The greatest happiness of the greatest number is the utilitarian philosophical view which sits very comfortably with the individualistic paradigm because it conceptualizes the notion of the good as the aggregate of lots of different individual utilities. The ontological consequence of this—i.e. the assumptions made about what constitutes human life and how and why it is the way that it is—is the idea that the essence and meaning of human existence can be captured by isolating these individual characteristics and seeing how they connect to each other. So individual characteristics as different as height, weight, blood pressure, bone density, hair colour, IQ, biological sex and size of tumour for example can each in turn be linked to the presence of other characteristics in the individual like health of mother, poor nutritional status in childhood, genetic coding, parental heredity, age, chromosome structure, and exposure to tobacco smoke. The causal link is from one individual characteristic to another.

Now all of this is intuitively meaningful—in the modern Western world the individual and the individuated self are touchstones of the way we live our lives and the way the state regulates our lives—we have for example individual national insurance numbers, passport numbers, birth certificates, tax codes, and genomic structures. Individual variables seem natural. Further in medical terms there have been some remarkable successes in isolating disease mechanisms and offering curative technologies using the individual approach– although far less than the popular imagination often supposes—using these principles.

However, there are two fundamental objections which suggest that an additional way of viewing things might be helpful. First the individualist approaches dehumanize people—people are reduced to some subhuman characteristic—a number, a genetic code, a pathological organism, a utility. But second, and more importantly, and notwithstanding the advances that have followed in the wake of some of the individualistic connections which have been made, above all it ignores or relegates the fact that humans live in groups and that those groups are in relations with each other and that membership of those groups is a defining characteristic of identity and of profound importance to most people—one’s family, class, tribe, caste,

gender, ethnicity, nationality are all paramount social markers in life. Moreover, the relationships within which we live our lives, the relations with other people, the relationships within and between different groups, shapes the nature of our human selves, our experiences, and our behaviour (Kriznik et al. 2018). The defining characteristic of human life is belonging —to be a member of multiple groups and communities. We live our lives in a network of interlinked and overlapping relations with others. Knowingly or not, the desire to belong has far reaching consequences on the types of behaviours that we adopt and the choices that we make. Not surprisingly therefore, the effects of social exclusion or isolation from social groups are of paramount importance when trying to explain the health of an individual.

What this makes us pause and reflect on is not that the individual understanding of human affairs is unimportant—that would clearly be an absurd position to adopt. Rather it is that a full understanding of the human condition requires additionally another set of concepts—which capture human relationships—relational concepts—in order to develop a rounded account of human life (Kriznik et al. 2018). And moreover inequity and injustice are best understood in relational not individualistic terms.

Social theorists have grasped the idea of a well-rounded approach very neatly in the conception of the dynamic interaction between agency and structure. The idea of agency is that we are all unique biological, psychological, and physical individuals. We all engage in individually motivated actions and behaviours which are in part the results of our unique individuality. But the sum of all human behaviours is the social structure which is the product of the millions and billions of human relationships that are the medium for individual actions. Those structures or webs of human relationships are relational and in turn they constrain, drive, and facilitate individual human behaviour. So we have individual behaviour, the medium for its expression which are human relationships, and social structures which are the sum of all those relationships which in turn impinge on and delimit the possibilities of individual behaviour (Giddens 1979, 1984; Elder-Vass 2010).

This rather abstract approach allows us in turn to consider some of the thorny problems at the heart of health needs assessment. Thinking of the dynamic interaction between agency and structure moves us beyond the methodological individualism of traditional epidemiology and therefore of health needs assessment and provides an escape from the individual level of

explanation (Frohlich et al. 2001). This in turn allows for a fuller understanding of the dynamics of the development of health inequalities. (Abel and Frohlich 2012),

This way of thinking has been linked to what is called capability theory (Sen 2009). Under austerity policies, the notion of capabilities has started to enter into JSNA, HiAP (see earlier section on some political and philosophical reflections). The core characteristic of capability theory is its focus on what people are effectively able to do within relationships with each other (Abel and Frohlich 2012). Individuals being able to engage effectively in what they really want to do, is the core idea. These engagements include being active, healthy, and being able to work but the list is not limited to these activities. In the capability approach, resources, and their fair distribution to individuals (the focus of the traditional utilitarian approach) are not the central interest. Resources are not ends in themselves—they are means to ends. And neither are resources reducible to monetary utilities. People's abilities to realize their life goals and plans are the focal point. In the capability approach, the issue of justice, fairness, and need does not apply to resources *per se* but to the range of options for agency—the capabilities (Abel and Frohlich 2012).

Sen is a key thinker in relation to these arguments. He makes the case for a dynamic approach to social justice. He has argued that to think about justice like this is a major shift away from the traditional ways that philosophers have thought about justice. This is because they were locked into the utilitarian/ distributional tradition (Sen 2009). This is important in the context of needs assessment which is fundamentally utilitarian and implies that through its rationality and market allocative efficiency it will be possible to deliver fairness by market redistribution. This follows a tradition which goes back, according to Sen, to the Enlightenment. The utilitarian position is a rationalist position writ large, i.e. a position which is about the manipulation of ideas, rather than the observation of empirical facts (Millican 2007). The ideas about social justice which are being manipulated are that it is possible to design institutional arrangements that will deliver justice and this will be the basis of a perfect society. For Sen, justice is a relative concept and is about relations between people. Justice is a process, an aspiration; it is about advancing justice or reducing injustice. It is not about finding or describing the perfectly just society. Because social structures and their properties emerge out of human relationships, it means

that to try to legislate to change social systems to make them more just or fair can only ever be partially effective. In a sociological sense justice and injustice are properties of social systems not abstract transcendental things that can be made by social actors. Sen's approach is comparative, plural, iterative, dynamic, and acknowledging of alternatives.

Justice in this view is not a given—a rationally derived static universal principle. It is about relations between people and arises as a consequence of social action and social structure. Therefore, injustice will also arise socially in social interaction and is decided upon morally or metaphysically. The judgement about whether the relations between people, such as differences in health, are just or unjust is a value judgement. In short, seeking to bring about equality in relation to health by the utilitarian redistribution of resources is never likely to work, or to produce fairness and justice because justice is not a quality of individuals or institutions. Equality is about human relationships and the utilitarian approach at the heart of health needs assessment is based on an alternative individualistic ontology.

Sen's argument is that theories of justice major on something; it could be happiness as in the case of classical utilitarianism, and it could be resources or income. Sen argues that in contrast to these utility-based or resource-based lines of thinking, individual advantage is judged in the capability approach by a person's capability to do things they have a reason to value. A person's advantage in terms of opportunities is judged to be lower than that of another if they have less capability—less real opportunity—to achieve those things that they have reason to value. The focus is on the freedom that a person actually has to do this or be that—things that they value doing or being (Sen 2009). Sen's approach is about human life and the opportunities for living—living as against just existing. Justice for Sen cannot be created by social institutions. Justice should aim to reduce injustice, i.e. change the nature of the relationships between people, rather than aiming to produce a perfectly just society.

Conclusion

Health needs assessment can be seen as a highly rational and straightforward means of identifying health needs, of linking needs to

patterns of health inequities, of marshalling appropriate resources to match those needs and then deploying resources accordingly. And of course that is what it aspires to do. But that aspiration is based on the traditional rationalist approach of utilitarianism and in turn on an individualist ontology. Need, as we have shown, is not a static, objective thing. It is therefore intrinsically difficult to measure and as soon as one starts to try to capture the idea fundamental questions about fairness and justice are raised.

The objective and measurable concept of need is located in an individualist ontology. When we think instead in relational terms about equity, justice, and human capabilities a different perspective is possible. Capabilities theory captures the idea of equity in a far more nuanced way than individualistic utilitarian accounts. It also offers a more complete way of understanding how we might rethink health needs assessment.

So rather than seeking to measure individualistic objective variables and then seeking to apply resources accordingly, the relational capabilities approach bids us to think about the relations between service providers and users in a novel way. It requires us to not to try to match resources to a completely slippery and spuriously objective concept of need, but instead makes us consider the nature of the relationships between people and services.

Maximizing health outcomes, a utilitarian fundamental principle, may not be what social justice requires and alleviating injustice may require more than maximizing efficiency (Venkatapuram 2011). The argument then hinges on several fundamental things: the degree to which the structure and organization of services permits people to meet their own capabilities, the degree to which it allows human potentials to be realized, the degree to which the relationships with services do not distort or alienate people from themselves or from others. The capability approach privileges human functioning, not maximizing utility or achieving an idealized and biologically improbable disease free state (Venkatapuram 2011).

This means that service design should reflect and respect human dignity; this means respect for an individual person, but at the same time acknowledging the limitations which disease and disability genuinely impose on people while recognizing that there is not a direct cause and effect linear relationship between disease state and social functioning. It should acknowledge the fact that illness and disease by their very nature tend to exacerbate disconnectedness between the person and their normal

role responsibilities, their primary social attachments, and their desired capabilities. The experience of disease and disability can also produce a profound separation of the individual from their sense of self or their sense of who and what they want to be. The capability approach therefore requires us to respect the lifeworlds of ordinary people and work with them to build their skills, assets, and capabilities (rather than focusing on their deficits and trying to correct them via resource redistribution). These skills, assets, and capabilities allow them to manage their lifeworlds with minimal interference. The kinds of skills which enhance capabilities include interpersonal relationships, technical skills to manage the routine aspects of social and economic and domestic life, skills to develop emotional and psychological resistance (often referred to as coping or resilience mechanisms) and an ability to make life seem meaningful. These skills enable people to manage the routine travails of ordinary living as well as the more significant life events which engulf everybody from time to time (Kelly 2010b). It also allows people to manage the material lifeworld they inhabit. This is important because the material and psychological lifeworlds mediate the stressors—physical, psychological, and biological—which assault the human body periodically. The greater the ability people have to control their lifeworlds, the greater the resilience they will have. Skills to control the lifeworld are quintessentially capabilities. The inability to exert that control forms the basis of the patterning of health inequities because the ability to exert control is not spread uniformly through the population. Following Sen's prescription, we should seek not to measure need in a potentially spuriously scientific way, but rather acknowledge that the *total* population, all of us, are in need of strengthening our capabilities. Further it is relatively easy to predict where the need to develop more capabilities and skills is greatest and that is among the poor, the disadvantaged, subgroups, and minorities, and people with disabilities. Efforts to develop and build the skills and capabilities should be proportionately, but not exclusively, focused on these groups. The level of self-empowerment to help to realize these capabilities needs to be appropriate for the individual. This is an important consideration when deciding where to deploy resources. When this happens, it almost always involves active public participation to determine what it is that people value.

Moreover, upstream efforts need to embrace a public health preventive approach; an education in basic skills for living, appropriate role modelling

as the basis of skills for human interaction, proper deportment, manners, respect for others, management of emotions, and the development of a balanced sense of self and identity—are the basics of human socialization. This means that the early years are particularly important and that taking the edge off encounters between people that are destructive and harmful is paramount.

While all of this plays out on life's grand stage, it must also apply to the way health services are provided and delivered. If services are organized around allocative efficiency alone and neglect the sense of self, the identity, the skills required to negotiate the system, and they alienate patients and the public from and systematically deskill the recipients of care, they meet no one's needs at all, and serve only to make the patterns of inequities worse. They become, in other words, a contributor to the problem, rather than a solution to it. Unfortunately, the utilitarian approach with its individualistic ontology, and its emphasis on ideal rationality, is focused on a question, which on the face of it is not unreasonable, of how to match resource deployment to need. This is in fact the wrong question, so it often ends up doing exactly the opposite of what it is trying to do and making matters worse. A purely deficits approach to health needs assessment may well be neat and tidy, however it only tells one side of the story. Widening the approach to encompass assets starts to get complex and messy. Where Sen's capability theory is involved there is no ready-to-go formula. Instead of avoiding what is hard to do we should embrace the challenge. It is after all, the challenge of understanding what it is to be human. Fortunately, there are many people who have risen to this challenge and remarkable things are happening across the Globe. While helping people in need is a virtue we mustn't lose sight of the fact that we are all part of the human species and we all live on the same planet. None of us are equal until all of us are equal.

We should understand needs assessment in terms of building assets and capabilities rather than focusing on deficits. In the context of the aftermath of the global financial crisis, austerity, the ageing population, rising levels of obesity, and costly healthcare systems there are clear implications for the nature of health needs assessment. What is required is greater capacity to harness insight from routine digital data, more acceptance of ideas about creating agency among those most in need and acknowledging the impact of the structural determinants of health on capability. Population

approaches, targeting those in greatest need allow the harder edge of human existence to be ameliorated.

It does mean though that the temptation to try to find purely rationalist solutions which can only ever work in theory, or indeed in Utopia—nowhere—rather like transcendent theories of justice, must be resisted. It must be acknowledged that it is about human relationships and allowing those relationships to be as humanly meaningful and fulfilling and permitting of enhancing human capabilities as possible. The most important task in a good and just society is to prevent the erosion of those things which protect and maintain human capabilities. It is to protect the virtuous and the virtues and to enhance them where possible and to protect them by supporting social arrangements which facilitate that. Relationships cannot be legislated for, nor made to happen by complex processes of resource allocation. Justice and the social arrangements that maintain relationships are in the end the emergent properties of social relations. Those relations must be cultivated in a humane, and as far as possible, just way that protects and enhances people's capabilities. This must be the prerequisite for any state wanting to deploy its healthcare resources in a way that is both effective and meaningful. Building capability into service design is a fundamental prerequisite.

11.2

The political economy of non-communicable diseases

Lessons for prevention

Anne Marie Thow, Raphael Lencucha, and K. Srinath Reddy

Introduction to non-communicable diseases

Non-communicable diseases (NCDs) are the major cause of death and disability globally, and the prevalence of these diseases continues to rise, particularly in low and middle-income countries (LMIC) (WHO 2013). Annual deaths from NCDs increased by 14.1% between 2005 and 2015 (Wang et al. 2016). Cardiovascular disease—mainly ischaemic heart disease and stroke—is the largest contributor to global mortality, accounting for 17.9 million deaths in 2015 (Sacco et al. 2016). The number of adults with diabetes, worldwide, has quadrupled since 1980 (NCD Risk Factor Collaboration 2016), and the number of deaths from cancer increased by 17% between 2005 and 2015, with tracheal, bronchus, and lung cancer the leading causes of cancer deaths (Wang et al. 2016). Obesity prevalence doubled between 1980 and 2008, from 6.4% to 12%, with half of this rise occurring between 2000 and 2008 (Stevens et al. 2012; WHO 2016). In 2014, one in three adults aged over 18 years were overweight (Stevens et al. 2012; WHO 2016).

A large proportion of NCD deaths are premature (over 40% occur before the age of 70), and 80% of these premature deaths occur in LMIC (WHO 2014b). The four major NCDs (cardiovascular disease, cancer, chronic respiratory disease, and diabetes) are responsible for over 80% of NCD deaths (WHO 2014b). Although NCDs are still often thought of as diseases of the wealthy, the burden of these diseases in LMIC has escalated rapidly over the past few decades and people with these diseases in LMIC are far more likely to die than those in high-income countries (Sommer et al.

2015). The World Health Organization's (WHO) South East Asia and Western Pacific Regions (including India and China respectively), account for approximately half the diabetes cases in the world (WHO 2016). Between 1970 and 2008, the proportion of newly reported cancers occurring in LMIC increased from 15% to 56%; by 2030, the proportion is expected to be 70% (Wagner and Brath 2012). By 2020, it is estimated that chronic respiratory disease will be the fourth leading cause of lost 'disability-adjusted life years' in LMIC (Checkley et al. 2014).

These diseases have a devastating impact at the personal and household level; in addition to causing death, chronic diseases have a high burden of morbidity. For example, the complications of diabetes include blindness, kidney failure, and lower limb amputation—all of which impact significantly on quality of life as well as participation in employment (WHO 2016). As a result of their associated premature mortality and morbidity, NCDs pose a substantial household and national economic burden, both from the cumulative healthcare costs associated with chronic conditions and lost economic productivity. The economic losses due to cardiovascular disease, chronic respiratory disease, cancer, diabetes, and mental health between 2005 and 2025 are projected at US$ 47 trillion, representing 75% of global GDP in 2010 (US$ 63 trillion) (Bloom et al. 2011). Not only this, but the investment required to prevent NCDs is significantly less than the costs currently associated with these diseases: a 10% reduction in mortality from ischaemic heart disease and stroke would reduce economic losses in LMICs by an estimated US$25 billion per year (three times greater than the investment required) (WHO 2011). Recent estimates suggest that investment of an additional $1.50 per capita for prevention in the 20 countries with the highest NCD burden would avert 15 million deaths, 8 million incidents of ischaemic heart disease, and 13 million incidents of stroke in the 20 countries (Bertram et al. 2018).

Despite the rising tide of NCDs, it is widely accepted that these diseases are largely preventable. For example, at least one-third of the 12 million cancer cases that occur annually are preventable (Boyle and Levin 2008). In this chapter, we focus on five major modifiable risk factors for NCDs: tobacco use, alcohol use, unhealthy diets, physical inactivity, and air pollution (Lim et al. 2013; WHO 2017). In 2016, tobacco use was responsible for 7.1 million deaths, mainly from cancer and respiratory disease, with most of these deaths occurring in China, India, the United

States, and Russia (Global Burden of Disease 2017). In 2010, dietary risk factors (particularly diets low in fruits and vegetables and those high in sodium, but also including diets high in fats and sugars) were the largest contributors to the global disease burden—and particularly risk for cardiovascular disease, diabetes, and some cancers Lim et al. 2013). Alcohol use/consumption is the seventh leading risk factor for NCDs, in terms of the morbidity burden as measured by disability-adjusted life years —and globally, alcohol exposure has increased by 15.2% since 1990 (Global Burden of Disease 2017). Physical inactivity is associated with an increased risk of cancer (breast and colon), diabetes, ischaemic heart disease and stroke, and even low amounts of activity are beneficial in reducing risk (Kyu et al. 2016). In 2014, the prevalence of physical inactivity in high-income countries was almost double that of LMIC. However, with changes to work and leisure, the prevalence of physical inactivity is increasing in LMICs (WHO 2016). In 2017, air pollution was estimated to cause one-quarter of all adult deaths from heart disease and stroke, 43% from chronic obstructive pulmonary disease and nearly a third from lung cancer, and is also associated with diabetes (WHO 2016; Global Burden of Disease 2017; Bowe et al. 2018).

In this chapter, we discuss how these four major risk factors emerged in a context whereby economic interests converge with public policy to produce environments of risk. The important thread running through this chapter is that the global rise in NCDs is conditioned by modifiable political and economic patterns. This chapter concludes by presenting a number of strategies that public health practitioners can take to remedy this situation.

Policy action on risk factors is essential for NCD prevention

The World Health Organization (WHO) *Global Action Plan for the Prevention and Control of Noncommunicable Diseases 2013–2020* was agreed by member states at the World Health Assembly in 2013 (WHO 2013). The NCD global action plan sets out a clear vision and targets for addressing the heavy global burden of NCDs, including nine voluntary global targets with a strong focus on all of these modifiable risk factors:

A 25% relative reduction in the overall mortality from cardiovascular diseases, cancer, diabetes, or chronic respiratory diseases
At least 10% relative reduction in the harmful use of alcohol, as appropriate, within the national context
A 10% relative reduction in prevalence of insufficient physical activity
A 30% relative reduction in mean population intake of salt/sodium
A 30% relative reduction in prevalence of current tobacco use in persons aged 15+ years
A 25% relative reduction in the prevalence of raised blood pressure or contain the prevalence of raised blood pressure, according to national circumstances
Halt the rise in diabetes and obesity
At least 50% of eligible people receive drug therapy and counselling (including glycaemic control) to prevent heart attacks and strokes
An 80% availability of the affordable basic technologies and essential medicines, including generics, required to treat major noncommunicable diseases in both public and private facilities

The member states of the WHO have also agreed on a comprehensive package of effective policy options to support achievement of these targets by reducing the prevalence of all four major risk factors for NCDs (WHO 2013):

Policy options for tobacco control focus on implementation of the WHO Framework Convention on Tobacco Control (FCTC), which includes mandating smoke-free environments, graphic health warning labels on tobacco products, bans on advertising, promotion and sponsorship, and taxes on tobacco products.
Policy options for promoting a healthy diet include breastfeeding promotion, restrictions on the food marketing, creating incentives for reformulation of food to reduce sugar, salt, and fat content, promoting healthy food environments, social marketing, nutrition labelling, and taxes and subsidies.
Policy options for reducing the harmful use of alcohol include strengthening health services' response and community action, addressing drink–driving and availability of alcohol, restrictions on marketing, and taxation. A critical component of global recommendations for all four risk factors is protection of policy making from influence by vested interests.
Policy options identified for promoting physical activity include promotion of 'active transport', recreational activity and sport, including through urban planning and transport policies, creation of healthy built environments which support physical activity, and public campaigns to promote activity.

Growing recognition of the link between environmental risk factors—and, in particular, air pollution—has resulted in emerging global consensus regarding the need for policy action in this sphere for effective NCD prevention (Lelieveld et al. 2015; WHO 2017). This will require policy change across health, transport, housing, and energy sectors to reduce air pollution from particulate matter. Innovation by countries has included support for clean household energy, cleaner vehicle standards and support for public transport (WHO 2018).

Achieving the Sustainable Development Goal targets related to NCDs and the global NCD targets will require structural, policy-led change that addresses environments in which people live, work, and play, with attention to contextual and regional differences (Reddy 2015). These environments have a significant impact on peoples' capacity to engage in healthy behaviours, and can either support and incentivize the healthier choices, or the opposite. For example, redesigning streets to form squares and one-way streets, implementing traffic calming measures and creating bicycle lanes, creating or renovating playgrounds, improving lighting, and enhancing

aesthetics are associated with increased physical activity, as measured by an increase in the percentage of people engaging in active transport and other measures of activity, and will also have benefits in reducing traffic-related air pollution (Heath et al. 2006). Similarly, there is a growing body of evidence that indicates that food environments have a major influence on food choice and consumption, such that shifts in access, pricing, portions, marketing, and other powerful drivers of eating can have major effects on weight (Wansink and Sobal 2007; Brownell et al. 2010).

However, there has not yet been widespread system policy implementation to create supportive environments for health promotion and NCD prevention. This lack of action stems from policy tensions that arise when government attempts to control health-harming products come up against powerful economic interests. Companies that produce alcohol are notorious for resisting any type of regulation. This resistance often utilizes arguments and corresponding tactics that locate the cause of NCDs at the individual, rather than environmental level (Roberto et al. 2015). These tensions are also seen with industries with interests contrary to reducing car use, in relation to interventions aimed to reduce physical inactivity and pollution. As we will discuss, this emphasis on individual responsibility has important implications for how governments and the public health community addresses NCD prevention. The message of personal responsibility often translates into public health approaches such as health communication campaigns and voluntary standards to guide industry practices. Alone, these approaches are largely ineffective when environments continue to make the healthy choice the more difficult choice (Golden et al. 2015).

The structural, environment-focused policies required to prevent NCDs —including labelling, taxation, restrictions on marketing, and reform of transport and planning policy—require change in finance, commerce, trade, planning, and communications policies. Achieving health oriented policy change in these sectors, especially those that govern unhealthy commodities and physical environments, has proved challenging because of the overt or covert influence of industry over government decision-making or more nuanced misalignments between the mandates of government sectors and health objectives (Miller and Harkins 2010; Lencucha et al. 2015; Schram 2017). Governments that do implement strong environmentally focused NCD prevention policy consistently face challenges in national and

international economic forums; for example, tobacco, alcohol and nutrition labelling measures have all been challenged at the World Trade Organization (WTO) (Lencucha and Drope 2015; Global Burden of Disease 2017; Mitchell and Casben 2017; Thow et al. 2017). It is for this reason, that a political economy perspective is indispensable in understanding and acting on product and environmental risk.

Global political economy and environments of risk

A political economy perspective on health is one that links individual health risk (e.g. choice or biology) with political and economic structures and practices. This perspective asks: 'How do economic interests intersect with political decisions to shape the environments in which individuals live?'. In its simplest form, this perspective brings together and analyses political and economic structures and how these structures shape the conditions for health. For example, as we discuss in more depth, political decisions driven by pressures to free the commercial sector from regulation have led to product environments where healthy choices are difficult.

Political structures refer to public policy, what a government decides to do or not do, and the institutions, namely rules, norms, and strategies established by government, that form and enact policy (Dye 1972; Ostrom 1986). Importantly, observers note that the contemporary political economy is also marked by a deliberate retreat of the state from public life, whereby non-state actors, whether powerful individuals, companies, or other groups, play an important role in shaping the economic patterns of society (Strange 1996; Zohlnhöfer et al. 2018). By considering the political economy of NCDs prevention one can examine how structural factors can impact the incidence and prevalence of disease. This perspective serves as a backdrop to understand why health-harming products continue to dominate the consumer environment despite their known risk for NCDs. The same perspective can elucidate how political decisions and economic interests shape how we move about the built environment (e.g. by foot, by bike, or by car) and how this movement is conditioned by the existence of road systems, forms of public transportation, and access to safe alternative transportation (e.g. curbed bike lanes on busy streets).

When ‘environments of risk’ are considered from a political economy perspective, it enables public health actors to critically assess sociopolitical factors that generate product environments characterized by health-harming products, built environments that condition physical inactivity over physical activity, and marginalization of pollution reduction. This type of analysis positions these five modifiable risk factors, not as ‘behavioural’ risk factors, but in a context wherein individual choice is bounded by political economic structures that often make the healthy choice the difficult choice.

To begin, we examine these global political economic patterns and the underlying (or at least purported) rationality informing these patterns. Neoliberalism has emerged as a dominant way of thinking about the relationship between governments, markets, and society. Benatar and colleagues note that ‘neoliberalism has triumphed as the prevailing and dominant paradigm of global capitalism’ (Benatar et al. 2018). Early proponents of neoliberalism were driven by the goal of economic freedom, both in terms of individual freedom to make economic choices from a wide range of options, and the ability of companies to provide a wide range of appealing options available to consumers (e.g. Friedman 2002). As Gill notes ‘these (neoliberal) policies are cast within a neoliberal discourse of governance that stresses the efficiency, welfare, and freedom of the market, and self-actualization through the process of consumption’ (Gill 1995, p. 401). In this view, economic freedom has intrinsic value, as an expression of the human aspiration and capacity to express one’s agency, and instrumental value, a means of upholding political and economic freedom (Friedman 2009). This neoliberal vision has been largely, if not uniformly, institutionalized since the 1980s (Labonté and Stuckler 2016). David Harvey notes that neoliberalism is ‘in the first instance a theory of political economic practices that proposes that human well-being can best be advanced by liberating individual entrepreneurial freedoms and skills within an institutional framework characterized by strong private property rights, free markets, and free trade. The role of the state is to create and preserve an institutional framework appropriate to such practices’ (Harvey 2007).

As indicated, a key tenet of neoliberalism is the separation of market from state control, with the idea that consumer decisions, not government control, will correct market failures. The ongoing result of the neoliberal paradigm is an acute tension between those who believe that government

should take an active role in protection and promotion of health by intervening in the market, and those who seek a clearer separation between government and market whereby responsibility is left to individuals to make healthy choices (or not) and thus shape the market through these decisions. In sum, the dominant neoliberal paradigm has created a situation where governments struggle, or neglect, to regulate in the public interest because of a dominant paradigm that argues for the virtue of separating market and state, and a legacy of pressure from powerful institutions to conform to a set of policies that drives a separation of market and state. Opponents of the current neoliberal orthodoxy argue that 'We need to work harder to reclaim the narrative: we do not have a fiscal crisis. We have a crisis of inadequate taxation. We are not living in conditions of economic scarcity. We are living in conditions of extreme inequality' (Labonté and Stuckler 2016, p. 316). This argument is tied to the widespread recognition that although neoliberalism is thought of as a theory and practice involving freeing markets from state control, in reality neoliberalism is largely perpetuated by state decisions and often brings seemingly paradoxical state interventions to protect market activity (e.g. government bailouts to large companies) (Brenner et al. 2010).

In this context, the intent of public health regulation to reduce consumption of commodities associated with NCD risk gives rise to a very real tension for governments, with a perceived choice between profits and public health interests. The companies that benefit from the continuation of behaviours associated with NCD risk are all major contributors to GDP and employment in many countries. In addition to this, risky commodities are often more profitable than healthier alternatives. For example, highly processed foods generally have higher profit margins due to their long shelf life when compared to fresh, unprocessed foods, and there is minimal profit to be had from active transport. However, it is important to note that profitability does not directly translate to economic benefits for government or society, and often leads to wealth concentration and heightened economic inequality (Goda and Lysandrou 2013; Saez and Zucman 2016). An example of this tension is seen in the public discourse regarding taxation of tobacco, alcohol, pollution, and unhealthy foods and beverages. If finance ministers see this as a revenue measure with diminishing returns (as consumption/pollution falls), neoliberal opponents can sway them with the 'freedom from nanny state' and 'regressive impact on poor' arguments. If

taxation is projected as a public health imperative, with a particular focus on the socioeconomic aspect of the NCD burden, broader public support can be built up (Sassi et al. 2018; Thow et al. 2018a).

Tobacco, food, and alcohol companies, as well as companies with a vested interest in individually-oriented transport, are strongly transnationally integrated, both vertically and horizontally, and are valued in the billions. The world's top ten food companies, which produce primarily highly processed foods, own almost all the familiar international brands and in 2017 had combined sales of over 400 billion dollars (Top 100 food and beverage companies n.d.). This is more than the GDP of Thailand, and equivalent to half of Indonesia's GDP. In 2016, seven of the top 10 biggest companies in the world were petroleum and car companies, including China National Petroleum (#3), Royal Dutch Shell (#5), Exxon Mobil (#6) and Volkswagen (#7) (Fortune Global 500 List 2017).

Despite a global decline in tobacco consumption, transnational tobacco companies continue to generate increasing profits. For example, Philip Morris International saw a rise in profits from roughly 7 billion Canadian dollars (CAD) to over 9 billion CAD from 2006 to 2012. The same increases can be seen with British American Tobacco and Japan Tobacco (Physicians for a Smoke Free Canada n.d.). The total profits for the big six tobacco companies rose from 35 billion USD in 2012 to over 60 billion USD in 2015 (Bowers 2012). It is this massive wealth that drives the tobacco industry to employ every means to fight tobacco control efforts.

This perception of profit doesn't take into account the negative externalities that arise from consumption of tobacco, alcohol and unhealthy foods, or that are associated with living in built environments that disincentivize physical activity or generate air pollution—namely poor health, social costs, and lost productivity—but it is nevertheless an influential perception (Kankeu Tchewonpi et al. 2013; Lencucha et al. 2018b). The economic paradigm just described creates a framework for decision-making in which costs that are harder to quantify are less likely to be considered in decision-making; for example, costs in the form of quality of life, social capital, or rising inequality (Stiglitz 2017). The vertical integration of these industries can also result in significant inequality in the way that profits accrue, geographically. The profits from value adding often accrue to companies based in high-income countries, with a strong extractive element evident in the GDP and employment gains in LMICs.

For example, although tobacco is a significant contributor to GDP for many countries in Africa, such as Malawi, the economic gains to tobacco farmers is dwarfed by the huge profits made by transnational tobacco companies (Makoka et al. 2017).

Industry power and the political economy of non-communicable disease risk

The enormous size and reach of these 'industries of risk' translates into significant political power. In a global political economy largely driven by the ideas and corresponding policies of neoliberalism, industry is positioned as creator of wealth and the voice of industry is often given preference. Thus, when the health sector talks about policy change in economic sectors that will reduce consumption of profitable commodities, their voice is often drowned out by others with a vested interest in these commodities. In this section, we explore three key ways in which industry exercises power in politics and policy making, to the detriment of governments efforts to reduce consumption of harmful commodities and create built environments that foster activity. Drawing on Lukes' conception of power, we consider ways in which industry actively exerts power in formal decision-making forums ('decision-making power'), shapes the agenda in political debates ('non-decision-making power'), and exercises ideological power (Lukes 2005).

Decision-making power focuses on policy preferences revealed through political action.

Industry actors invest heavily in shaping government policy through establishing relationships, and direct lobbying efforts. The power of these relationships is widely recognized in the area of tobacco control. The tobacco industry is notorious for employing different tactics to aggressively influence policy; namely to prevent the regulation of their products (Saloojee and Dagli 2000). In the United States, industry actors are formally consulted on the negotiating text of trade agreements by the Office of the US Trade Representative, while public health actors are not. It is common for governments to consult with industry on economic policy decisions and this practice often conflicts with the aims of health sectors to protect health policy from industry influence. For example, the Philippines Inter-Agency Committee on Tobacco was established to coordinate tobacco control policy

within government but is chaired by a representative from the trade ministry who views the tobacco industry as a legitimate stakeholder and thus the industry has a reserved seat at the agency (Lencucha et al. 2015).

The influence of relationship building and policy lobbying has also been used effectively by the alcohol industry (McCambridge et al. 2018). For example, the alcohol industry in sub-Saharan Africa—taking the mantle of 'technical expert'—has supported governments in the drafting of their national alcohol policies (Bakke and Endal 2010). Evidence from Lesotho, Malawi, Uganda, and Botswana shows that the resulting policies minimized a public health approach to alcohol and maintained a narrow focus on the economic benefits from trade and alcohol. In terms of addressing alcohol problems, the policy content focused on individual drinkers, with no mention of effective environmental interventions (Bakke and Endal 2010). Similarly, in Thailand, there has been little action on environment-focused alcohol policy—in part because alcohol company executives sit in the national policymaking body (Treerutkuarkul 2017).

Industry also exerts direct power in decision-making through involvement in the negotiation of trade and investment agreements, and through using dispute settlement mechanisms in these agreements to influence policy. For example, the Government of Thailand proposed graphic warning labels on alcohol that highlighted the associated harms, similar to approaches used in tobacco control (Cecchini and Belloni 2015). This policy proposal was withdrawn in 2010 after Specific Trade Concerns were raised at the World Trade Organization (O'Brien 2013). Similarly, despite neoliberal commitment to free trade arguably increasing access to medicines and health technologies in developing country markets, commercial interests prevent affordable access to these products through a variety of trade provisions (United Nations 2016). In particular, strict patent protection that benefits international pharmaceutical companies mean that affordability of NCD treatments remains a challenge in LMICs.

Investor-State Dispute Settlement mechanisms are included in many international trade and investment agreements and enable foreign investors to directly contest government policy (this is in contrast to traditional 'state-state' mechanisms of dispute settlement, where only governments can bring challenges regarding national policies that inhibit trade or investment). These mechanisms create avenues for industry to contest regulation that undermines 'reasonable expectations' of profits—which resonates with the

tension between risky products and public health regulation described earlier (Hawkins and Holden 2016). For example, the tobacco multinational Philip Morris brought a claim against Australia under an International Investment Agreement (IIA) between that country and Hong Kong Special Administrative Region in China, in 2011. This claim challenged Australia's mandatory 'plain packaging' of tobacco products as an unreasonable measure that would expropriate trademarks and undermine good will indirectly (Allens Arthur Robinson 2011). Philip Morris International filed a similar claim in 2010 against Uruguay's decision to expand graphic health warning labels on tobacco products (Lencucha 2010; Porterfield and Byrnes 2011).

Non-decision-making power is that which sets the agenda in debates and makes certain issues unacceptable for discussion in 'legitimate' public forums. A key element of exercising non-decision-making power is framing discourse and public debate regarding an issue. The tobacco industry has consistently attempted to shape the discourse on government regulation by drawing on the powerful value of personal freedom. Early efforts to dissuade governments from regulating tobacco products, were supported by the message that individuals should have the freedom to choose the products that they want to consume. That the government should not intervene with the personal decisions of its citizens. The following statement by the Institute of Economic Alternatives, an ardent supporter of the tobacco industry, on tobacco product regulation reflects the logic used to oppose public regulation: 'We argue that the interests of consumers are nearly always better advanced by the provision of accurate information and free choice than by prohibitions and restrictions on commercial speech. Markets can correct themselves more quickly than governments … Restrictions on product development and marketing in the nicotine industry have led to … failures of both government and the market. Buttressed by political grandstanding, corporate rent-seeking, rigid ideology, and old-fashioned puritanism, the result has been a disaster for the only group of people whose interests are of direct relevance: smokers' (Snowdon 2013, p. 41). These frames, however, don't acknowledge the disproportionately high experience of NCD risk factors, and concomitant NCD morbidity and mortality, among people of low socioeconomic status. The narrow definitions and frames of 'benefit' ignore the significant impact of NCDs on economic productivity and on inequalities (Nugent et al. 2018).

Another of the powerful messages used by industry in opposition to government regulation of their products is that such regulation will create economic ripples that will harm employment throughout the supply chain. In LMICs this message is tied to economic development. Industry argues that regulation will result in loss of employment, with particular emphasis to the most vulnerable, the farmers. The tobacco industry has long argued that tobacco regulation will hurt tobacco farmers and have convinced government officials of this point. We see this argument being made by industry representatives in the media (Karombo 2018; Khan 2018) and by government officials in high-level policy venues such as the World Trade Organization (Lencucha et al. 2016). These arguments harken back to the ideas of economic freedom and growth that underpin the neoliberal paradigm.

However, recent research has questioned the evidence base for the claims that farmers are prosperous from crops such as tobacco. A study conducted in Malawi in 2014 found that smallholder tobacco farmers who were on contract with tobacco leaf buying companies, after accounting for family labour costs, were making roughly 220 USD per year, less than one dollar per day (Makoka et al. 2017). In the same study independent tobacco farmers were finding themselves in debt at the end of the season. This is in a context where the CEO of British American Tobacco tops 20 million USD in salary and bonuses in one year (Treanor 2012). Similar arguments are evident in the food industry's opposition to taxes on sugar-sweetened beverages, which are linked to increased risk of diabetes and obesity, on the basis of their potentially regressive fiscal impact on poor households (Thow et al. 2018a). For example, in the Philippines, the industry argued consistently that the proposed sugar-sweetened beverage tax should be reduced because it was anti-poor, and would be 'crucial to the fate of millions of low-income Filipino consumers' (PhilStar.com 2017). This argument has been found to ignore the disproportional health benefits that accrue to low-income consumers, as their higher price sensitivity leads them to decrease their consumption more than their higher income counterparts (Thow et al. 2018a).

Strong frames that create tension between profits and public health regulation are also evident in public industry submissions to government. For example, food industry submissions regarding the proposed TransPacific Partnership Agreement assumed that trade liberalization would

raise living standards and benefit the economy and country; food was framed exclusively as an economic commodity with implications for revenue generation, with no connection to nutritional health (Friel et al. 2016).

Ideological power shapes thoughts and behaviour by invoking strong values, emotions, and ethical principles. Marketing and other strategies that seek to create brand loyalty and influence habit formation in children can be a source of ideological power. Powell has argued that the food industry has used the school system to integrate and normalize messages of personal responsibility over diet and the idea of energy balance (i.e. emphasizing physical activity as a remedy for unhealthy diet). He shows how Coca-Cola systematically worked to shape the discourse towards healthy choice and consumer responsibility by implementing over 250 'anti-obesity' programmes in schools. Powell and Gard interrogate a number of programmes that Coca-Cola designed to stimulate physical activity among the children. Underlying these types of programmes is a message that there is no bad food but bad choices. For example, messages that consumption of a 'high energy' product like Coca-Cola, must be followed by the decision to exercise in order to balance the energy in with energy out. Food industry interests have pushed these types of messages at all levels. Brownell and Warner provide the example of how the Sugar Association in the United States enlisted the support of US government officials to oppose the WHO draft strategy to address issues of diet and physical activity. The Association pushed the message that there should be greater emphasis on personal responsibility, a focus on physical activity, and the oft made assertion that there are no good and bad foods just bad choice (Brownell and Warner 2009).

Ewing and Cervero (2010) conducted a meta-analysis of over 200 studies that examined the relationship between transportation and the built environment. One prominent finding is that Vehicle Miles Travelled (VMTs) was positively associated with the accessibility of the destination, such as work. They also found that mixed-use settings, such as retail outlets, schools, grocery stores, had a negative relationship with VMTs. For example, they also found that having a bus stop nearby was positively associated with public transportation usage. These factors are examples of how the way that the built environment is designed shapes modes of transportation. If we take one step back, we can think about how policy can

shape these environments and one step further to see how certain economic interests can shape this policy. For example, the rise of car culture in the United States was partly driven by ideas of personal freedom tied to convenient mobility (Seiler 2009). The rise of affordable personal use vehicles was supported by public policy that lead to car-friendly infrastructure developments in cities, such as roads and parking lots, and policies that facilitated access to cheaper fuel sources, through subsidized fuel extraction, refinement, and transport to urban centres.

How public health can support strong policy for non-communicable disease prevention

Despite the power wielded by industry interests in the policy process, there has been innovation and meaningful policy change for NCD prevention. In this section, we examine cases of public health success—where governments have successfully regulated in the face of strong economic interests. In many cases, this innovation is led by LMIC; in part due to the devastating burden of NCD morbidity and mortality in these countries. These case studies provide the opportunity to draw lessons from experience and consider how public health actors can protect policy space and support regulation to promote healthy product and built environments.

Strong, local evidence

Assembling strong, local evidence to underpin policy is essential to convince policy makers of the need to take action, and of the solutions needed—even though alone it is insufficient for policy change. The power of evidence of effectiveness is clear from the decision by the Government of Peru to scale up strong environmentally focused regulation regarding the hours alcohol can be sold. Data on the impact of a local ban in the district municipality of La Victoria in Lima on the sale of alcohol (Sundays to Wednesdays up to midnight and Thursdays to Sundays up to 03:00) over 2 years showed that, compared to a district without a ban, violent incidents had halved. Subsequently, a similar ban was established in the entire Metropolitan area of Lima, and the national police began an intensive action campaign for zero tolerance to driving under the influence of

alcohol. A year later, the number of violent deaths had decreased by 11%, homicides by 19%, and the number of victims of alcohol-attributable traffic crashes by 28% (WHO 2014a).

It is not just quantitative evidence that it required to underpin policy change. A turning point in tobacco control legislation was brought about by evidence that the tobacco industry had acted unethically in promoting their products, undermining the assumption by policy makers that consumers had full access to information about the harms and benefits of the product. Availability of adequate, accurate information regarding products is an important assumption in a market-based economy—and asymmetry of information is a recognized aspect of market failure. For example, a free choice may involve knowing the risk and benefits of consuming a medicine whereby the consumer can decide if the benefits outweigh the risks. In the United States in the mid-1990s, a series of lawsuits were filed against the tobacco industry in an attempt to retrieve damages caused by tobacco to consumers and the pressing burden of tobacco-related illness on the health system (Schroeder 2004). One of the important outcomes of these suits, and particularly the Master Settlement Agreement, was the requirement that the tobacco companies release internal documents for public scrutiny. At the time, the CEOs of the major tobacco companies were testifying that tobacco was not addictive and posed no, or at least minimal, harm to users. Contrary to this testimony the internal documents revealed that the tobacco industry was well aware of the harms of tobacco use and more importantly, despite this knowledge, had been aggressively and deceptively marketing their products to consumers. This is a history of the most sinister cases of corporate deception where ‘The tobacco industry knowingly and successfully deceived the public for 50 years about the connection between smoking and cancer’ (Leahy 2014). The example of tobacco industry deception illustrates how economic interests can shape consumer decisions by controlling the information available to consumers.

As discussed earlier, the frames and norms surrounding a product have dramatic implications on the extent to which the companies producing the product have access to the policy making arena. For example, there is now no question as to the risk posed by tobacco products, to the extent that Philip Morris, one of the largest tobacco companies, acknowledges the harms of tobacco consumption on their website. The National Cancer Institute in the United States asserts that ‘there is no safe tobacco product,

and there is no safe level of exposure to tobacco smoke' (National Cancer Institute n.d.). This categorical position informs decisions to exclude tobacco interests from accessing arenas where health policy, and now even other social policy, is being made. For example, the World Bank instituted a policy in 1991 that prohibits the organization from any involvement with tobacco (World Bank n.d.). Article 5.3 of the FCTC implores governments to protect health policy from tobacco industry interference (WHO 2003), given the aforementioned efforts of the tobacco industry to shape policy in their favour (Bialous and Peeters 2012; Gilmore et al. 2015). In contrast, we still see companies like Pepsi Co partnering with health groups in the fight against NCDs (Yach et al. 2010). Evidence regarding both the scale of the problem and the influence of industry in policy making will help to change norms and frames regarding other NCD risk factors.

Coalitions

Theories of the policy process highlight the influence of strong coalitions of actors with shared interests, in shaping policy outcomes (Sabatier 1987; Weible et al. 2012; Shiffman 2016). Key features of strong actor coalitions in a health context include their ability to construct compelling frames of the issue and convincing reasons to act. It is also critical that they engage with the politics of the issue, and develop relationships outside of the health sector (Shiffman 2016). An example in relation to policy action on NCDs is CLAS (the Healthy Latin America Coalition) (NCD Alliance 2017). CLAS is a coalition with 250 member organizations who has developed a rapid-response system for nutrition policy advocacy, based on consensus position statements. When there is a nutrition policy crisis in a Latin American country then the Coalition can coordinate a strong public health voice to protect good policies—they don't have to gain consensus every time, as they can speak on the basis of the agreed statements. For example, when the Mexican health commission wanted to lower the rate of the sugar-sweetened beverage tax, the coalition organized a coordinated lobby to retain the tax.

Strong coalitions across sectors have also been effective in supporting urban planning policies that promote and support physical activity. Cities that encourage physical activity through active transport are now seen as a priority from both sustainability and health perspectives (Giles-Corti et al.

2015). In Australia, draft urban planning legislation incorporated health considerations because of concerted lobbying by health actors (Harris et al. 2017). Health was explicitly identified as a relevant issue for planning policy in submissions by health-focused agencies, who also connected health to wider planning concerns including economic issues, transport, public open space, and environmental sustainability.

Prepare for push-back from industry

As described in detail earlier, effective policies to prevent NCDs will be contested by the industries that stand to lose with decreased consumption or use of their products. Pro-active consideration of these arguments and development of thoughtful responses is a critical component of protecting policy space for NCD prevention. Industry is predictable in their focus on the economic and profit implications of policies to prevent NCDs, and strategic counterarguments to industry lobbying can help to minimize their impact. For example, when South Africa proposed their soft drink tax, industry argued strongly against it on the basis of job losses: they stated that 3,400 jobs would be lost in the sugar-sweetened drinks production; 25,200 jobs would be lost in 'upstream' jobs; 19,200–29,000 jobs in retail and 15,400 job losses directly and indirectly as a result of reduced demand for drinks (Wilkinson and Bhardwaj 2017). Data from an independent think tank showed that these estimates were vastly overestimated, as the industry analysis assumed that producers would not shift to producing healthier, untaxed drinks (which would result in more jobs) and did not consider that with the funds raised from the tax, treasury spending would also result in some jobs being created. This balanced data helped to keep the policymakers focused on the health concerns, and the tax was passed (Cullinan 2017). Economic interests have the ability to wield massive resources to move such arguments into the public discourse. In the case of tobacco, health proponents have recognized that it is crucial to intercept such messages by instituting rules within government that either prevent industry access to government decision-makers or ensure that such access is transparent and the information about any such consultations is open to public scrutiny.

Healthier economic policy

Finally, it is essential for public health actors to identify specific opportunities for economic policy change that creates healthy environments for NCD prevention. Using tools such as Health Impact Assessment can be vital in identifying specific points at which economic policy can negatively impact on health and NCDs (Hirono et al. 2016). At a practical level, it is important that health policy actors strategically frame health policy objectives in ways that ensures that they are able to defend necessity and non-discrimination as key principles for trade compliance. For example, analysis of concerns regarding nutrition labelling for NCD prevention at the World Trade Organization revealed a lack of clarity regarding the necessity of the measures, as well as practical concerns, such as the use of stickers to label imports (Thow et al. 2017). However, it is also important to go beyond simply health focused policy measures to consider broader, whole-of-government objectives that determine how governments balance competing objectives. It is essential for governments to clearly identify national interests in relation to NCDs and, more broadly, public health, to set the context for economic policymaking—including (and in some ways, especially) the negotiation of international trade and investment agreements. For example, policy incoherence with respect to nutrition in South Africa has its roots in whole-of-government priorities that preference economic indicators over nutrition (Thow et al. 2018b). It is also important to recognize that government has numerous tools that can be used to foster healthy product environments. The regulatory role of government can be complimented by targeted interventions to ensure that healthy products, such as fruits and vegetables are accessible and affordable. Governments can leverage economic resources to subsidize or incentivize healthy food production, including subsidies to small retail outlets to carry products like fruits and vegetables (Story et al. 2008; Lencucha et al. 2018a).

Despite the dominant neoliberal economic paradigm that often preferences industry interests over public health, significant changes to economic policy can and have been made in the interests of public health. After the Phillip Morris challenge to plain packaging, the Government of Australia made a decision not to agree to investor-state dispute settlement (Voon and Mitchell 2016). Similarly, the Governments of Brazil, South Africa, and India have terminated a number of their bilateral investment

agreements, due to the constraints they place on domestic policy space (UNCTAD 2016). Strategic engagement by public health actors with the sectors that govern NCD risk—as well as recognition of the political economy of NCD risk—can support meaningful policy change for environments that promote health.

Immunization and vaccination

Eleonora A.M.L. Mutsaerts and Shabir A. Madhi

Introduction

History of vaccination

The origins of vaccine-derived immunity date back to 900 AD when the Chinese observed that individuals surviving smallpox were immune to renewed illness. This led to the earliest documented experiments on vaccination by inoculating smallpox into scarified skin, a process called variolation. Although variolation was effective in conferring immunity to smallpox, it carried a significant risk of severe disease or even death in some recipients. The practice of smallpox inoculation spread to Africa and Turkey, before arriving in Europe and the Americas. In eighteenth-century Britain, Edward Jenner observed immunity to smallpox in cow-maids who developed cowpox after close exposure to cows. In 1796, he experimented inoculating a 13-year-old boy with vaccinia virus (cowpox) and challenged the child with smallpox virus to prove the concept of immunity. This led to the first smallpox vaccine being developed in 1798; ultimately resulting in eradication of smallpox 200 years later.

Subsequent to the success of developing a smallpox vaccine, Louis Pasteur developed the rabies vaccine in 1885, followed by antitoxins and vaccines against cholera, typhoid, plague, diphtheria, tetanus, anthrax, and tuberculosis through the 1930s. It was however only after the mid-1940s, that systematic immunization became common practice. The Expanded Programme on Immunization (EPI) was launched in 1974 by the World Health Organization (WHO). The goal of EPI was to immunize children worldwide with six core vaccines: diphtheria, tetanus, pertussis, measles, polio, and tuberculosis. Vaccination of children is now regarded as one of the

most successful public health interventions of the 20th century and continues to have vast impact on preventing infectious disease and death worldwide.

Challenges to immunization programmes

Following initiation of the EPI programme, only 5% of children in low- and middle-income countries (LMICs) received the full series of vaccines in the 1970s, which increased to around 80% by the late 1980s. However, global vaccine coverage reached a plateau and even declined in some places by the mid-1990s. Consequently, approximately 19.9–30 million children born each year would be underimmunized or unvaccinated. This is further accentuated by inequity in vaccine coverage, with children from the lowest economic quintile in many LMIC being 2–3 fold less likely to be fully immunized than those from the highest quintile. This paradox is manifest by the increased susceptibility of children from poverty-stricken backgrounds to developing vaccine-preventable diseases, as well as having less access to curative healthcare services.

Reasons for underimmunization of children are multifactorial and include lack of political commitment to prioritize immunization programmes; lack of access to health facilities in marginalized and poverty-stricken communities; vaccine hesitancy due to social, cultural, and religious issues and mis-information; logistical issues in vaccine supply such as maintaining cold-chain and sterile needle and syringe availability; as well as high pricing of newly developed vaccines. Furthermore, vaccine hesitancy, especially in high- and middle-income settings are fostered by antivaccine lobby groups, often based on unsubstantiated concerns.

To address some of these barriers, which prevent the full public health value of vaccines being realized, the Global Alliance for Vaccines and Immunization (Gavi) was established in 2000 as a partnership of governments, private sector, philanthropists, and civil society. The mission of Gavi is to reduce the number of unvaccinated children, as well as expedite the inclusion of new life-saving vaccines into public immunization programmes in low-income countries.

Public health impact of vaccination

Even at current vaccine coverage rates of approximately 83% of children being fully immunized, childhood vaccination is estimated to save 2 to 3 million lives annually. The benefit of immunization is evident from the decline in global mortality attributed to many pathogens for which vaccines have been deployed. See Figure 11.3.1.

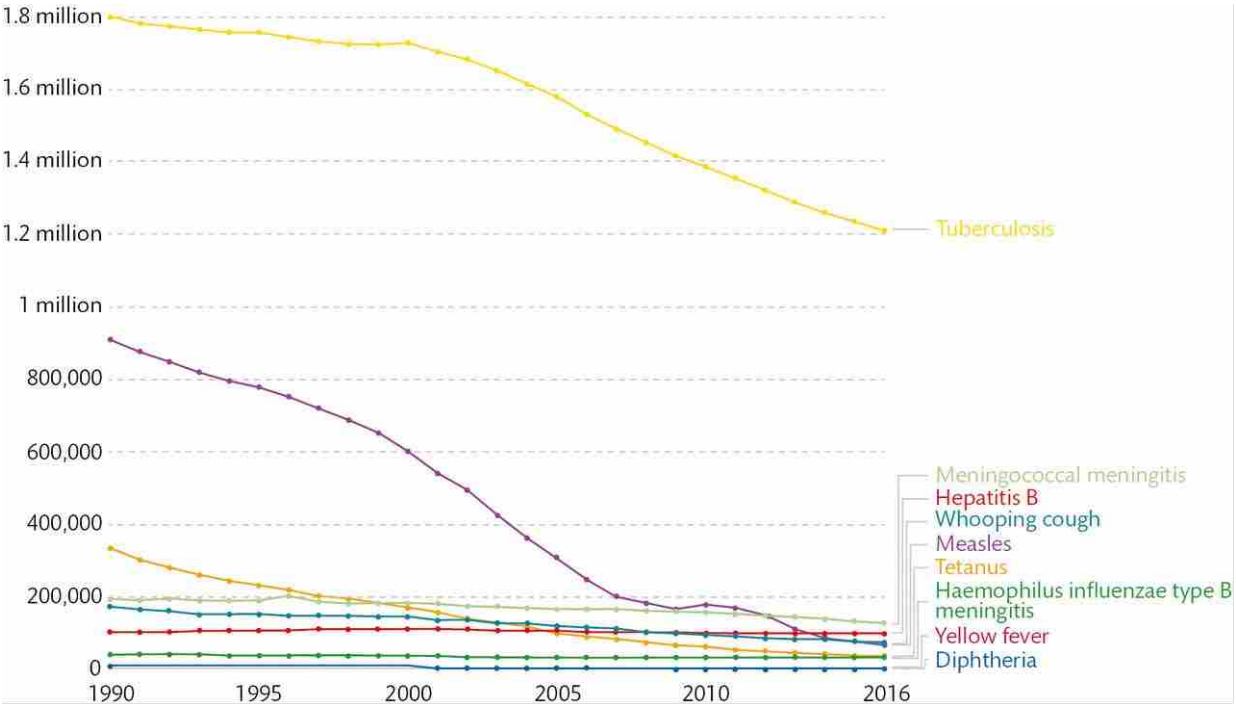

Fig. 11.3.1 Trends in deaths due to vaccine-preventable diseases from 1990 to 2016.

Smallpox	250 (1900–1949)	0	100%	2.9 (1900–1949)	0	100%

Disease	Pre-vaccine, cases per million per year (year)	Post-vaccine, cases per million per year (all post-vaccine cases refer to 2006)	Reduction cases, %	Pre-vaccine, deaths per million per year (year)	Post-vaccine, deaths per million per year (all post-vaccine cases refer to 2004)	Reduction deaths, %
Tetanus	4 (1947–1949)	0.14	96.6%	3.2 (1947–1949)	0.01	99.6%
Hepatitis A	465 (1986–1995)	51	89%	0.5 (1986–1995)	0.06	88.7%
Acute hepatitis B	273 (1982–1991)	44	83.9%	1 (1982–1991)	0.16	83.6%
Haemophilus influenza type b	84 (1980s)	0.17	99.8%	No data	0.02	No data
Pneumococcal disease	233 (1997–1999)	139	40.5%	24 (1997–1999)	16.5	31.3%
Varicella	16,018 (1990–1994)	2046	87.2%	0.41 (1990–1994)	0.06	84.3%

Data source: Roush and Murphy (2007)—Historical comparisons of morbidity and mortality for vaccine-preventable diseases in the United States. In *The Journal of the American Medical Association*, 298, 18, 2155–63. OurWorldInData.org/vaccination. Licensed under CC BY-SA by the author Max Roser/data converted to table.

Notable successes of vaccination:

Eradication of smallpox by 1979 after a global immunization campaign. Until the 1960s, smallpox killed two million people per year.
Reduction of the number of polio cases from 350,000 per year in 1988 (endemic in 125 countries) to 74 cases in 2015 (endemic in three countries).
Eradication of neonatal tetanus in two-thirds of developing countries, with annual neonatal tetanus attributed deaths being reduced from 1.2 million in 1980 to less than 50,000 in 2015. The reduction in neonatal tetanus is a result of increase in tetanus toxoid vaccine coverage in pregnant women, coupled with changes in birthing and practices and prenatal care of newborns.
Reduction in the number of measles deaths by 79% between 2,000 (n = 580,000) and 2015 (<50,000), thereby preventing more than 20 million measles deaths during this period.
Eradication of rinderpest disease in animals.

Note: In addition to immunization, broader social and economic development, including improved sanitation, increased access to healthcare facilities, and improved infant nutrition are also likely to have played a role in the decline in childhood deaths due to vaccine-preventable disease.

Broader impact of vaccination

Immunization of infants is widely heralded as a cost-effective healthcare intervention, second only to access to potable water. It is estimated that the economic benefit of vaccination is approximately 44-fold greater than the up-front cost of immunization, inclusive of direct treatment cost and the life-time loss of productivity averted by prevention of disease. The benefits of immunization extend beyond the prevention of disease in the individual, with health benefits also potentially accruing to society at large by the interruption of transmission of some pathogens (indirect immunity) or person-to-person circulation of some live-attenuated vaccines (herd immunity). Furthermore, the societal valuation of vaccines could include broader outcomes, including the effects on comorbidities, nosocomial infections, educational attainment, cognitive development, labour productivity, income, savings, investment, and fertility.

Advances in the vaccine landscape

Since the 1970s, significant advances have occurred in the development of new vaccines. Vaccine development was fostered by progress in biotechnology and enhanced understanding of immunity against different pathogens, including newly designed adjuvant technology. The number of vaccines that have been licensed in the past two decades or are in the final stages of clinical development, exceeds the total number of vaccines that were developed in the previous two centuries; Table 11.3.2.

Table 11.3.2 Vaccine development timeline

Expanded Programme on Immunization recommended vaccines

See Table 11.3.3

Table 11.3.3 Recommended routine immunizations for children

Antigen	Age of first dose	Doses in primary series	Booster dose	Considerations
BCG	Birth	1		
Hepatitis B	Birth	3 or 4; with DTPCV		
Polio	6 wks (bOPV)–8 wks (IPV)	4 (bOPV + IPV); 3–4 (1–2 IPV, 2 bOPV); 3 (IPV)		
DTP containing vaccine	6 wks	3	3 Boosters 12–23 mths (DTPCV); 4–7 yrs (Td); and 9–15 yrs (Td)	
Haemophilus influenzae type b	6 wks–59 mths	2–3		Not recommended for children >5 yrs
Pneumococcal (conjugate)	6 wks	2–3	After 2 doses: 9–15 months	
Rotavirus	6 wks with DTP1	2 (Rotarix); 3 (Rota Teq)		Not recommended if >24 mths old
Measles	9 or 12 mths (6 mths min)	2		HIV early vaccination
Rubella	9 or 12 mths with measles	1		Achieve and sustain 80% coverage
HPV	9 yrs of age (females only)	2		Target 9–14-yr-old girls; Older age ≥ 15 yrs 3 doses
Recommended for children living in certain regions				
Japanese encephalitis	6–9 mths	1 (live-attenuated and live recombinant); 2 (inactivated Vero-cell-derived)		

Antigen	Age of first dose	Doses in primary series	Booster dose	Considerations
Yellow fever	9–12 mths with measles	1		
Tick-borne encephalitis	≥1 yr (FSME-Immun and Encepur) ≥3 yrs (BE_Moscow and EnceVir)	3	At least 1 every 3 years	
Recommended for children in some high-risk populations				
Typhoid	>6 mths (Typhbar); 2 yrs (Vi PS); 5 yrs (Ty21a)	1 (Typhbar, Vi PS); 3 or 4 (Ty21a)	Every 3 yrs (Vi PS); Every 3–7 yrs (Ty21a)	
Cholera	1 yr (Shanchol, Euvchol, mORCVAX); 2 yrs (Dukoral)	2 (Shachol, Euvchol, and mORCVAX); 3 at 2–5 yrs or 2 ≥6 yrs (Dukoral)	Every 6 mths (Dukoral 2–5 yrs); Every 2 yrs (Dukoral ≥6 yrs); After 2 yrs (Shanchol, Euvchol, mORCVAX)	
Meningococcal	9–18 mths (Men A conjugate); 2–11 mths / ≥12 mths (MenC conjugate) 9–23 mths / ≥2 yrs (quadrivalent conjugate)	1 (MenA conjugate); 2 / 1 (MenC conjugate); 2 / 1 (quadrivalent conjugate)	After 1 yr (Men C conjugate)	
Hepatitis A	1 yr	At least 1		
Rabies	As required	2		PrEP vs. PEP
Dengue (CYD-TDV)	9 yrs	3		Seroprevalence
Recommended for children receiving vaccinations from immunization programmes				
Mumps	12–18 mths with measles	2		Coverage criteria > 80%;

Antigen	Age of first dose	Doses in primary series	Booster dose	Considerations
Seasonal influenza (inactivated)	6 mths	2 (<9 yrs); 1 (≥9 yrs)	Revaccinate annually: 1 dose	Priority risk groups: pregnant women, lower dosage for children 6–35 mths
Varicella	12–18 mths	1–2		Achieve & sustain ≥ 80% coverage

Bacillus Calmette–Guérin (BCG)

Tuberculosis (TB), caused by *Mycobacterium tuberculosis* (MTB), is now the leading vaccine-preventable cause of death worldwide. An estimated 1.7 billion people are infected with MTB globally, contributing to 10.4 million active cases in 2016, 10% of which is related to HIV-infection. There were an estimated 1.2 million deaths resulting from TB in 2016. The risk of developing TB following MTB infection is greatest in children under 2 years of age, with 30–40% of those infected with MTB progressing to disease. MTB infection during childhood manifests either as pulmonary TB (PTB) or as the more severe spectrum of extrapulmonary TB (30–40% of cases). Childhood TB serves as an indicator of ongoing *M. tuberculosis* transmission in a population.

Immunocompromised individuals are at heightened risk of progressing from MTB infection to disease, or having re-activation of underlying dormant MTB infection. HIV-infected individuals who are not treated with antiretroviral treatment (ART) have a 10% annual risk of TB disease, compared to a life-time risk of 10% among the general population. Although this risk is reduced if initiated on ART, it remains significantly greater in HIV-infected individuals than the general population. Other factors facilitating spread of and predisposition to TB include poverty, overcrowding, poor ventilation, tobacco use, and diabetes. The risk of TB is also increased in refugees, migrants, urban poor, and incarcerated individuals.

Despite availability of treatment, around 40% of TB cases remain undiagnosed. To achieve the United Nations Sustainable Development Goal of ending TB epidemics by 2030, there is an increased focus on early detection and treatment of TB cases; as well as provision of chemo-

prophylaxis in high-risk groups such as HIV-infected adults, children with MTB infection less than 5 years of age, and household contacts of active TB cases. In addition, vaccination with BCG vaccine of infants at birth, or shortly thereafter, remains a key component to achieve the End TB strategy; as does the development of new TB vaccines.

BCG was first introduced in humans in 1921, making it one of the oldest vaccines. It is a freeze-dried preparation of a live-attenuated strain of *M. bovis*. Currently, more than 10 manufacturing strains exist. Despite ongoing research for the development of new anti-TB vaccines, the absence of an established immunological correlate of protection is a major impediment to vaccine development. As such, BCG is the only available TB vaccine and also provides protection against leprosy. However, BCG vaccine effectiveness varies considerably between different manifestations of TB, vaccine effectiveness wanes over time and there is variability between different BCG vaccine strains. Neonatal BCG vaccination is reportedly associated with 59% (RR 0.41, 95% confidence interval [CI]: 0.29–0.58) protection against PTB, possibly being lower in countries closer to the tropics; and >80% against extrapulmonary TB during childhood. Recent evidence indicates that BCG vaccination might also protect against *M. tuberculosis* primary infection. The duration of protection following BCG vaccination at 10–15 years of age is uncertain. Currently, the additional benefit from booster doses is being re-investigated.

BCG vaccination is recommended in settings with a high TB incidence and/or high leprosy burden. A single dose is recommended at birth to all healthy neonates. The vaccine is contraindicated in individuals known to be allergic to vaccine components, immunocompromised individuals including symptomatic HIV-infected, and ART naïve with CD4% ≤25%. Children infected with HIV, who are receiving ART, and are clinically and immunologically stable should be vaccinated with BCG.

New TB candidate vaccines are currently being developed, prioritizing development of vaccines targeted at adolescents and adults, considering they contribute to >90% of TB cases and are the primary source of MTB transmission in communities.

Hepatitis B

Hepatitis B virus (HBV) causes acute hepatitis and chronic hepatitis; the latter could progress to hepatocellular carcinoma (HCC). Serological prevalence of the hepatitis B surface antigen (HBsAg) is used to measure endemicity of active HBV infection. HBsAg sero-positivity was estimated at 3.5% of the world population in 2015; including 257 million people living with chronic HBV. The prevalence of sero-positivity is highest in the Western Pacific (6.2%) and Africa (6.1%). Global mortality due to HBV infection was estimated at 887,220 in 2015 including deaths due to HCC, cirrhosis, and acute hepatitis. HBV infection in infancy has a higher risk of causing chronic infection than when acquired later in life. In HBV endemic areas, co-infection with other viral infections commonly occurs, including co-infection with HIV, hepatitis C virus, and hepatitis D virus.

Hepatitis B vaccines were first licensed in 1982 and contain the HBsAg surface protein. In 1986, recombinant vaccines were developed, which are now most widely used. Immunization with a complete primary series of three doses of HBV induces protective antibody levels (i.e. HBsAg antibody ≥10 mIU/ml) in >95% of infants; and protection is likely lifelong. Hence, no booster doses are recommended. Hepatitis B vaccines are available either as a monovalent vaccine or in combination with diphtheria-tetanus-pertussis (DTP) ± *Haemophilus influenzae* type b (Hib) and inactivated polio vaccine (IPV); only the monovalent vaccine should be used for immunization at birth. WHO recommends that hepatitis B vaccine should be given immediately after birth to prevent vertical acquisition from highly-infectious mothers (i.e. Hepatitis B antigen positive), which should be followed by two or three further doses to complete the primary series. As of 2018, 102 (53%) countries had introduced hepatitis B vaccination at birth. Neonatal vaccination provides partial (estimated 30–40%) prevention against perinatal infection.

Hepatitis B vaccination is recommended in persons at high risk of HBV infection in older age groups, including patients who frequently require blood or blood products. If resources are available, catch-up campaigns in unvaccinated cohorts are recommended. HIV-infected adults, in whom there is possibly waning of immunity, may need re-vaccination. Other measures to prevent HBV transmission include hepatitis B immunoglobulin at birth (costly and unavailable in most low-income countries) and screening of donated blood for transfusion.

Global coverage with three doses of hepatitis B vaccine was estimated at 84% in 2015. Routine HBV immunization has contributed to a reduction in prevalence of chronic hepatitis B infection in children aged 0–5 years from 4.7% in the pre-vaccination era to 1.3% in 2015. An estimated 14.2 million cases of chronic HBV infection were prevented by hepatitis B vaccine among children under 5 years of age worldwide in 2013.

Polio

Poliomyelitis is an acute communicable disease caused by three poliovirus serotypes (1, 2, or 3). Prior to routine introduction of vaccination, poliovirus was the major pathogen causing permanent disability in children; 1 in 200 susceptible individuals developed paralytic poliomyelitis.

Both oral, live-attenuated vaccines (OPV) and injectable, inactivated virus vaccines (IPV) are available. Live OPV vaccines contain attenuated virus strains, which may replicate and re-obtain their potential for transmission and neurovirulence, causing isolated cases or outbreaks of paralytic poliomyelitis. Since 2009, type 2 polio virus was removed from OPV, to eliminate vaccine-derived polio infections from this strain. The tri-valent OPV has since been replaced by the bivalent OPV (bOPV containing type 1 and 3 Sabin viruses) in immunization programmes still using OPV.

The EPI recommends three to four doses of bOPV and at least one dose of IPV. The advantages of bOPV compared with IPV include low cost, ease of administration, superior intestinal mucosal immunity, and potential for boosting immunity in household and community contacts. A sequential IPV-bOPV or IPV-only schedule can be used in countries with sustained high vaccination coverage and low importation risk from neighbouring countries. However, WHO does not recommend this switch in endemic countries and regions with high risk of wild poliovirus (WPV) importation.

In 1988, the World Health Assembly aimed at eradicating poliomyelitis by 2000 through initiation of the Global Polio Eradication Initiative. Since then, global incidence of poliomyelitis dropped by >99%. Wild poliovirus (WPV) type 2 was eradicated in 2015 and no detection of WPV type 3 occurred since November 2012. Countries with endemic polio have dropped from 125 in 1988 to 2 in 2015 (Afghanistan, Pakistan).

Diphtheria

Diphtheria is caused by *Corynebacterium diphtheriae*. In the past, diphtheria was one of the most devastating infectious diseases with case-fatality rates up to 50%. Diphtheria toxoid-based vaccines were developed in the late 1940s, but only became widely accessible worldwide in the 1970s when EPI was initiated. Introduction of the vaccine contributed to a >90% reduction of reported diphtheria cases from 1980 to 2000. Nevertheless, diphtheria remains a considerable health problem in countries with low vaccine coverage; including among displaced populations and refugees. Approximately 86% of children globally receive three doses of diphtheria-containing vaccines. Due to increased vaccination coverage in children, a shift in age distribution to adolescents and adults has occurred.

Diphtheria toxoid-containing vaccines contain a formaldehyde-inactivated preparation of diphtheria toxin, adsorbed onto alum to increase immunogenicity. Since the 1940s, a combination vaccine containing DTP has been widely used. Diphtheria toxoid, tetanus toxoid, and pertussis vaccine are also available in combination with HBsAg and *Haemophilus influenzae* type b conjugate vaccines (pentavalent vaccines), and IPV (hexavalent vaccines containing acellular pertussis vaccine). Routine infant immunization includes a three-dose primary series (starting at 6 weeks and 4 weeks apart) and a booster at 15–18 months. Presence of maternal diphtheria antibody interferes with immune responses following the first two doses during early infancy, however, protective antibody levels are reached after the third primary series dose. The diphtheria vaccine does not prevent infection, but inhibits diphtheria toxin's effects, thereby preventing systemic illness.

Immunity wanes over time after a three-dose primary vaccination schedule. In order to achieve protection, a booster dose is required. It is recommended that individuals ≥7 years of age should receive the low-dose diphtheria toxoid (Td) vaccine, to reduce risk of vaccine reactions.

Tetanus

Clostridium tetani is the causative bacterium of tetanus. It is acquired through exposure to *C. tetani* spores in contaminated skin wounds or tissue injury. All age groups are at risk; although neonates contributed to the highest burden of tetanus related deaths in the past. Tetanus infection is associated with case-fatality rates up to 100% in the absence of medical care.

In countries with suboptimal immunization programmes, including low coverage rates of tetanus vaccination during pregnancy, tetanus remains a considerable public health problem. Most cases of tetanus still occur in neonates in LMIC, as well as some cases in mothers. Poor hygiene during delivery/abortion, cultural practices, and cord care practices contribute to maternal and neonatal tetanus. Incidence rates are highest in rural and difficult to reach areas, where delivery predominantly takes place at home without sterile practices. In countries where maternal and neonatal tetanus is uncommon with high coverage rates in infants and pregnant women, the majority of cases occurs in adolescents and adults after injuries. Due to poor surveillance systems in LMIC, there is a lack of robust data on tetanus incidence. Nevertheless, it is estimated that approximately 34,000 neonates died from tetanus in 2015, a 96% reduction compared to 1988 (787,000 cases).

Tetanus-toxoid-containing vaccines (TTCV) are incorporated in routine immunization programmes around the world. Use of combination vaccines containing diphtheria toxoid is recommended. Prevention of neonatal tetanus is targeted by immunizing women of childbearing age with TTCV, either during or outside of pregnancy. By doing so, both the mother and the newborn (through transplacental transfer of tetanus antibodies) are protected. Administration of TTCV is recommended to women of childbearing age in countries with high risk for neonatal tetanus. In any country, tetanus vaccination history should be verified in all pregnant women when visiting the antenatal clinic for the first time and any missing doses should be administered. In all settings, clean procedures during delivery are important.

Recovery from tetanus disease does not induce natural immunity. Individuals who have been infected remain susceptible and thus need to be immunized. WHO recommends administration of three primary and three booster doses through routine childhood immunization (booster doses at 12–23 months, 4–7 years, and 9–15 yrs).

Pertussis

Pertussis, also known as whooping cough, is caused by *Bordetella pertussis* and is endemic globally. Prior to the vaccine era, pertussis was a common childhood disease with infections occurring in most individuals and >50% presenting with clinical symptoms. Young infants are at highest risk of death

due to pertussis infection. Pertussis can be prevented by vaccination and immunization programmes in children have been successful in reducing pertussis cases and deaths. Combined with diphtheria and tetanus toxoid, the pertussis vaccine was introduced in the EPI in 1974. Vaccination prevented >1.3 million pertussis related deaths worldwide in 2001 and 687,000 deaths in 2008.

Two type of pertussis vaccines are available. Whole-cell (wP) vaccines contain killed *Bordetella pertussis* bacteria and are commonly used in most LMIC. Acellular (aP) vaccines contain subunit pertussis toxin in combination with 1–4 other immunogenic pertussis proteins, including filamentous haemagglutinin, pertactin, and fimbriae. Many high-income countries (HICs) have replaced wP with aP vaccines in order to decrease adverse events following vaccination.

A rise in pertussis incidence in a number of countries using the aP vaccine has been reported. The increase in cases was partly attributed to cyclical patterns, improved surveillance, increased awareness, and more sensitive laboratory testing using polymerase chain reaction. However, aP vaccines have shorter duration of protection (4–5 years) than wP (10–12 years) and do not confer mucosal protection or prevent transmission as effective as wP. WHO recommends that countries currently using wP do not change to aP. In HICs, pertussis remains the least controlled vaccine-preventable disease; possibly contributed to by the transitioning from the wP to aP vaccines.

Pertussis vaccination is aimed at reducing severity of pertussis in infancy. The global target is to vaccinate >90% of infants with three doses of pertussis vaccine. In some countries a booster dose of TdaP is recommended in adolescents and adults to prevent pertussis in this population. There is insufficient evidence whether the booster dose is able to reduce severe pertussis in children; however, a booster dose of aP might be required decennially considering the duration of protection from aP. Furthermore, vaccination of pregnant women has been a recent focus of pertussis immunization, aimed at protecting young infants against pertussis disease during the first 2–3 months of life when risk of severe pertussis disease and death is greatest; and they are too young to have derived immunity from direct vaccination. Vaccination of pregnant women has been demonstrated to be safe and has >90% effectiveness in preventing pertussis in their infants. It is recommended that vaccination occurs from the second trimester onward, and at least 30 days before the anticipated birth of the child to optimize

transplacental transfer of antibody to the foetus. Maternal pertussis vaccination, however, has been shown to interfere with immune responses to aP and possibly pneumococcal conjugate vaccine (PCV) (due to diphtheria toxoid included in the dTap vaccine given to mothers—which is similar to the cross-reacting material (CRM) protein used to conjugate polysaccharide in PCV-CRM_{197} formulations). The clinical relevance of this interference in antibody responses in the infants of vaccinated women requires further investigation.

Haemophilus influenzae type b

Haemophilus influenzae type b (Hib) bacteria are responsible for severe pneumonia, meningitis, and other invasive diseases. The greatest burden of disease prior to routine Hib polysaccharide-protein conjugate vaccine (HibCV) immunization was in children aged 4–18 months, with younger children deriving immunity from maternal transfer of antibody and older children through natural immunity derived from Hib exposure. HIV-infected children have a 6-fold higher risk of Hib invasive disease compared to HIV-uninfected.

Hib disease is difficult to diagnose because it requires immediate laboratory testing in patients, before receiving antibiotics; and sampling of cerebrospinal fluid in cases of meningitis. Furthermore, the highest burden of severe disease and mortality from Hib in LMIC is due to pneumonia, for which the sensitivity of blood culture in diagnosing cases is <5%, and there are no other pragmatic diagnostic tools by which to make a pathogen specific diagnosis.

Prior to vaccine introduction in LMIC in 2000, Hib was estimated to cause 2–3 million cases of serious disease in children <5 and 386,000 deaths. In 2015, the number of Hib deaths dropped to around 30,000 (uncertainty range [UR] 18,400–40,700), a 90% reduction from 2000. HibCV is currently used in 191 (98%) WHO member states.

Although HibCV was introduced into high-income immunization programmes since the late 1980s, there was a lag of approximately a quarter of a century before the majority of low-income countries (LICs) were able to include the vaccine into their public immunization programme. This introduction was enabled by Gavi support, as well as a HibCV price reduction from approximately $20 per dose when first licensed to less than

$2 per dose nowadays as part of a combination vaccine with other vaccine epitopes. HibCV immunization has been associated with >90% reduction in invasive Hib disease (especially meningitis) in countries administering the vaccine in routine immunization programmes; as well as approximately 20% reduction in all-cause radiologically confirmed pneumonia.

The vaccine consists of proline-rich protein, a cell wall component of the Hib polysaccharide, conjugated to a protein to stimulate a T-cell dependent immune response. This induces immunity in young infants and establishes memory cell repertoire. The vaccine can be administered singularly, but is nowadays mainly combined with DTP ±HepB ±IPV. WHO recommends HibCV in all infant immunization programmes. The vaccine may be administered as a three primary dose schedule without a booster (3p+0); 2 dose primary schedule with a booster (2p+1); or a three-dose primary schedule with a booster (3p+1), depending on local epidemiology and the national schedule. Booster doses are currently used in most resource-rich countries, but are not generally recommended in the EPI schedule. Booster dosing might, however, be required for HIV-infected children in whom waning of immunity has been shown in the absence of treatment with ART.

Pneumococcal vaccines

Diseases caused by *Streptococcus pneumoniae* include pneumonia, meningitis, and bacteraemia, and other less severe but more frequent mucosal illnesses such as otitis media, sinusitis, and bronchitis. An estimated 294,000 (UR 192,000–366,000) HIV-uninfected children and 23,300 (15,300–29,700) HIV-infected children aged 1–59 months died of pneumococcal disease in 2015, predominantly in LMIC. The burden of pneumococcal disease is highest in children under 2 and the elderly.

Introduction of PCVs into immunization programmes has resulted in a dramatic decline in vaccine-serotype invasive pneumococcal disease (IPD) incidence, even in unvaccinated age groups due to the indirect effect of vaccination. This is achieved by PCV reducing nasopharyngeal acquisition of vaccine-serotypes among the young vaccinated children, who are also the main source of transmission in communities, and consequently interrupting the transmission of the vaccine-serotypes among unvaccinated age groups.

Two PCV vaccines are currently recommended: a 10-valent (PCV10) and 13-valent (PCV13) vaccine. The vaccines are designed to cover the

serotypes associated with severe pneumococcal disease in children. PCV10 includes protein D as the conjugating protein, which may provide some protection against non-encapsulated *Haemophilus influenzae* mucosal infection, a common cause of otitis media and possibly pneumonia. Similar to Hib conjugate vaccine, PCV also induces a T-cell dependent immune response resulting in memory responses; as well as protecting against nasopharyngeal colonization (50% efficacy). This indirect protection of unvaccinated individuals, including adults at high risk for pneumococcal disease, is achieved once infant vaccine coverage rates are approximately 50%.

Vaccine efficacy of PCV is >85% against vaccine-serotype IPD, approximately 50% against vaccine-serotype acute otitis media, and 30% against all-cause radiologically confirmed pneumonia hospitalization. Although there is replacement by non-vaccine-serotypes in the nasopharynx, this has not translated into substantial increase in non-vaccines serotype IPD incidence in children. However, recent data from the United Kingdom, indicate that the indirect protection against vaccine-serotype IPD in the elderly following childhood vaccination, has been offset by an increase in non-vaccine-serotype IPD. Substantial increase in non-vaccine-serotype IPD has also been observed in HIV-infected adults in South Africa, following childhood PCV13 immunization.

WHO recommends three doses, either as a three-dose primary series (3p + 0) or as a two-dose primary series and a booster dose at 9–15 months of age (2p+1 schedule), depending on locally relevant factors. A two-dose primary series at 6 and 14 weeks induces similar immunogenicity compared to a three-dose primary series schedule at 6, 10, and 14 weeks; with the advantage of using the third dose as a booster dose which is required in some settings to sustain durability of protection and might be more effective in preventing nasopharyngeal colonization.

By 2018, PCV had been introduced in the national immunization programme in 138 countries and a further three countries are planning on vaccine introduction in 2018. High costs of PCV ($20 per dose in middle-income countries and approximately $3.50 per dose in LICs) pose a significant burden on national health budgets. As a result, reduced dosing schedules are being evaluated in settings with low pneumococcal circulation and continued monitoring for prevalence of *S. pneumonia* colonization.

PCV vaccination is also licensed for use in high-risk adults, including HIV-infected adults and the elderly; for whom a single dose of vaccine appears to be adequate. In HIV-infected adults not on ART, PCV vaccination was associated with a 74% reduced risk for recurrent vaccine-serotype IPD; whereas in the elderly (>50 years of age), PCV immunization was associated with an efficacy of 46% (95%CI 22–63%) at preventing vaccine-serotype pneumonia. Currently, broader spectra for PCV sero-coverage are being developed, which would include 15–25 serotypes.

Pneumococcal polysaccharide vaccines (PPV) exist and contain 23 serotypes (PPV-23). PPV is not immunogenic for most serotypes in children <2 years of age and protective immunity in older individuals may be limited or short lived as it stimulates a T-cell independent response which does not result in memory induction. Furthermore, repeat dosing with PPV is associated with immune hyporesponsiveness. PPV-23 could be used 1–2 months after priming with PCV in specific groups at risk for severe infection such as sickle cell disease, chronic renal failure, immunosuppression, cerebrospinal fluid leaks, asplenia, diabetes mellitus, or chronic liver, heart, or lung disease. This could increase coverage for those serotypes not included in PCV. In resource-limited settings there is limited evidence to support routine immunization of the elderly and high-risk populations with PPV-23.

Rotavirus

Rotaviruses are responsible for most cases of severe diarrhoeal disease in young children globally in the absence of vaccination. Approximately 215,000 deaths per year were due to vaccine-preventable rotavirus infections in children <5 years of age, according to WHO estimates from 2013. Almost every child is infected by rotaviruses by 3–5 years of age. The median age of primary infection ranges from 6 to 9 months in LIC, and 2–5 years in HIC. Most (90%) cases of rotavirus-associated deaths occur in LIC and are associated with lack of healthcare facilities. Rotaviruses are responsible for up to a half of diarrhoea related hospital admissions and approximately 40% of all-cause diarrhoea deaths in LMIC in the absence of vaccination.

Rotavirus vaccine introduction has contributed to a 50% decrease in diarrhoeal deaths in children under 5 in Mexico and a significant decline in rotavirus gastroenteritis hospitalizations in the United States.

Currently, two oral, live, attenuated rotavirus vaccines are available: Rotarix™ (derived from a monovalent strain of human rotavirus) and RotaTeq™ (a re-assorted pentavalent bovine-human rotavirus). Both vaccines are safe and highly effective in preventing severe gastrointestinal disease. There is a small increased risk of intussusception (~1–2/100,000 infants) mainly after the first dose of vaccine, but this risk is far outweighed by the benefits of immunization.

In LIC, vaccine efficacy (45–70%) can be lower than in industrialized settings (>90%), however, rotavirus vaccination still results in large numbers of severe gastroenteritis cases and deaths being prevented, because of the high incidence of severe rotavirus disease.

WHO recommends rotavirus vaccine introduction in routine immunization programmes either as a two-dose course (Rotarix™) or a three-dose course (RotaTeq™). In India (Rotavac, Rotasiil), Vietnam (Rotavin-M1) and China (Lanzhou lamb) additional rotavirus vaccines are licensed and produced, however these are not available internationally. The manufacturers recommend that the last dose is given no later than 32 weeks of age, because of theoretical concerns of increased risk for intussusception in older children, however, WHO recommends that the rotavirus vaccines may be given with DTP vaccines until two years of age. In 2018, 94 countries worldwide have introduced rotavirus vaccines. Due to the less than desired vaccine efficacy of current live-attenuated formulations in LMIC, research is ongoing on improved formulation –including the development of subunit systemically administered vaccines.

Measles

The highly contagious measles virus caused epidemics every 2 to 3 years prior to vaccine introduction in 1963. Measles was responsible for 30 million cases of infection and >2 million deaths worldwide on an annual basis in the pre-vaccine era; with more than 95% of individuals infected before reaching 15 years of age. Despite availability of a vaccine since the 1960s, measles remained an important cause of death among children. In 2000 there were an estimated 850,000 deaths from measles, which decreased to an estimated 89,780 by 2016 due to a concerted effort at increasing vaccine coverage rates in routine immunization programmes, as well as undertaking periodic

community-wide supplementary immunization activities. This resulted in more than 20.4 million deaths being prevented between 2000 and 2016.

The age of measles acquisition varies with population immunity and birth rate. Infants and toddlers are at increased risk to acquire measles in LIC, refugee camps, countries with low population immunity, high birth rates, and high population density. Once vaccination coverage improves, a transition occurs from infection during childhood to adolescence or adulthood in cohorts that have not been vaccinated before.

As part of the Global Vaccine Action Plan, the WHO targets measles elimination in 5 of 6 WHO regions by 2020. The definition of elimination is the interruption of transmission in a specific geographical area for ≥12 months and is confirmed after sustaining this for ≥36 months. Once sufficient immunity in the population is reached, measles virus transmission can be interrupted. Due to its high infection rates (R_0), measles requires the highest coverage rates (approximately 90–95%) for herd protection to materialize. Global coverage of the first measles dose by 12 months was 85% in 2016, and even lower (78%) in sub-Saharan Africa and South Asia.

The measles vaccine is a live-attenuated virus and may be given as a monovalent vaccine or in combination with rubella, +/– mumps, +/– varicella (MR, MMR, MMRV). The timing of measles vaccine administration depends on coverage, measles incidence, and age at which visits take place in the immunization schedule. For example, countries with weaker immunization programmes reaching suboptimal coverage and high measles virus transmission may offer doses at younger ages (6–9 months) and may need to use supplemental vaccination campaigns. All children should receive two doses of measles vaccine. In countries with ongoing transmission, the first dose should be administered during infancy (at 9 months) and the second dose between 15 and 18 months of age. In areas of high measles and maternal HIV incidence, an addition dose should be given at 6 months to mitigate against the lower transplacental acquisition of measles antibody in children born to HIV-infected women, as well as more severe disease in HIV-infected children. If measles transmission is low, the first dose may be administered at 12 months.

Countries should reach ≥95% coverage with both doses in order to achieve measles elimination. During every contact with health services, children should be evaluated for missed doses and should be vaccinated if necessary.

Rubella

Rubella virus causes an acute, but mild infection and usually affects children and young adults. The importance for public health is related to its teratogenic outcomes. Rubella infection in pregnant women may result in miscarriage, foetal death, or congenital defects. Congenital rubella syndrome (CRS) is associated with ophthalmic (e.g. cataract, glaucoma, microphthalmia); auditory (e.g. sensorineural deafness), cardiac (e.g. patent ductus arteriosus, ventricular septal defects) and craniofacial (e.g. microcephaly) defects. Women of childbearing age who are susceptible to rubella are at highest risk of CRS. In countries that have not introduced rubella-containing vaccines (RCV), the burden of CRS is estimated to be similar as in 1996 when approximately 22,000 children were born with CRS in Africa (95%CI: 6,127–51,472), 46,000 (95%CI: 1,016–168,910) in South East Asia and 12,634 (95%CI: 1,545–21,396) in the Western Pacific Region. Many HIC and some LMIC have introduced rubella vaccination with high coverage rates and have almost reached rubella and CRS elimination.

Rubella vaccine, a live-attenuated vaccine, is mostly based on the RA 27/3 strain. The vaccine is often given as part of combination vaccine with measles (MR), measles and mumps (MMR), ± varicella (MMRV). The main purpose of rubella immunization is to decrease incidence of primary infection in pregnant women and thus protect against CRS in their offspring. When vaccine coverage is low (e.g. only offered in private sector), viral circulation may decline, and result in a shift of primary infection occurring during childhood to adolescence and adulthood. This may result in a paradoxical increase in CRS cases.

WHO recently recommended that countries that are providing two doses of measles vaccine should consider incorporating routine infant immunization against rubella when giving the second dose of measles vaccine. This approach (ideally accompanied by an initial immunization campaign targeting a wide range of adolescents and women of childbearing age) is preferred to the alternative strategy of immunizing adolescent girls and females of childbearing age, as this may be undermined by low vaccine coverage and ongoing circulation of the virus. Due to high response rates of a single dose of rubella vaccination and long-term persistence of protection, a booster dose is not required.

Human papilloma virus

Human papilloma virus (HPV) is a group of viruses, of which at least 13 types could cause precancerous lesions that may progress to cancer. HPV commonly causes infections in the reproductive tract, the majority resulting in asymptomatic infection with spontaneous resolution. HPV is transmitted through sexual contact and most people are infected shortly after the onset of sexual activity. HPV-16 and HPV-18 are responsible for 70% of cervical cancers and precancerous cervical lesions. HPV is also associated with anogenital and oropharyngeal cancers. In LMIC, cervical cancer is the second most common cancer in women. An estimated 630,000 new cases of HPV-related cancer occurred in 2012, of which 84% were cervical cancer. Most deaths due to cervical cancer (85%) were in LMIC.

Three HPV vaccines are licensed and available: bivalent (HPV types 16 and 18), quadrivalent (HPV types 16, 18, 6, and 11), and non-avalent (HPV types 6, 11, 16, 18, 31, 33, 45, 52, and 58) vaccines. All of the vaccines are recommended to be administered prior to onset of sexual activity and prevent cervical cancer. The quadrivalent and non-avalent HPV vaccines also protect against common genital wart-causing strains.

WHO recommends inclusion of HPV vaccination in all national immunization programmes. HPV is indicated primarily for girls aged 9–14 years with a two-dose schedule to prevent cervical cancer. Vaccination of females ≥15–25 years or males is only recommended if feasible, cost-effective, and affordable. The risk of HPV infection in boys is reduced if a vaccination coverage >80% is achieved in girls. A three-dose vaccine schedule in women 15–25 years of age with precancerous cervical lesions has recently been shown to be effective in preventing progression to cervical cancer; but not in older women.

By May 2018, 80 (41%) countries had introduced HPV vaccine in their national immunization programme. The implementation of HPV vaccine in immunization programmes is technically and logistically a departure from the services used for EPI vaccination; as the targeted age groups rarely visit childhood immunization centres. Introduction of HPV vaccine should be part of a larger comprehensive strategy for the prevention of cervical cancer and other HPV-related diseases. As part of this strategy, health personnel should be trained, people should be educated about behaviours leading to HPV acquisition, and women should be informed about screening, diagnosis, and treatment of precancerous lesions and cancer. Also, availability of cervical

cancer screening and treatment of invasive cancers should be addressed. It is important that HPV vaccination does not replace the need for screening during adulthood, because older age groups will not have been vaccinated and the vaccine does not prevent all high-risk HPV types.

Vaccines recommended when living in certain regions

Japanese encephalitis

Japanese encephalitis virus (JEV) is the main cause of viral encephalitis in Asia. Japanese encephalitis (JE) is a zoonotic viral disease. The virus amplifies in pigs and wading birds and is spread primarily by *Culex* mosquitoes. The most important vector, *Culex tritaeniorhynchus*, breeds in flooded rice fields and water pools and usually bites at night time. Elimination of JEV is not possible due to the animal reservoirs. However, control is possible by vaccination of humans in endemic regions. Because viraemia in humans is too low for transmission, they are a dead-end-host. The season for JEV transmission is from April/May to September/October in temperate climates. In the tropics or subtropics, transmission increases during the rainy season. However, during the dry season transmission may be possible if irrigation systems are in place.

The burden of JE is unclear due to lack of surveillance and difficulty of laboratory confirmation. An estimated 68,000 clinical cases occur every year, with approximately 13,600 deaths. Most cases of JE are mild, but case-fatality rates can be as high as 30% in case of encephalitis. Encephalitis may result in permanent neurologic or psychiatric sequelae in 30–50% of cases. 24 countries are endemic for JE, all of them in the WHO Southeast Asia and Western Pacific regions. People living in rural areas, close to rice fields, and in close proximity to pigs are at increased risk for JE.

Safe and effective vaccines can prevent JE. In all areas where JE disease is a public health concern, JE vaccination is recommend as part of the national immunization schedule. Three JE vaccines are currently available and recommended: inactivated Vero cell-derived vaccines, live-attenuated vaccines, and live recombinant (chimeric) vaccines. Inactivated Vero cell-derived vaccines are recommended as 2-dose (from 6 months of age), whereas live-attenuated (from 8 months of age) and live recombinant vaccines (from 9 months of age) are given as a single dose.

JE vaccination does not induce herd immunity, so high coverage is required in populations at risk. If this is sustained, elimination of viral circulation can occur. A common immunization strategy in JE endemic areas should encompass a one-time campaign in the primary target population (depending on local epidemiology, commonly <15 years), and inclusion of JE vaccine into the national routine childhood immunization schedule. If the burden of disease in older age groups is high, they may also be targeted for vaccination.

Yellow fever

Yellow fever (YF) is a viral disease transmitted by mosquitoes and affects humans and other primates. The virus is endemic in tropical areas in Africa (29 countries) and Central and South America (13 countries). YF can cause acute viral haemorrhage and is named ‘yellow’ due to jaundice being one of the clinical manifestations. The burden of YF is estimated at 84,000–170,000 cases of severe disease and 29,000–60,000 YF deaths in Africa in 2013. YF may be transmitted in sylvatic (jungle), intermediate, or urban cycles. Sylvatic YF is common in primates, other than humans. In humans it is predominantly seen in Central and South America in young men working in close proximity to the rain forest. Intermediate YF transmission occurs in humid settings in Africa infecting both humans and non-human primates. Urban YF transmission is associated with large epidemics, where *Aedes aegypti* transmits the virus from person-to-person in densely populated areas. Only a minor proportion of individuals who are infected with the virus develop severe symptoms. Among those with severe symptoms, around half die in 7–10 days. Most (>90%) of YF deaths occur in sub-Saharan Africa, with children being at highest risk.

YF can be prevented by a very effective live-attenuated vaccine. A single dose is adequate to confer sustained lifelong immunity against disease. Infant immunization at the same time as measles vaccination is recommended in YF-endemic countries. Additionally, mass immunization campaigns are recommended in settings with high risk of YF and low vaccination coverage.

Tick-borne encephalitis

Tick-borne encephalitis can cause viral infections of the central nervous system. It is endemic in in eastern, central, and northern Europe, northern China, Mongolia, and the Russian Federation. An estimated 10,000–12,000 clinical cases of tick-borne encephalitis are reported every year. In general, infections occur after tick bites during outdoor activities in the forest.

Vaccination using a formalin-inactivated strain of the virus could protect against tick-borne encephalitis if administered as a three-dose primary series. The need for public immunization varies between geographical areas, depending on the local incidence of tick-borne encephalitis. If the disease is highly endemic (incidence of clinical disease ≥5 cases/100,000 population per year prior to vaccination), WHO recommends vaccination in all age groups.

Vaccines recommended in high-risk populations

Typhoid

The enteric bacterium *Salmonella enterica* serovar Typhi (*S. Typhi*) causes typhoid fever, a life-threatening infection. Transmission occurs via the faecal-oral route through contaminated food and water. The only known reservoir of *S. typhi* are humans. *S. typhi* infection is associated with lack of safe water and sanitation, poor hygiene when handling food, high population density, overcrowding, low socioeconomic status, and low literacy rates.

LMICs have a substantial burden of typhoid disease, which has however decreased with improved sanitation, hygiene, and access to potable water. Globally, the burden ranges from 11 to 21 million cases and around 128,000–161,000 deaths annually. The incidence of typhoid fever varies significantly between countries in Asia and Africa. Children have the highest incidence of typhoid fever, in particular between 5 and 15 years of age.

Three types of typhoid vaccines are available: typhoid conjugate vaccine (TCV), unconjugated Vi polysaccharide (ViPS), and live-attenuated Ty21a vaccines. The licensed TCV vaccines are preferred at all ages due to their increased immunogenicity, use in younger children, and longer duration of protection. TCV should be prioritized in countries with a high burden of typhoid disease or antimicrobial resistance. Countries could also consider routine use of ViPS vaccine in individuals ≥2 years of age, and Ty21a

vaccine for individuals ≥6 years of age depending on costs and programmatic issues.

Cholera

Cholera is a diarrhoeal disease that may cause rapid dehydration and is caused by toxigenic serogroups of the *Vibrio cholera* bacterium. Risk factors for cholera include lack of clean drinking water, poor sanitation, and poverty. In the past, cholera outbreaks caused millions of cases and hundreds of thousands of deaths. Some LMICs still experience major epidemics and cholera remains an important public health issue in many countries; especially in areas with fragile infrastructure during times of unrest/wars, natural disaster, and in refugee camps. Cholera endemicity is defined as the detection of cholera due to local transmission in a specific area in the last 3 years. A country with one or more endemic regions is classified as a cholera-endemic country. A cholera outbreak is defined as the detection of at least one confirmed case of cholera and proof of local transmission. Outbreaks occurred in Haiti and Yemen between 2010 and 2017 and regions in Asia and sub-Saharan Africa have shown surges in endemic disease. The burden of cholera is highest is Africa and southern Asia (99% of all cases). Risk of cholera is increased in humanitarian emergencies and around 50% of the cases and deaths occur in children under 5.

Two types of oral cholera vaccines are available: WC-rBS, a killed whole cell monovalent vaccine with a recombinant B subunit of cholera toxin; and WC, a killed modified whole cell bivalent vaccine without the B subunit. WHO recommends that, along with other preventive measures, cholera vaccines should be used where disease is endemic and considered in areas at risk for outbreaks. The parenteral cholera vaccine has poor efficacy and is no longer recommended.

Meningococcal disease

Meningococcal meningitis is a serious bacterial infection affecting the membrane around the brain and spinal cord. If untreated, case-fatality rates may go up to 50% or could cause severe neurological sequelae (10%). The *Neisseria meningitidis* bacteria may be responsible for meningococcal meningitis. There are 12 *N. meningitidis* serogroups, of which A, B, C, W,

X, and Y can cause epidemics. The disease mainly affects children and young people and can occur as single cases, clusters, or epidemics.

Depending on the serogroup, the geographical burden of disease differs; however, due to inadequate surveillance, estimates of global burden of meningococcal disease are uncertain. The meningitis belt, an area in sub-Saharan Africa stretching from Senegal to Ethiopia (26 countries), has the highest burden of meningococcal disease. Risk of meningococcal disease is increased when the nasopharyngeal mucosa is damaged in the dry season due to dust winds, colds nights, and upper respiratory tract infections in combination with transmission facilitated by overcrowding.

Vaccines against specific serogroups are administered routinely or during outbreaks. There are three types of vaccines available: polysaccharide vaccines, conjugate vaccines, and protein-based vaccines. Polysaccharide vaccines can be bivalent (serogroups A, C), trivalent (A, C, W), or tetravalent (A, C, Y, W) and are usually given during outbreaks. However, protection decreases after several years and, apart from serogroup A, are poorly immunogenic in infants. These vaccines have largely been replaced by polysaccharide-protein conjugate vaccines (Men-CV)

Men-CVs confer longer-lasting immunity, induce herd immunity, and prevent nasopharyngeal colonization—hence also interrupting transmission of the bacteria. They are immunogenic in children from 1 year of age onward. Currently available vaccines include monovalent (A or C) or quadrivalent (A, C, Y, W) conjugate vaccines, also in combination with HibCV (HibMenC). Epitope specific protein based vaccines are available for serotype B.

Mass immunization campaigns using meningococcal A conjugate vaccine in the meningitis belt have contributed to a 58% decline in the meningococcal meningitis A cases and 60% reduction in the risk of epidemics since 2010. More than 280 million individuals have been vaccinated in 21 countries located in the belt as of November 2017. However, epidemics due to meningococcal serogroups W, X, and C still occur, with a burden of 30,000 cases of meningococcal disease reported annually.

Hepatitis A

Hepatitis A virus (HAV) can cause mild to severe liver disease. Most HAV infections are asymptomatic during childhood, but symptoms commonly occur when infected later in life. The virus is transmitted via the faecal-oral route by ingesting contaminated food or water, or through close contact with an infected person. The risk of hepatitis A infection is associated with socioeconomic factors such as income, availability of clean water, sanitation, and hygiene. The burden of hepatitis A is estimated to have increased from 117 million to 126 million in the period between 1990 and 2005, with deaths due to hepatitis A rising from 30,283 to 35,245 in the same period.

In most LICs, anti-HAV antibodies are present in 90% of children by the time they reach 10 years of age. Asymptomatic childhood infection induces immunity and few are susceptible to symptomatic disease during adolescence and adulthood. Yet, middle-income countries often have intermediate HAV endemicity. As sanitation and hygiene improve, a number of individuals will not be infected during childhood, but may be at risk of symptomatic infection during adult life. Hence, when HAV endemicity decreases, the number of clinical cases of hepatitis A will increase. In HIC, the prevalence of anti-HAV antibody is low, as is circulation of the virus.

Hepatitis A can be prevented by safe and effective vaccines. Inactivated and live-attenuated vaccines are available and result in long-lasting protection in adults and children. WHO recommends HAV vaccination to be integrated in the national routine immunization schedule for children ≥1 years of age in countries with high incidence of acute hepatitis A, who are transitioning from high to intermediate endemicity if it is cost-effective. Large scale vaccination in highly endemic countries is not recommended.

Rabies

Rabies is a viral disease transmitted from animals to humans through bites or scratches. Dogs are responsible for 99% of rabies transmissions and are the main source of human rabies deaths. Rabies can also be found in domestic animals and wildlife. Rabies is present in more than 150 countries and causes an estimated 59,000 human deaths and approximately 3.7 million disability-adjusted life years lost on an annual basis. Once clinical signs appear, it almost always results in death due to acute progressive encephalitis.

The majority of cases occur in Asia and Africa, with 40% in children under 15 years of age.

The principle strategy for rabies control consists of vaccination of dogs and prevention of dog bites.

Vaccination of humans and immunoglobulins exist, but they are usually not accessible to people living in remote areas. Vaccination is effective before or after exposure to rabies.

Dengue

Dengue virus is transmitted to humans by female mosquitoes. The primary vector is the *Aedes aegypti* species and to some extent the *Aedes albopictus* species. People with dengue infection develop flu-like illness, but infected individuals may develop severe fatal complications. Four dengue serotypes exist: DEN-1, DEN-2, DEN-3, and DEN-4. Infection will result in lifelong protection against the specific serotype, but there is limited and temporary cross-immunity to other serotypes. Instead, new infection by other serotypes increases the risk of developing severe dengue. In Asia and Latin America, severe dengue is a significant cause of serious illness and death among children.

In recent decades, dengue incidence has increased rapidly from 0.4–1.3 million in 1995–2005, to 2.2 million in 2020 and 3.2 million in 2015. Around 50% of the global population is at risk for dengue infection. Dengue is commonly found in the tropics and subtropics, predominantly in urban and semi-urban regions. Local risk factors include rainfall, temperature, and urbanization.

Prevention and control of dengue can be achieved by successful vector control. The first dengue vaccine (Dengvaxia, CYD-TDV) was licensed in 2015 for use in persons 9–45 years of age living in endemic settings. Vaccination is not recommended when seroprevalence is <50% in the targeted age group. Recent findings showed that vaccination resulted in more severe disease and hospitalizations from dengue in individuals previously seronegative at time of first vaccination compared to unvaccinated individuals. WHO now recommends a ‘pre-vaccination screening strategy’, in which only dengue-seropositive persons are vaccinated, the logistics of which might prove challenging.

Currently, other tetravalent live-attenuated vaccines are being developed in phase III clinical trials. Development of new vaccine candidates based on subunit DNA and purified inactivated virus platforms is also ongoing.

Vaccines recommended in certain immunization programmes

Mumps

Mumps is a viral infection spreading between humans via airborne droplet or direct contact. It is also known as infectious parotitis because of infection in the salivary (parotid) glands. Infection with mumps during childhood causes mild disease, primarily affecting children aged 5–9 years. Infection in adults may occur and may cause more serious complications such as meningitis (up to 15% of cases), orchitis, or deafness.

Mumps incidence infection rates ranges from 100 to 1,000 cases per 100,000 population in absence of vaccination. Vaccination against mumps resulted in a reduction of incidence. The vaccine has been incorporated in childhood immunization schedules of many middle- and high-income countries, usually combined with measles and rubella (MMR) immunization. WHO recommends mumps vaccination in countries with a high burden of mumps, an established routine vaccination programme and persistent high vaccination coverage with measles and rubella of more than 80%. Similarly to rubella vaccine, insufficient coverage of mumps vaccination during childhood can cause a shift in age distribution to infection at older ages, when the course of disease is more severe.

Seasonal influenza

Influenza viruses can cause seasonal influenza epidemics as well as sporadic cases and outbreaks outside of the influenza season. Symptomatic influenza attack rates of 5–10% have been reported in adults and 20–30% in children; with as many of 50% of individuals demonstrating sero-conversion following seasonal epidemics. Persons with increased risk of severe disease and complications include pregnant women, children under 5 years of age, the elderly, and individuals with chronic conditions or immunosuppression. Healthcare workers are also at increased risk of influenza acquisition due to increased exposure and higher risk of spreading disease. In tropical areas,

influenza occurs throughout the year, whereas temperate climates typically show a seasonal peak in incidence during winter.

WHO recommends protection of high-risk groups against severe influenza illness and death by annual influenza vaccination. These risk groups include pregnant women who are considered as the highest priority group, children aged 6 months to 5 years, elderly persons (>65 years), individuals with chronic medical conditions and healthcare workers. Vaccine effectiveness is dependent on the closeness of the genetic match between the vaccine and wild-type circulating strains, and could vary from 0% to 70% year-by-year. Influenza viruses continuously evolve over time. Therefore, it is important to monitor wild-type circulating viruses and update the vaccine formulation bi-annually.

Vaccination of pregnant women has been shown to protect the women (50% efficacy), as well as their infants <6 months of age (50% efficacy) against symptomatic influenza infection. Furthermore, a 20% reduction in all-cause pneumonia hospitalization has been reported in randomized controlled trials in the young offspring of vaccinated pregnant women.

A number of challenges exist with influenza vaccine development, including dependency on egg-culture for vaccine virus propagation, uncertainty of predicting the drifts in the upcoming wild-type strains; and short duration of protection. This is being addressed by the search for universal influenza vaccines, at least against group A viruses, which cause the most severe seasonal epidemics. Furthermore, the threat of virus shift resulting in a pandemic from a new novel strain of influenza virus, warrants countries to have a pandemic plan in place, which includes how they will procure and dispense vaccines should such a pandemic arise. Ideally, a ‘universal’ influenza virus vaccine should also confer cross-protection against pandemic virus; however, this is less likely to be realized over the next 5–10 years.

Varicella and Zoster vaccines

Varicella zoster virus (VZV) is a highly contagious virus that causes varicella (chickenpox), mostly during childhood, and herpes zoster (shingles) later in life. In absence of vaccination, almost all individuals are infected by the time they reach mid-adulthood. VZV epidemiology depends on climate, population density, and risk of exposure. The disease is generally

mild, but severe disease may develop (e.g. cellulitis, pneumonia, encephalitis, death), especially in infants and immunocompromised individuals. After primary infection, the virus may establish latency in sensory nerve ganglia and reactivate later in life, causing herpes zoster. Typically, herpes zoster affects elderly and immunocompromised persons.

Multiple formulations of live-attenuated varicella vaccine based on the OKA strain are available. It may be given as a monovalent dose or in combination with the MMR vaccine (MMRV). Routine immunization against VZV is employed in many resource-rich countries. Coverage of ≥80% is required to prevent a shift of infection to older age groups. Herpes zoster vaccination is currently not recommended due to limited availability of data. The recently licensed zoster vaccine in the United States showed efficacy for preventing herpes zoster of 70% (95%CI 54–81%).

Vaccination of special populations

Refugees, asylum-seekers, migrants

Refugees, asylum-seekers, and migrants may have increased risk for acquisition of infectious diseases because of mass population movement; limited access to clean water, shelter, and sanitation. Children in these populations also have increased risk of respiratory infections, diarrhoea, and skin infections. Despite high vaccination coverage in the countries of origin, young children may have missed vaccinations due to interruptions by civil unrest and war. Also, individuals may not have access to healthcare, health insurance, or registration in the health system.

Vaccination of refugees, asylum-seekers, and migrants may be challenging if populations are on the move. All vaccines should be administered according to the national routine immunization schedule of the country of stay. Priority vaccines include measles, mumps, rubella, and polio. Furthermore, refugees might benefit from early vaccination against cholera, especially if in or from settings where cholera is endemic.

HIV-infected

HIV-infected individuals require special consideration because of increased susceptibility to severe disease from infections, including TB, pneumococcal

disease, and measles. HIV-infected persons have reduced immunogenicity following vaccination when administered in advanced stages of AIDS, but HIV-positive adults and children are able to mount moderate to good vaccine responses. Waning of immunity may result in reduced protection over time for some vaccines. Individuals may require administration of booster doses, especially if children were vaccinated prior to initiation of antiretroviral therapy.

HIV-exposed-uninfected children and HIV-infected children, who were vaccinated when already on antiretroviral therapy, have similar responses to vaccination as HIV-unexposed children. Except for BCG, asymptomatic HIV-infected individuals should receive all EPI vaccines at the indicated ages. BCG vaccination should be given to children receiving ART, who are clinically well and immunologically stable. In neonates newly diagnosed with HIV, BCG vaccination should be delayed until antiretroviral therapy is initiated and the infant is confirmed immunologically stable. If an HIV-infected child has an acute severe illness, vaccination should be delayed, as for any severely ill child.

Healthcare workers

Healthcare workers have increased risk for acquisition of vaccine-preventable diseases. It is important that healthcare workers can maintain delivery of healthcare services during epidemics. They should also avoid spreading disease to vulnerable patient groups. Appropriate vaccination for BCG, hepatitis B, polio, diphtheria, measles, rubella, meningococcal, influenza, varicella, and pertussis is recommended, especially if at increased risk of exposure.

Emerging vector-borne diseases

Vector-borne diseases require vectors, such as mosquitoes, ticks, or sand flies for transmission between hosts or rely on other animals as reservoirs or carriers. They account for an estimated 17% of all infectious diseases and have the highest burden in tropical and subtropical areas. Since 2014, major outbreaks of chikungunya, dengue, malaria, Zika, and Ebola have affected populations and claimed many lives around the world.

Ebola

Ebola virus disease, previously called Ebola haemorrhagic fever, is a severe and often fatal illness in humans. The virus was first discovered in 1976, during outbreaks in South Sudan and the Democratic Republic of Congo. The largest outbreak occurred in 2014–2016 in West Africa. Five Ebola virus species have been identified, of which the Zaire species was responsible for the recent outbreak.

The virus is transmitted from wild animals to humans and can spread between humans. Case-fatality rates vary between 25% and 90%. Treatment consists of supportive care, including rehydration, but no cure is available.

An experimental vaccine (rVSV-ZEBOV) was shown to protect against the virus in a trial in Guinea. WHO supports Ebola vaccination in high-risk populations in the Democratic Republic of Congo using a ring vaccination strategy. This involves tracing contacts of recently confirmed cases as well as contacts of contacts. Other preventive measures should target reducing the risk of transmission and containment of outbreaks.

Maternal immunization

Despite considerable progress in the reduction of under-5 mortality, a significant number of deaths still occurs during the neonatal period and progress has been slower in this age group. Of 700,000 deaths in the first month of life, 28% is attributable to infectious diseases. It is therefore important to protect infants already in the first weeks of life. Yet, primary immunization schedules usually start at 6 weeks of age in most LMIC. Maternal immunization could reduce the morbidity and mortality from infectious diseases at birth. Transplacental transfer of maternal antibodies successfully protects newborns against tetanus, influenza, and pertussis after maternal immunization during pregnancy. New maternal vaccines currently being developed include immunization for group B streptococcus and respiratory syncytial virus.

Universal access to immunization

In 2012, the World Health Assembly adopted the Global Vaccine Action Plan (GVAP), which sought to deliver universal access to immunization. This was expected to avert 24.6–25.8 million vaccine-preventable deaths in this decade alone. Key to the GVAP agenda is ensuring equitable access to immunization services, regardless of geographic location, ethnic or religious beliefs, and socioeconomic background. Efforts to achieve this include Gavi's support for the introduction of new vaccines in the poorest countries by subsidizing vaccine procurement. As a result, the timelines by which PCV and rotavirus vaccines were introduced into public immunization programmes have been drastically reduced and 20 out of 25 countries within the meningitis belt have introduced the MenA conjugate vaccine. Furthermore, steady progress has been made in the field of polio and tetanus eradication/elimination.

However, immunization equity analyses still show that economic disparities, place of residence, and education status continue to determine a child's vaccination status. In many regions, vaccine supply remains a challenge with 16 countries reporting one or more stock-outs of vaccines lasting for more than one week in 2017. As a result, an estimated 19.9 million (15%) of the annual birth cohort of 132 million are either not vaccinated or underimmunized. The continued presence of vaccine-preventable deaths is primarily due to low immunization coverage rates. Understanding the mediators contributing to underimmunization and non-vaccination of children is, therefore, fundamental to derive the full benefits that vaccines stand to offer at an individual and societal level.

In this context, there is a need for community-engagement and a bottom-up approach that includes societal, cultural, and religious considerations to address the barriers contributing to underimmunization of children.

11.4

Principles of infectious disease control

Robert J. Kim-Farley

Principles of infectious disease control: overview

Infectious diseases remain a leading cause of morbidity, disability, and mortality worldwide. Lower respiratory infections result in the highest mortality for any category infectious diseases and comprise the fourth leading causes of death worldwide (WHO 2020). Their control is a constant challenge that faces health workers and public health officials in both industrialized and developing countries. Only one infectious disease, smallpox, was eradicated and stands as a landmark in the history of the control of infectious diseases. The international community is now well down the path towards eradication of poliomyelitis and dracunculiasis (Guinea worm infection). Other infectious diseases, like malaria and tuberculosis, foiled eradication attempts or control efforts and are re-emerging as increasing threats in many countries, including both developing and developed countries. Some infectious diseases, such as tetanus, will always be a threat if control measures are not maintained. Newer infectious diseases, like AIDS and COVID-19, demonstrate the truth of McNeill's statement that infectious disease will remain 'one of the fundamental parameters and determinants of human history'. The history of infectious diseases is an exciting story in itself and readers interested in the subject are referred to McNeill (1976) or the comprehensive work on the history of human diseases (Kiple 1993).

This chapter provides a global and comprehensive view of infectious disease control through examination of the magnitude of disease burden, the chain of infection (agent, transmission, and host) of infectious diseases, the varied approaches to their prevention and control, and the factors conducive to their eradication as well as emergence and re-emergence. Although this

chapter provides many examples of infectious diseases that illustrate modes of transmission and approaches to infectious disease control, this chapter does not attempt to be comprehensive in listing all infectious diseases. Detailed recommendations on control measures for any specific disease are outlined periodically in the updated reports of the American Public Health Association, *Control of Communicable Diseases Manual* (Heymann 2014), the comprehensive two-volume work *Mandell, Douglas and Bennett's Principles and Practice of Infectious Diseases* (Bennett et al. 2020), and the textbook *Infectious Diseases* (Gorbach et al. 2004). For readers specifically interested in paediatric infectious diseases there is the comprehensive two-volume *Feigin and Cherry's Textbook of Pediatric Infectious Diseases* (Cherry et al. 2014); for infectious diseases in emergency medicine settings there is the textbook *Infectious Diseases: Emergency Department Diagnosis & Management* (Red and White Emergency Medicine Series) (Slaven et al. 2006); and for tropical infectious diseases there is *Tropical Infectious Diseases: Principles, Pathogens, and Practice* (Guerrant et al. 2011). A comprehensive treatment of the worldwide distribution of infectious diseases is provided in *Atlas of Human Infectious Diseases* (Wertheim et al. 2012). The Centers for Disease Control and Prevention (CDC) publishes up-to-date disease surveillance information for the United States and recommendations for control measures in the *Morbidity and Mortality Weekly Reports* and provides annual summaries of notifiable infectious diseases in the *Summary of Notifiable Diseases, United States* (CDC 2016). Many other countries have similar types of publications. The World Health Organization (WHO) publishes worldwide surveillance information and recommendations for control measures in the *Weekly Epidemiological Record*. A more detailed background on infectious agents as determinants of health and disease is provided in Chapters 8.11–8.15.

Definitions of infectious diseases and their control

Infection occurs when an infectious agent enters a body and develops or multiplies. *Infectious agents* are organisms capable of producing inapparent infection or clinically manifest disease and include bacteria, rickettsia, chlamydiae, fungi, parasites, viruses, and prions. An *infectious disease*, or communicable disease, is an infection that results in clinically manifest disease. Infectious disease may also be due to the toxic product of an

infectious agent, such as the toxin produced by *Clostridium botulinum* causing classical botulism. As this is a textbook of public health, the infectious diseases considered are those that manifest in human hosts and are a result of the interaction of people, animals, and their environment. Infectious diseases may be due to infectious agents exclusively found in human hosts such as rubella virus, in the environment such as *Legionella pneumophila*, or primarily in animals such as *Brucella abortus*.

Control of infectious diseases refers to the actions and programmes directed towards reducing disease incidence (new infections), reducing disease prevalence (infections in the community at any given point in time), or completely eradicating the disease. Control aimed at reducing the incidence of infectious disease or their risk factors can be considered as *primary prevention* of infectious disease. Primary prevention protects health through individual and community-wide measures, including such actions as maintaining good nutritional status, keeping physically fit, immunizing against infectious diseases, providing safe water, and ensuring the proper disposal of faeces.

Control aimed at reducing the prevalence by shortening the duration of infectious disease can be considered as *secondary prevention* of infectious disease. Secondary prevention corrects departures from good health through individual and community-wide measures, including such actions as screening that result in early detection of disease, prompt antibiotic treatment, and ensuring adequate nutrition. It should be noted that such control efforts in secondary prevention in a group of infected individuals may also result in primary prevention in uninfected people. For example, prompt and specific drug therapy for tuberculosis patients resulting in sputum conversion to culture-negative status renders them no longer a source of infection to others and treatment of HIV-positive pregnant women reduces transmission of HIV to their newborns.

Control aimed at reducing or even eliminating long-term impairments of infectious disease can be considered as *tertiary prevention* of infectious disease. Tertiary prevention reduces or eliminates disabilities, minimizes suffering, and promotes adjustment to permanent disabilities through such actions as providing orthopaedic appliances and its associated rehabilitation for victims of poliomyelitis, counselling and vocational training, and prevention of opportunistic infections. For example, the prevention of

opportunistic infections in HIV infection can be considered as tertiary prevention (Osterholm and Hedberg 2005).

Global burden of infectious diseases

A WHO analysis of the global burden of disease estimates that infectious diseases caused 12.3 million deaths, accounting for 21% of total global mortality of 56.8 million deaths in 2008 (WHO 2008). Five diseases—lower respiratory infections, AIDS, diarrhoeal diseases, tuberculosis, and malaria—account for some 81% of the total infectious disease burden. Most infectious disease (some 97%) deaths occur in the economically developing group of countries where approximately a quarter of deaths are due to an infectious cause (WHO 2008). However, infectious diseases are also of importance in more developed countries. In the United States, for example, influenza still ranks as an important cause of death.

The current magnitude of morbidity and mortality due to infectious diseases worldwide is highlighted by the the Institute for Health Metrics and Evaluation (IHME) as follows (http://www.healthdata.org/results/gbd_summaries):

Acute lower respiratory infections, including pneumonia and influenza, cause some 489 million episodes of illness each year and result in 2.49 million deaths annually. These infections are the highest cause of infant and child mortality in developing countries.

HIV newly infects about 1.9 million people each year and causes an estimated 864,000 AIDS-related deaths annually, down from a peak of 2.2 million that occurred in the mid-2000s. There were some 36.8 million people living with HIV in 2019.

Diarrhoeal diseases are also a major cause of morbidity and mortality in infants and children in developing countries. Each year there are some 6.6 billion episodes with 1.5 million deaths due to diarrhoeal disease, of which the vast majority are among children under 5 years of age.

Tuberculosis, caused by *Mycobacterium tuberculosis*, infects some 1.82 billion people, about one-fourth of the world's population, and is the leading cause of death of a single pathogen. It was estimated that 8.5 million people who developed clinical disease and 1.18 million died of tuberculosis in 2019.

Malaria was estimated to cause some 231 million cases and 643,000 deaths in 2019, mainly in children under the age of 5 years.

Influenza epidemics, caused by influenza A and B viruses, are estimated to kill from 500,000 to 1 million people worldwide each year. Influenza pandemics, of which there were three in the last century, have killed as many as 40–50 million people (as occurred during the 1918–1919 'Spanish flu' pandemic) and, as with the current concerns regarding highly pathogenic avian influenza H5 viruses, continue to threaten to re-emerge as a major public health emergency.

• *The COVID-19 Pandemic*, ongoing at the time of writing this chapter, has become the most important infectious disease public health pandemic in the last 100 years. Deaths from COVID-19 are projected to exceed 3.5 million deaths worldwide by mid-2021.

Chain of infection: agent, transmission, and host

The chain of infection is the relationship between an infectious agent, its routes of transmission, and a susceptible host. The prevention and control of infectious diseases depend upon the interaction of these three factors that may result in the human host clinically manifesting disease.

Agent

The infectious agent is the first link in the chain of infection and is any microorganism whose presence or excessive presence is essential for the occurrence of an infectious disease. Examples of infectious agents include the following:

Bacteria: for example, spirochetes and curved bacteria such as *Borrelia burgdorferi* causing Lyme disease; Gram-negative rods such as *Yersinia pestis* causing plague; Gram-positive cocci such as *Streptococcus pyogenes*, group A causing erysipelas; and Gram-positive rods such as *Mycobacterium tuberculosis* causing tuberculosis.
Rickettsiae: for example, *Rickettsia ricketsii* causing Rocky Mountain spotted fever, and *Rickettsia prowazekii* causing epidemic louse-borne typhus fever.
Chlamydiae: for example, *Chlamydia psittaci* causing psittacosis (ornithosis), and *Chlamydia trachomatis* causing trachoma and genital infections.
Fungi: for example, *Trichophyton schoenleinii* and *Microsporum canis* causing tinea capitis (ringworm of the scalp), and *Trichophyton rubrum*, *Trichophyton mentagrophytes*, and *Epidermophyton floccosum* causing tinea pedis (ringworm of the foot, or athlete's foot).
Parasites: for example, helminths such as *Trichinella spiralis* causing trichinosis, filaria such as *Brugia malayi* causing filariasis (which may lead to the symptom of elephantiasis), nematodes such as *Enterobius vermicularis* causing enterobiasis (pinworm disease), trematodes such as *Clonorchis sinensis* causing clonorchiasis (oriental liver fluke disease), cestodes such as *Taenia solium* causing taeniasis (beef tapeworm disease), and protozoa such as *Trypanosoma cruzi* causing American trypanosomiasis (Chagas' disease).
Viruses: for example, Paramyxoviridae such as measles virus which causes measles, Togaviridae such as rubella virus which causes rubella, Picornaviridae such as the hepatovirus which causes hepatitis A, and arthropod-borne viruses (arboviruses) such as dengue viruses which cause dengue fever.
Prions: small proteinaceous infectious particles which cause such diseases as kuru, Creutzfeldt–Jakob disease (and its variant associated with exposure of humans to the bovine spongiform encephalopathy, or 'mad cow', agent), and the Gerstmann–Straussler–Scheinker syndrome.

There is increasing evidence that some infectious agents, often with cofactors, are associated with human tumours. Examples include: *Schistosoma haematobium* with bladder cancer, *Schistosoma japonicum* with colorectal cancer, *Clonorchis sinensis* with cholangiocarcinoma,

hepatitis B and C viruses with hepatocellular carcinoma, *Helicobacter pylori* with gastric cancer, and human papillomaviruses with cervical cancer. Some 2.2 million cancers cases are attributed by the International Agency for Research on Cancer (IARC) to infectious agents.

Agents can be described by their ability to infect (infectivity), be transmitted (infectiousness), and cause disease (pathogenicity) as well as their ability to cause serious disease (virulence). The *infectivity* of an infectious agent is the extent to which the agent can enter, survive, and multiply in a host and is measured by the ratio of the number of people who become infected to the total number exposed to the agent. Rhinoviruses that can cause the common cold are examples of infectious agents with high infectivity.

The *infectiousness*, or transmissibility, of an infectious agent is the extent to which the agent can be transmitted from one host to another. It is measured by the basic reproduction number (known as R_0) which is determined by the number of secondary infections in a susceptible population that result from a primary infection. Epidemic-prone diseases such as measles and pertussis caused by measles virus and *Bordatella pertussis* bacteria, respectively, are examples of diseases due to highly infectious agents with an R_0 of 10 or greater.

The *pathogenicity* of an infectious agent is the extent to which clinically manifest disease is produced in an infected population and is measured by the ratio of the number of people developing clinical illness to the total number infected. Examples of highly pathogenic infectious agents are the measles virus and the human (α) herpesvirus 3 (varicella-zoster) causing measles and chickenpox, respectively, in which most infected susceptible people will manifest disease.

The *virulence* of an infectious agent is the extent to which severe disease is produced in a population with clinically manifest disease. It is the ratio of the number of people with severe and fatal disease to the total number of people with disease. An example of a highly virulent infectious agent is HIV whereby nearly all untreated people with AIDS will die.

Characteristics of infectious agents that affect pathogenicity include their ability to invade tissues (invasiveness), produce toxins (intoxication), cause damaging hypersensitivity (allergic) reactions, undergo antigenic variation, and develop antibiotic resistance. An example of an infectious agent with high *invasiveness* is the *Shigella* organism which can invade the

submucosal tissue of the intestine and cause clinically manifest shigellosis (bacillary dysentery). An example of an infectious agent that has a high degree of ability to *produce toxins* is the *Clostridium botulinum* organism which can elaborate toxins in inadequately prepared food and cause classical botulism. An example of an infectious agent that is highly *allergenic* is the *Mycobacterium tuberculosis* organism which can cause tuberculosis. An example of an infectious agent that has a high degree of *antigenic variation* is the type A influenza virus which frequently experiences minor antigenic changes—antigenic 'drift'. Influenza A viruses, on an irregular basis, may also undergo a major antigenic change creating an entirely new subtype—antigenic 'shift'. Antigenic shifts that have the characteristic of high transmissibility between people may result in an influenza pandemic when large numbers of individuals are exposed to the new subtype for which they have no prior immunity. An example of an infectious agent that can develop *antibiotic resistance* that challenges control efforts is *Neisseria gonorrhoeae* that has both chromosomally mediated and resistance transfer plasmid-mediated genetic factors for antibiotic resistance.

The *infective dose* of an infectious agent is the number of organisms needed to cause an infection. The infective dose may vary depending upon the route of transmission and host susceptibility. An example of an infectious agent that needs only a very low infective dose (as few as ten organisms) is *Escherichia coli* O157:H7 which causes enterohaemorrhagic diarrhoea. An example of an infectious agent that needs a relatively higher infective dose is *Vibrio cholerae* which requires around 100 million bacteria to be ingested to cause cholera disease in a healthy adult.

Control measures for infectious diseases directed at inactivating the agent are designed according to the type of agent and its reservoirs and sources. For example, an agent like *Vibrio cholerae* can be inactivated through adequate chlorination of the water supply. This is a chemical method for provision of safe water to control cholera. An agent like hepatitis B virus can be inactivated through adequate autoclaving of injection and surgical equipment. This is a sterilization method to control hepatitis B. Details of these and other methods of control directed at the agent are provided in the sections in this chapter on control measures applied to the agent and the environment.

Routes of transmission

Control efforts are often designed to break the routes of transmission, the mechanisms by which infectious agents are spread from reservoirs or sources to human hosts. A *reservoir* of an infectious agent is any person, other living organism, or inanimate material in which the infectious agent normally lives and grows. The *source* of infection for a host is the person, other living organism, or inanimate material from which the infectious agent came. *Horizontal transmission* refers to transmission between individuals whereas *vertical transmission* refers to the specific situation of transmission between parent to offspring (e.g. transplacentally *in utero*, during passage through the birth canal, or through breast milk). The routes of transmission have been summarized in the *Control of Communicable Diseases Manual* (Heymann 2014) as follows:

Direct transmission

Direct and essentially immediate transfer of infectious agents to a receptive portal of entry through which human or animal infection may take place. This may be by direct contact such as touching, biting, kissing or sexual intercourse, or through direct projections (droplet spread) of droplet spray onto the conjunctiva or onto the mucous membranes of the eye, nose, or mouth during sneezing, coughing, spitting, singing or talking (risk of transmission in this manner is usually limited to a distance of about 1 metre or less from the source of infection). Direct transmission may also occur through direct exposure of susceptible tissue to an agent in soil, through the bite of a rabid animal, or transplacentally (Heymann 2014).

Indirect transmission

Vehicle-borne

Contaminated inanimate materials or objects (fomites) such as toys, handkerchiefs, soiled clothes, bedding, cooking, or eating utensils, surgical instruments or dressings; water, food, milk, and biological products including blood, serum, plasma, tissues or organs; or any substance serving as an intermediate means by which an infectious agent is transported and introduced into a susceptible host though a suitable portal of entry. The

agent may or may not have multiplied or developed in or on the vehicle before being transmitted (Heymann 2014).

Vector-borne

Mechanical: includes simple mechanical carriage by a crawling or flying insect through soiling of its feet or proboscis, or by passage of organisms through its gastrointestinal tract. This does not require multiplication or development of the organism.

Biological: propagation (multiplication), cyclic development, or a combination of these (cyclopropagative) is required before the arthropod can transmit the infective form of the agent to humans. An incubation period (extrinsic) is required following infection before the arthropod becomes infective. The infectious agent may be passed vertically to succeeding generations (*transovarian transmission*); *trans-stadial transmission* indicates its passage from one stage of the life cycle to another, as from nymph to adult (for example, ticks infected with *Rickettsia rickettsii* can remain infected with this agent as they pass from nymph to adult stages). Transmission may be by injection of salivary gland fluid during biting, or by regurgitation or deposition on the skin of faeces or other material capable of penetrating through the bite wound or through an area of trauma, often created by scratching or rubbing. This transmission is by an infected non-vertebrate host and not simple mechanical carriage by a vector as a vehicle. An arthropod in either role is termed a vector (Heymann 2014).

Airborne transmission

The dissemination of microbial aerosols to a suitable portal of entry, usually the respiratory tract. Microbial aerosols are suspensions of particles in the air consisting partially or wholly of microorganisms. They may remain suspended in the air for long periods of time, some retaining and others losing infectivity or virulence. Particles in the 1- to 5-micrometre range are easily drawn into the alveoli of the lungs and may be retained there. Not considered as airborne are droplets and other large particles that promptly settle out (see ‘Direct transmission’).

Droplet nuclei: usually the small residues that result from evaporation of fluid from droplets emitted by an infected host (see earlier). They also may be created purposely by a variety of atomizing devices, or accidentally as in microbiology laboratories, abattoirs, rendering plants, or autopsy rooms. They usually remain suspended in the air for long periods.

Dust: the small particles of widely varying size that may arise from soil (e.g. fungus spores), clothes, bedding, or contaminated floors (Heymann 2014).

Control measures for infectious diseases directed at interrupting transmission are designed according to the type of transmission for the agent. Direct transmission of an agent like *Neisseria gonorrhoeae*, for example, can be reduced by using condoms as a barrier method of control of gonorrhoea. Vector-borne transmission of an agent like *Plasmodium falciparum* can be reduced by using a residual insecticide against *Anopheles* mosquitoes as a chemical vector control method for malaria. Airborne transmission of an agent like *Mycobacterium tuberculosis* from sputum-positive pulmonary tuberculosis patients in hospital can be reduced using special ventilation to create a negative pressure in the patient's room as an environmental method of control of tuberculosis. It should be recognized that some infectious agents may have more than one route of transmission. Poliovirus, for example, can be spread via direct transmission through the faecal–oral route and pharyngeal spread, or indirect transmission through contaminated food or other materials. Details of these and other methods of control directed at interrupting transmission are provided in the section on 'Tools for control of infectious diseases' in this chapter.

Host

The human host is the final link in the chain of infection. The infectious agent may enter the host through the following portals of entry.

Respiratory tract: infectious agents can be inhaled into the respiratory tract and will be deposited at different levels of the pulmonary tree according to the size of the aerosol, droplet nuclei, or dust particles. For example, *Mycobacterium tuberculosis* in airborne droplet nuclei, 1–5 μm in diameter, may be inhaled into the alveoli of the lungs of a vulnerable host and result in tuberculosis.
Intact skin: some infectious agents, such as *Necator americanus* which causes hookworm disease, can penetrate the intact skin.
Gastrointestinal tract: an infectious agent, such as *Vibrio cholerae* which causes cholera, may enter via the gastrointestinal tract. People who have a compromised gastric function, such as gastric achlorhydria, may be at increased risk of disease.
Mucous membranes: infectious agents, such as measles viruses, may be deposited on mucous membranes, including the conjunctiva of the eye, by droplet spread or by direct contact with infected people or contaminated objects.
Genitourinary system: some infectious agents, such as *Escherichia coli* which causes urinary tract infections, can enter the urinary tract via an ascending route from the urethra colonized with the organism. Structural abnormalities of the urinary tract and procedures such as urinary catheterization may predispose the host to disease. Sexually transmitted infectious agents, such as *Neisseria gonorrhoeae* which causes gonorrhoea, may enter the male or female genital orifices.
Placenta: certain infectious agents, such as rubella virus which causes congenital rubella syndrome, can cross the placenta resulting in transplacental transmission, a direct route of transmission from the mother to the foetus that is a form of vertical transmission.

Infectious agents also enter the host though *mechanisms that get past the body's natural barriers*, including wounds that break the integrity of the skin or mucous membranes; invasive procedures, parenteral injections, parenteral infusions, blood transfusions, or organ transplants that may introduce an agent into the body; or insect vectors that may inject agents through the skin.

The most important *host factors* regarding developing clinically manifest disease and the severity of disease are immune status and age. Infants, young children, and the elderly are at generally higher risk from more

severe disease due to immaturity or deterioration of their immune systems, respectively. Host co-infections or other health conditions that diminish the immune status, for example, HIV infection or malnutrition, respectively, are also risk factors.

Many *host defence mechanisms* help prevent infection or disease. *Non-specific* host defence mechanisms include the intact skin (by providing a natural barrier), sinus and nasal cilia (by moving mucus and particles towards the nasal cavity), tears, saliva, and mucus (by preventing drying and containing lysozymes and other components with antimicrobial properties), and gastric acid (by the antimicrobial and antiparasitic properties of hydrochloric acid). *Specific* host defence mechanisms include naturally acquired immunity from previous infection, transplacentally acquired passive immunity in the newborn from the mother, artificially acquired active immunity from immunization, and artificially acquired passive immunity from immunoglobulins and antitoxins.

Host responses to infection that prevent or reduce the severity of infectious disease include: (1) polymorphonuclear leucocytosis stimulated by some bacterial infections that increases the number of phagocytic white blood cells; (2) fever that may slow the multiplication of some infectious agents; (3) antibody production that may neutralize some infectious agents or their toxins; (4) interferon production that may block intracellular replication of viruses; and (5) cytotoxic immune cell responses that kill cells infected with viruses.

The *manifestation of infection* in the host may vary from inapparent (subclinical) infection to severe disease that may even result in death. The interaction between an infectious agent, routes of transmission, and host factors determine the spectrum of signs and symptoms. Sometimes the host may become an asymptomatic carrier of the infectious agent and be a source of infection for others.

Control measures for infectious diseases directed at the host are designed according to the immune status of the host and the likelihood of host exposure to certain infectious agents. For example, measles disease can be prevented by active immunization with measles vaccine to develop host immunity. Pneumonic plague can be prevented in those in close contact with patients with plague pneumonia by chemoprophylaxis using antibiotics such as tetracycline or sulphonamide. Details of these and other methods of

control directed at the host are provided in the section on control measures applied to the host in this chapter.

Tools for control of infectious diseases

The primary concern of infectious disease control in public health, whether in developing or industrialized countries, is the reduction, elimination, or even eradication of infectious disease. This is accomplished by directing control measures to the agent, the routes of transmission, or the host. Such control measures include: (1) identifying and then reducing or eliminating infectious agents at their sources and reservoirs, (2) breaking or interfering with the routes of transmission of infectious agents, and (3) identifying susceptible populations and then reducing or eliminating their susceptibility.

The tools for control of infectious diseases are related to recognition and evaluation of the patterns of diseases and the results of interventions to control them. In infectious disease control, the most important tool for recognition and evaluation is *surveillance* of disease defined as:

the process of systematic collection, orderly consolidation and analysis, and evaluation of pertinent data with prompt dissemination of the results to those who need to know them, and particularly those who are in a position to take action. It includes the systematic collection and evaluation of:

Morbidity and mortality reports
Special reports of field investigations of epidemics and of individual cases
Isolation and identification of infectious agents by laboratories
Data concerning the availability, use, and untoward effects of vaccines and toxoids, immune globulins, insecticides, and other substances used in control
Information regarding immunity levels in segments of the population
Other relevant epidemiologic data

A report summarizing the aforementioned data should be prepared and distributed to all cooperating persons and others with a need to know the results of the surveillance activities. The procedure applies to all jurisdictional levels of public health from local to international (Heymann 2014).

Surveillance, therefore, is ‘information for action’. More detailed information on surveillance or on field investigations is given in Chapter 5.19.

Tools for control related to *interventions* include:

Control measures applied to the host: active immunization, passive immunization, chemoprophylaxis, surgical intervention, behavioural change, reverse isolation, barriers, and improving host resistance.
Control measures applied to vectors: chemical, environmental, and biological.
Control measures applied to infected humans: chemotherapy, surgical intervention, isolation, quarantine, restriction of activities, and behavioural change.
Control measures applied to animals: active immunization, isolation, quarantine, restriction or reduction, chemoprophylaxis, and chemotherapy.
Control measures applied to the environment: provision of safe water, proper disposal of faeces, food and milk sanitation, and design of facilities and equipment.
Control measures applied to infectious agents: cleaning, cooling, pasteurization, disinfection, and sterilization.

Achieving maximum impact on control of a specific infectious disease may involve more than one of these interventions. For example, the control of hepatitis A infection can be achieved through interventions that may include: active immunization, passive immunization, food preparation, and hand-washing behaviours, provision of safe water, food sanitation, and proper disposal of faeces.

The tools for control can also be considered according to the level at which they are applied: individual, institutional, or community based. At the *individual level*, control measures, usually initiated by a clinician, are directed towards the specific infectious disease threats to the specific person. Examples include chemoprophylaxis to prevent wound infection, pre-exposure prophylactic immunization against rabies for a veterinarian, and use of diphtheria antitoxin in a patient with diphtheria.

At the *institutional level*, control measures, usually initiated by the officials of the institution, are directed to a group of people who are in close contacts with each other, such as people in day-care centres, schools,

military barracks, hospital wards, nursing homes, and correctional facilities. Examples include: (1) administering amantadine hydrochloride or rimantadine for chemoprophylaxis or chemotherapy of influenza A in a high-risk institutional population; (2) quarantining institutionalized young children during a measles outbreak; and (3) hepatitis B immunization of staff and clients of institutions for the developmentally disabled.

At the *community level*, control measures, usually initiated by local, state, or national public health agencies, are directed to the community at large. Examples include childhood immunization programmes, provision of safe water, regulation of food supplies, and recall of contaminated food products.

It should be noted that some control measures, such as immunization, may take place at all levels while others, such as the provision of safe water to a community, are more specifically applied at a particular level.

The tools for the control of infectious diseases and their relationship to the chain of infection are the focus of the remainder of this chapter.

Control measures applied to the host

Control measures applied to the host range from relatively easily administered immunization to behavioural changes that may be extremely difficult for an individual to accept and practise. This section details the types of control measures applied to susceptible hosts and gives examples of their application in the control of selected infectious diseases.

Active immunization

One of the most efficient control measures applied to a host is one that renders the host immune from infectious disease by an infectious agent. Active immunization is a cornerstone of public health measures for the control of many infectious diseases and is considered one of the most cost-effective methods of individual, institutional, and community protection for vaccine-preventable infectious diseases. The most powerful example of the potential impact of active immunization against an infectious disease is that of smallpox vaccination. Mobilization of political will on a worldwide basis, coupled with full application of the strategies of active surveillance

and containment immunization against smallpox, ultimately resulted in the complete global eradication of the disease and cessation of transmission of the infectious agent, variola virus.

Active immunization is usually considered synonymous with the term vaccination, and is the process of administration of an antigen that can induce a specific immune response that protects a susceptible host from an infectious disease. Some draw a distinction between the two terms. Narrowly defined, *vaccination* is the process of administration of an antigen and *immunization* is the development of a specific immune response. Administering an antigen without evoking an immune response is possible, since no vaccine is 100% effective. Conversely, someone can become immunized even if they were not administered an antigen. For example, the live, attenuated oral polio vaccine viruses can be transmitted from the recipient to other close contacts.

Active immunization can be accomplished through different types of antigens, including the following:

Inactivated toxins: diphtheria toxoid is an example of a formaldehyde-inactivated preparation of diphtheria toxin that protects against clinically manifest disease, although the immunized person may still become infected with toxin-producing strains of *Corynebacterium diphtheria*. Tetanus toxoid and *Clostridium perfringens* toxoid (pig bel vaccine) are other examples of inactivated toxin preparations.
Inactivated complex antigens: whole-cell pertussis vaccine is an example of a heat or chemically treated preparation of killed whole pertussis bacteria that protects against clinically manifest disease, although the immunized person may still become infected with *Bordetella pertussis*. Inactivated polio vaccine and inactivated influenza vaccine are other examples of inactivated vaccines.
Purified antigens: acellular pertussis vaccine is an example of a vaccine composed of isolated and purified immunogenic pertussis antigens. Other vaccines with purified components include polyvalent capsular polysaccharide pneumococcal, polysaccharide meningococcal, protein-polysaccharide conjugate *Haemophilus influenzae* type b, and plasma-derived hepatitis B vaccines.
Recombinant antigens: hepatitis B recombinant vaccine is an example of a vaccine composed of hepatitis B surface antigen subunits made through recombinant DNA technology. Human papillomavirus vaccine is another example of a DNA recombinant vaccine.
Live, attenuated vaccines: measles vaccine is an example of a vaccine containing live infectious agents that are of reduced virulence, but induce protective antibodies against measles viruses. Other live, attenuated vaccines include oral polio, mumps, rubella, yellow fever, and bacille Calmette–Guérin (BCG) vaccines.
• *Messenger RNA (mRNA) vaccines*: some of the COVID-19 vaccines are examples of a new vaccine technology that utilizes mRNA to deliver one or more of the SARS-CoV-2 genes into the body’s cells that then cause those cells to make spike proteins that are subsequently released from the cell and provoke an immune response.

Protective *antibody responses* usually take 7–21 days to develop. Although most vaccines must be given before exposure to be effective, some vaccines may protect even if administered after exposure to an infectious agent. For example, measles vaccine may provide protection against measles disease if

given within 72 hours of exposure. This occurs since the percutaneous route of administration of the antigen evokes an immune response faster than the measles virus results in disease through the respiratory route of natural exposure.

Duration of protection varies from only months, such as with killed whole-cell cholera vaccine, to years or even life with some live attenuated vaccines, such as measles vaccine. Some inactivated toxoids and vaccines, such as tetanus toxoid, may require a priming series of doses to be optimally effective and additional booster doses to maintain protective antibodies. Many new technologies are being explored that may increase the number and efficacy of vaccines available against infectious disease, including immune stimulating complexes, live viral or bacterial vector vaccines, and timed-release vaccines.

It should be recognized that vaccines vary in their efficacy and no vaccine is 100% effective. *Vaccine efficacies* vary with type of vaccine, manufacturing techniques, storage, and handling conditions, skill of administration, age of vaccination, and other host factors. Vaccines for routine use are safe. However, no vaccine is 100% safe. Potential vaccinees, or their parents or guardians, should be screened for contraindications and be informed of potential side effects.

Immunization schedules for the routine control of infectious diseases preventable by immunization vary between countries and are usually based on expert advice to governments and physicians. For example, general and specific recommended policies for immunization in the United States are provided by the Advisory Committee on Immunization Practices and are published online (ACIP 2018). In addition, the American Academy of Pediatrics periodically publishes comprehensive immunization recommendations in its *Report of the Committee on Infectious Diseases* (Committee on Infectious Diseases 2018). At the global level, the WHO publishes recommended immunization schedules and control strategies for vaccine-preventable diseases that are periodically updated by expert advisory groups in the WHO *Weekly Epidemiological Record*.

In *outbreak settings*, immunization schedules may be modified. For example, the age of immunization for measles may be lowered to 6 months of age during a measles outbreak. In such situations, children receiving vaccine before the routinely recommended age of immunization should be

immunized again at the recommended age since immunization at the earlier age may not have been optimally effective.

Immunization programmes include vaccines for routine child, routine adult, travel, selected high-risk populations, and occupational settings. For example, tetanus toxoid is universally recommended; yellow fever vaccine is only recommended in geographic areas of epidemiological risk (i.e. in certain areas of Africa and South America); typhoid fever vaccine is only recommended for individuals subject to unusual exposure to typhoid, including people living in the same household as known carriers; and anthrax vaccine is only recommended for veterinarians and people occupationally exposed to possibly contaminated industrial raw materials.

Beyond protection of the individual, vaccination may also provide a degree of community protection. This phenomenon of community immunity is known as herd immunity. *Herd immunity* is the relative protection of a population group achieved by reducing or breaking the chains of transmission of an infectious agent because a sufficient percentage of the population is immune, that is, resistant to infection through immunization or prior natural infection. When the immunity level in a population becomes such that the effective reproduction number of the disease in that population, R, is less than 1, the disease will eventually die out. Herd immunity is a complex phenomenon and varies according to the infectious agent, its routes of transmission, the degree to which immunization protects against infection versus only clinically manifest disease, and the distribution of immunization in the population. Typically, for childhood vaccine-preventable diseases, the immunity levels in the population to achieve herd immunity range from around 84% (for rubella) to over 90% (for pertussis). The mechanisms of herd immunity are several, including ‘direct protection of vaccinees against disease or transmissible infection and indirect protection of non-recipients by virtue of surreptitious vaccination, passive antibody, or just reduced sources of transmission and, hence, risks of infection in the community’ (Fine 1993).

A particularly difficult problem for vaccine-preventable infectious disease control programmes is complacency by the population that can result from the very successes of the programmes and highlights the continuing need to educate the public and decision-makers. Low rates of vaccine-preventable infectious disease may mistakenly lead parents to consider that vaccination is no longer important for maintaining their

children's health and may result in political leaders reducing funding for immunization programmes. Low disease rates may also focus undue attention on the relatively rare serious side effects of vaccination in relation to current rates of disease. Such side effects should only be compared in relation to rates of disease and its complications that would occur without immunization programmes (Kim-Farley 2017).

A comprehensive treatment of active immunization is given by Plotkin and Orenstein (2012).

Passive immunization

Passive immunization is a temporary immunity in a host due to the protection afforded by antibody produced in another host or artificially as in the use of laboratory-made monoclonal antibodies against SARS=CoV-2 that mimic the body's immune system to fight the virus. Passive immunity may be acquired either naturally or artificially.

Naturally acquired passive immunity is achieved through transfer of maternal antibodies via the placenta. It is the way that newborn infants are provided with a temporary immunity against many infectious diseases for which the mother is immune. This immunity wanes over time and eventually leaves the infant susceptible to these diseases.

An important use of transplacental immunity as a control measure is in the prevention of tetanus neonatorum (neonatal tetanus) by immunization of women before or during pregnancy with tetanus toxoid. This is especially important in developing countries where the disease typically occurs when the umbilical cord is cut with an unclean instrument contaminated with tetanus spores or when substances contaminated with tetanus spores are placed on the umbilical stump after delivery. Control by active immunization of the infant cannot be achieved in sufficient time since the average incubation period is only 6 days (with a range from 3 to 28 days). An adequately immunized mother, however, will usually effectively transfer maternal antibodies against tetanus across the placenta to her newborn and prevent tetanus neonatorum.

Another example of naturally acquired passive immunity is the relative protection against measles disease in a young infant born to a mother who previously had the disease. Typically, such infants are immune for approximately 6–9 months or more after birth, depending upon the level of

residual maternal antibodies present at the time of pregnancy. Other diseases for which there is usually an effective transplacental immunity in infants, for variable amounts of time, include diphtheria, mumps, poliomyelitis, rubella, and varicella (chickenpox). It should be noted that if the mother is not immune, or if residual maternal antibodies have significantly waned, then the infant may be susceptible to disease.

Research is ongoing as to other infectious diseases that may be preventable in the neonate or infant through immunization of the mother before or during pregnancy. Examples include *Haemophilus influenzae* type b, group B streptococcal and meningococcal diseases (Insel et al. 1994). Many diseases, however, are not prevented by transplacental immunity (e.g. transplacental immunity to pertussis in infants has not been demonstrated even though antibodies cross the placenta).

Breastfeeding is a form of naturally acquired passive antibody transfer to neonates and infants. Breast milk and colostrum contain secretory immunoglobulin A (IgA) antibodies that may play a protective role in the prevention of infections with such agents as respiratory syncytial virus, rotavirus, and *Haemophilus influenzae* type b.

Artificially acquired passive immunity is acquired through administration of an antibody-containing preparation, antiserum, or immune globulin. It has a place in the control of certain infectious diseases in special situations. This immunity also wanes over a relatively short period of time.

Examples of the use of artificially acquired passive immunity to control infectious disease include the following:

Rabies: natural immunity to rabies in humans does not exist. Susceptible individuals bitten by an animal known or suspected to be rabid should receive rabies immune globulin to neutralize the rabies virus in the wound. It should be noted that, besides passive immunization with rabies immune globulin, such individuals should also receive active immunization with rabies vaccine.

Hepatitis A: in areas where sanitation is poor, hepatitis A infection commonly occurs at an early age and therefore most adults in developing countries are already immune. However, outbreaks may occur in industrialized countries. Passive immunization with immune globulin may be given to: (1) all household and sexual contacts of patients with hepatitis A; (2) other food handlers in an establishment where hepatitis A has occurred in a food handler; (3) all individuals in an institution where a focal outbreak of hepatitis A has occurred; and (4) persons from industrialized countries travelling to highly endemic areas. It should be noted that vaccines for active immunization for hepatitis A are now available and may be a preferred approach.

Diphtheria: treatment of this disease is an example of the use of an antibody-containing product (diphtheria antitoxin) produced in an animal (only diphtheria antitoxin from horses is available) administered as part of the treatment regimen for secondary prevention of disease. In suspected cases of diphtheria, the antitoxin must be given as soon as possible because it is only effective in neutralizing diphtheria toxins not yet bound to cells.

Other important infectious diseases, including hepatitis B, measles, tetanus, varicella, COVID-19: depending upon the circumstances of exposure, susceptibility of the host, and status of the host's general immune system there are circumstances under which hepatitis B immune globulin, tetanus immune globulin, varicella-zoster immune globulin, SARS-CoV-2 monoclonal antibodies, or immune globulin may be warranted.

Chemoprophylaxis

Chemoprophylaxis is the prevention of infection or its progression to clinically manifest disease through the administration of chemical substances, including antibiotics. Chemoprophylaxis can also consist of the treatment of a disease to prevent complications of that disease. Chemoprophylaxis may be specifically directed against a particular

infectious agent or it may be non-specifically directed against many infectious agents. The use of antibiotics before surgical procedures is an example of non-specific chemoprophylaxis to prevent wound infections in the postoperative period. Examples of specific chemoprophylaxis are given next.

The use of chemoprophylaxis to *prevent development of infection* is illustrated by using chloroquine to prevent malarial parasitaemia caused by *Plasmodium vivax*, *Plasmodium ovale*, *Plasmodium malariae*, and chloroquine-sensitive strains of *Plasmodium falciparum*. For some chloroquine-resistant strains of *Plasmodium falciparum*, alternative regimens include mefloquine alone, doxycycline alone, primaquine alone, or an atovaquone/proguanil combination. Primaquine may be given to reduce the risk of a relapse from intrahepatic forms of *Plasmodium vivax* and *Plasmodium ovale* after discontinuation of chemoprophylaxis with any chemosuppressive drugs other than primaquine. Determination of a specific malaria chemoprophylactic regimen is complex. It must consider the geographic area, the possibility of pregnancy, the weight of an individual (dose size for children is determined by body weight), and the risks of adverse reactions to the chemoprophylactic regimen.

Other examples of prevention of development of infection include the following:

The use of silver nitrate, erythromycin, or tetracycline instilled into the eyes of a newborn to prevent gonococcal ophthalmia by transmission of *Neisseria gonorrhoeae* from an infected mother during birth.

The use of tetracycline, sulphonamides (including sulfadiazine and trimethoprim-sulfamethoxazole), chloramphenicol, or streptomycin in close contacts of confirmed or suspected cases of plague pneumonia to prevent plague pneumonia by transmission of *Yersinia pestis*.

The use of benzathine penicillin in those in sexual contact with confirmed cases of early syphilis to prevent syphilis by transmission of *Treponema pallidum*.

An example of the use of chemoprophylaxis to *prevent the progression of an infection to active manifest disease* is the use of isoniazid (INH) to prevent the progression of latent infection with *Mycobacterium tuberculosis* to clinical tuberculosis. People less than 35 years of age who are

tuberculosis test positive should receive INH to prevent clinical tuberculosis. The decision to use INH, especially in individuals more than 35 years of age (who are at higher risk of clinical hepatitis from the use of the drug), must be determined based on such information as length of infection, closeness of association with a current case, status of the immune system, presence of acute liver disease, possibilities of pregnancy, and risks of adverse reactions.

Other examples of prevention of progression of an infection to active manifest disease through the use of chemoprophylaxis include the following:

Co-trimoxazole or pentamidine to prevent subclinical latent infection with *Pneumocystis jirovecii* (formerly *carinii*) from progressing to clinically manifest *Pneumocystis* pneumonia in immunosuppressed people such as HIV-infected individuals.

Mebendazole, albendazole, or pyrantel pamoate to prevent infection with *Necator americanus*, *Ancylostoma duodenale*, and *Ancylostoma ceylanicum* from progressing to the clinically manifest anaemia of hookworm disease.

Pyrimethamine combined with sulfadiazine and folinic acid (to avoid possible bone marrow depression) to prevent asymptomatic infants congenitally infected with *Toxoplasma gondii* from progressing to clinically manifest chorioretinitis and other sequelae of congenital toxoplasmosis.

In some situations, establishing *screening* programmes to detect and treat asymptomatic infections or unrecognized disease in defined populations is useful. An example is the screening for *Chlamydia trachomatis* in sexual partners of people infected with *Chlamydia trachomatis*, women with mucopurulent cervicitis, sexually active women 25 years of age or younger, and women older than 25 years of age with risk factors for chlamydia. A more detailed background on screening as a public health function is given in Chapter 11.4.

An example of the use of chemoprophylaxis to *treat an infectious disease to prevent complications of the disease* is the use of penicillin (or erythromycin in penicillin-sensitive patients) to treat streptococcal sore throats caused by *Streptococcus pyogenes* group A to prevent acute rheumatic fever.

Other examples of prevention of complications of an infectious disease through the use of chemoprophylaxis include the following:

Tetracycline for adults, or penicillin for children, for treatment of Lyme disease caused by *Borrelia burgdorferi* in the erythema chronicum migrans stage to prevent or reduce the severity of late cardiac, arthritic, or neurological complications.
Benzathine penicillin for treatment of syphilis in its primary, secondary, or early latency period to prevent late manifestations of the disease such as cardiovascular syphilis.
Ketoconazole for treatment of blastomycosis caused by *Blastomyces dermatitidis* in its early stages to prevent progression of chronic pulmonary or disseminated blastomycosis that may lead to death.

Potential problems with the use of chemoprophylaxis may include compromise of the host's own non-specific defence mechanisms, other replacement infectious agents causing disease by growing in the place of the infectious agent affected by the specific chemoprophylactic regimen (e.g. severe diarrhoea from intestinal infections with *Clostridium difficile* may occur when the normal bacteria flora in the intestines have been lost due to antibiotics), and emergence of resistant strains of the infectious agent. The development of antibiotic resistance can be reduced by using antibiotics only when needed, selecting the proper antibiotic (or, in some situations, the appropriate multidrug therapy) for the infectious agent, and ensuring compliance with the appropriate regimen for the duration of treatment.

Control by surgical intervention

Surgical intervention is an additional method of infectious disease control. Particularly in conjunction with chemoprophylactic prevention measures and as primary prevention, some communicable diseases of public health importance can have improved control through addition of surgical intervention.

An example of the use of surgical intervention for infectious disease control is its use as an effective measure for HIV primary prevention. There is sufficient evidence that male circumcision, the surgical removal of the

foreskin of the penis, reduces the risk of HIV infection. Three randomized controlled trials have determined a 50% to 60% reduction in the incidence of HIV among heterosexual men who had circumcision compared to those who were not circumcised (Smith et al. 2010). Though male circumcision should be conducted with a comprehensive HIV prevention package, including promotion of safer sex practices, provision of condoms and appropriate use of pre-exposure prophylaxis (PreP). WHO/UNAIDS recommends male circumcision particularly in countries and regions with heterosexual epidemics, high HIV, and low male circumcision prevalence (WHO 2017). It should be noted that the impact of circumcision on the transmission of non-HIV sexually transmitted infections is still controversial (MacNeily 2011).

Additional examples of surgery as a primary prevention measure include tonsillectomy, tympanostomy, and prophylactic appendectomy. Tonsillectomy (removal of the tonsils), though performed less frequently than in the past, is most commonly used to prevent recurrent tonsillitis and obstructive sleep apnoea (Patel et al. 2014). Tympanostomy tube placement, a procedure involving a small incision in the eardrum (myringotomy) and placement of a tube, can allow drainage of fluid and is used as a preventive measure for otitis media (middle ear infection) when infections are recurrent (Lieberthal et al. 2013). Regarding prophylactic appendectomy, or removal of an apparently normal appendix during abdominal surgery for other indications, while a clear benefit has not been established by randomized trials, there appears to be very little increased morbidity and so the decision to remove during laparoscopic procedures should be made on a case by case basis (Occhionorelli et al. 2014). Also, there is the rare circumstance of prophylactic appendectomy for a sole physician wintering over in Antarctica to avoid the possibility of having to perform an emergency auto-appendectomy as occurred in a Russian physician in 1961 (Rogozov and Bermel 2009).

Behavioural change

Perhaps the most challenging tool for the control of infectious diseases, and sometimes one of the most powerful and cost-effective, is behaviour change in the host that reduces or eliminates risk of exposure to an agent. Everyone has developed habits of living (lifestyles) that are not easily changed. Some

of these behaviours are protective against infectious diseases. Others render the individual at higher risk of infection.

Examples of higher risk of exposure to infectious agents through behaviour, and behaviour changes that can have an impact on the chain of transmission, include the following.

Sexual behaviour

Many infectious agents are transmitted by the direct transmission route through sexual contact, including *Chlamydia trachomatis* causing chlamydial genital infections, *Neisseria gonorrhoeae* causing gonorrhoea, *Treponema pallidum* causing venereal syphilis, *Calymmatobacterium granulomatis* causing granuloma inguinale, *Haemophilus ducreyi* causing chancroid, herpes simplex virus causing herpes simplex, *Trichomonas vaginalis* causing trichomoniasis, human papillomaviruses causing condyloma acuminata, and HIV causing AIDS.

Abstinence behaviour, that is, refraining from sexual activity with other persons, eliminates the risk of transmission of these agents through sexual contact. The delaying of age of first sexual activity avoids the risk of transmission of these agents at an early age. Restricting sexual contact to only between two uninfected people who do not have sexual activity with any other people virtually eliminates the risk of transmission of these agents through sexual behaviours. The exceptions are due to other routes of transmission of some of these agents (e.g. HIV acquired through intravenous drug use in one partner being transmitted through sexual contact to the other partner). Limiting the number of sexual partners, and limiting those sexual partners to people who also have few sexual partners, reduces the risk of exposure. However, at the individual level, if one of these sexual partners has an infectious agent transmissible by sexual contact, the risk of transmission may still be high. Finally, condom use during sexual activity in high-risk situations will markedly reduce, but not eliminate, transmission. A more detailed background on sexually transmitted infections is provided in Chapter 8.12.

Intravenous drug use behaviour

Injection of drugs using non-sterile needles or syringes previously used by other intravenous drug users may transmit infectious agents in blood

through the vehicle-borne route of indirect transmission, including HIV causing AIDS; hepatitis B virus causing viral hepatitis B; and *Plasmodium vivax*, *Plasmodium malariae*, and *Plasmodium ovale* causing malaria.

Abstinence behaviour, that is, refraining from intravenous drug use, eliminates the risk of transmission of such agents through contaminated needles and syringes. Using a sterile needle and sterile syringe for intravenous drug use will break the chain of transmission of these infectious agents through this route. Some community public health programmes, in addition to promoting drug abstinence and drug rehabilitation, conduct needle and syringe exchanges and education regarding methods of decontamination to help promote the use of sterile injection equipment among intravenous drug users (see Chapter 9.2).

Eating behaviour

Eating certain foods may result in exposure to infectious agents through the vehicle-borne route of indirect transmission. These behaviours include consuming raw molluscs by which an infectious agent like the hepatitis A virus can cause viral hepatitis A, eating raw eggs by which an infectious agent like a *Salmonella* serotype can cause salmonellosis, and consuming raw beef by which an infectious agent like *Taenia saginata* can cause beef tapeworm infection.

Although food and diet are strongly ingrained behaviours, modification of dietary patterns is possible. Cooking foods like beef, pork, and eggs can markedly reduce risk of transmission of infectious agents. In addition, reducing risks by elimination of infectious agents from the food may be possible (see the section on control methods applied to the environment). Eating shortly after cooking so that foods are not left standing at ambient temperatures for extended times and paying attention to food recalls are also important behaviours. Hand washing before eating also reduces risk of transmission of many infectious agents that are spread through direct or indirect routes of faecal–oral transmission, such as *Shigella dysenteriae*, *Shigella flexneri*, *Shigella boydii*, and *Shigella sonnei* which may cause shigellosis (bacillary dysentery), which is estimated to cause 600,000 deaths per year with two-thirds of the cases in children under 10 years of age (Heymann 2014).

Working behaviour

In certain occupations, many behaviours may result in exposure to infectious agents and should be targets for control programmes in occupational safety and health settings. Specific examples include the following:

Dental workers performing procedures with bare hands may result in exposure to hepatitis B viruses from infected patients.
Health workers improperly handling used needles may result in needle-stick injuries leading to exposure to HIV from infected patients.
Hospital laboratory workers improperly processing specimens containing infectious agents without appropriate glove or eyewear protection may result in exposure to these agents.
Veterinarians who do not properly handle animals may result in brucellosis (undulant fever) due to exposure to *Brucella abortus*, *Brucella melitensis*, *Brucella suis*, or *Brucella canis*.

Occupational hazards related to non-infectious materials may predispose an individual to increased risk of infectious diseases. For example, working conditions and behaviours in industrial plants and mines that lead to silicosis due to long-term inhalation of free crystalline silica dust will greatly increase the risk of developing tuberculosis.

Working behaviours appropriate for the particular occupational setting may include wearing protective clothing, eyewear, and gloves; not eating food at the worksite; hand washing, and changing clothes after work; receiving appropriate vaccinations for the working environment; meticulous adherence to needle disposal and equipment sterilization procedures; and using hooded laboratory benches when handling infectious specimens that can become aerosolized.

Other behaviours

Other behaviours that may reduce the transmission of infectious agents include the following:

Scheduling outdoor activities at periods of low vector activity, applying insect repellents, and sleeping under bednets reduce the indirect transmission of vector-borne agents of infectious diseases like malaria.
Searching oneself or a young child for attached ticks every 3 to 4 hours when playing or working in tick-infested areas reduces the indirect transmission of vector-borne agents of infectious diseases like Rocky Mountain spotted fever.
Avoiding sharing of utensils, cups, toothbrushes, or towels reduces the indirect transmission of vehicle-borne agents of infectious diseases like mononucleosis.
Wearing of shoes reduces the direct transmission of infectious agents like those causing hookworm disease.
Frequently bathing and regular washing of clothes in hot soapy water controls body lice.
Breastfeeding reduces diarrhoeal diseases in the infant, although it may transmit HIV from HIV-infected mothers.
Hand washing after defecation or touching potentially contaminated surfaces, people, or animals (including those found in petting zoos) prior to preparing food or touching one's own eyes, mucous membranes, or mouth reduces the risk of direct or indirect transmission of a wide variety of infectious agents.
Large family sizes and crowding may facilitate airborne transmission of infectious agents in droplet nuclei for infectious diseases like tuberculosis.

Some of these other behaviours, like crowding, are conditioned by circumstances such as poverty that are not easily or directly amenable to programmes promoting behavioural change.

Reverse isolation

Certain rare circumstances exist where a means of avoiding transmission of an infectious disease to a highly susceptible host is to provide reverse, or protective, isolation. Such isolation attempts to protect infection-prone patients from potentially harmful infectious agents. Reverse isolation procedures range from provision of a private room with the use of masks, gloves, and gowns by all people entering the room, to elaborate facilities with laminar airflow rooms and sterilization of all food. Protective isolation

is usually conducted for a limited time until the normal immune system recovers, a regimen of passive immunization is begun, or a bone marrow transplant is successful.

Examples of people who may need periods of reverse isolation include those who have such diseases as X-linked agammaglobulinaemia, DiGeorge's syndrome, and severe combined immunodeficiency; or those who have received therapies, such as some forms of cancer chemotherapy, that have severely compromised the person's immune system in combating many infectious diseases.

Barriers

One tool of control that can be applied to the host is the use of barriers between the host and the infectious agent. The effectiveness of such barriers, however, may be dependent on the behaviour of the host to use them consistently and education to use them correctly. Examples of barriers include the following:

Screens, bednets (including bednets impregnated with pyrethroid insecticides such as permethrin), long-sleeved shirts and trousers (with the cuffs tucked into boots as a mechanical barrier), and repellents (such as N,N-diethyl-meta-toluamide, also known as DEET) to prevent transmission of malaria through the bite of infected female *Anopheles* mosquitoes or West Nile virus through *Culix* mosquitoes.
Condoms to prevent transmission of HIV and other sexually transmitted infectious agents through sexual intercourse.
Masks (air-purifying respirators) to prevent transmission of tuberculosis through airborne droplet nuclei from patients with sputum-positive pulmonary tuberculosis.

General improvement in host resistance

Improving host resistance though general improvement of the immune system is a non-specific approach, but may be important in certain settings. Kwashiorkor, marasmus, and other forms of malnutrition debilitate the host's immune system and may make an individual more susceptible to infectious diseases. Moreover, people who are malnourished and contract an

infectious disease are at higher risk of the disease being of greater severity and leading to other complications.

Malnutrition also encompasses micronutrient deficiencies. Vitamin A deficiency, for example, has been linked to higher rates of mortality associated with measles disease. Correcting vitamin A deficiency, through programmes of supplementation, fortification, and dietary modification in high-risk populations, can reduce mortality rates due to measles.

A complex interaction exists between infectious diseases, such as diarrhoeal diseases, and malnutrition. A downward spiral of infection may lead to malnutrition that, in turn, leads to more infections, and so on. If unchecked, especially in developing countries, this downward spiral can ultimately result in death.

Further, infectious diseases themselves can impact host resistance. Measles' proposed "immune amnesia" has been shown to have long-term effects on child mortality (Mina et al. 2015).

International travel

The special situation of international travel combines many control measures applied to the host already mentioned. The increase in the numbers of travellers, the speed of travel, and the ability to reach areas previously infrequently visited have reduced the effectiveness of surveillance for infectious diseases at ports of arrival and increased infectious disease risks. Advice for prevention against infectious diseases must be both general and specific.

General advice includes such issues as avoidance of eating and drinking potentially contaminated food or drink (including ice) and swimming or bathing in polluted water. Specific advice provided by health professionals should be provided based on information about the area to be visited and may include such measures as active immunization against yellow fever, active or passive immunization against hepatitis A, chemoprophylaxis against malaria, repellents against potentially infected mosquitoes, and not walking barefoot in areas of risk for infection with hookworms *Strongyloides stercoralis* and *Strongyloides fuelleborni*. A more detailed background on international travel and health is provided in the annually updated WHO publication on *International Travel and Health* (WHO 2012b).

Control measures applied to vectors

Vector-borne transmission is the only or main route of transmission for many infectious diseases. There exist more than 100 arthropod-borne viruses that may produce clinically manifest diseases in humans. Control of vector-borne diseases includes measures to: (1) change behaviour and create barriers to the susceptible host, (2) reduce or break the chain of transmission of the infectious agent from an infected host to the vector, and (3) directly control the vector population itself. Chemical, environmental, and biological controls are the primary means of directly controlling the vector population.

Chemical control

Chemicals used in the control of vectors that act as digestive poisons, contact poisons, or fumigants include minerals, natural plant products (botanicals), chlorinated hydrocarbons, organophosphates, and carbamates. Chemical control measures include the following public health interventions:

Spraying chemical insecticides such as organochlorine insecticides (e.g. dichlorodiphenyltrichloroethane, or DDT, and dieldrin), organophosphorus insecticides (e.g. malathion and fenitrothion), and carbonate insecticides (e.g. propoxur and carbaryl) to prevent malaria through control of mosquitoes.

Spraying chemical biodegradable insecticides such as temephos (Abate®) to prevent onchocerciasis through control of *Simulium* fly vectors.

Using traps impregnated with decamethrin to prevent African trypanosomiasis (sleeping sickness) through reduction of the population of infective species of *Glossina* (tsetse fly) vectors.

Treating snail-breeding places with chemical molluscicides to prevent schistosomiasis due to the free-swimming cercariae (larval forms) of *Schistosoma mansoni, Schistosoma haematobium, and Schistosoma japonicum* that develop in snails.

Treating step-wells and ponds with chemical insecticides such as temephos (Abate®) to prevent dracunculiasis due to infected cyclops (a crustacean copepod).

Suppressing rat populations by poisoning, preceded, or accompanied by measures to control fleas, as an additional measure to supplement environmental sanitation to control rodent populations to prevent human plague.

The use of spraying for control of mosquitoes is complicated due to concerns about environmental contamination by chemicals such as DDT and dieldrin which have led to them being banned in many countries. In addition, the emergence of mosquito vectors resistant to the insecticides diminishes their effectiveness in many areas. New methods of application, such as ultra-low-volume spraying of malathion, reduce the amounts of insecticide used.

Environmental control

Environmental control of vectors includes the following public health interventions:

Eliminating breeding sites of mosquito larvae by filling and draining areas of stagnant water and removing objects around houses that may collect water.
Destroying the habitats of the tsetse fly vector.
Properly implementing landfill procedures, placing lids on rubbish bins, covering food for human consumption, screening privies, cleaning up spilled food, and appropriately storing food.
Placing roach and fly traps.
Constructing rat-proof houses.
Eliminating rodent habitats.

It is also important to note that certain development projects may have an impact on the environment that facilitates the growth of vector or intermediate-host populations and results in increased infectious diseases. Construction of artificial waterways may serve as breeding sites for *Simulium* fly vectors that can transmit *Onchocerca volvulus* resulting in onchocerciasis. Irrigation schemes can foster the growth of snail intermediate hosts required for the transmission of species of *Schistosoma* resulting in schistosomiasis. Carefully conducted environmental and health impact studies that consider the impact of a construction project on the vector and intermediate-host populations, and ways to modify the project to reduce such populations, are important environmental control measures.

Biological control

Biological control of vectors includes the following public health interventions:

Introduction of predators and parasites: the introductions of *Gambusia affinis*, a small fish that feeds on mosquito larvae, and of *Coelomomyces*, a fungal parasite, are examples of control measures that are effective against *Aëdes* mosquitoes.
Insect growth regulators: the use of such regulators may result in death or sterility of vectors by interfering with normal insect development. An example is the use of methoprene (Altosid®) to control flood water mosquitoes.
Genetic modification: although still at an experimental phase, researchers have developed transgenic, or genetically modified, mosquitoes that are malaria resistant with higher survival rates that could eventually replace mosquitoes that carry malaria parasites.

Control measures applied to infected humans

Control measures may be applied to infected people at the individual level, in the institutional or hospital setting, and at the community level.

Hospital infection control

The hospital setting is a unique situation that requires special efforts to prevent and control nosocomial infections, or healthcare-associated infections (HAIs), which are infections that originate or occur in a hospital or other healthcare setting. HAIs are a major problem worldwide. In the United States alone, some 2 million HAIs occur annually resulting in an estimated 90,000 deaths (McKibben et al. 2005). It has been estimated that HAIs result in some US$35.7–45 billion in annual direct medical hospital patient costs based on using the Consumer Price Index for inpatient hospital services (Scott 2009).

Infection control programmes for hospitals should ideally include the following elements:

An infection control committee responsible for overall coordination of infection control activities.
One or more infection control practitioners (Infection Preventionists) responsible for nosocomial disease surveillance, analysis of data, consultation, and training of hospital staff.
A hospital epidemiologist to supervise the infection control practitioners, oversee data collection and analysis, and implement any needed emergency infection control measures.
An engineer to direct engineering and preventive maintenance operations, especially ventilation equipment.
A sanitarian to develop procedures for proper disposal of liquid and solid wastes; and sanitation of water, ice, and food.
Effective guidelines for patient care practices.
Surveillance of patient care practices, patient infections, and environmental contamination by infectious agents.
Coordination with other departments (microbiology laboratory, central services, housekeeping, food service, and laundry).
Vector control.
Thorough investigation of problems.

Examples of specific control measures that may be applied to infected humans at the individual, institutional, and community levels are detailed next.

Chemotherapy

Treatment of people with infectious diseases or subclinical infections may be a control tool for some infectious diseases. Such treatment may or may not have an impact on disease progression in the patient. It should be noted that rapid case detection and prompt application of appropriate chemotherapeutic agents are needed to limit infectivity.

Some important examples of control by chemotherapy include the following:

Treatment of patients with sputum-positive pulmonary *tuberculosis* with appropriate multidrug therapy will usually result in sputum conversion rendering them non-infectious to others within a few weeks. Recommended treatment regimens include isoniazid (INH) combined with one or more of the following antibiotics: rifampin, streptomycin, ethambutol, and pyrazinamide. The WHO has recommended that adherence to a complete course of multidrug therapy be directly observed by another responsible person as part of the DOTS (directly observed treatment, short-course) global strategy for the control of tuberculosis.
Patients with *leprosy* treated with appropriate multidrug therapy are considered no longer infectious within 3 months of regular and continued treatment. Recommended treatment regimens for multibacillary leprosy include the following antibiotics: rifampicin, dapsone, and clofazimine.
Treatment of patients with *streptococcal sore throats* with penicillin (or erythromycin for penicillin-sensitive patients) will usually render them no longer infectious after 24–48 hours.
Patients with *pertussis* treated with antibiotics such as erythromycin or trimethoprim-sulfamethoxazole, although they may not affect the patient's symptoms, will usually result in the patient no longer being infectious after 5–7 days.

Of special note is the situation of treatment of people who are carriers:

> A person or animal that harbors a specific infectious agent without discernible clinical disease, and which serves as a potential source of infection. The carrier state may exist in an individual with an infection that is unapparent throughout its course (such an individual is commonly known as *healthy or asymptomatic carrier*), or during the incubation period, convalescence, and post-convalescence of a person with a clinically recognizable disease (commonly known as *incubatory or convalescent carrier*). Under either circumstance the carrier state may be of short or long duration (*temporary or transient carrier, or chronic carrier*). (Heymann 2014)

A chronic carrier of diphtheria, for example, may shed the infectious agent *Corynebacterium diphtheriae* for 6 months or more, but appropriate antibiotic therapy will usually promptly stop the carrier state. Another example is that of untreated patients with typhoid fever due to *Salmonella typhi*. Between 2 and 5% of such patients will become permanent carriers. Treatment with appropriate antibiotics may be effective in ending the carrier state.

Antibiotic treatment may not always eliminate a carrier state for some infectious agents. For example, the treatment of people with salmonellosis with an antibiotic may not terminate the period of communicability and can even result in emergence of antibiotic-resistant strains. However, antibiotic therapy may be still warranted under certain circumstances.

In some situations, establishing screening programmes in defined target populations for identification of asymptomatic or unrecognized infections that could be transmitted to others may be appropriate. Such screening should include the necessary follow-up with appropriate chemotherapy and counselling. An example would be screening close contacts of diphtheria patients with nose and throat cultures for the presence of *Corynebacterium diphtheriae*. Identified carriers with positive cultures should be treated with appropriate antibiotic therapy.

Control by surgical intervention

Surgical intervention is an additional method of infectious disease control in an infected person. Particularly in conjunction with chemotherapeutic control measures, some communicable diseases of public health importance can be better controlled through the addition of surgical therapy.

In the first part of the 20th century, surgery played a major role in control of tuberculosis (TB) until the availability of effective medications mid-century (Sihoe et al. 2009). With the increase of multidrug-resistant (MDR) and extensively drug-resistant (XDR) TB, surgical intervention is again being considered as an adjunct treatment option (Kempker et al. 2012). The American Thoracic Society, CDC and Infectious Diseases Society of America released a 2003 report communicating that surgical therapy should be used only as an adjunct to medical treatment (Blumber et al. 2003). Recent research has shown early pulmonary resection surgery, removing either part or all of a lung, as an adjunct to chemotherapy may result in high rates of cure for both MDR and XDR TB (Kang et al. 2010). The WHO additionally recommends that any adjunct surgical therapy may be warranted earlier (rather than later) in disease progression (WHO 2008a). It should be noted that treating TB would constitute primary prevention to stop transmission to others.

Surgical therapy can also play a role in treatment of other infections such as Methicillin-Resistant *Staphylococcus aureus* (MRSA). Surgical

debridement, or the removal of dead or contaminated tissue from a wound to prevent further infection, is recommended in complicated MRSA infections, or when there is bone or joint involvement (Liu et al. 2011). Another example is that of gangrene, a condition in which cell death occurs due to lack of sufficient blood supply caused by infection and/or noncommunicable conditions such as diabetes. Gangrene can be caused by only a non-infectious condition manifested as dry gangrene, or by a variety of bacteria, manifested as wet gangrene, gas gangrene, internal gangrene, and necrotizing fasciitis (an infection that results in the death of soft tissue).

Isolation

Isolation is the 'separation, for a period at least equal to the *period of communicability*, of infected persons or animals from others, in such places and under such conditions as to prevent or limit the direct or indirect transmission of the infectious agent from those infected to those who are susceptible to infection or who may spread the agent to others' (Heymann 2014).

The US CDC and the Hospital Infection Control Practices Advisory Committee (HICPAC) have provided guidelines for isolation precautions in hospital settings (Siegel et al. 2007). There are two levels of isolation precautions, namely: (1) a standard precautions level designed for the care of all hospitalized patients; and (2) a transmission-based precautions level designed for the care of hospitalized patients that are suspected or confirmed to be infected by agents spread by contact, droplet, or airborne routes of transmission. These are summarized from guidelines as follows.

Standard precautions are universally applied precautions designed to reduce the risk of transmission by infectious agents from blood; body fluids, secretions, and excretions; non-intact skin; and mucous membranes. The essential elements of standard precautions include hand washing; personal protective equipment (use of gloves, appropriate application of mask and eye protection or a face shield, and utilization of gowns); proper handling of patient care equipment; adequate environmental control measures for routine care, cleaning, and disinfection of frequently touched surfaces; appropriate handling, transporting, and processing of used linen; proper handling and disposal of needles, scalpels, and other sharp instruments; adequate protection when undertaking patient resuscitation;

respiratory hygiene/cough etiquette; and placement of patients who contaminate the environment in private rooms.

Airborne precautions are used, in addition to standard precautions, in settings where patients are suspected or confirmed to be infected by agents transmitted by airborne droplet nuclei. The essential elements of airborne precautions include preferably placing patients in an airborne infection isolation room (AIIR) that has monitored negative air pressure (if necessary, it is possible to use cohorting of patients with the same active infections); use of mask respirators (N-95 air-purifying respirators); and limiting patient movement and transport from the room (placing a surgical mask on the patient if they are being moved for an essential purpose). An example of an infectious disease for which patients are recommended to be placed under airborne precautions is a patient in hospital with measles through the fourth day of rash. Although isolation of patients with measles not in hospital is not practical in the general population, schoolchildren should remain out of school until at least the fourth day of rash.

Droplet precautions are used, in addition to standard precautions, in settings where patients are suspected or confirmed to be infected by agents transmitted by droplets. The essential elements of droplet precautions include placement of patients in a private room (if necessary, it is possible to use cohorting of patients with the same active infections or maintaining a spatial separation of at least 3 feet between the infected patient and other patients and visitors); use of a mask when working within 3 feet of the patient; and limiting patient movement and transport from the room (placing a surgical mask on the patient if they are being moved for an essential purpose). Examples of infectious diseases for which patients are recommended to be placed under droplet precautions include pharyngeal diphtheria caused by *Corynebacterium diphtheriae* and pneumonic plague caused by *Yersinia pestis.*

Contact precautions are used, in addition to standard precautions, in settings where patients are suspected or confirmed to be infected or colonized by agents transmitted by direct or indirect contact. The essential elements of contact precautions include placement of the patient in a private room (if necessary, it is possible to use cohorting of patients with the same active infections); use of gloves when entering the patient’s room and removing them before leaving the room; wearing a gown when entering the patient’s room and removing the gown before leaving the room; limiting

patient movement and transport to essential purposes only; and, when possible, dedicate the use of patient care equipment to a single patient (if necessary, it is possible to use such equipment on a cohort of patients with the same active or colonized infections). Examples of infectious diseases for which patients are recommended to be placed under contact isolation precautions include cutaneous diphtheria caused by *Corynebacterium diphtheriae*, *C. diff* infections caused by the bacterium *Clostridium difficile*, and disseminated herpes simplex caused by herpes simplex virus.

Quarantine of potentially infected persons

Quarantine is the 'Restriction of activities for well persons or animals who have been exposed (or are considered to be at high risk of exposure) to a case of communicable disease during its period of communicability (i.e. *contacts*) to prevent disease transmission during the incubation period if infection should occur' (Heymann 2014).

Two categories of quarantine are as follows (Heymann 2014):

> *Absolute or complete quarantine*: the limitation of freedom of movement of those exposed to a communicable disease for a period of time not longer than the longest usual incubation period of that disease, in such a manner as to prevent effective contact with those not so exposed.
>
> *Modified quarantine*: a selective, partial limitation of freedom of movement of contacts, commonly on the basis of known or presumed differences in susceptibility and related to the assessed risk of disease transmission. It may be designed to accommodate particular situations. Examples are exclusion of children from school, exemption of immune persons from provisions applicable to susceptible persons, or restriction of military populations to the post or to quarters. Modified quarantine includes: *personal surveillance*, the practice of close medical or other supervision of contacts to permit prompt recognition of infection or illness but without restricting their movements; and *segregation*, the separation of some part of a group of persons or domestic animals from the others for special consideration, control or observation; removal of susceptible children to homes of immune persons; or establishment of a sanitary boundary to protect uninfected from infected portions of a population. (Heymann 2014)

Examples of diseases where quarantine may be considered include the following.

Pneumonic plague: people who have been in the same household or in face-to-face contact with patients with pneumonic plague and who do not accept chemoprophylaxis should be placed under *absolute quarantine* with strict isolation, including careful surveillance, for 7 days.
Measles: although absolute quarantine is impractical, a *modified quarantine* is recommended in settings where young children are living in dormitories, wards, or institutions. When measles occurs in such institutional settings, strict *segregation* of infants is recommended.
Lassa fever: close *personal surveillance* of all close contacts is recommended. Such people include those who live or are in close contact with Lassa fever patients as well as laboratory personnel testing specimens from such patients.

Restriction of activities

Controlling infectious disease transmission by restriction of the activities of people in the community who are potentially infectious to others may be appropriate in certain circumstances. Examples include the following:

Individuals with a diarrhoeal disease should be excluded from handling food and caring for patients in hospital, children, and elderly people.
Known carriers of *Salmonella typhi* should be excluded from food-handling and care of patients.
People with staphylococcal disease should avoid contact with debilitated people and infants.
People with rubella should be excluded from school or work for 7 days after the onset of rash and from contact with pregnant women.

Behavioural change

Behaviour change in an infected person to protect others may be difficult to accomplish and often requires continuing education and counselling. However, this should be considered in preventing the transmission of infectious agents in the following situations.

Sexual behaviour

Examples of infectious agents transmitted through sexual activities are discussed in the earlier section on control measures applied to the host and in more detail in Chapter 8.12. Individuals who suspect that they may have a sexually transmitted infection should be encouraged to have health-seeking behaviours. Persons with a sexually transmissible infectious agent should be treated and asked to cooperate with health officials to trace their sexual contacts. Patients with diseases such as lymphogranuloma venereum and syphilis, for example, should refrain from sexual contact until all lesions are healed. HIV-infected individuals should be counselled to treat genital ulcer disease promptly since such disease may increase transmissibility of HIV. Also, HIV-infected people should avoid sexual intercourse with HIV-negative individuals or, if having sexual intercourse with HIV-negative individuals, use methods such as condoms to reduce the risk of transmission. For a more detailed overview of HIV and AIDS see Chapter 8.13.

Intravenous drug use behaviour

In addition to counselling to abstain from intravenous drug use and establishing drug rehabilitation programmes to help individuals who wish to abstain, promoting behaviour change in the use of injection equipment is important. Discouraging the sharing of injection equipment and education on methods for the decontamination of needles and syringes for intravenous drug use reduce risks of transmission of infectious agents through contaminated injection equipment.

Food preparation behaviour

Individuals who should be restricted from handling food (e.g. carriers of *Salmonella typhi*) should be counselled regarding their condition and potential to infect others if they handle food. Food handlers who have an infectious disease that is potentially transmissible through the vehicle-borne means of food should be discouraged from handling food for others. The importance of hand washing, especially after defecation and before handling food, should be stressed.

Other behaviours

Other behaviours that may reduce risk of transmission of infectious agents to other people include the following:

Cough and sneeze behaviour: patients with infectious diseases directly transmitted by droplet spread or airborne transmitted by droplet nuclei (e.g. patients with sputum-positive tuberculosis) should cover their mouth and nose when coughing or sneezing.
Avoidance of contaminated drinking water: people suffering from dracunculiasis should avoid entering a source of drinking water if they have an active ulcer or blister.
Avoidance of vector bites: patients with the vector-borne disease of African trypanosomiasis (sleeping sickness) with trypanosomes in their blood should prevent tsetse flies from biting.
Avoidance of donating organs or bodily fluid by certain people: individuals who are infected with HIV or who have sexual and other behaviours that have placed them at increased risk for HIV infection should not donate blood, plasma, tissues, cells, semen for artificial insemination, or organs for transplantation.

Control measures applied to animals

A zoonosis is any infectious agent or infectious disease that may be transmitted under natural conditions from vertebrate animals, both wild and domestic, to humans. A detailed approach to zoonoses is given in the comprehensive work *CRC Handbook Series in Zoonoses* (Beran and Steele 1994). In the control of zoonoses many approaches are used that are applied to animals, including the following.

Active immunization

Active immunization, or vaccination, of selected animals may protect susceptible animal hosts from certain infectious diseases. This protection of animals, in turn, prevents susceptible humans from exposure to the infectious agent of those diseases from animals. An example of an infectious disease in animals in which some control can be achieved through immunization in selected animal populations is rabies. The

reservoir of the rabies virus is varied and includes dogs, foxes, wolves, skunks, raccoons, and bats. Preventive measures include efforts to vaccinate all dogs.

Other examples of immunization of animals under certain conditions include: (1) immunization of young goats and sheep using a live attenuated strain of *Brucella melitensis* and calves using a strain of *Brucella abortus* in areas of high endemicity for brucellosis; and (2) immunization of animals at risk for acquiring infection with *Bacillus anthracis* that could be transmitted to man causing anthrax.

Restriction or reduction

Restriction is the limiting of the movement of animals and includes isolation and quarantine. Reduction is the killing, known as culling, of selected animals. Selective use of restriction of animals or reduction of animal populations that are infected, or potentially infected, with a zoonotic infectious agent are methods used to decrease or eliminate the opportunity of exposure of susceptible humans, or other animals, to such animals.

The example of rabies can also be used to illustrate the use of restriction or reduction of an animal population to help control an infectious disease. Heymann (2014) recommends the following measures:

Preventive measures

Register, licence, and vaccinate all owned dogs, and other pets when feasible, in enzootic countries; control ownerless animals and strays. Educate pet owners and the public on the importance of local community responsibilities (e.g. pets should be leashed in congested areas when not confined on the owner's premises; strange-acting or sick animals of any species,—domestic or wild—should be avoided and not handled; animals that have bitten a person or another animal should be reported to relevant authorities, such as the police/local health departments; if possible, such animals should be confined and observed as a preventive measure; and wildlife should be appreciated in nature and not be kept as pets). Where animal population reduction is impractical, animal contraception and repetitive vaccination campaigns may prove effective.

Detain and observe for 10 days any healthy-appearing dog or cat known to have bitten a person (stray or ownerless dogs and cats may be euthanized and examined for rabies by fluorescent microscopy); dogs and cats showing suspicious clinical signs of rabies should be euthanized and tested for rabies.

Euthanize unvaccinated domestic animals bitten by known rabid animals; if detention is elected, hold the animal in a secure facility for at least 6 months under veterinary supervision, and vaccinate against rabies 30 days before release. If previously vaccinated, booster immediately with rabies vaccine, and detain for at least 45 days.

Cooperate with wildlife conservation authorities in programmes to reduce the carrying capacity of wildlife hosts of sylvatic rabies, and to reduce exposures to domestic animals and human populations—such as in circumscribed enzootic areas near campsites, and in areas of dense human habitation (Heymann 2014).

Epidemic (epizootic) measures

In urban areas of industrialized countries, strict enforcement of regulations requiring collection, detention and euthanasia of ownerless and stray dogs, and of non-immunized dogs found off owners' premises; control of the dog population by castration, spaying or drugs have been effective in breaking transmission cycles (Heymann 2014).

Other measures

Other examples of restricting or reducing of animal populations include the following:

Rat-proofing dwellings and reduction of the rat population to prevent rat bites that may transmit the infectious agents *Streptobacillus moniliformis* and *Spirillum minus* causing the rat-bite fevers of streptobacillosis and spirillosis, respectively.
Rat suppression by poisoning (after achieving flea control) in rodent populations with a high potential for epizootic plague.
Elimination of animals infected with *Brucella abortus*, *Brucella melitensis*, *Brucella suis*, and *Brucella canis* by segregation or slaughter to prevent brucellosis.
Slaughtering dairy cattle that test positive for infection with *Mycobacterium bovis*, the infectious agent of bovine tuberculosis.

Chemoprophylaxis and chemotherapy

Chemoprophylaxis of an animal is using chemical substances (e.g. antibiotics) that prevent infection or its progression to clinically manifest infectious disease in the animal. Chemotherapy of an animal is using these chemical substances to treat an infectious disease in an animal. Both chemoprophylaxis and chemotherapy are control measures that may be used to reduce or prevent the opportunity of an infectious agent from being transmitted from an animal to susceptible humans. However, caution should be applied in the routine use of chemoprophylaxis in cattle, feed lots, and poultry farms that can promote the emerging of drug resistance and its associated problems in humans as well.

Psittacosis is an example of a zoonosis controlled by chemoprophylaxis or chemotherapy in selected animal populations. The infectious agent, *Chlamydia psittaci*, may be directly transmitted to humans from infected birds when the dried droppings, secretions, or dust from the feathers of such infected birds are inhaled. Imported psittacine species of birds should be placed under quarantine and receive an appropriate antibiotic chemotherapeutic regimen such as chlortetracycline administered in their feed for 30 days.

Another example is chemoprophylaxis in selected dogs at high risk of infection with *Echinococcus granulosus*. This infectious agent can be

transmitted to humans through hand-to-mouth transmission of the tapeworm eggs from dog faeces causing echinococcosis due to *Echinoccus granulosus*, or cystic hydatid disease. Such high-risk dogs should periodically receive antihelminth treatment with a chemotherapeutic agent such as praziquantel (Biltricide®).

Control measures applied to the environment

Control measures applied to the environment are designed to interrupt the routes of transmission by which an infectious agent may be spread through the environment. Just as the routes of transmission are varied, so, too, are the control methods that can be applied. Control measures that affect transmission that can be applied to the host, agents, vectors, infected humans, and other animals are reviewed elsewhere in this chapter. Environmental factors may also have a direct impact on the host, agent, or vector. For example, low humidity may predispose to certain infections due to a greater permeability of mucous membranes in the host; cold, dry climates inhibit development of the infective larvae agent of hookworm disease; and higher altitudes and colder climates limit habitats of the mosquito vector.

The recognition of the relationship between disease and filth led to a sanitary revolution in industrialized countries that markedly reduced infectious diseases even before the arrival of the antibiotic era. Improved methods for storing and preserving food, better housing, and smaller families with a resultant decrease in the risk of infections at an early age all contributed to reductions in infant and child mortality rates.

This section focuses on general environmental control measures not mentioned elsewhere. Some of these methods, such as provision of safe water, have the potential to prevent several different infectious diseases and significantly reduce rates of disease in the community.

Provision of safe water

It has been estimated that some 663 million still lack safe drinking water in 2015 (WHO and United Nations Children’s Fund 2015). Contaminated drinking water, sometimes the result of poorly designed or maintained

systems of sewerage, may lead to the water-borne indirect transmission of such infectious agents as *Giardia lamblia* causing giardiasis, pathogenic serotypes of *Salmonella* causing salmonellosis, and *Cryptosporidium* species causing cryptosporidiosis.

Purification of water can occur though natural methods or human intervention. Examples of natural methods that contribute to water purification include the processes of evaporation and condensation, filtration through the earth, plant growth, aeration, and reduction and oxidation of organic material by bacteria. Purification of water for public consumption is conventionally done through such processes as coagulation of colloids by aluminium salts (such as aluminum sulfate, or alum) or with other techniques; filtration through such materials as coal, sand, or diatomaceous earth; and disinfection with such chemicals as chlorine derivatives. In special situations, boiling and distillation can be used for purification (Solomon et al. 2009).

Proper disposal of faeces

It has been estimated that some 2.4 billion people in the developing world do not have an adequate system for proper disposal of faeces with some 946 million people practising open defecation (WHO and United Nations Children's Fund 2015). Infectious agents in faeces that may result in infectious diseases include poliovirus causing poliomyelitis; *Shigella dysenteriae*, *Shigella flexneri*, *Shigella boydii*, and *Shigella sonnei* causing shigellosis; and *Entamoeba histolytica* causing amoebiasis.

Infectious agents in faeces may be transmitted by the direct transmission route (including the faecal–oral mode), the vehicle-borne route (including water as noted in the previous section), and the vector-borne route (including the simple mechanism of flies carrying infected faeces on their feet). Public health environmental control measures to interrupt these routes of transmission by ensuring the proper disposal of faeces include the following:

Appropriate on-site disposal through such means as properly constructed sanitary privies in rural areas with no sewerage systems.
On-site disposal of domestic wastewater (such as use of septic tanks or cesspools).
Sewerage systems with treatment of wastewater. Such treatment may include preliminary treatment, sedimentation, chemical coagulation and flocculation, biological treatment (such as activated sludge units and trickling filters), stabilization ponds, sludge management, and disinfection (usually with chlorine) of effluents discharged into drinking, bathing, or shellfish-growing waters.

The importance of personal health-promoting behaviours of using toilets, keeping toilets clean, and hand washing after defecation are a part of control efforts aimed at the proper disposal of faeces.

Food sanitation

Food-borne infectious diseases remain a problem in both industrialized and developing countries. In the United States in 2011 alone, it is estimated that some 48 million people became ill, 128,000 were hospitalized, and 3,000 died of food-borne-related diseases (CDC 2012a). Significant food-borne outbreaks and sporadic cases continue to occur due to such factors as the following:

Contamination of meat, poultry, and eggs with infectious agents, including pathogenic serotypes of *Salmonella*, *Yersinia pseudotuberculosis* and *Yersinia entercolitica*, and *Listeria monocytogenes.*
Contamination of vegetables, especially lettuce and leafy green vegetables, with the infectious enterohaemorrhagic strain of *Escherichia coli* O157:H7. Other outbreaks in fruits, juices, and vegetables have been due to contamination with hepatitis A and pathogenic serotypes of salmonella.
Problems in food storage, handling, and preparation in commercial eating places and in homes.
Larger and more centralized production and processing facilities, coupled with increasingly extensive distribution networks, which may result in transmission of infectious agents to many people if a commercial product becomes contaminated.

Industrialized countries have significantly reduced the transmission of some infectious agents through major public health programmes in food sanitation, including: (1) inspecting eating and drinking establishments, (2) inspecting meat and poultry, (3) improving shellfish sanitation, and (4) promoting adequate cooking, canning, and refrigeration methods. Some cities and counties have instituted restaurant grading systems based on inspection reports, including required public display of the restaurant’s grade as a guide for consumers.

Examples of vehicle-borne indirect transmission of infectious agents through food that can be controlled though a comprehensive public health food sanitation programme include the following:

Pathogenic serotypes of *Salmonella* transmitted by ingesting food made from infected animals or contaminated by the infectious agent in faeces that may cause salmonellosis. Methods of control—preventive measures: ‘a) handwashing before, during and after food preparation; b) refrigerating prepared foods in small containers; c) thoroughly cooking all foodstuffs derived from animal sources, particularly poultry, pork, egg products, and meat dishes; d) avoiding recontamination within the kitchen after cooking is completed; and e) maintaining a sanitary kitchen and protecting prepared foods against rodent and insect contamination’ (Heymann 2014).

Staphylococcus aureus causing staphylococcal food intoxication by ingesting food containing the staphylococcal enterotoxin. Methods of control—preventive measures: ‘Reduce food-handling time (from initial preparation to service) to a minimum, no more than 4 hours at ambient temperature. If foods are to be stored for more than 2 hours, keep those that are perishable hot (above 60°C/140°F) or cold (below 5°C/41°F), in shallow containers, and covered’, ‘Temporarily exclude people with boils, abscesses and other purulent lesions of hands, face or nose from food handling’ (Heymann 2014).

Trichinella spiralis transmitted by ingesting raw or improperly cooked meat or meat products, mainly pork, containing infectious encysted larvae that may cause trichinosis. Methods of control—preventive measures:

1. Educate the public on the need to cook all fresh pork and pork products and meat from wild animals at a temperature and for a time sufficient to allow all parts to reach at least 71°C (160°F), or until meat changes from pink to grey, which allows a sufficient margin of safety. This should be done unless it has been established that these meat products have been processed either by heating, curing, freezing, or irradiation adequate to kill trichinae.
2. Grind pork in a separate grinder, or clean the grinder thoroughly before and after processing other meats.
3. Adopt regulations to encourage commercial irradiation processing of pork products. Testing carcasses for infection with a digestion technique is useful, as is immunodiagnosis of pigs with an approved ELISA test.
4. Adopt and enforce regulations that allow only certified trichinae-free pork to be used in raw pork products that have a cooked appearance, or in products that are traditionally not heated sufficiently in final preparation to kill trichinae.
5. Adopt laws and regulations to require and enforce the cooking of garbage and offal before feeding to swine (Heymann 2014).

Milk sanitation

Milk may be a vehicle for indirect transmission of such infectious agents as: *Mycobacterium bovis* causing tuberculosis, *Corynebacterium diphtheriae* causing diphtheria, *Listeria monocytogenes* causing listeriosis, and *Campylobacter jejuni* and *Campylobacter coli* causing *Campylobacter* enteritis.

Public health control measures to break the chain of transmission of infectious agents through milk include:

Mechanization and sanitization of milking processes.
Refrigeration of milk to inhibit bacterial growth.
Pasteurization of milk through high-temperature short-time, batch, ultra-pasteurization, or ultra-high-temperature methods that help to kill any bacteria from the cow or others that may have come into direct contact with milk during the milking and handling process.
Monitoring milk quality by testing for bacteria using a standard bacterial plate count, by testing for density of coliform organisms, and by use of the phosphatase test to assay for pasteurization.
Periodically testing cows for tuberculosis and brucellosis.

The use of raw milk for human consumption may result in outbreaks. A study showed that some 60% of dairy-related outbreaks reported to the CDC between 1993 and 2006 were associated with raw milk products (CDC 2012b). It should be noted that post-pasteurization contamination of milk may also result in outbreaks of milk-borne diseases.

Design of facilities and equipment

The design and proper maintenance of buildings, rooms, and equipment can help break the chain of transmission of infectious agents. Laminar airflow hoods in laboratory workbenches, ventilation systems in hospitals, and disposable intravenous equipment are examples of systems designed to reduce risk of transmission. Routine maintenance needed to retain the original design standards for control of transmission of infectious agents include: (1) replacement of air filters, (2) cleaning of cooling towers, (3) monitoring of negative and positive pressure rooms and their airlocks, and (4) replacement of in-dwelling peripheral venous catheters.

Examples of infectious agents whose transmission can be reduced through proper design and maintenance include the following:

Legionella species, the infectious agents responsible for legionellosis, are usually transmitted through airborne transmission via aerosol production. Transmission of the agent from cooling towers can be reduced by periodically cleaning off any scale or sediment, routinely using biocides to kill slime-forming organisms, and draining such towers when not in use.
Staphylococcus aureus, the infectious agent responsible for staphylococcal disease in medical and surgical wards of hospitals, can be controlled by enforcing strict aseptic technique, including procedures to change intravenous infusion sites at least every 48 hours and replace in-dwelling peripheral venous catheters every 72 hours.
Bacillus anthracis, the infectious agent responsible for anthrax, can be transmitted, among other ways, through inhalation of anthrax spores. Proper design of industrial plants that handle raw animal fibres includes providing facilities for adequate ventilation and control of dust, washing, and changing clothes after work, and eating away from the places of work.

Other methods

In addition to the environmental methods of control of transmission of infectious agents already mentioned, the following are other methods, some specific and some general, that should also be noted.

Improvement of housing conditions to *reduce crowding* (as measured by the number of people per room and not total population density). Reduction in crowding is a general measure that can reduce the transmission of infectious agents, especially direct transmission from direct contact or direct projection (droplet spray).

Improvement in working conditions can affect the risk of infectious disease. For example, control of particulate matter by proper ventilation in occupations such as textile mill workers, metal grinders, and pottery factory workers can reduce inflammation of the lungs and thus decrease the risk of developing tuberculosis. Excessive physical exertion and the stress of exhausting work can also increase the risk of tuberculosis.

Improved *irrigation* and agricultural practices and *removing vegetation* or *draining and filling* of snail-breeding sites can reduce or eliminate the freshwater snail hosts of such infectious agents as *Schistosoma mansoni*, *Schistosoma haematobium*, and *Schistosoma japonicum* that cause schistosomiasis in humans.

Adequate screening of blood, serum, plasma, tissues, or organs can break the chain of vehicle-borne transmission from such biological products. Examples include screening for hepatitis B surface antigen and HIV antibodies in donated blood to prevent transmission of hepatitis B and HIV, respectively.

Installation of *screened living and sleeping quarters* and use of *bednets*, including bednets impregnated with a synthetic pyrethroid such as permethrin, can reduce exposure to mosquitoes infected with the infectious agents of malaria.

• Erecting *plexiglass barriers* around student desks or between workers on a food processing line as a measure, in addition to masking, to reduce the risk of droplet spread of SARS-CoV-2 to prevent COVID-19.

Control measures applied to the agent

Control of some infectious diseases can be achieved through means that remove the infectious agents from the environment or inactivate the agents. Physical measures (such as heat, cold, ultraviolet light, and ionizing radiation) and chemical measures (such as liquid disinfectants and

antiseptics, gases, and chlorination) can be used. Examples of control measures applied to infectious agents include the following:

Cleaning is the removing of infectious agents from surfaces through such physical actions as vacuum cleaning or washing and scrubbing using soap or detergent and hot water. Cleaning also helps remove organic materials that might support the growth or survival of infectious agents.
Cooling may inhibit bacterial multiplication and some infectious agents, such as *Trichinella* cysts and *Taenia solium* larvae (cysticerci), can be killed by freezing temperatures.
Pasteurization is heating to a temperature of 75°C/167°F for 30 minutes to kill pathogenic vegetative bacteria. It does not inactivate bacterial spores. Pasteurization is a commonly used process to help ensure safety of milk and to prolong its storage quality.
Disinfection is the reduction or killing of vegetative harmful bacterial infectious agents outside the body or on objects. Disinfection may not inactivate all bacterial spores and viruses. *Disinfectants* are used to eliminate pathogenic bacteria from the skin surface and from contaminated inanimate surfaces and include: (1) alcohols, (2) halogens such as iodine and chlorine, (3) surface active compounds such as the quaternary ammonium compound benzalkonium chloride, (4) phenolics, and (5) alkylating agents such as glutaraldehyde and formaldehyde. *Antiseptics* are a class of disinfectant that can be applied on body surfaces; they have a lower toxicity than environmental disinfectants and are usually less effective in killing microorganisms.
Sterilization is the complete removal or killing of all infectious agents in, or on, an object. Sterilization of equipment for surgery and wound dressings; parenteral administration of drugs, vaccines, or nutrients; catheterization; and dental work are all important means of controlling infectious diseases by killing infectious agents. Sterilization can be accomplished through use of fire, pressurized steam (such as in an autoclave), heated air, certain gases (such as ethylene oxide), ultraviolet light, ionizing radiation, liquid chemicals, and filtration. The method of sterilization chosen depends on the type of equipment to be sterilized.

The use of sterilized *disposable equipment*, such as disposable needles, syringes, and catheters, has the potential to reduce the risk of transmission

of infectious agents. However, it must be assured that such equipment is disposed of properly and is not reused. For example, disposable syringes cannot be properly resterilized because the plastic from which they are made cannot withstand the heat necessary for sterilization. Technologies, such as the single-use disposable needle and syringe developed for immunization programmes, help assure such disposable equipment is not reused.

Control and prevention programmes

The preceding sections have considered the issues and given examples of control measures for infectious diseases at individual, institutional, and community levels and the tools for control directed at the host, routes of transmission, and the agent. Control and prevention programmes using these tools must be developed according to a number of factors including: (1) the risk of disease; (2) the magnitude of disease burden (as measured by mortality, degree of disability, morbidity, and economic costs); (3) the feasibility of control strategies; (4) the cost of control measures; (5) the effectiveness of such measures (on current levels of disease and impact on future cases or outbreaks); (6) the adverse effects or complications of the control measures; and (7) the availability of resources. Public health planning for the control of infectious diseases must consider these issues to design optimal, evidence-based control and prevention programmes.

The tools of disease surveillance for recognition and evaluation of the patterns of disease can provide information on the risk and magnitude of disease burden to individuals, people in institutions, subgroups of populations, and the community at large. Establishment and maintenance of the infrastructure for surveillance, including a system for the reporting of notifiable infectious diseases and unusual events, must be a high priority.

Feasibility of possible control and prevention strategies must be assessed through operational research, pilot projects, or from field experience. The fact that a particular measure can help control a disease does not mean it can be applied on a sufficient scale to have the desired impact. The cost of control activities (in both human and material resources) can be assessed through costing studies that can also provide the data needed to conduct more rigorous cost–benefit and cost-effectiveness analyses. A costly

measure, even if it provides a high degree of control for an infectious disease, may not be affordable to the society or reasonable to apply in the light of other less expensive alternative strategies. For example, use of sterile, disposable products may be costlier than reusable, sterilizable products. Effectiveness of control measures may be assessed through epidemiological studies to find out their impact on reduction in the incidence or prevalence of disease.

The availability of resources for prevention and control programmes forces public health planners to set priorities by taking into account all these factors and then designing programmes that have maximum impact within available resources. Planners have a responsibility to mobilize additional necessary resources by raising public awareness and generating political will. Effective communication of disease burden and the results achievable through well-managed and effective control programmes can be a powerful tool for advocacy. Ideally, communities or their representatives should actively participate in the planning, execution, and evaluation of public health programmes.

Prevention effectiveness is 'the measure of the impact on health (including effectiveness, safety and cost) of prevention policies, programmes, and practices. The assessment of prevention effectiveness is the ongoing process of applying evaluation tools to prevention practices' (CDC 1995). Recognizing that systems for assessing the effectiveness of prevention strategies (including prevention strategies for infectious diseases) are weak or non-existent in both developing and industrialized countries alike, the CDC has suggested the following objectives for prevention effectiveness activities: 'evaluate the impact of prevention, use results of evaluation research to establish programme priorities, and establish or apply standardized methods to compare the benefits and effectiveness of alternative prevention strategies' (CDC 1995).

The current situation of *international migration* of many people worldwide presents an additional complexity to the design of programmes for the control of infectious diseases. Pertinent issues include refugee camps, legal status of migrants in recipient countries, and temporary return migration. Public health officials must consider the most effective mix of combined control measures applied to the host, agent, and routes of transmission when designing suitable control and prevention programmes (Gellert 1993). Particularly in terms of humanitarian emergencies, whether

due to human violence or natural disaster, crowding can make diseases such as measles, acute respiratory infections (ARI)s and meningitis of particular concern for groups of displaced persons (Heymann 2014). A recent statement by the American Society of Tropical Medicine and Hygiene's Executive Committee calls for US migration policy to be evidence-based, compassionate, and maintain international human rights law. They further argue that investment in the health needs of the world's vulnerable populations is beneficial not only to these affected populations, but to the United States as well, as infectious diseases are a global issue (Rosenthal et al. 2017).

International commerce and transportation are important areas of concern for public health infectious disease control programmes, especially as the speed of travel has increased. The tools of control include such measures as:

Spraying insecticides effective against mosquito vectors of malaria in aircraft before departure, in transit, or on arrival.
Rat-proofing or periodic fumigation to control rats on ships, docks, and warehouses to prevent plague.

Specific international control measures relating to aircraft, ships, and land transportation for infectious diseases are detailed in the *International Health Regulations (2005)* (WHO 2005).

The challenge facing infectious disease control programmes is to design an optimal set of interventions at local, institutional, community, national, and international levels supported and accepted by the political leadership and the people to whom these measures are applied.

Eradication

A unique end point in the control of infectious diseases is that of eradication. Eradication is the cessation of all transmission of an infectious agent by extermination of that agent. To date, only one human infectious disease, *smallpox*, and one animal infectious disease, rinderpest, have been eradicated. The WHO World Health Assembly in May 1980 confirmed its global eradication some 3 years after the last naturally acquired case of

smallpox in October 1977 (Fenner et al. 1988). The magnitude of this accomplishment is appreciated when one realizes that, in the early 1950s, it was estimated that 50 million cases of smallpox still occurred each year in the world, some 150 years after Edward Jenner had performed the first vaccination and wrote: ‘it now becomes too manifest to admit of controversy, that the annihilation of the Small Pox, the most dreadful scourge of the human species, must be the final result of this practice’ (Fenner et al. 1988). Rinderpest (known as cattle plague or steppe murrain) was an infectious viral disease of cattle and some other even-toed ungulates, that was associated with a high mortality rate. In 2011, after widespread vaccination campaigns, the United Nations declared the disease eradicated.

The goal of global eradication has been set by the World Health Assembly for two other infectious diseases, poliomyelitis caused by wild poliovirus and dracunculiasis (Guinea worm infection), the latter caused by the infectious agent *Dracunculus medinensis*. A high level of sustained political will, aggressively applied disease surveillance, and effective control measures are the required elements to achieve eradication of the infectious agents for these diseases.

Impressive progress has been made towards the global *eradication of poliomyelitis* since the 1988 World Health Assembly set the goal for its eradication. Polio cases have decreased by over 99% since that date, from some 350,000 cases in over 125 countries to only 22 reported cases in 2017. In 2018, only parts of three countries in the world (Nigeria, Pakistan, and Afghanistan) remain endemic for the disease (WHO 2018). Poliomyelitis control measures that will lead to eradication include the following:

Achieving and maintaining high levels of routine coverage of infants with at least three doses of oral polio vaccine.
Mass application of oral polio vaccine in countries where poliomyelitis is endemic through national immunization days, usually by providing oral polio vaccine to every child less than 5 years of age twice each year, separated by 4–6 weeks, and conducted during the low season of poliovirus transmission.
‘Mopping-up’ operations after the use of national immunization days has reduced transmission of disease to defined focal geographic areas, usually by providing oral polio vaccine house-to-house to all children less than 5 years of age on two occasions separated by 4–6 weeks.
Aggressive action-oriented surveillance for acute flaccid paralysis. Such surveillance includes: (1) case investigation, (2) a laboratory network for isolation and characterization of polio-viruses in suspect cases of poliomyelitis and people in close contact with them, and (3) limited outbreak response immunization providing one house-to-house round of oral polio vaccine to children less than 5 years of age living in the same village or neighbourhood of the patient.

Significant strides in the *eradication of dracunculiasis* have also been made. Over the last three decades the total number of dracunculiasis cases has declined by more than 99%. In 2017, only 30 cases were reported from just two countries, Chad and Ethiopia (WHO 2018a). Dracunculiasis control measures that are leading to its ultimate eradication include the following:

Establishing a national programme office, conducting baseline surveys, and preparing and refining a national plan of action.
Educating the population in endemic areas that the source of Guinea worm comes from their drinking water.
Ensuring that people with blisters or emerging worms do not enter sources of drinking water through behaviour changes and by converting step-wells into draw-wells.
Promoting the boiling or filtering of water through a fine mesh cloth to remove copepods. Treating drinking water with chlorine or iodine will also kill the copepods and infective larvae.
Providing non-infected water through construction of wells or rainwater catchments.
In selected endemic villages, controlling copepod populations with temephos (Abate®) insecticide placed in reservoirs, tanks, ponds, and step-wells.
Implementing an intensified surveillance and aggressive case-containment strategy as programmes get close to achieving eradication.

The eradication of a disease requires a unique set of conditions, including the following: (1) a defined, accessible reservoir of the infectious agent; (2) affordable and effective control measures that can interrupt the chain of infection directed at the host, agent, or route of transmission; and (3) a surveillance mechanism adequate to monitor and ultimately certify the disappearance of the infectious agent.

It is likely that measles may be targeted for global eradication in the future. Some countries and geographic regions have already targeted measles for elimination—a term sometimes used to describe the eradication of a disease from a large geographic area. Other diseases that may potentially be targeted for eradication in the future include: mumps, rubella, hepatitis B, leprosy, and diphtheria.

Emerging infectious diseases

New, emerging, and re-emerging infectious diseases have become a focus for the attention of public health prevention and control programmes in both industrialized and developing countries. Such infectious diseases have

thwarted any expectation that infectious diseases will soon be eliminated as public health problems and resulted in a widening spectrum of diseases, many of which were once thought to be almost conquered. Krause has reflected on this as follows:

> Bacteria reproduce every 30 minutes. For them, a millennium is compressed into a fortnight. They are fleet afoot, and the pace of our research must keep up with them, or they will overtake us. (Krause 1998)

Many factors contribute to the emergence of new or re-emergence of those previously known (Lederberg et al. 1992; CDC 1994; Murphy 1994), including the following:

Human *demographic change* by which people begin to live in previously uninhabited remote areas of the world and are exposed to new environmental sources of infectious agents, insects, and animals.
Breakdowns of sanitary and other public health measures in overcrowded cities and in situations of civil unrest and war.
Economic development and changes in the use of land, including deforestation, reforestation, and urbanization.
Climate change, including global warming, which may extend the favourable habitats for vectors such as mosquitoes.
Other *human behaviours*, such as increased use of child-care facilities, sexual and drug use behaviours, and patterns of outdoor recreation.
International travel and commerce that quickly transport people and goods vast distances.
Changes in food processing and handling, including foods prepared from many different individual animals and transported great distances.
Evolution of pathogenic infectious agents by which they may infect new hosts, produce toxins, or adapt by responding to changes in the host immunity.
Development of resistance of infectious agents such as *Mycobacterium tuberculosis* and *Neisseria gonorrhoeae* to chemoprophylactic or chemotherapeutic medicines.
Resistance of the vectors of vector-borne infectious diseases to pesticides.
Immunosuppression of people due to medical treatments or new diseases that result in infectious diseases caused by agents not usually pathogenic in healthy hosts.
Deterioration in surveillance systems for infectious diseases, including laboratory support, to detect new or emerging disease problems at an early stage.

Examples of emerging infectious disease threats include the following:

Coronavirus disease 2019 (COVID-19) a severe acute viral respiratory illness caused by the the coronavirus SARS-CoV-2 was first identified in December 2019 in Wuhan, China. It clearly demonstrates the ability for a previously unknown virus with an animal origin (bat) to cross species and create a pandemic killing millions of susceptible people.

Toxic shock syndrome, due to the infectious toxin-producing strains of *Staphylococcus aureus*, illustrates how a new technology yielding a new product, super-absorbent tampons, can create the circumstances favouring the emergence of a new infectious disease threat.

Lyme disease, due to the infectious spirochete *Borrelia burgdorferi*, illustrates how changes in the ecology, including reforestation, increasing deer populations, and suburban migration of the population, can result in the emergence of a new microbial threat that has now become one of the most prevalent vector-borne disease in the United States.

Shigellosis, giardiasis, and hepatitis A are examples of emerging diseases that have become threats to staff and children in child-care centres as the use of such centres has increased due to changes in the work patterns of societies.

Opportunistic infections, such as *Pneumocystis* pneumonia caused by *Pneumocystis jirovecii* (formerly *carinii*), chronic cryptosporidiosis caused by *Cryptosporidium* species, and disseminated cytomegalovirus infections, illustrate emerging disease threats to the increasing number of people who are immunosuppressed because of cancer chemotherapy, organ transplantation, or HIV infection.

Food-borne infections such as diarrhoea caused by the enterohaemorrhagic strain O157:H7 of *Escherichia coli* and water-borne infections such as gastrointestinal disease due to *Cryptosporidium* species are examples of emerging disease threats that have arisen due to such factors as changes in diet, food processing, globalization of the food supply, and contamination of municipal water supplies.

Hantavirus pulmonary syndrome first detected in the United States in 1993 and caused by a previously unrecognized hantavirus illustrates how exposure to certain kinds of infected rodents can result in an emerging infectious disease.

Nipah virus disease first detected in Malaysia in 1999 and caused by a previously unrecognized Hendra-like virus demonstrates how close contact with fruit bats and pigs can result in an emerging infectious disease.

Severe acute respiratory syndrome (SARS), a viral respiratory illness caused by the SARS-associated coronavirus (SARS-CoV) that was first reported in Asia in February 2003 and spread to more than 20 countries in North America, South America, Europe, and Asia affecting over 8,000 people and killing over 700 before the SARS global outbreak was contained in 2004, shows the need for continued vigilance in surveillance and outbreak response capacity (WHO 2003).

The emergence of the novel influenza A virus in birds, highly pathogenic avian influenza (H5N1), that has occasionally infected humans is an example of an antigenic shift in an influenza virus that, should it develop into a form easily transmissible from human to human, could potentially lead to a pandemic.

Middle East respiratory syndrome (MERS), a viral respiratory disease caused by a novel coronavirus (MERS-CoV) was first identified in Saudi Arabia in 2012. There have been 1,888 laboratory-confirmed cases and 670 deaths since 2012. It is an example of a virus that had infected an animal reservoir (camel) for over 20 years before being noted in humans (Cotton et al. 2014). The majority of cases (>85%) and deaths have been reported in the Arabian Peninsula. The virus was exported and resulted in the largest outbreak outside the region of origin, in South Korea, in 2015.

Ebola virus disease (EVD), a viral haemorrhagic fever that was first discovered in 1976 in the Democratic Republic of Congo and Sudan, was responsible for an outbreak of unprecedented magnitude it was discovered for the first time in West Africa in 2014. It is an example of a major outbreak of a disease that had been previously confined to more geographically isolated areas. There have been over 11,000 fatalities and the outbreak led to individual cases in a number of other countries due to international travel (CDC 2016a).

Zika virus, a vector-borne disease, was first isolated in Uganda in 1947 (Dick et al. 1952), but became a global concern with the outbreak of Zika virus in the Americas beginning in 2015. Zika virus can be transmitted via vector (*Aëdes* mosquitoes), vertical transmission from mother to foetus, via sexual contact or possibly blood transfusion. It is an example of an infectious disease being introduced into large susceptible populations with dramatic numbers of people affected. While cases are typically mild or asymptomatic, the disease can result in birth defects such as microcephaly (CDC 2016b).

Antimicrobial drug resistance as a major factor in the emergence and re-emergence of infectious diseases deserves special attention. Although significant reductions in infectious disease mortality have occurred since the introduction of antimicrobials for general use in the 1940s, antimicrobial drug resistance has emerged because of their widespread use in humans.

Drugs that once seemed invincible are losing their effectiveness for a wide range of community-acquired infections, including tuberculosis, gonorrhoea, pneumococcal infections (a leading cause of otitis media, pneumonia, and meningitis), and for hospital-acquired enterococcal and staphylococcal infections. Resistance to antiviral (e.g. amantadine-resistant influenza virus and aciclovir-resistant herpes simplex), antifungal (e.g. azole-resistant *Candida* species), and antiprotozoal (e.g. metronidazole-resistant *Trichomonas vaginalis*) drugs is also emerging. Drug-resistant malaria has spread to nearly all areas of the world where malaria occurs. Concern has also arisen over strains of HIV resistant to antiviral drugs. Increased microbial resistance has resulted in prolonged hospitalizations and higher death rates from infections; has required much more expensive, and often more toxic, drugs or drug combinations (even for common infections); and has resulted in higher healthcare costs (CDC 1994).

Antimicrobial drug resistance has also emerged because of the use of antimicrobials in domesticated animals. For example, the use of fluoroquinolones in poultry has created a reservoir of quinolone-resistant *Campylobacter jejuni* that has now been isolated in humans. The Food and Drug Administration's Veterinary Feed Directive (VFD) (Final Rule effective 1 October 2015) was put into place to regulate drugs used in animal feeds, and stipulates that VFD drugs must be used only under supervision of a licensed veterinarian (FDA 2015).

An aggressive public health response to these new, emerging, and re-emerging infectious disease threats must be made to characterize them better and to mount an effective response for their control. For example, the 1999 outbreak of West Nile fever in New York City and surrounding areas that, within a 4-year period, spread throughout the United States demonstrates how a viral encephalitis, initially classified as Saint Louis encephalitis and later confirmed to be due to West Nile virus, can reach far beyond its normal setting.

The WHO has outlined the following high-priority areas (WHO 1995):

Strengthen global surveillance of infectious diseases.
Establish national and international infrastructures to recognize, report, and respond to new disease threats.
Further develop applied research on diagnosis, epidemiology, and control of emerging infectious diseases.
Strengthen the international capacity for infectious disease prevention and control.

(Emerging infectious diseases are addressed in detail in Chapter 8.17.)

Bioterrorism: the deliberate use of biological agents to cause harm

Another unfortunate source of an infectious disease threat is the spectre of biological warfare or bioterrorism, especially in an age where terrorist acts are frequent events (Christopher et al. 1997). The 2002 World Health Assembly resolution urges member states ‘to treat any deliberate use, including local, of biological and chemical agents and radionuclear attack to cause harm also as a global public health threat, and to respond to such a threat in other countries by sharing expertise, supplies and resources in order rapidly to contain the event and mitigate its effects’ (WHO 2002).

The WHO recommends the following (WHO 2004):

Public health authorities, in close cooperation with other government bodies, should draw up contingency plans for dealing with a deliberate release of biological or chemical agents intended to harm civilian populations. These plans should be consistent or integral with existing plans for outbreaks of disease, natural disasters, large-scale industrial or transportation accidents, and terrorist incidents.

Preparedness for deliberate releases of biological or chemical agents should be based on standard risk-analysis principles, starting with risk and threat assessment to determine the relative priority that should be accorded to such releases in comparison with other dangers to public health in the country concerned. Considerations for deliberate releases should be incorporated into existing public health infrastructures, rather than developing separate infrastructures.

Preparedness for deliberate releases of biological or chemical agents can be markedly increased in most countries by strengthening the public health infrastructure, and particularly public health surveillance and response, and measures should be taken to this end.

Managing the consequences of a deliberate release of biological or chemical agents may demand more resources than are available, and international assistance would then be essential.

Many countries are developing rapid response capability to deal with such contingencies, especially in the light of the 2001 bioterrorist attack using anthrax in the United States.

Conclusion

Only through worldwide concerted action will the effort to control infectious disease be effective. We are now in an era where, as Nobel Laureate Dr Joshua Lederberg has stated, ‘The microbe that felled one child in a distant continent yesterday can reach yours today and seed a global pandemic tomorrow’ (quoted in CDC 1994). As Hans Zinsser stated over 60 years ago:

> Infectious disease is one of the few genuine adventures left in the world. The dragons are all dead and the lance grows rusty in the chimney corner. . . About the only sporting proposition that remains unimpaired by the

relentless domestication of a once free-living human species is the war against those ferocious little fellow creatures, which lurk in the dark corners and stalk us in the bodies of rats, mice, and all kinds of domestic animals; which fly and crawl with the insects, and waylay us in our food and drink and even in our love (Hans Zinsser 1934, quoted in Murphy 1994).

11.5

Medical screening

Theories, methods, and effectiveness

Tang Jin-ling and Li Li-ming

Introduction

Since the middle of last century, cancer, and cardiovascular disease have overtaken infectious disease as the top killers of human life. Cardiovascular disease can be successfully prevented through modification of risk factors, whereas against cancer we rely largely on early detection and early treatment. On one hand, checks for risk factors of cardiovascular disease has become almost a clinical routine with a hope to prevent severe complications. On the other hand, screening for cancer has rapidly become a widespread medical practice in the past decades. Genetic testing, one of the most exciting scientific breakthroughs in biomedical sciences in the twentieth century, further raised the enthusiasm for screening. Screening in various different disguises has become an important part of modern public health and clinical medicine.

Broadly speaking, screening exists in forms from firmly established and well-planned population screening programmes to ubiquitous use of diagnostic methods for early diagnosis to experiments with new diagnostic methods by individual clinicians in search of silent diseases. Well-organized screening programmes can indeed do more good than harm but the obsessive search of silent diseases may have often caused overdiagnosis and overtreatment. In this chapter, we will discuss the theories, methods, effects, and pitfalls of health screening in both the narrow and broad concepts with an aim to promote appropriate use of disease screening and efficient use of healthcare resources. Cancer will be used most of time as examples to illustrate when necessary.

What is medical screening?

After decades of tremendous efforts fighting against chronic diseases, we have yet to find preventive and therapeutic methods that are as powerful as hygiene, antibiotics, and vaccines used for combating infectious diseases.

Chronic diseases differ from infectious diseases in an important way that it takes years or even decades to become severe enough and cause symptoms, suffering, disabilities, or death. Moreover, rapid advances in biomedical technology, notably in testing and imaging, have made it possible to detect many chronic diseases when they are still asymptomatic. New diagnostic innovations are also applied to identify risk factors of chronic disease for primary prevention. It is further assumed that intervention on risk factors can prevent the occurrence of disease and treatment of silent disease can retard or stop disease progression, improve prognosis, and ultimately reduce suffering and mortality. Early detection and early intervention have formed the foundation for combating chronic disease in modern medicine. In public health, this strategy is known as medical screening, health screening or population screening (Wilson and Jungner 1968; Morrison 1992; NSC 1998; Raffle and Gray 2007).

Screening is defined as the systematic application of a simple test or inquiry to well persons to detect those having a specific preclinical disorder or increased risk of disease for the purpose of early treatment or prevention with an ultimate aim of improving the health of the screened population. In brief, screening is early detection and early intervention aimed to improve health. Figure 11.5.1 uses Pap smears for screening cervical cancer to show the participants flow and main components of a screening programme.

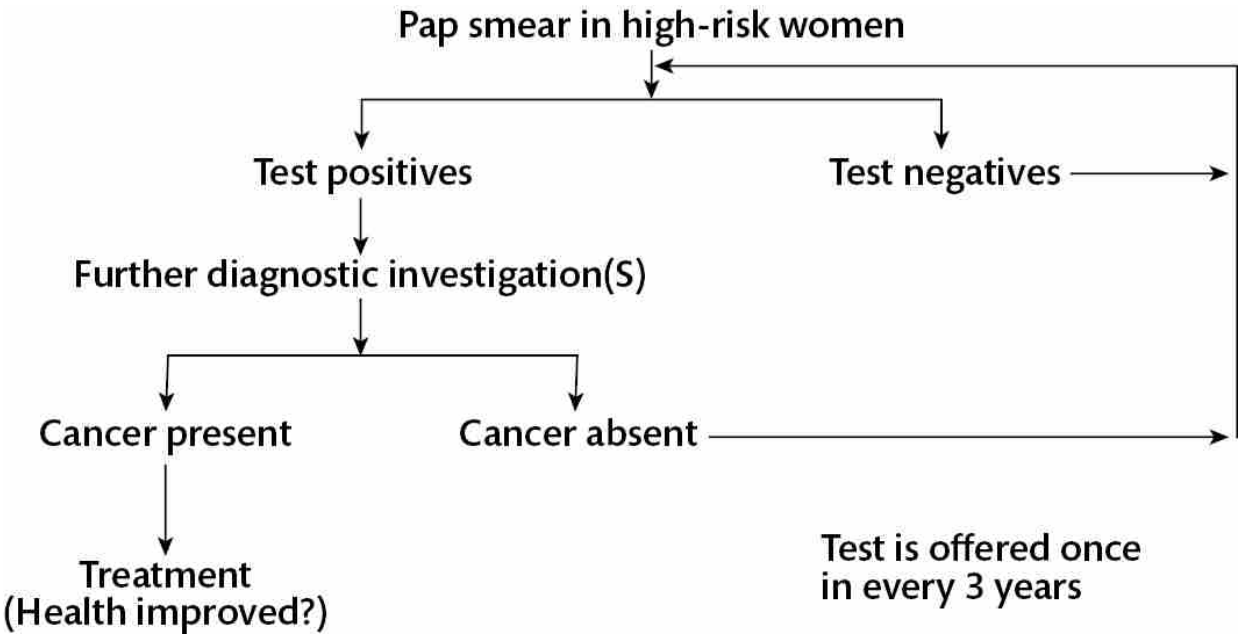

Fig. 11.5.1 Participants flow and components of a screening programme: Pap smear for screening cervical cancer.

Public health tends to emphasize that screening be a systematic approach. Screening is not simply the application of a new test; it is a carefully planned, systematically organized, and regularly repeated, collective effort that combines early detection and early treatment with an ultimate goal of improving those who are screened. 'Systematic' also means that the decisions on issues such as whether or not to screen, who to screen, and how to screen, how to further confirm diagnosis, and how to treat should be carefully determined based on scientific evidence before a screening programme is implemented so as to make sure that it is desired by and will benefit the population to be screened.

The 'test' is referred to a wide range of medical procedures that can be performed in order to detect a risk factor and a silent disease, such as laboratory tests and imaging techniques and endoscopic examinations. The 'inquiry' is referred to an interview or questionnaire used to obtain information about a person's occupational history, family history, disease history, lifestyle, and other information that can be used to estimate current or future risk of disease. Information from tests and inquiries can be used independently or more often in combination to predict the risk of disease, for example, by using scores or multiple regression models such as the Framingham cardiovascular risk equation.

Screening is offered to ‘well persons’ rather than patients. Well persons are not those who are totally free of any disorder. They may have disorders other than the one to be screened for and even the screened disorder but have not sought medical attention on account of symptoms of that disorder. Different from clinical practice, those who are screened are not those who have brought themselves to doctors for suspecting an illness but are those invited by healthcare professionals for checks and inquiries. This is a considerable deviation from the long-practised medical paradigm in which patients only see the doctor when they are sick and thus creates new ethical concerns.

For cancer, screening is mostly targeted at a disease at its preclinical stage. The goal is to prevent more severe complications or death from the disease. Pap smears, mammograms, and faecal occult bleed tests are examples in case. Screening can also be targeted at risk factors for prevention of the first occurrence of disease. For example, smoking, hypertension, hyperlipidaemia, and elevated blood glucose are often checked with a hope to prevent myocardial infarction and stroke through lifestyle and prophylactic interventions on these risk factors.

Although we normally talk about screening for a single disease, a screening programme can be multiphasic and targeted at more than one disease or all major risk factors of a disease at the same time. In this sense, periodical health checks can also be viewed as a kind of screening although with more complexities. Health checks can identify overt diseases. But health checks for silent diseases and risk factors should be assessed with similar scientific rigour and managed with similar standards as we do for screening.

Unlike drugs, a screening programme is a complex intervention with many components. Its potential benefits and harms are determined by multiple factors including the test, further diagnostic investigations, follow-up interventions, and the way they are organized. Screening will fail if any of the major components fail.

Last but not least, screening must be able to achieve the ultimate goal of improving the health of the screened population. Against this goal, many screening programmes and similar efforts may not be justified.

Some historical accounts

The aforementioned section depicts the picture of screening in the eyes of public health workers. However, screening can be a different concept to others including clinicians and the public. In fact, screening did not appear in this exact modern clothe at its onset. Screening is an evolving concept and new ideas are still being proposed and adopted.

Pre-modern screening before 1960

The idea of screening is not new. As early in 1861, Dr Horace Dobell, an eminent British physician recommended that physicians should perform periodic checks on everyone, irrespective of whether they were seeking medical help. In 1990, Dr George Gould, an American physician, argued that ranchers check their cattle, merchants check their stock, accountants check their books, generals check their armies, governments check their budgets, but why physicians do not regularly check the healthy people——and they should. However, their recommendation for regular and non-specific medical examinations of healthy people did not take firm hold immediately.

Historically, it is generally believed that the concept of modern screening originated in early last century from the practice of health checks organized by the army for selecting out those who were unsuited to the needs of the military machine, by insurance companies as a means of selecting premiums, and by large cooperations in selecting suitable employees (Raffle and Gray 2007). Early screening programmes also included testing for infectious disease, for example, tuberculosis, which was typically organized by the government. Most early screening activities, however, did not meet the stringent criteria for modern screening programmes. These criteria for screening are the results of scientific evaluation of health checks and early screening programmes and of better understanding of the natural history of chronic diseases in the past few decades.

In the 1950s, screening was already firmly in place in the United States, whereas it was just beginning in Britain. For example, in 1957, the Commission on Chronic Illness in the United States recommended a wide range of screening, including diabetes, glaucoma, and cancer of the mouth, skin, breast, cervix, and rectum. However, scientific evidence for the effectiveness of screening was lacking and doubts about screening started to mount.

Modern screening era since 1960

In particular, in 1968, two reports were published, one is by the Nuffield Provincial Hospital Trust and the other by the World Health Organization. Both questioned some of the general beliefs of screening. The Nuffield Trust evaluated 10 existing screening or proposed screening activities in the United Kingdom and concluded most of them were ineffective or even harmful. Wilson and Jungner's report for the World Health Organization discussed various aspects of screening and proposed, importantly, 10 criteria a screening programme should meet. They further argued that even if these principles were all met, research was still needed to provide evidence on the benefit, harm, and affordability of a screening programme.

Two randomized controlled trials were established to evaluate the effectiveness of screening, one at Kaiser Permanente in 1964 and the other in South-East London in 1967. Both trials failed to find a positive result on multiple outcomes including death that would support multiphasic screening. Decades later, these early reports and evaluation trials on screening have eventually reoriented the practice of screening from multiphasic health checks to specific disease screening: general health checks are not screening. Today, we have cumulated a great amount of evidence about modern screening and found often it was not effective or marginally effective. But they always cost and have arms.

Screening in the twenty-first century

In the past, screening was decided by experts, delivered as a utilitarian programme, and complied with by dutiful and grateful patients. But things have changed in the twenty-first century. There are pressures for change in screening. Transition away from paternal paradigm of medical care, heightened expectations from patients, right of patients for information, increasing new technologies among other factors have been changing the concepts, principles, and practice of screening.

The concept of screening that was firmly established in the late last century has never been universally accepted without challenges and variations. In fact, the early practice of screening has never truly disappeared; they continue to exist in different covers. In addition, new ideas of detecting silent diseases and checks for risk factors are being developed and adopted by millions of individual healthcare workers without

demonstrated evidence on their benefits and harms. In the name of early diagnosis of disease, many variations of screening truly exist, from experimental use by individual clinicians, to improvised or opportunistic testing in clinics and hospitals, to popular health checks, and to well-organized efficacy-proven screening programmes for specific diseases.

The rapid rise of general health checks with an increasingly large number of items included in it represents a worrying return to the early practice of screening before the 1960s. These new or so-called new ideas and atypical screening activities must also be brought into discussion as they constitute much of the inappropriate or even bad practice of screening and their effectiveness is uncertain. We should know what bad screening activities are like so we can prevent them from being introduced. It is particularly difficult to stop an ineffective intervention once they are already in practice. For example, prostate-specific antigen (PSA) was first introduced in the late 1980s in Western countries and is now still widely used although it has been proven ineffective (Hoffman 2011).

When would screening be potentially effective?

The concept of identifying future risks or the potential of disease of individuals is remarkably attractive and has permeated to nearly all aspects of medicine. The ever-increasing technological and biological wizardry of medicine raises expectations and further tempts clinicians and the public. However, so few medical interventions are like screening that is so appealing at the first glance but disappointing at the end. In addition, screening is so complex and difficult to be provided with high standard and quality so that they will eventually realize the benefits promised. As a result, only a few screening programmes can truly do more good than harm and are thus worthwhile (only programmes that can do more good than harm at a reasonable cost should be recommended). When implemented, they should be managed in such a way as to achieve a level of quality which can ensure that the balance of good and harm demonstrated in research is reproduced in the ordinary service setting.

What would make a screening programme potential beneficial? The potential benefits and harms of a screening programme are mostly determined by the following three factors: the disease, the screening test(s), and the treatment(s). We will explain why in the following sections.

The disease

About the disease, three important aspects are relevant and should be assessed: (1) the disease to be screened for must have a long detectable preclinical phase; (2) the severity of the disease must be considered as a large health burden to the population in terms of suffering, disability, destitution and/or death; and (3) the preclinical phase of the disease must be relatively prevalent.

The preclinical or asymptomatic phase of a disease is the time period from the onset of the disease to the time symptoms appear and a diagnosis is made routinely by a doctor (Fig. 11.5.2). A long preclinical phase is the prerequisite for the disease to be detected and treated early enough so that treatments would be more effective. For example, most infectious and acute diseases that have a very short asymptomatic phase are not suitable for screening, while most cancers may have a latent period of many years are often a suitable target for screening.

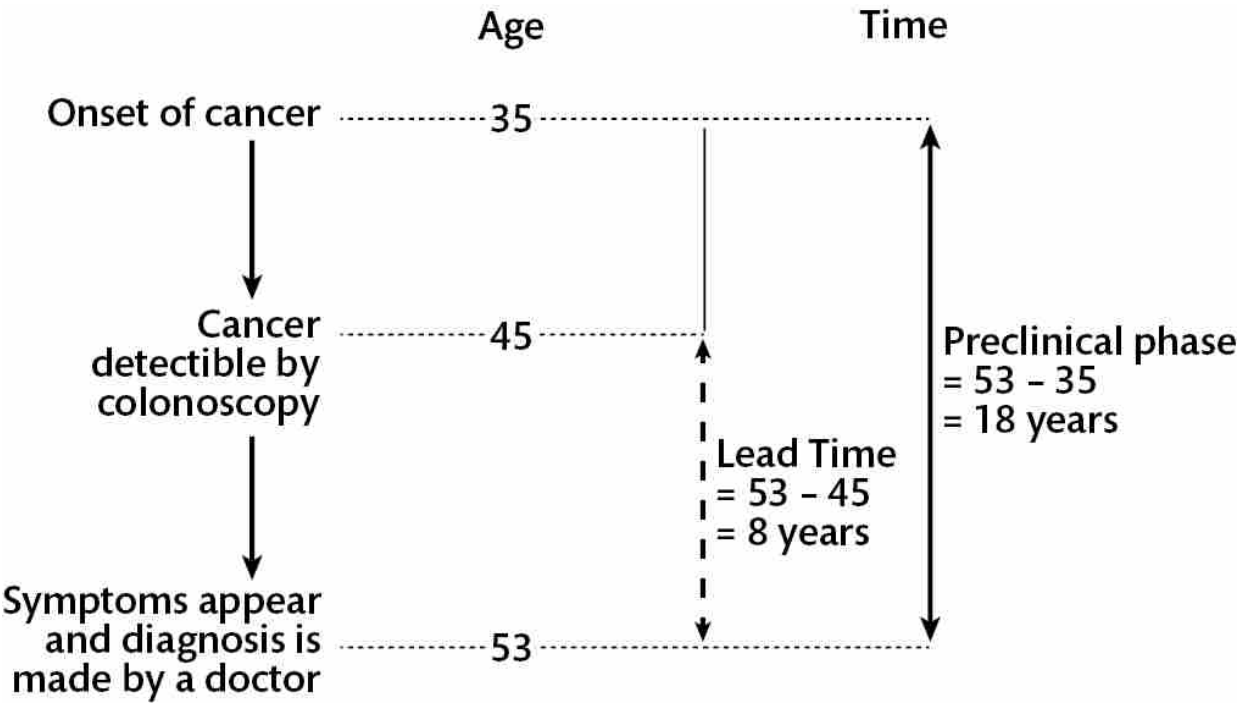

Fig. 11.5.2 Screening test and lead time in a hypothetical case of colon cancer.

Most cancers may have a long preclinical phase but the actual length of that period is normally unknown. First, it is almost impossible to know when a cancer started in a person. Second, most cancer patients currently diagnosed are asymptomatic and are almost always offered treatment and the natural progress of cancer is thus altered. This makes it impossible to know when symptoms would occur in these patients if there were no treatment. Lack of knowledge on the preclinical period of cancer makes it difficult to estimate accurately the effectiveness of screening and creates unsubstantiated belief and blind enthusiasm for screening.

The burden of disease is a relative concept. Diseases such as cancer that causes severe suffering, disability, and death are generally more suitable for screening than diseases such as minor skin problems. The view on the burden of a disease may vary greatly across populations and over time in the same population. For example, in some African countries where infectious disease is the major threat to life, cancer would be deemed much less important than in Western countries where cancer has become the major killer. Screening and management of hypertension, hyperlipidaemia, and diabetes mellitus for prevention of major cardiovascular complications were certainly less eminent a century ago than today in most populations.

The prevalence determines the total number of cases that can be detected by screening in the screened population. If the disease is rare and too few cases can be identified, no matter how effective the treatment would be, screening would not be able to have an important impact on the health of the population. When would a disease be deemed prevalent and justified for screening? There is no universal answer to the question either. Again the answer may vary across populations and over time dependent on resources available, opportunity costs, and values of people at the time the decision needs to be made.

The prevalence of a disease is positively related to the prevalence of the risk factors and the average duration of the preclinical phase. These relations suggest that screening be more likely effective in people with increased risk factors of the screened disease. Second, the prevalence of the undiagnosed but detectable preclinical disease also depends on whether or not the population has been screened recently. Recent screening in a population would reduce the number of undiagnosed asymptomatic patients. This suggests that in order for the screening programme to be cost-effective, two subsequent rounds of testing should not be kept too close to each other in

time. For example, breast mammogram or Pap smear should be performed again in the same person every 3–5 years rather than more frequently.

Risk factors and early-stage cancer can be considered similar in that both increase the future risk of severe complications, suffering, and death. Thus, cardiovascular risk factors that can increase the risk of myocardial infarction and stroke are often also screened and corrected with medications. These factors usually include hypertension, hyperlipidaemia, and type II diabetes, which are common and can effectively controlled through lifestyle modification and therapeutic drugs.

The screening test

The screening test refers to the test or a series of tests used in a screening programme to identify those who are likely to have the disease and warrant further confirmatory diagnostic investigations. Screening is feasible only if a good screening test is available. The test should be sufficiently accurate. Precisely, it should have relatively a high sensitivity and specificity. The ability of a test to correctly classify people who truly have the preclinical disease as test positive is called sensitivity and the ability to correctly classify those who are truly free of the disease as negative is called as specificity (Table 11.5.1).

Table 11.5.1 Classification of disease status by the gold standard and screening test

Test	Gold standard		
	Dis. (+)	Dis.(–)	Totals
Test (+)	a True positive	b False positive	a + b
Test (–)	c False negative	d True negative	c + d
Totals	a + c	b + d	N = a + b + c + d

If sensitivity and specificity are not perfect, which is always the case, errors will occur in the test results. Those who truly have the disease but are test negative, suggesting absence of disease are false negative results. False negative results will lead to missing the opportunity of early diagnosis and treatment. On the other hand, those who are truly free of the disease but test positive, suggesting presence of disease are false positive results. False positive results would result in unnecessary confirmatory diagnostic investigations and even further unnecessary treatments and harms. As screening can detect and treat conditions that will never cause symptoms and suffering in the rest of a person's life, unnecessary treatment is much commoner than usually expected.

Furthermore, the screening test should be able to give a sufficient lead time. Lead time is the period from the time an asymptomatic patient is detected by screening to the hypothetical time symptoms would appear and diagnosis be made by a doctor if the screening test had not been performed (Fig. 11.5.2). For a group of patients, this lead time can be approximated with some data and assumptions (Morrison 1992). For any individual patient, lead time is always a hypothetical concept and inestimable. For a screening programme to be effective in reducing morbidity and mortality in a population, there must be enough lead time in a sufficient number of cases detected. If lead time is insufficient, patients will not be treated in time to retard or stop the progression of the disease.

Finally, the test should also be simple, rapid, inexpensive, and safe so that it can be applied to a large number of people at an affordable cost and people and clinicians will accept it and make efforts to do it (Cochrane and Holland 1971; Sackett and Holland 1975; Morrison 1992) Otherwise, screening could become either too expensive to be affordable or too unattractive so people will not come for it. For example, conduct of the test should be easy to learn. Those that can be administered by non-medical personnel will cost less than those that require skills from years of medical training. Moreover, screening that requires hospitalization for a few days to go through complex and invasive procedures are unlikely to be popular to eligible participants.

The treatment

If screening can bring about any good, it will be from the treatment rather than the test and any other activities in it. Therefore, for a screening

programme to be potentially beneficial, there must be treatments available that are effective and acceptable in asymptomatic patients. Neither do treatments used for late-stage patients necessarily help early-stage patients nor would treatments acceptable to symptomatic patients equally acceptable to asymptomatic patients. In brief, the treatments for early stage of patients must be re-evaluated in randomized controlled trials if they are to be used in screening for treating preclinical patients.

Performance of the screening test

Screening is a combination of early detection and early treatment of preclinical diseases. Success of a screening programme is thus first determined by the test. The test is related to both the benefits and costs and harms of screening. This section will explain how they are related and how we can 'manipulate' the test so as to increase benefits and reduce costs and harms.

What would make a good test for screening? As already described, a good test for screening should be accurate, feasible, and acceptable. We will now analyse the role of accuracy for screening. Accuracy is referred to the ability of a test to correctly classify true disease status, either presence or absence. It is thus commonly expressed in two separate parameters: sensitivity and specificity.

Sensitivity and specificity

Sensitivity is the ability to detect the disease in those who truly have the disease, while specificity is the ability to rule out the possibility of disease in those truly free of the disease.

Sensitivity and specificity are estimated through scientific research. Such research normally starts with two groups of people, one truly with the disease of concern and the other truly free of the disease. Then the test is applied to all participants in both groups. Normally, a positive test result will suggest the presence of disease and a negative result absence of disease. According to true disease status and test results, the participants can be classified into four categories: (a) true positive; (b) false positive; (c) false negative; and (d) true negative (Table 11.5.1).

Sensitivity is expressed as the percentage of those having a positive result in those who truly have the disease and specificity is the percentage of those having a negative result in those truly free of the disease. Sensitivity can also be viewed as the probability of a true patient being detected by the test and specificity the probability of a person truly free of the disease being confirmed by the test. If sensitivity is not perfect, some true patients will turn out to be test negative. We call these negative results false negatives. Conversely, if specificity is not perfect, some of those truly free of the disease will turn out to be test positive. We call these positive results false positives (Table 11.5.1).

For example, assuming there are 100 participants truly having the disease and 200 truly free of the disease included in a diagnostic study, 95 out of the 100 participants truly having the disease turned out to be positive (a = true positives) and 5 negative (c = false negatives); 180 out of the 200 people truly free of the disease turned out to be test negative (d = true negatives) and 20 positive (c = false negatives). This gives

Sensitivity = a/(a + c) = 95/(95 + 5) = 95%
Specificity = d/(b + d) = 180/(20 + 180) = 90%

Predictive values

Information on the accuracy of a test is not directly useful for practice, where we have only the test results with which we wish to find out the true disease status. In practice, the questions concerned are: (1) how likely is a person to truly have the disease given a positive test result, and (2) how likely is a person to be truly free of the disease given a negative test result? The answer to the first question can be estimated by the positive predictive value and the second by the negative predictive value. The positive predictive value (PPV) is the probability of truly having the disease given a positive test result and the negative predictive value (NPV) the probability of being truly free of the disease given a negative test result.

However, predictive values cannot be estimated simply from sensitivity and specificity without knowing the prevalence of the disease in the population to which the test is applied. Put it differently, estimation of predictive values also requires knowledge on the prevalence of disease. Given sensitivity, specificity and prevalence, predictive values can be estimated by the following equations:

PPV = P.SN / {P.SN + (1–P)(1–SP)}

$$NPV = (1–P)SP / \{P(1–SN) + (1–P)SP\}$$

Where SN = sensitivity

SP = specificity

P = the prevalence of the disease in the population tested

From the aforementioned equations, we can see that predictive values are determined by characteristics of both the test and disease, precisely, the accuracy of the test and the prevalence of the disease in the population to which the test is applied. The prevalence of the disease is also called the pre-test probability of disease. The accuracy of the test is normally assumed to be a stable feature of a test and can be generalized from the research population to other populations, although this stability assumption may not be necessarily true in all circumstances. As a result, the same positive (or negative) test result may mean a different probability of having (or being free of) the disease in populations with a different prevalence of disease.

Assuming that a test has both sensitivity and specificity of 95%, a very good test for screening, the predictive values will differ hugely as the prevalence varies (Fig. 11.5.3). As the prevalence increases, the PPV will increase but the NPV will decrease. As screening is normally conducted in populations with a relatively low prevalence of disease, results of a screening test will generally have a low PPV and high negative predictive.

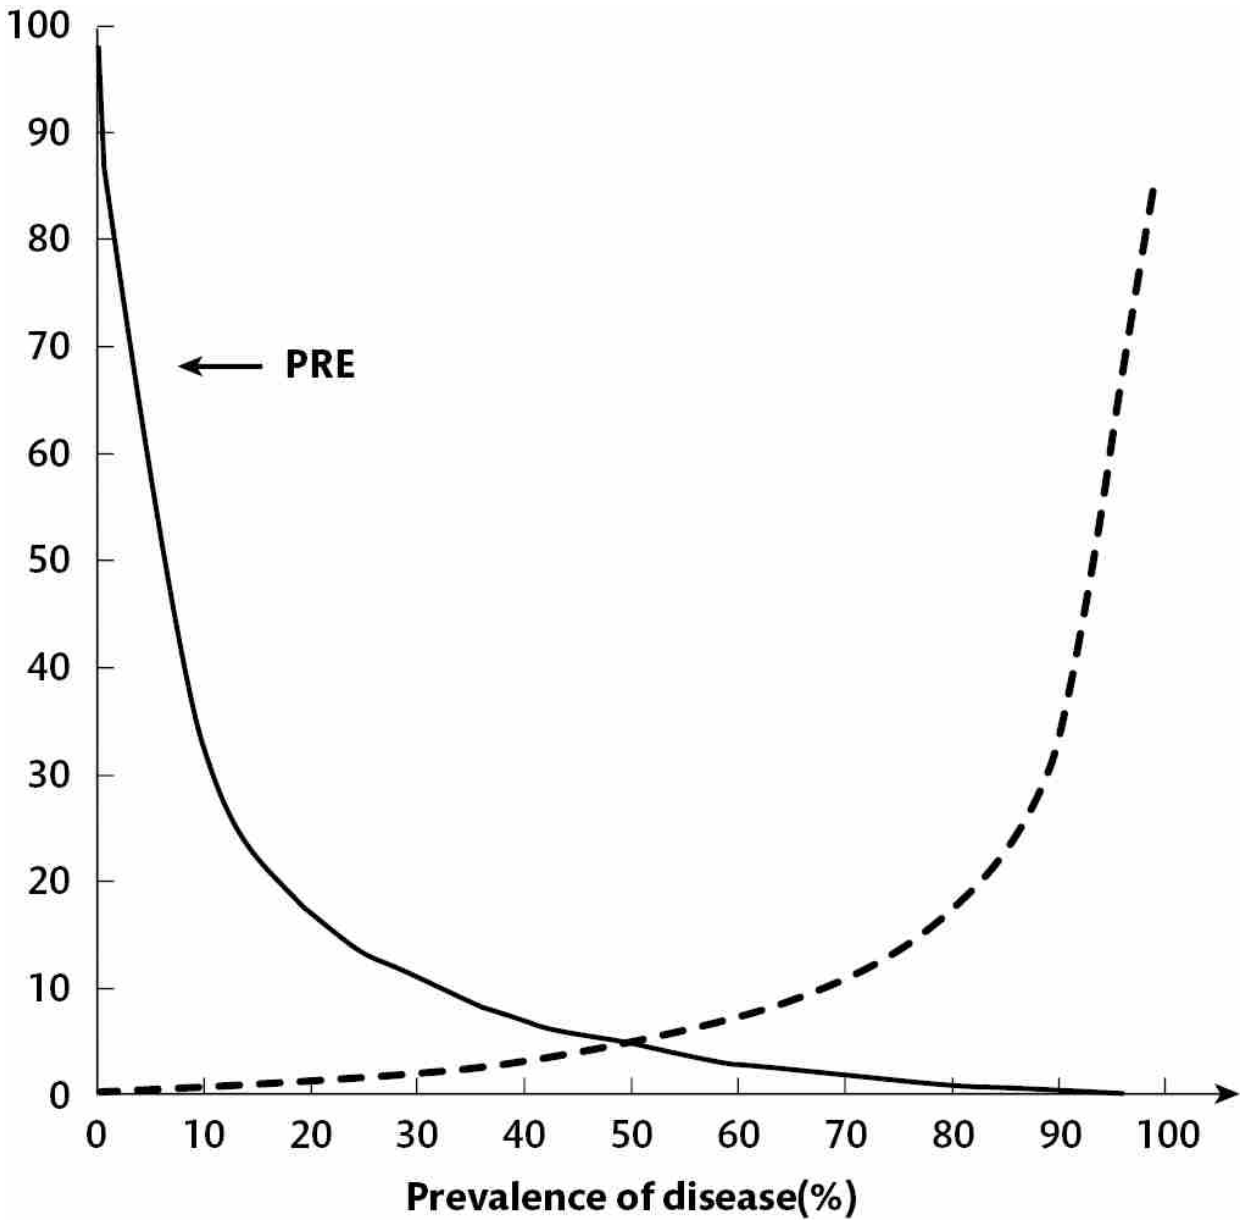

Fig. 11.5.3 Prevalence of disease and prediction error rate of test positive and negative results.

For screening, a high NPV is good as those with a negative test result can be reassured free of the disease. But a low PPV will be of a concern as it would mean many or most of test-positive results are not true positive and further expensive and time-consuming investigations would have to be conducted in them without a gain. The false positive rate in test-positive results is one minus the PPV and is often over 50% and can be as high as 90% or higher in some screening programmes. Thus, much of the efforts in

screening has to be made to reduce false positive results so as to minimize related costs and harms.

Two methods of reducing the rate of false positive results are obvious. One is to screen in people with a relatively high risk of the disease concerned. For example, the prevalence of lung cancer is higher in people of older age and smoking cigarettes, two major risk factors of lung cancer, than in the general adult population. Thus, screening for lung cancer can reduce cost in those of older age and smoking cigarettes. More complex methods can be used to identify high-risk people by incorporating more risk factors of the screened disease (Tammemägi et al. 2013). For the same reason, breast cancer screening should be focused on women aged 40 or above.

The other method is to ‘manipulate’ the sensitivity and specificity of the test so as to achieve a desired PPV for screening.

Balancing between sensitivity and specificity

The results of a medical test are in nature normally quantitative rather than qualitative and often arbitrarily divided into a dichotomous result by using a cut-off value to facilitate clinical interpretation. Those with a result equal to or above the cut-off value are considered test positive, while those with a result below the cut-off are deemed negative. Different cut-off values can be used and will give rise to different combinations of sensitivity and specificity. The sensitivity and specificity of a test is inversely related: specificity decreases as sensitivity increases and vice versa. This means importantly we cannot increase both sensitivity and specificity at the same time by choosing a particular cut-off value unless the test is improved technically.

Different combinations of sensitivity and specificity of a test may be used in different clinical settings. A high sensitivity test will help detect most patients, whereas a high specificity will help reduce false positive results and reduce the costs of further investigations. For example, in such settings as the emergency room, we may use a low cut-off value to have a high sensitivity so as not to miss even a small risk of a life-threatening problem. This will result in a high sensitivity but a large number of false positives will result due to the low specificity. Thus, those who are indicated free of a severe problem is certain but those who are indicated of having the problem will have to go through further investigations to confirm the diagnosis.

Conversely, in such settings as down-syndrome screening, a relatively high cut-off value is used to achieve a high specificity and high PPV so as to minimize the number of amniocentesis which may cause unnecessary abortion.

In screening, the prevalence is generally low and the percentage of those free of the disease which is complementary to the prevalence will be high. Consequently, a small error in the test results in those free of disease will generate a large number of false positives and considerably increase the costs and harms of further investigations in those who do not truly have the disease. Should we lower the cut-off so as to maximize the number of patients detected and potential benefits from treatments or should we increase the cut-off so as to minimize the costs and harms of further unnecessary investigations? They are the issues that need to be carefully debated in planning a screening programme. The choice of the cut-off value is central to balancing sensitivity and specificity and further to the consequent balance between benefits and costs of the entire screening programme.

How can we prove screening works?

A high risk of a severe disease, a good test, and an effective treatment are the prerequisites for a screening programme to be eventually beneficial. However, these criteria are not a guarantee that potential benefits of screening will be realized in practice. How can we find out whether a screening programme can truly bring about more good than harm?

Take cancer screening as an example, an intuitive method for evaluating the benefits of screening is to compare the survival between asymptomatic cases detected by screening and symptomatic cases diagnosed as a result of symptoms. Let’s call the former type of patients ‘screening-detected’ and the later ‘routinely diagnosed’. A higher survival rate in screening-detected patients than in routinely diagnosed patients is then considered as evidence that screening is beneficial in reducing fatality and increase survival.

Such comparisons used to be widely conducted. However, they are severely flawed and their results misleading. A few biases almost certainly exist to cause a false conclusion. The major ones include lead time bias, length time bias, and selection bias.

Lead time bias

Lead time is the duration of time from the time the disease is detected by screening to the time symptoms would appear in the same person if there were no screening (Fig. 11.5.2). Lead time always exists in screening; otherwise, screening will not detect patients any earlier and become equivalent to no screening. Purely due to lead time, screening-detected patients will surely survive longer than routinely diagnosed patients simply because the former was diagnosed and treated earlier and observed longer over time than the later. In other words, if early detection and early treatment is not effective and do not affect the natural progress of the disease, screening-detected patients will live longer by exactly the amount of lead time than routinely diagnosed patients. We call this false survival benefit lead time bias.

To illustrate, in scenario A of Figure 11.5.4, the patient is diagnosed and treated as a result of appearance of symptoms in the absence of screening, in scenario B the patient is detected and treated early as a result of screening but does not live any longer than that in scenario A as screening is not effective, and in scenario C the patient is also detected by screening but has lived longer than that in scenario A, showing a benefit of screening. As lead time always exists, the patient in scenario B will always look like surviving longer than that in scenario A. The extra survival in the patient in scenario B is however purely a result of lead time. Screening is beneficial only when the extra survival in screening-detected patients is longer than the lead time such as in scenario C. But we can distinguish scenario C from B if and only if we know the lead time.

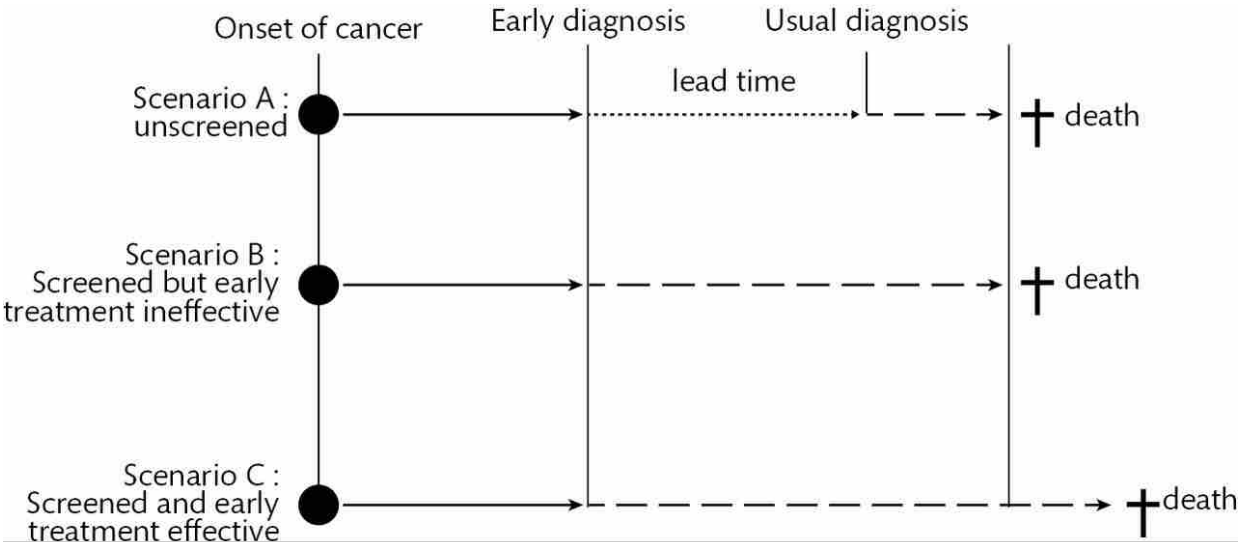

Fig. 11.5.4 How lead time affects survival time after screening?

But lead time cannot be estimated. It cannot be estimated by using the onset time of disease which is impossible to know for most chronic diseases. Nor can lead time to be estimated by the difference between the detection time by screening and the time symptoms appear as the two time points cannot be known in the same patient. In reality, the time symptoms appear cannot be known if screening is conducted and detected the patient. Conversely, the detection time by screening cannot be known if screening is not provided and diagnosis is made as a result of symptoms.

Lead time bias is like asking two persons who will live a longer life. If one is 25 years' old and the other 40 and they both will die at the age of 80, the younger person can live from now for another 55 years and the older only 40 years. The younger will live 15 years more than the older from now purely because of the lead time ——we see the younger 15 years earlier. Therefore, we cannot deduct from this observation that the younger will truly live a longer life as their life span is the same. In the context of screening, the younger person is like screening-detected patient and the older routinely diagnosed patient. Lead time is always a part, if not all, of the extra survival observed in screening-detected patients as compared with routinely diagnosed patients.

In conclusion, all comparisons of survival between screening-detected patients and routinely diagnosed patients are flawed and subject to lead time bias.

Length time bias

Length time bias is another inevitable bias in comparing the survival between screening-detected patients and routinely diagnosed patients. It occurs because the same cancer progresses at a different rate in different people.

Screening detects relatively benign cancer rather than the worst. To illustrate, Figure 11.5.5 shows three types of patients with the same cancer: slow-progress cancer (a, b, and c), cancer with a moderate progress rate (d, e, and f), and fast-progress cancer (g, h, and i). Assume cancer started all at the same time. By the time of screening, the fast-progress cancer would have progressed to a stage at which symptoms have appeared and diagnosis made at a routine clinical setting. On the other hand, slow-progress cancer is still too small to be detectable by the screening.

Screening tends to detect cancer that progresses more slowly and has inherently better prognosis than cancer that is routinely diagnosed. In addition, like slow-progress cancers, some screening-detected cancers may stop progress, regress, or even spontaneously resolve so that it will never cause a problem before people die from other causes. Thus, screening-detected patients are bound to have a better prognosis and survive longer than routinely diagnosed patients, even if screening is not effective. We call this false conclusion on the benefit of screening length time bias.

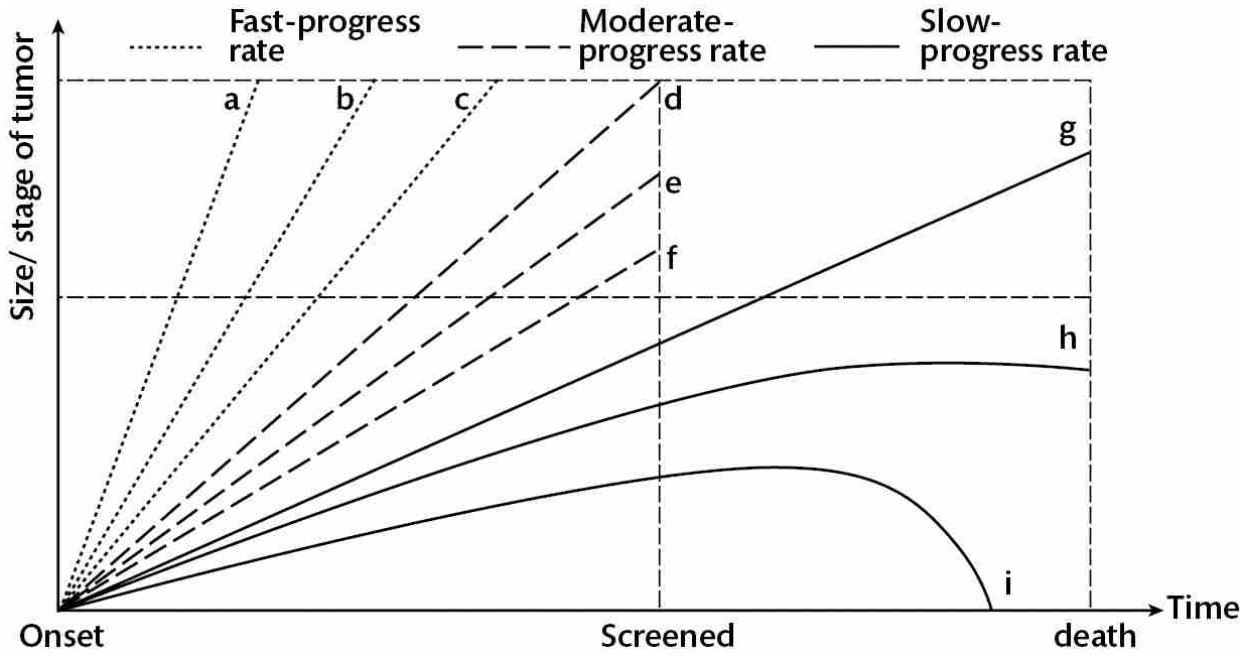

Fig. 11.5.5 Length time bias: fast-progress tumours come to medical attention before screening is performed, whereas tumours with a moderate progress rate allow more time for detection.

Confounding

Comparison of screening-detected patients with routinely diagnosed patients is inherently flawed for evaluation of the effectiveness of screening programmes. To avoid these biases, we can alternatively compare screened people with those who are not screened regardless of whether or not they are found to have the disease. The non-screened population can be those who are in the same community and offered screening but have not received screening or another population in which screening did not provide at all. Screening will be considered effective if the mortality of the screened disease in the screened population is found to be lower than that in the non-screened population. For example, the mortality of prostate cancer was reduced in screening region as compared with the rest of Australia, suggesting PSA screening be effective (Bartsch et al. 2008). However, such comparisons are like any other cohort studies and subject to the problem of confounding.

Confounding is a bias that arises in comparison due to incomparability in factors that may affect the prognosis of the screened disease between screened and non-screened populations. We would like to think that those who were screened had the same characteristics as those who were not

screened. However, there may exist many possible differences between screened and non-screened populations, which may cause confounding. For example, if people at a higher risk of the screened disease are more eager to be screened, e.g. women with a family history of breast cancer are more willing to get a mammography, a screening test will look worse than it truly is. This will cause underestimation of the true benefit of screening.

Confounding can also make screening look better than it truly is. For example, if one has to travel a long distance to get tested, more young and healthy people will be screened and fewer people in the screened population would die and screening would seem to make a positive difference. As screening is not compulsory and people mostly volunteer themselves to screening, this bias is also called volunteer bias or referral bias, a form of selection bias. Due to selection processes, the screened and non-screened will not be comparable and confounding will inevitably occur.

Like in clinical trials, the best way of tacking confounding, or selection bias some would like to call, is to conduct a randomized controlled trial. In randomized trials, people are randomly allocated to comparison groups so that any prognostic factors of the disease will be balanced among compared groups so that confounding will be eliminated.

Evaluation of screening by the randomized controlled trial

Randomized controlled trials in screening differ from usual clinical trials. In order to minimize contamination of screening service between compared groups, communities, or clusters of people rather than individuals are randomized. Screening service is offered to those in the intervention communities but not the control communities. Such trials are known as cluster randomized controlled trials. A lower mortality from the screened disease in the screened group than the control group will suggest screening is beneficial.

As illustrated in Figure 11.5.6, in a randomized controlled trial of screening for cancer, there are four categories of people in each of the compared groups: those free of cancer, fast-progress cancer, cancer with a moderate progress rate, and slow-progress cancer. Because of randomization, the proportion of each category will be comparable between screened and non-screened communities. Screening will affect the prognosis of only those with cancer at a moderate progress rate and mortality in the

other 3 categories are comparable and will cancel each other. Thus, any lowered mortality in the screened group can be attributed to screening. As only those with cancer at a moderate progress rate are compared, lead time bias and length time bias are also be avoided at the same time confounding is controlled by randomization.

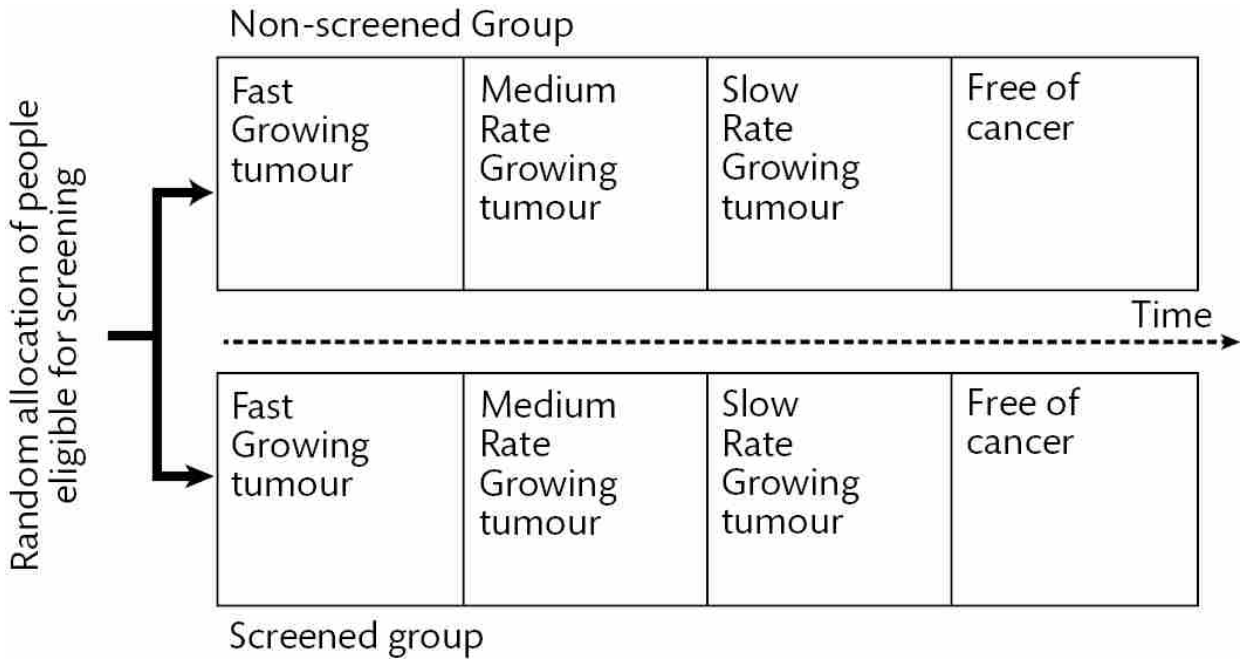

Fig. 11.5.6 Randomized controlled trial designed to evaluate a screening programme.

Now it is widely accepted that screening programmes for healthy people are justifiable only when randomized controlled trials have clearly demonstrated that benefits outweigh harms. The benefits should be estimated on important endpoint outcomes such as death rather than intermediate surrogate outcomes such as blood test and imaging results. For example, randomized controlled trials show that mammography can significantly reduce mortality from breast cancer in women over 50 years old (Wells 1998), whereas chest X-rays with or without sputum cytology do not affect mortality from lung cancer (Bech et al. 2003).

Cluster trials on screening are normally large and expensive and difficult to organize. They have also a low statistical power as most people in such a trial do not contribute to the comparison so the benefit if any is greatly diluted. Alternatively, trials are conducted in which only screening-detected

cancer patients are included and randomized to receive either a treatment or no treatment as control. It is generally considered unethical to give no treatment to cancer patients in the control group. Such trials are relatively rare. With a better understanding of the natural progress of cancers, many cancer patients are now willing to watchfully wait rather than to be treated immediately. This makes such trials more acceptable (Holmberg et al. 2002; Wilt et al. 2012). In theory, the control group can be given a treatment with proven benefit in screening-detected cancer. If there is such a treatment, it already forms evidence supporting screening.

However, trials of screening-detected patients, at best, can only be viewed as efficacy trials like those for drugs as they do not take into account the organizational aspects of a screening programme. If poorly organized, a screening programme may still fail even if the test is sufficiently accurate and treatment effective. In reality, compromises are often made in ways people are selected for testing, the test is conducted, and treatments delivered. Compromised management standard and quality may make a screening programme eventually fail to bring about any good to the screened population (Raffle and Gray 2007). Thus, the overall effectiveness of a screening programme can only be reliably evaluated in randomized controlled trials that randomly allocate eligible people to screening or usual care.

Balancing the benefits, costs, and harms of screening

Randomized controlled trial may show a screening programme is beneficial but the benefit comes at a cost. The costs include money, human resources and time, and inconvenience, worries and harms caused to the screened and incur at every stage of screening from the test to further investigations to the treatment.

Benefits

Screening will be futile if early treatment does not bring about extra benefit and can be effective only when treatments of early detected patients has greater benefits than usual care. The total population gain in the benefit from a screening programme will be determined by the total number of cases detected as well as the effectiveness of treatment. The former is in turn

determined by the prevalence of disease and sensitivity of the test. The higher the prevalence, the larger the number of patients can be potentially detected; the higher sensitivity is, the larger the proportion of patients can be eventually picked by screening. The total life years gained from screening is the product of the number of cases treated and the average extra survival gained from early treatments. Given that treatments are effective, the cost-effectiveness of screening can be increased by screening only persons at a high risk of the disease, by using a test of high sensitivity, by using a cut-off value that gives rise to a high sensitivity, and/or by testing the same persons more often.

Costs and harms

The benefits of screening come at a cost and with harm. Costs and harms can result from the screening test, further diagnostic investigations, and treatment. Harms may occur in the following forms:

harms and inconvenience caused by the initial test;
negative labelling effects: stress and anxiety caused by a false positive result;
harms and inconvenience caused by unnecessary investigations in false positive persons;
harms and inconvenience caused by unnecessary treatment of those who do not have the disease or have the disease that would never progress to the clinical stage and would have not been treated if there were no screening;
prolonged stress and anxiety if detected patients cannot be effectively treated;
a false sense of security caused by false negative results which could delay final diagnosis.

Increasing benefits and reducing costs and harms

The costs and harms of the initial test and of the final treatment are largely unavoidable. There is not much that can be done to reduce them. In contrast, confirmatory diagnostic investigations are where a large proportion of costs and labelling effects can be avoided. These further investigations are normally expensive and time-consuming, and are often invasive and can cause harm. Further investigations are unnecessary and the costs and harms

incurred can be reduced if false positive results can be reduced. All screening programmes should make efforts to do so.

As most people do not have the screened disease in the screened population, a relatively low specificity can result in a large number of false positive results which can outnumber many times the true patients detected. The lower the prevalence is, the higher the false PPV will be; the higher the specificity is, the lower the false PPV will be. The rate of false positive results can thus be considerably reduced by increasing the specificity and by screening in high people and at a longer interval between two tests. As sensitivity and specificity of a test are inversely related, specificity can only be increased with a compromise in sensitivity and missing diagnosis of a few more patients. This can be done by changing the cut-off value. A good screening programme must carefully choose the cut-off value so as to achieve a desirable combination of sensitivity and specificity, which will, in turn, help favourably balance the benefit against the cost and harm.

In brief, avoidable costs and harms of screening occur largely as a result of false positive test results and can be reduced by screening in high-risk people and by using a relatively high specificity. Having said that, time is an important factor to consider as well. As technology advances fast, a few years of waiting may substantively reduce the costs of the initial test and end up with an improved test with greater accuracy as well.

Illustration 1: screening for prostate cancer

In this section, we will use prostate cancer screening, in particular, data in the United States (US), as an example to demonstrate the rationale, principles, methods, and problems of screening.

Severity and prevalence of prostate cancer

Cancer is a terrifying disease. It relentlessly metastasizes throughout the body. It causes death if not treated, and often even it is treated. And the best way to treat it is to catch it early. These views about cancer seem strong enough to lend support to screening activities for cancer. Prostate cancer seems no exceptional.

Prostate cancer is common. It is a leading cause, and the second cause of death from cancer in men in the US. The lifetime risk of receiving a

diagnosis of prostate cancer was approximately 9% in 1985 and reached 16% in 2007 (Altekruse et al. 2010). Silent prostate cancer is also prevalent. One of the early studies showed that the prevalence of latent carcinoma of prostate at autopsy was 12% (Breslow et al. 1977). More recently, a systematic review of 29 autopsy studies of men who died of other causes showed the prevalence of incidental prostate cancer increases with age (Bell et al. 2015). It was found in some 5% in men aged 30 years or below and as common as 59% in men aged 80 years or above.

The median age at diagnosis is 67 years and the median age at death is 81 years (Altekruse et al. 2010). Some 60% of patients die from competing causes in 10 years after diagnosis of prostate cancer. These findings suggest prostate cancer be a slow progressing cancer and have a long preclinical phase. Studies estimated that asymptomatic prostate cancer can be detected with prostate-specific protein (PSA) by a lead time of 5–10 years (Draisma et al. 2009).

About 80% of prostate cancer patients are local and has not spread outside of the prostate. The 5-year survival rate for these patients is nearly 100%. In contrast, patients diagnosed with metastatic prostate cancer that has spread to distant lymph nodes, bones, or other organs, the 5-year survival rate is only about 29% (ACS 2018). The sharp contrast in survival of the local and distant cancers suggest that many patients can be detected early and their survival be greatly prolonged by early treatment.

The test—prostate-specific protein

Prostate-specific antigen (PSA) is the primary driving force for the rise of prostate cancer screening (AUA 2013; Hoffman 2018). PSA is a protein produced by normal as well as malignant cells of the prostate gland. The PSA test measures the level of PSA in a man's blood. The blood level of PSA is often elevated in men with prostate cancer. PSA testing was introduced in the late 1980s. In the US, the Food and Drug Administration (FDA) approved in 1994 the use of the PSA test in conjunction with a digital rectal exam to test asymptomatic men for prostate cancer.

Before the 1980s, solid cancers could be diagnosed only by symptoms, signs, and imaging and rarely by a simple blood test. PSA was considered an exciting breakthrough and caused great enthusiasm for screening for prostate cancer. By the early 2000s, approximately 75% of men aged 50 years or

above had undergone PSA testing and 90% of prostate cancer were detected by means of screening in the US.

PSA testing is safe, quick, simple, and inexpensive and thus generally acceptable to healthy men and feasible for testing a large number of people. The major concern is its accuracy. Using the cut-off value of 4.0 ng/ml as is normally recommended, specificity is 91% but sensitivity is only 21% which will miss 79% of cancers. Twelve per cent (12%) of the tested will turn out to be positive and only 30% of test-positives are truly positive. Using a lower cut-off value of 3.0 ng/ml, sensitivity will be increased to 32% which is still relatively low but will lower specificity to 85% (Wolf et al. 2010). Eighteen per cent (18%) of the tested will turn out to be positive and only 28% of the positive results are truly positive. The further investigation is biopsy of the prostate. Approximately, 70% of the test-positive men will not benefit from biopsy but may have harms including stress, bleeding, pain, clot formation, infection, and urinary difficulties.

The treatment

When prostate cancer is confirmed, the usual treatment is radical prostatectomy. PSA testing had become widespread before the benefits of aggressive treatment of asymptomatic prostate cancer was demonstrated in research. Till 2002, a Scandinavian randomized controlled trial of 694 men with asymptomatic prostate cancer and aged below 75 years showed radical prostatectomy as compared with watchful waiting could reduce the risk of death from 8.9% to 4.6%, a relative reduction of 48% during a median follow-up of 6.2 years (Holmberg et al. 2002). The mortality reduction persisted through 15 years of follow-up (Bill-Axelson et al. 2011). However, only about 5% of the cancer patients in this trial were detected by screening and over 75% were palpable. It is thus questionable whether this result is applicable to patients with prostate cancer mostly detected by screening and impalpable.

Unfortunately, the PIVOT trial (Prostate Cancer Intervention Versus Observation Trial) in the US failed to confirm this benefit of radical prostatectomy in men with prostate cancer mostly detected by screening and of earlier stage than those in the Scandinavian trial (PIVOT 2009). The trial randomized 731 men to either radical prostatectomy or watchful waiting.

After 12 years of follow-up, no statistically significant difference was found in overall and prostate-specific mortality (Phillips 2011).

It remains controversial whether current treatment methods for early stage of prostate cancer can prolong life. These trials are relatively small and did not take into account the standard and quality of screening, which may further compromise the benefit. Large randomized controlled trials were eventually mounted to directly compare the screened and non-screened populations. They are tougher and ultimate evaluations of PSA screening.

Randomized controlled trials of PSA screening

By 2010, six large randomized controlled trials on PSA screening have been completed and published with a total number of participants of 387,286 men studied (Djulbegovic et al. 2010). The median follow of the six trials ranged from 4 years to 15 years but was 9 years or longer in five trials. A systematic review of these trials showed that compared with usual care, PSA screening with or without digital rectal examination could on average detect 50% more, or 20 more in every 1000 screened, men with prostate cancer. The extra patients detected by screening are all stage I or stage II cancers. Harms are not reported in the majority of trials and found relatively rare if reported.

Importantly, five trials with 302 500 randomized participants showed a relative risk 0.88 on mortality from prostate cancer, a result which is statistically not significant. Four trials with 256 019 randomized participants showed a relative risk of 0.99 on all-cause mortality, again statistically insignificant. There is large heterogeneity in the proportion of extra prostate cancers detected but all the trials showed homogeneously no effect on reducing mortality. These results suggest that the increased detection of early-stage prostate cancer has not translated into a benefit in reducing overall mortality and mortality specific to prostate cancer.

In conclusion, some 30 years later since PSA was introduced for screening, the current best evidence does not seem to support that PSA screening is effective in reducing the outcomes that are important for patients. It may be argued that in some circumstances PSA may reduce mortality specific to prostate cancer. However, PSA screening may have increased the risk of death from other causes and thus led to no reduction in overall mortality, which constitutes strong evidence against PSA screening. Having made that conclusion, it still remains a possibility that the lack of

effect of PSA screening is partly a result from a likelihood that many silent prostate cancer patients may have also been detected and treated in the usual care group in these trials.

Illustration 2: screening for cardiovascular risk factors

Unlike cancers, cardiovascular diseases share many common risk factors. These factors are mostly well understood and can be effectively controlled with currently available interventions. The amenable cardiovascular risk factors include, notably, hypertension, hyperlipidaemia, smoking, body weight, lack of physical activities, and type II diabetes mellitus. In this section, we will use hypertension to illustrate how screening can be used for risk factors for the purpose of primary prevention, although these cardiovascular risk factors are usually checked together.

Hypertension pressure—the most frequently checked condition

Blood pressure has probably taken over the measurement of body temperature and become the most frequently checked clinical condition in today's medicine. It is checked often in routine clinical encounters, in general, health checks, and even at home with automated sphygmomanometers. Searching for hypertension is normally not taken as a part of screening programme and thus has not been debated and challenged for the evaluation we ask for cancer screening. This has further abetted the culture of measuring blood pressure.

Hypertension is common and its cardiovascular complications are severe and prevalent. Blood pressure can be easily measured. Blood pressure-lowering drugs can effectively reduce the risk of cardiovascular complications and are widely used. These all make hypertension suitable for screening. Indeed, worldwide hypertension has been widely screened and treated. However, treating hypertension is not merely for the sake of lowering blood pressure; it is for lowering the risk of severe cardiovascular complications and death.

Effectiveness of searching for hypertension

It is not clear whether screening for hypertension in the general population would help reduce future risk of cardiovascular complications and deaths. A systematic review of randomized controlled trials of general health checks, all or most of which included measuring blood pressure, found general health checks in general practice could effectively reduce cardiovascular risk factors such as blood pressure and blood cholesterol but had no effect on both cardiovascular mortality and overall mortality (Si et al. 2014). This finding is consistent with a previous larger systematic review which also included randomized trials in non-primary care settings (Krogsbøll et al. 2012).

That not all detected hypertensive patients are eventually treated may partly account for the lack of effect of routinely checking blood pressure and other cardiovascular risk factors on reducing mortality. In the context of screening, blood pressure checks should not be encouraged if the majority of detected patients are eventually treated. It is possible that blood pressure checks are already common in the general population so that the difference in the intervention and usual care groups is too small to be detectable. It is also possible that the benefit from checks for cardiovascular risk factors has been cancelled by harms of treatments and of checks for other diseases. More recently, a large randomized controlled trial provides evidence for checks for only cardiovascular risk. The trial randomized 59,616 participants from a general population and compared the effect of checks for hypertension and other major cardiovascular risk factors followed by repeated lifestyle interventions over 5 years. At the end of 10 years' follow-up, screening did not show any effect on ischaemic heart disease, stroke, and mortality (Jørgensen et al. 2014).

Screening for hypertension and other cardiovascular risk factors in the current medical context seems to have failed in the most important criteria for screening: screening should be able to reduce severe complications and deaths that the screened condition may cause. There is another important issue that needs to be addressed in searching for hypertension and in screening in general: what is the clinical condition we are screening for? If the condition screened is difficult to define, a screening programme is likely to be stretched and eventually become doubtful.

What constitutes hypertension?

Regular checks for hypertension reemphasized the ultimate criteria for screening: screening programmes should be recommended when and only when they can produce more good than harm at an affordable cost for a population. However, the good and harm ratio for hypertension screening changes as the diagnostic criteria for hypertension change. Hypertension is, in essence, an 'arbitrary' condition which is reflected in the choice of cut-off value for defining it. This has important implications for screening for hypertension and screening in general.

Epidemiological studies have shown beyond reasonable doubt that the risk of cardiovascular disease increases as blood pressure increases. The relation is largely linear for blood pressure between 120 mmHg and 180 mmHg systolic or between 70 mmHg and 110 mmHg diastolic, a range most adults' blood pressure falls into. There is no clear turning point below which cardiovascular risk does not increase with blood pressure (Law and Wald 2002; Lacey et al. 2018). Compared with those with the lowest blood pressure values, all others are hypertensive; conversely, compared with those with the highest blood pressure values, all others are normal tensive. There is no blood pressure value that can be used objectively and undebatably for defining hypertension. Any cut-off value will be a result of the trade-off in balancing among various factors. A higher cut-off value will result in fewer hypertensive patients for whom treatment will be more effective, whereas a lower cut-off value will result in more hypertensive patients for whom treatment will be less effective. Where should the cut-off value be set?

The fundamental requirement is that treatment of hypertension thus defined should be able to do more good than harm. Furthermore, resources available to, and the values of, the population concerned must also be taken into account (Jackson et al. 2005; MacMahon et al. 2005; Tang and Hu 2005). This was exactly how once the cholesterol cut-off for prescribing Statin was set in the United Kingdom (Pickin et al. 1999; Gaw and Packard 2000). Previously defined hypertension was widely accepted and treatments are effective. However, around the year 2000, the cut-off for hypertension was reduced to 90/140 mmHg. A systematic review of randomized controlled trials showed that antihypertensive drugs did not reduce risk of cardiovascular disease and related mortality in mild hypertension created by the new criteria (Lenzer 2012; Brunström and Carlberg 2018). This conclusion is very likely to be applicable to those who have an even lower blood pressure but will be diagnosed as hypertensive according to the new

US guidelines in which the cut-off is lowered to 130/80 mmHg (Whelton et al. 2017). The new definitions will make any screening programmes for early, mild hypertension questionable.

Importantly, changing of disease definitions has been happening to hyperlipidaemia, type II diabetes mellitus and many other risk factors and diseases including cancer (Welch et al. 2011; Doust et al. 2017; Yang et al. 2017). The implications of changing the definition of cancers for cancer screening will be discussed later in this chapter.

Health checks as multiphasic screening

Modern concept and practice of systematic screening originated in early attempts of general health checks. Today we emphasize systematic planning and rigorous evaluation of benefits and harms of screening programmes through randomized controlled trials. Since the 1960s, many randomized controlled trials on screening of individual diseases have been conducted and the results are often disappointing. In the same time, general health checks, the old practice of screening has not disappeared. In fact, in recent decades it has been on a continuous increase and become a large business in many countries including China (Ren 2016). Modern general health checks may include hundreds of tests and examinations in one package. Many of them are new tests including genetic testing and have not been rigorously evaluated and proven to be able to do more good than harm.

Health checks can be viewed as an application of many screening tests for many different diseases in one programme. On one hand, often only a fraction of people with identified problems are adequately followed up with further investigations and treatments and the benefit of the tests and examinations are not fully realized. On the other hand, further investigations and treatments of some detected problems may do harms without a benefit. Against the ultimate standard for screening that is a demonstration of benefits in reducing mortality and prolonging life in randomized controlled trials, are general health checks effective and worthwhile?

In 2012, a systematic review identified 14 randomized controlled trials with a total 182,880 participants included and summarized the evidence for the effects of general health checks in adults on reducing morbidity and mortality (Krogsbøll et al. 2012). In this review, general health checks were defined as screening for more than one disease or risk factor in more than

one organ system, regardless of whether they were performed once or repeatedly. Many trials included risk factors for cardiovascular disease and screening techniques for cancer.

Nine trials provided data on total mortality, 8 on cardiovascular mortality, 8 on cancer mortality. It showed no benefit in reducing mortality from health checks: the risk ratio is 0.99, 1.03, and 1.10 respectively for total mortality, cardiovascular mortality, and cancer mortality. None of these results are statistically significant. The review also failed to find any benefits on hospitalization, disability, worry, additional physician visits, and absence from work. Although the debate may continue, it is almost certain that benefits of general health checks for reducing mortality, the ultimate aim of screening, would be trivial, if any at all.

The authors of the review wrote in the Cochrane editorial as follows:

> In spite of the consistently negative results of screening and lifestyle counselling, general health checks remain a popular political tool for combating the burden of ischaemic heart disease and other chronic diseases. Lately, the British government has started a general health check for the population. Danish left wing parties went to the polls in 2011promising the same but changed their minds shortly after gaining power. In 1968 the World Health Organization proposed that several criteria should be fulfilled before systematic screening could be recommended. These criteria have often been interpreted as criteria for screening for early stages of diseases, but they also apply to systematic screening for high risk of diseases. Some of the main criteria are that the disease in question should be serious and that a valid screening instrument is available, both of which are fulfilled for ischaemic heart disease. However, the most important criterion is that screening should reduce morbidity and mortality in the target population.

The authors made a rather strong recommendation that doctors should not offer general health checks to their patients, and governments should abstain from introducing health check programmes (Gøtzsche 2014).

It was the early debates over the value of health checks that led to the modern concept of more organized screening programme focused on specific diseases (Raffle and Gray 2007). Given the widespread of different ideas and practices of screening that are often ineffective, it is time to revisit these debates. It is reasonable to argue that screening ideas such as general health checks should include only those tests and examinations that are clearly targeted at specific diseases and proven effective on important outcomes.

Early detection and overdiagnosis

Screening and overdiagnosis

With the availability of rapid-growth new technologies, the idea of early diagnosis and early treatment have been increasingly applied in clinical settings often before they are demonstrated effective. This has caused overdiagnoses. Overdiagnosis occurs when people without symptoms are diagnosed with a disease that ultimately will not cause them to experience symptoms or early deaths (Moynihan et al. 2012). Screening and overdiagnosis are related. Screening is about early detection and early treatment, whereas overdiagnosis is often in the form of early diagnosis that does not lead to a benefit.

Overdiagnosis can result from overdetection or overdefinition (Broderson et al. 2018). Overdetection is a major form of overdiagnosis in cancer and partly driven by advances in technologies (Orme et al. 2010). It can occur by identifying abnormalities that are never going to cause harm, which include those that do not progress, that progress too slowly to cause symptoms or harm during a person's remaining lifetime, or that resolve spontaneously.

Overdefinition is the major type of overdiagnosis for such conditions as hypertension, hyperlipidaemia, diabetes mellitus, and osteoporosis. It can occur by lowering the cut-off vale for disease diagnosis and by including more parameters in the diagnostic criteria without evidence that doing so helps people feel better or live longer.

Overdiagnosis in hypertension

As just discussed, hypertension is not black and white disease entity. Rather, it is an arbitrarily defined clinical condition by using a cut-off. With a hope to prevent early and in more people, the cut-off value for diagnosing hypertension has been reduced a few times so more and more people are now diagnosed, alerted, or treated.

In 1998, the cut-off value for hypertension was further lowered from 160/95 mmHg to 140/90 mmHg. In China, this change in the cut-off increased the prevalence of hypertension by 134% and created over 100 million new patients. A similar phenomenon was also observed for hyperlipidaemia and type II diabetes. It was estimated in 2002, the total drug costs for hypertension, hyperlipidaemia, and type II diabetes could amount to 56% of the total healthcare expenditure of the government if all the patients were treated with drugs (Hu et al. 2017).

In 2015, 23.2% or approximately 244.5 million of the Chinese adult population aged 18 years or above were hypertensive, and another 41.3% or approximately 435.3 million had pre-hypertension according to the current Chinese guidelines (Wang et al. 2018). In 2017, it was recommended in the US that the cut-off value for hypertension be further lowered to 120/80 mmHg (Whelton et al. 2017). Using these new criteria, the total number of hypertensive patients in China will be further doubled and increased to approximately 500 million or prevalence of 46.4% (Wang et al. 2018).

Given that there is insufficient evidence that drug treatment of mild hypertension can reduce morbidity and mortality (Krogsbøll et al. 2012; Jørgensen et al. 2014; Si et al. 2014) the new cut-off value for hypertension will create sweeping overdiagnosis worldwide.

Overdiagnosis in cancer

Cancer is usually considered a black and white disease entity. Once found, it kills. In fact, cancer is very much like hypertension which is a continuous condition and the risk of suffering and death increases as the severity or size of cancer increases. Early-stage, asymptomatic cancer is merely a ‘risk factor’ of future suffering and death rather than a current misfortune.

The relation of cancer to mortality can be illustrated in Figure 11.5.7. Cancer does not start with a large lump of cancerous cells. Instead, it begins with cancerous mutations in cells when they divide. These cancerous cells may multiply and form an *in situ* cancer. The *in situ* cancer may further grow in size and even become invasive spreading into surrounding tissues and the lymph nodes nearby. Local cancer may further progress into the metastatic stage and spread to another organ. Although most patients may die of a cancer at the metastatic stage, early-stage cancers are not necessarily lethal. In fact, many may regress or even resolve spontaneously, stop progress, or grow so slowly that they will not cause harms before the individual die of other causes (Black 1998). This means that some early-stage cancer may not harm in a person’s lifetime. Indeed, autopsy studies found that subclinical cancer exists in a large proportion of people who died of accidents or other causes rather than cancer (Welch et al. 2010).

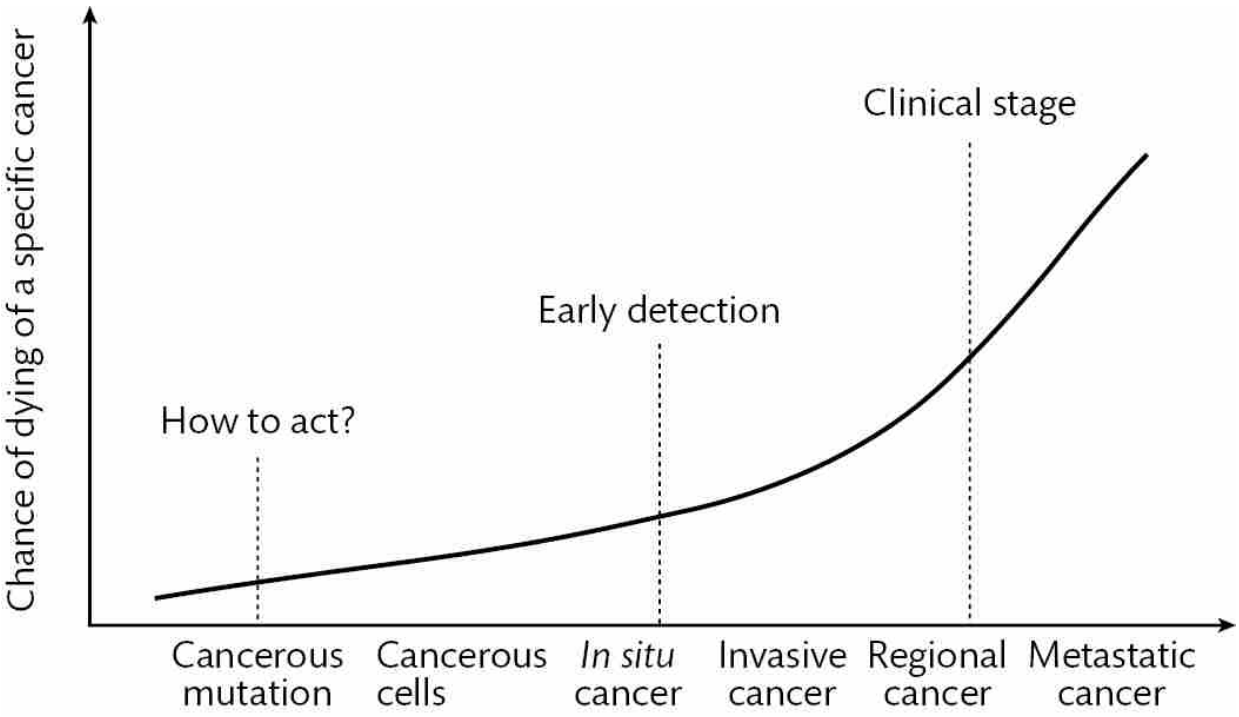

Fig. 11.5.7 Stage of cancer and the chance of dying from that cancer.

Now we can see that the relation between cancer and mortality is, essence, similar to that between hypertension and mortality. Again, where should we draw the cut-off for diagnosing cancer in such a circumstance? Unlike hypertension, we do not deliberately discuss and play with the cut-off value in diagnosis of cancer. But the truth is we keep pushing down the cut-off value in the size of the tumour: the cut-off is lowered every time more powerful diagnostic methods are made available. There is no doubt that cancers detected through current imaging technologies are much smaller those diagnosed through symptoms and physical examination. As a result, the definition of cancer has been changing as well but stealthily due to advances in diagnostic technology. Most cancer patients we diagnosed today are small and asymptomatic and would not have been diagnosed and treated in the days before the rise of modern technology. Have these advances in medicine truly helped reduce suffering and death? The evidence shows not necessarily.

Again, take prostate cancer as an example. A meta-analysis of 19 autopsy studies found that the prevalence of unsuspected prostate cancer in men aged 70–79 years was as high as 36% in Caucasians and 51% in African-Americans (Jahn et al. 2015). After PSA was introduced in the late 1980s in

the US, the incidence of prostate cancer quickly increased by over 100%. Between 1999 and 2006, the annual age-adjusted incidence of prostate cancer in men maintained above 150 per 100,000 men. About 80% of prostate cancers were, however, clinically confined to the prostate and only 4% had metastasized (Hoffman 2011). Given the great increase in the incidence, the mortality of prostate cancer, however, remained largely the same between 1975 and 2007. The combination of increasing incidence and stable mortality is a clear sign of overdiagnosis. Furthermore, evidence from six randomized controlled trials with a total of 387 286 participants do not support the routine use of PSA for screening prostate cancer (Djulbegovic et al. 2010).

Thyroid cancer is more striking an example of overdiagnosis. While the chances of tests to detect a thyroid 'abnormality' are high, the risk it will ever cause harm is low (Tang and Hu 2005; Welch et al. 2011). In the United Sates, an analysis in 2006 showed many of the newly diagnosed thyroid cancers were the smaller and less aggressive forms not requiring treatment (Davies and Welch 2006) but carried a risk of damaged nerves and long term medication if treated. In South Korea, the rate of thyroid cancer was increased by 14 times from 1993 to 2011. Most of the increase are believed to be overdiagnosis, attributable to the early detection of papillary thyroid cancer by ultrasound (Ahn et al. 2014; Park et al. 2016). Furthermore, a systematic review found that it is unclear that ultrasonography plus follow-up cytology for screening thyroid cancer can decrease mortality rates or improve important patient outcomes (Lin et al. 2017).

Other diseases

Overdiagnosis is not limited to hypertension and cancer and in fact is ubiquitous in medicine. Next are a few more examples.

Pulmonary embolism

Pulmonary embolism is usually considered a 'not to be missed' diagnosis. Historically, pulmonary embolism was nearly universally fatal, diagnosis made on clinical grounds and often only discovered after death. Anticoagulants were established management standard. In the late twentieth century, computed tomography pulmonary angiography allowed to detect pulmonary embolism reliably and non-invasively. Progressively smaller

pulmonary embolisms are now being found and the incidence of diagnosed pulmonary embolism has been doubled but the death rate remained largely unchanged, suggesting smaller subclinical pulmonary embolism is overdiagnosed (Prasad et al. 2012).

Abdominal aortic aneurysms

Abdominal aortic aneurysms is another typical example of detecting clinically less important abnormalities. A study of 201 men aged between 60 and 75 with hypertension or heart disease compared the number of abdominal aortic aneurysms that can be identified by ultrasound and that by physical examination. In five people with aneurysm of 5 cm or greater, physical examination can find 4. In 5 with aneurysm between 4 and 5 cm, physical examination detected only 1. In 8 with aneurysm smaller than 4 cm, physical examination failed to identify any. Ultrasound could detect all of them, creating three times more subclinical aneurysms. Most of these aneurysms are below the size for which surgery is recommended and thus represent typical overdiagnosis (Lederle et al. 1988).

Stroke

Silent stroke was found by MRI scans to exist in over 10% of people from the general population without clinically diagnosed stroke. The prevalence of silent stroke increases as age increases. It was 7%, 8%, 10%, and 15%, respectively, in those aged 30–49, 50–59, 60–69, and 70–79 years. It is not a certain treatment of silent stroke is beneficial (Das et al. 2008).

Chromic kidney disease

The new US guidelines recommend that an estimated glomerular filtration rate below 60 ml/min/1.73 m^2 and sustained for 3 months or longer is deemed abnormal. According to these criteria, more than 10% of adults in the US are now classified as having some form of chronic kidney disease (Levey et al. 2009).

Lessons from early detection

Advances in diagnostic methods have made diagnosis of disease at their clinical stage much easier, more quickly, and more reliably, which has

reduced unnecessary treatments and increased the effectiveness in those treated. However, at the same time, these advances are also being used widely to find diseases at their preclinical stage. Furthermore, diagnostic criteria for diseases are being expanded, making more and more people become patients. Modifying the definition of disease normally creates mild or early stage of diseases. However, it is often unclear whether the preclinical patients thus created and identified will benefit from treatment.

From the perspective of screening, many of the activities for detecting and treating early or mild diseases do not seem justifiable. Early detection is happening extensively at a large number and still on an increasing trend. The number of early patients thus created or discovered is likely many times more than those found by appropriately organized screening programmes. If there is no benefit, it is a considerable waste. We thus argue that new diagnostic methods for detecting asymptomatic patients should not be introduced into practice before they are rigorously evaluated in the way we do for screening. Guidelines should also be made for defining a new disease or modifying the diagnostic criteria of a current disease so that a benefit will be guaranteed to result.

Conclusions

Intuitively screening is highly appealing but in practice frequently ineffective.

All screening programmes cost and have harms. Decades of epidemiological research show that it is much less often than many would expect that screening can do more good than harm. This re-emphasizes urgently the ultimate criteria for screening: only those programmes that can do more good than harm at an affordable cost should be recommended. Policy makers should assess carefully as regards the disease, the test, and treatments to see whether they are suitable for screening. The ultimate evidence about the benefit and harm of a screening programme should be from randomized controlled trials. Screening programmes should also be organized in high standard and quality so that the benefit demonstrated in research can be reproduced in practice.

But not all efforts for early detection and early treatment occur in the form of systematic screening. In fact, more often they take place in routine clinical services and increasingly in general health checks. In some places, health

checks may account for most of early detection activities and should be planned and evaluated as carefully as we do for screening of specific diseases. Even if effective, a screening programme will benefit only a few at a large cost to the entire population. Even worse, the harm starts immediately but the benefit if any takes much longer to appear. Thus, the decision to introduce a new screening programme should be taken as seriously as we make important healthcare decisions like building a large new hospital.

Finally, is the benefit of a screening programme worth its costs and harms? The answer to this question inevitably varies across populations that have different resources available, different health needs to address, and different views on the value of the benefit and harm. Screening should be recommended to a population only when a benefit–harm ratio is deemed desirable to that population.

11.6

The practice of environmental health in an era of sustainable development

Yasmin E.R. von Schirnding and Lynn R. Goldman

Introduction to environmental health practice

Roots of environmental health practice

The practice of environmental health goes back to earliest times. For example, cleanliness, water supply and sanitation have played an important role in disease prevention throughout recorded history (Rosen 1958). Many of the world's water and sanitation practices had their origins in the ancient civilizations of India, Egypt, and Mesopotamia—a testimony to their hydraulic engineering skills. It was the Romans who excelled in sanitary engineering however, with the Cloaca Maxima, the great sewer of Rome, still forming part of the drainage system of modern Rome. Personal hygiene and cleanliness were emphasized by early and prehistoric societies, and were regarded as a sign of spiritual purity (Rosen 1958).

For thousands of years the theory prevailed that disease was linked to the gods, and only gradually did the idea evolve (for example, in the writings of the Greek physician Hippocrates in *Airs, Waters and Places* (400 BCE) that disease was linked to natural causes such as climate and the environment (Rosen 1958). *Airs, Waters and Places* also provided practical advice on how to address environmental health issues (perhaps an early example of health impact assessment) by suggesting that before a place was colonized, it was necessary for the character of the soil to be assessed.

In the course of the subsequent demise of Greek-Roman civilization, much scientific knowledge was lost, and in the Middle Ages, unsanitary conditions prevailed, especially in cities, although regulations were implemented with penalties for pollution of water supplies and other

environmental nuisances. Quarantine was also a way in which environmental health was practised, to protect from the corruption of air (the theory of miasma—'bad air'), in addition to personal hygiene measures.

During the mid-nineteenth century and beyond, awareness of threats to public health from poor sanitation grew, and with this 'sanitary awakening', widespread sanitary reform measures were implemented. These were spearheaded by an enquiry by Edwin Chadwick, a Poor Law Commissioner, who, in 1842, published a major report on sanitary conditions in England (Chadwick 1842). Chadwick's investigation into the causes of poverty concluded that people often became poor as a result of ill-health from an adverse environment (that situation prevails today). In 1848, with the passage of the Public Health Act in the United Kingdom (Calman 1998), provision was made for the appointment of Inspectors of Nuisances—the predecessors of today's environmental health officers. A national board of health, and district health boards were also recommended.

It was John Snow who traced the origin of the cholera epidemics in London to contaminated water, and who thereby conducted one of the first comprehensive environmental epidemiology investigations—a key function of importance in the practice of environmental health. In the United States, the Shattuck report in 1850 (Winslow 1949) similarly drew attention to the links between poor living conditions and health, and recommended the establishment of state and local boards of health, as well as local sanitary associations and regular (environmental) health surveys.

From its roots in antiquity to the sanitation movement of the 1800s, environmental health practice was fairly narrowly focused on sanitation, environmental hygiene, inspection and control, and has since gradually broadened to address health and environment concerns in the context of sustainable development (von Schirnding 2002a), with emphasis on ecosystems and ecology (Rapport et al. 2009). In the early- to mid-twentieth century, air pollution disasters (e.g. Meuse Valley, Belgium in 1930, Donora, Pennsylvania in 1948, and London, United Kingdom in 1952); industrial disasters like Bhopal, India; as well as mounting evidence of the carcinogenic, reproductive and other effects of chemicals (highlighted in Rachel Carson's *Silent Spring*, 1962) led to increased awareness of toxic chemicals in the environment. This awareness was further heightened by

such incidents as the Love Canal toxic waste site disaster in the United States in the 1970s.

Environmental health has thus expanded beyond its horizons. Today environmental health practitioners have to concern themselves with a wide variety of issues, with virtually any aspect of the environment having the potential to affect human health. The environment can impact chronic diseases such as cancer, lung diseases, or birth defects, as well as infectious diseases like gastroenteritis, respiratory infections, or vector-borne diseases like malaria. Typical environmental health concerns include ambient and indoor air quality, food safety, water quality, sanitation, waste management, housing quality, noise pollution, electromagnetic radiation, occupational and industrial hygiene, vector control, and toxic chemical exposures.

The environment has much broader impacts too—both positive and negative. For example it may provide protection and resiliency to natural disasters or predispose people to harm (for example from building in earthquake-prone areas). It may promote health through the provision of nutritious and safe food, drinking water, provision of recreational opportunities, interaction with nature, and so on.

In particular, concern about health effects associated with natural ecosystems and global (climate) change has grown in recent years, necessitating the need to address health issues in the context of complex (eco) systems analysis (McMichael et al. 2006; Patz et al. 2008; McMichael 2013). With growing appreciation of the links between ecology and health, the integrity of natural ecosystems, and the transdisciplinary and intersectoral nature of environmental health, there have been calls for new epidemiological approaches to dealing with environmental health hazards (Soskolne et al. 2007). With the global spotlight on sustainable development, practitioners have begun to look at environmental health risks more holistically, from the viewpoint of various economic sectors like housing, transport, or energy, and settings or systems like the city at large.

This approach can be tracked through the various United Nations (UN) conferences held on the environment and sustainable development going back over the past 40 or more years. These are briefly highlighted next, as well as some of the key principles and goals articulated therein.

Global initiatives

Following the UN Conference on the Human Environment held in Stockholm, Sweden (UN 1972), in 1983 the World Commission on Environment and Development (UNCED) headed by former Norwegian Prime Minister Gro Harlem Brundtland (World Commission on Environment and Development 1987) linked the issue of environmental protection to economic growth and development. The Commission's report 'Our Common Future' (World Commission on Environment and Development 1987) launched the concept of sustainable development into the mainstream of world debate.

Sustainable development essentially means meeting people's development needs in such a way as not to exceed the earth's carrying capacity in the longer term. Although specific definitions for sustainable development vary, broadly speaking, the concept is concerned with balancing environmental, social, and economic objectives in order to maximize societal well-being, both now and in the future.

The UN Conference on Environment and Development (UNCED) (UN 1992)—a watershed event popularly referred to as the 'Earth Summit'—resulted in the adoption of Agenda 21—a global action plan with concrete goals, targets, and outputs for measures needed to achieve environmentally sustainable development into the twenty-first century. It also resulted in the 'Rio Declaration' which encompassed important agreements on 27 principles adopted by 178 nations, including the Precautionary Principle, the Polluter Pays Principle, the Common But Differentiated Responsibilities principle (CBDR), and other principles such as the principle of intergenerational equity, the principle of access to information, and the decision-making process, and the principle of integrated decision-making (these are discussed further in Section 3). Several key conventions were also adopted, such as those on climate change (including the Kyoto Protocol) and on biological diversity (under which was negotiated the Cartagena Protocol).

The Rio Declaration, in its preamble, alluded to the central role of health in sustainable development by stating that 'Human beings are at the centre of concerns for sustainable development. They are entitled to a healthy and productive life in harmony with nature'. This concept was further developed during the World Summit on Sustainable Development (WSSD) (UN 2002a) which took place in Johannesburg, to review progress 10 years after UNCED.

At WSSD, health was singled out as one of the five priority issues to be addressed, along with water, energy, agriculture, and biodiversity (Annan 2002; UN 2002b). In the Johannesburg Plan of Implementation (JPOI) which emerged from this conference, particular emphasis was placed on health issues in relation to environment and poverty concerns. Improving access to safe water, sanitation, clean air, improved waste management, and sound management of chemicals were among the key issues of importance for environmental health practitioners that received special attention in Johannesburg (von Schirnding 2005).

This momentum was somewhat lost in the subsequent run-up to the twentieth anniversary of UNCED. 'Rio+20' (UN 2012) aimed to review progress over the past 20 years and to renew political commitments to sustainable development. While many new green economy policies were endorsed in the final Rio+20 document 'The Future We Want', no new international commitments nor legally binding agreements were made, albeit voluntary agreements were made by countries to meet their own sustainable development targets. Coming out of WSSD where health made a strong showing, and out of the Millennium Development Goals (MDGs) process (UN 2000) where health had a central position, health did not feature strongly at Rio +20. This confirmed the pressing need for the health community, and especially environmental health practitioners, to remain actively engaged in the sustainable development agenda (Kleinert et al. 2012; Singh et al. 2012).

Of note, all three conferences (UNCED with its focus on environment, WSSD with its focus on the social dimension, especially—poverty, and Rio+20 with its focus on the green economy) failed to ensure the integration of the three pillars of sustainable development. The process of setting sustainable development goals in the follow-up process to Rio+20 (the 2030 Agenda for Sustainable Development), which was initiated at the Sustainable Development Summit in 2015 (Barbier 2012; UN 2015; Bhandary et al. 2015) aims to ensure that these three pillars of sustainable development are not considered separately from each other. Progress towards achievement of these goals is now reviewed under the newly constituted High-level Political Forum on Sustainable Development (UN 2018), one of the important outcomes of the Sustainable Development Summit. Health, and environmental health in particular, can be used as a tool by practitioners to integrate across the three dimensions of sustainable

development. Measurable targets (and indicators) are needed to ensure health remains a prerequisite for, and an outcome of, sustainable development—in all its dimensions. This is discussed further in Section 7.

Concept and scope of environmental health

In considering the practice of environmental health, it is apparent from the foregoing discussion that the nature and scope of the discipline has undergone considerable transformation, especially in light of the emerging concept of sustainable development and sustainability. In its broadest context, environmental health is concerned with the health effects associated with the environment. This includes both the physical (natural or 'built') as well as the social environment. It is less concerned with the health of the environment *per se*, as it is with its impacts on human health. In this respect, environmental health is an integral part of the discipline of public health, with strong links to the environmental sciences.

The World Health Organization (WHO) has defined environmental health in various ways to include 'Those aspects of human health and disease that are determined by factors in the environment. It also refers to the theory and practice of assessing and controlling factors in the environment that can potentially affect health' (WHO 1989). While *health* has been defined by the WHO as 'A state of complete physical, mental and social well-being and not merely the absence of disease or infirmity' (WHO 1946), environmental health has tended to focus mainly on the physical environment, with less emphasis on the social environment and on social and mental well-being. Nevertheless, both the physical as well as the social aspects of the environment are important aspects of the realm of environmental health.

An updated definition of environmental health by the WHO gives added emphasis to this social component and describes environmental health as comprising 'those aspects of human health, including quality of life, that are determined by physical, chemical, biological, social, and psychosocial factors in the environment. It also refers to the theory and practice of assessing, correcting, controlling, and preventing those factors in the environment that can potentially affect adversely the health of present and future generations' (WHO 2004). This definition incorporates, as well, a focus on sustainability, in so far as it alludes to the health of both present

and future generations. Environmental health is thus not only concerned with the identification, control, and remediation of factors in the environment which can affect health, but also with disease prevention and enhancement of intergenerational human health.

The intersectoral nature of environmental health is recognized in the WHO's Constitution (WHO 1948), which states that the Organization shall 'promote, in cooperation with other specialized agencies, where necessary, the improvement of nutrition, housing, sanitation, recreation, economic, or working conditions and other aspects of environmental hygiene'.

The concept has its roots in a number of international strategies and fora, including the 1977 'Health-For-All' strategy of WHO (and its renewal and subsequent updates: WHO 1977, 1981, 1998; Yach 1996), the Alma-Ata conference on Primary Health Care in 1978 (WHO 1978), the World Health Assembly (WHA) Technical Discussion on Intersectoral Action (WHO 1986a), the Ottawa Charter on Health Promotion (WHO 1986b), the Sundsvall meeting on Supportive Environments for Health (Haglund et al. 1996), the WHO Commission on Environment and Health (WHO 1992), and the international conference on 'Intersectoral Action for Health—A Cornerstone for Health-for-All in the 21st Century', held in Canada in 1997 (WHO 1997; Kreisel and von Schirnding 1998).

Addressing the underlying multifactorial determinants of health is essential in order to ensure health improvements which are sustainable over the long term. Primary prevention is a key aspect of the work of the environmental health practitioner, and involves implementation of interventions before ill-health occurs. It includes health promotion interventions geared towards general health and well-being, as well as interventions on specific known causes of disease-for example the phaseout of lead—a well-documented neurotoxicant—in gasoline. Pollution prevention is an example of a primary preventive measure, involving strategies such as source reduction, waste minimization, reuse, recycling, emissions control, waste disposal, and clean-up. Secondary preventive measures can be implemented which are targeted at an early stage of exposure before health impacts manifest (for example lead screening), while tertiary preventive measures involve the early identification and treatment of people with a disease (Goldman 2016).

By addressing health, environment, and development concerns in an intersectoral way, a win–win situation occurs: the health sector gains

because disease prevention can move upstream and take advantage of the intersectoral approach to development and environmental improvements. The environmental sector gains because environmental issues can become grounded in matters of local and direct concern to people.

In the following subsections, we look briefly at some of the major trends in health, environment, and development in recent years, before highlighting environmental health issues and the burden of environmentally related disease, which are of importance in directing the work of the environmental health practitioner.

Global trends

Of overriding significance is the fact that on a global scale there has been unprecedented wealth creation and economic development in the past decades, coupled with intensified global efforts targeting major causes of death and disease throughout the world. The sanitary movement of the 1800s mentioned earlier had a major impact on the reduction of infectious disease mortality and resulted in major improvements (increases) in life expectancy. More recently this has been accelerated in part due to such initiatives as the MDGs process which set in motion an ambitious programme of goals and targets to eradicate poverty by the year 2015 (UN 2000), and its successor, the 2030 Sustainable Development Goals (SDGs) process.

Life expectancies for men and women have increased, and a greater proportion of total deaths now occur among people over the age of 70 years, compared with 20 years ago. Infectious disease mortality rates have declined, and burdens of HIV, TB, and malaria have all fallen. Substantially fewer children under the age of five years are dying (Wang et al. 2013), with deaths in this age group having declined by almost 60% since 1970. Between 1990 and 2015, the under-5 mortality rate dropped from 90 to 43 deaths per 1,000 live births (UNDP 2015). Nonetheless, in 2015, 16,000 children continue to die every day, mostly from preventable and environmentally related diseases like pneumonia, diarrhoea, and malaria. This burden is greatest in sub-Saharan Africa (SSA).

Despite huge progress in human development and poverty eradication over the past decades (over one billion people were lifted out of poverty since 1990), today, nearly one billion people still live in poverty, including a

higher percentage of women than men, and big gaps in progress remain in some regions of the world, especially in sub-Saharan Africa and southern Asia. Moreover, the distribution of income at the country level has worsened in much of the world, despite narrowing in gaps in health and education (UNDP 2011). At the same time, global wealth has become increasingly concentrated in the wealthiest one percent of the population**,** who had 32% of global wealth in 2000, compared to 46% in 2010 (UNDP 2016).

Human population growth is increasing by 75–80 million people a year (Sachs 2012) and is projected to grow to 9.7 billion by 2050 (UNDP 2016). In 2014, over half of the world's population lived in urban areas (UNDP 2016), and, with the addition of another 2.5 billion people by 2050, this number may rise to two-thirds of the world's population. Over half the population will be under the age of 18 years. Urban growth will be greatest in Africa and Asia, followed by Latin America and Oceania. By 2030 it is expected that there will be 41 mega-cities with populations of over 10 million inhabitants. The fastest growing cities are likely to have the highest concentration of slums or informal settlements. Already around 880 million people live in slums, and it is predicted that 40% of the world's future expansion will occur in slums (UNDP 2016).

With rapid economic development and urbanization in developing countries, cities are becoming increasingly overcrowded and polluted. Air and water pollution levels have been increasing, as has the generation of municipal and hazardous waste. In the last 30 years, however, in many industrialized nations stronger environmental laws have resulted in cleaner and safer drinking and recreational water as well as in improved air quality. On a global basis nevertheless, pollution of air and water supplies is worsening (Goldman and Torres 2009). Drinking water is under pressure from such factors as pollution, ageing infrastructure, population growth, and resulting increased demand and consumption. While demand is increasing, supplies are becoming more erratic and uncertain, with water-related impacts on agriculture, health, and income levels (UNDP 2016). In general, growth in incomes has been associated with deterioration in key environmental indicators such as carbon dioxide emissions, soil and water quality, and forest cover (UNDP 2011).

Environmental health issues

The practice of environmental health is inextricably involved with disease prevention and control. Environmental health practitioners face a growing diversity of environmental hazards to deal with, in many different settings, in developed and developing countries alike. Traditional risks associated with poverty often coexist alongside risks associated with urbanization and industrialization, agriculture, and land-use practices. For example, water supplies may be contaminated by pesticides and faeces exposing consumers both to microorganisms and toxic substances, and air pollution may stem both from burning dirty household fuels such as coal, wood, and other sources of biomass fuel used for cooking and heating, as well as from the use of industrial fossil fuels. In poor countries, accidental chemical releases may occur more commonly, and there may be fewer means to protect people. Poor countries (and the poor in wealthy countries) may also be more vulnerable to the health effects associated with natural disasters and climate change.

Problems may have to be dealt with simultaneously at the global, national, and local levels. Some problems may be of special relevance at the local or micro level (for example water supply and sanitation, waste disposal, or toxic chemicals) while other problems may be more important at the regional or global level (for example global climate change, or long-range transport of air pollution).

Health impacts associated with global change and disturbances to natural ecosystems (disruption of bio-geophysical systems such as the climate system and associated rising temperatures, declining rainfall, extreme weather events, degradation of land and water, depletion of resources, and other effects) (McMichael 2013) have to be dealt with at all levels and, as indicated earlier, may impact severely on poor countries and on the poor in general. Potential impacts are numerous such as heat-related mortality, health impacts associated with extreme weather events, changes in vector-borne disease distribution, disruption of agricultural production, or threats to drinking water supply. While poor countries have contributed least to global climate change, they have experienced the greatest variability in weather (such as loss in rainfall in some regions and flooding and others) with implications for agricultural productivity and livelihoods (UNDP 2011). Without appropriate action, by 2030, over 100 million more people could be living in poverty (UNDP 2018).

Problems may differ in urban and rural environments, although increasingly the divide between urban and rural is becoming blurred. While cities provide numerous benefits associated with increased job opportunities and provision of essential services and facilities, environment and health problems may nevertheless be profound, especially in cities that are not economically homogeneous. In informal settlement areas in particular, infectious diseases associated with inadequate water and sanitation, and dirty household fuels may be prevalent. Rich and poor people live in very different epidemiological worlds, even within the same city, and this situation occurs in both high-income as well as low-income countries (WHO and UN-Habitat 2010). Infant mortality rates are often higher among poor segments of urban populations in developed countries.

Lead poisoning illustrates very well the unequal burden of risk borne by poor inner-city children who are not only more exposed to sources of lead in and around the home environment (from flaking lead-based paint, for example, or contaminated air and dust), but are also more vulnerable to the toxic effects of lead, being often nutritionally deprived and having inadequate access to healthcare facilities. This is true even of children living in such countries as the United States and parts of Europe (Tong et al. 2000). Within inner-city areas, studies from South Africa have shown substantial socioeconomic differentials in blood lead burden among inner-city children (von Schirnding et al. 1991).

Poorer countries also have higher levels of household deprivation as evidenced by such factors as indoor air pollution, and inadequate access to clean water and sanitation. The environmental burdens of poverty fall directly on poor populations. As income levels rise, however, and with increased affluence and associated lifestyles and consumption patterns, these burdens tend to lessen, concomitant with environmental burdens which are more diffuse, indirect, and delayed, and affect a more temporally and spatially displaced public (UNDP 2011). Risks associated with community urban air pollution are an example.

With further economic development, these more localized burdens tend eventually to lessen too (or be displaced elsewhere), while environmental risks associated with global effects—for example, greenhouse gas emissions—tend to rise with high levels of materials and energy consumption and waste generation (UNDP 2011). The most disadvantaged people carry a double (or triple) burden of deprivation—they are more

vulnerable to the global effects of environmental degradation, have often to cope with new and emerging risks associated with rapid industrialization and urbanization, but also have to deal with threats to their immediate environment like indoor air pollution, dirty water, and poor sanitation.

Burden of environmentally related disease

It has been estimated by WHO (WHO 2016) that in 2012, globally around 12.6 million deaths (23% of all deaths), were attributable to modifiable environmental risks, and 22% of the disease burden measured in DALYs (disability-adjusted life year—a measure of overall disease burden, expressed as the number of years lost due to ill-health, disability or early death) attributable to environmental factors. Children under 5, and older adults were most affected. Among children under 5, it was estimated that 26% of all deaths could be prevented if environmental risks were removed. Adults between the ages of 50 and 75 were found to be most affected by environmental factors. Diseases with the largest environmental fraction (in DALYs) included cardiovascular diseases, diarrheal diseases, and respiratory tract infections. These are related to such factors as ambient and household air pollution, and water, sanitation, and hygiene.

Recent findings indicate a predominance of non-communicable disease risks compared with 1990. With advances in economic development and other factors, as alluded to earlier, there has been a shift away from infectious, parasitic, and nutritional diseases towards non-communicable diseases (NCD)s. In contrast, deaths associated with ambient air, chemical and soil pollution associated with modern industrial development are increasing (Landrigan et al. 2018)

Nevertheless, still today, pneumonia and diarrhoea (associated with household air pollution or water and sanitation) are the leading killers of young children. Diarrhoea accounts for 20% of deaths among children under the age of 5 years, while lower respiratory infections account for account for around 18% of deaths in children under 5. Nearly all of these deaths occur in sub-Saharan Africa and South Asia, reflecting uneven progress in reducing child mortality (UNICEF 2012). The highest fraction of deaths and disease that could be addressed by improving environmental conditions is in low-and middle-income countries. In 2015, 844 million

people lacked a basic drinking water service, while 2.3 billion lacked a basic sanitation service (WHO and UNICEF 2017).

The global burden of disease (GBD) estimates provide a sense of where environmental health practice could make a big impact in future. Continued support to improve access to water and sanitation services and a transition to cleaner household fuels is a high priority in much of sub-Saharan Africa and Asia**.** Nearly 90% of the deaths due to diarrhoea worldwide have been attributed to unsafe water, inadequate sanitation, and poor hygiene. In addition, around three billion people worldwide use solid fuels as their main cooking fuel (UNICEF 2012).

Further information on the relevance of global burden of risk estimates for environmental health practice is provided in Box 11.6.1 and Table 11.6.1, which are based on the 2015 GBD study (Forouzanfar et al. 2016). It should be noted that while both the WHO study (WHO 2016) and the GBD study (Forouzanfar et al. 2016) found environmental factors to be a major cause of premature death, disease, and disability, the GBD estimates are slightly at variance with those reported earlier by WHO. WHO for example attributed 12.6 million deaths to unhealthy environments, and the GBD 2015 study 9 million premature deaths (16% of global mortality). This discrepancy is most likely the result of differing definitions of environment (Landrigan et al. 2018). In respect of specific risk factors like ambient air pollution, and household air pollution, resulting discrepancies are probably in part due to changes in computational methodology, and in regard to water and sanitation, differing definitions of access to safe water.

Box 11.6.1 Global burden of risk estimates main priorities for environmental health practice, e.g. in prevention, research, and policy development

The 2015 global comparative risk assessment of burden of disease and injury provides data on major environmental risks, discussed here (Forouzanfar et al. 2016). It should be noted however, that the 2017 comparative risk assessment of burden of disease and injury provides alternate estimates, based on, inter-alia, different modelling processes for air pollution (Stanaway et al. 2018).

Of the 79 risk factors and risk clusters examined, several related directly to environmental factors, including water and sanitation, air pollution (ambient particulate matter pollution, household air pollution from solid fuels and ambient ozone pollution), residential radon, and lead

exposure. It was estimated that 9 million premature deaths in 2015 were from environmentally related disease, contributing to 16% of total global mortality.

In 2015 4.2 million deaths were due to ambient particulate air pollution, and 2.9 million deaths were associated with household air pollution from solid fuels.1.8 million deaths resulted from diseases related to unsafe water, sanitation, and handwashing.

Environmental factors were responsible for 21% of all cardiovascular disease related deaths, 26% of deaths due to ischaemic heart disease, 23% due to stroke, 51% due to chronic obstructive pulmonary disease (COPD), and 43% due to lung cancer.

Between 1990 and 2015, global exposure to such factors as unsafe sanitation and household air pollution each decreased by more than 25%, and attributable DALYs declined significantly for unsafe sanitation and water, and household air pollution.

Environmental risks declined steadily in relation to the sociodemographic index (SDI).

In 1990, household air pollution ranked fourth in leading risk factors, while in 2015 it ranked eighth. Ambient particulate matter pollution ranked sixth in 1990 and 2015. In 1990 unsafe water ranked second in leading risk factors, whereas in 2015 unsafe water ranked as the fourteenth leading risk factor. Unsafe sanitation ranked seventh in 1990 and nineteenth in 2015.

From 2005 to 2015, global deaths which were attributable to unsafe water and no hand washing with soap, fell by more than 12%. DALYs decreased by more than 20%. Even greater declines occurred in deaths and DALYs for unsafe sanitation since 2005. Reductions in the attributable mortality and DALYs due to diarrheal diseases associated with unsafe water, sanitation, and hygiene where especially marked.

In regard to household air pollution, since 2005, attributable deaths decreased by 13% to 2.9 million deaths in 2015, and the disease burden decreased by 20.3% over this period. Both ambient particulate matter and household air pollution where among the 10 largest contributors to global DALYs in 2015.

Table 11.6.1 Leading environmental risk factors: ranking in 1990 and 2015

Risk factor	1990	2015
Unsafe water	2	14
Unsafe sanitation	7	19
Handwashing	9	18
Ambient particulate matter	6	6
Household air pollution from solid fuels	4	8

In the following section we discuss the nature of environmental health effects and factors influencing exposure, and then go on to discuss how environmental health practitioners proceed to assess these.

Environmental health assessment

Nature of environmental health effects

Environmental health practitioners must concern themselves not only with addressing known exposures and disease outcomes associated with these, but also, importantly, diseases of unknown cause, with potential environmental links. In addition, still today, for many substances, it is not known whether or not there are safety thresholds for an adverse effect, and, if so, what those levels are.

Certain cancers and ‘subtle’ diseases and conditions related to environmental factors (e.g. lead in relation to intelligence, moderate hearing loss, or raised blood pressure) may not be recognized as such. Thus, the situation remains that much environmental disease goes unrecognized. With regard to chemicals, typically exposures to complex mixtures occur, which have not been well characterized.

Health outcomes

Environmental health effects result from a complex set of genetic, environmental, social, and other factors. Health effects may arise directly from a specific chemical, physical, or biological agent, or indirectly from factors associated with the broader physical and social environment (e.g. housing, land-use, transport, agriculture, or industry). While as indicated earlier, infectious agents resulting in such illnesses as diarrhoea and respiratory infections may be associated with inadequate water and sanitation and indoor air pollution, non-infectious agents are associated with non-communicable (chronic) illnesses. These include cancers, respiratory conditions like asthma, birth defects, and other illnesses.

Environmental health effects may include minor, temporary ill-health conditions, as well as acute illness and chronic disease. Effects are frequently irreversible. Acute ill-health effects may follow relatively shortly after an exposure (e.g. poisoning by pesticides, or following a chemical spill), whereas chronic exposure may occur as a result of an individual cumulative exposure over extended periods of time. A long time period may occur between the exposure and the health effect. An example would be asbestos exposure and mesothelioma (Selikoff et al. 1965). Dispersal of

the population at risk over time and the long incubation period make it difficult to reconstruct exposures. Some persistent pollutants like polychlorinated biphenyls (PCBs) and heavy metals like lead and mercury can accumulate in the environment for years, and may affect people over large distances, causing health effects long after their use has been discontinued. Acute health effects are usually easier to detect than chronic effects, which are difficult to relate to specific hazards or sources.

Multifactorial exposure

In addition, as indicated, many environmental diseases are multifactorial in so far as the causal factors are concerned, and it may be difficult to determine the effects of one exposure in the light of existence of effects of simultaneous exposure to other factors. Prevention has tended to focus on exposures associated with a single agent or medium (e.g. air or water); however, people are often exposed at the same time to a wide variety of physical, biological, and chemical agents, and may be exposed via several pathways (air, water, food) from one source. As indicated earlier, in developing countries people may be exposed both to hazards associated with poverty (unsafe drinking water and inadequate sanitation), pollution, unsafe agricultural and land-use practices, and so on. Relatively little is known, however, of the effects of cumulative exposures and how various risk factors might interact (Tickner 2005)—resulting in an additive or even synergistic (multiplicative) effect. The risk of health impacts associated with exposure to asbestos, for example, may be significantly increased (multiplied many times) in smokers (Selikoff et al. 1968).

Vulnerable groups

The poor, the elderly, women, and young children may be particularly affected. The elderly, for example, may be especially vulnerable to some toxic substances which may take longer to eliminate from the body. They may also be more vulnerable to respiratory illnesses associated with air pollution, for example. During pregnancy, women may have altered physiologies and metabolize toxic substances differently, while, during menopause, women may be especially vulnerable, for example, to the release of toxic substances such as lead from bones.

Children are particularly vulnerable to environmental insults, and are not merely ‘little adults’. They are more exposed than adults, as, due to their rapid metabolism, growth, and development, they drink, eat, and breathe in more of a contaminant relative to their bodyweight than do adults. Children also have enhanced hand-to-mouth activity and they play close to the ground, increasing their exposures still further. In addition, they have immature, and therefore vulnerable, physiologies. The unborn foetus may be especially vulnerable to toxic chemicals.

Thus, different groups have differing vulnerabilities and susceptibilities, including genetic dispositions, nutritional status, health, and physiological status which may influence their exposure (and response). Gene–environment interactions are known to be of importance and different subsets in the population may have different exposure–effect relationships. People may be more or less vulnerable at various stages of their lives.

To intervene on the causes of disease thus requires a good understanding of the health risks and their causes, as well as the susceptible individuals/population, so that surveillance and monitoring systems can be developed to identify in advance potential problems, thereby enabling effective interventions to be designed and implemented.

Role of epidemiology and toxicology

An important part of the work of the environmental health practitioner involves assessing the risks to which people may be exposed in the environment. While there is less uncertainty today about the extent of both direct and indirect risks to human health which are associated with factors in the environment, nevertheless there is still much to be learned about the way in which the environment influences human health.

In conducting health assessments, it is necessary to establish the nature of exposure and health outcome relationships, and to assess causality. Of the various fields that contribute to environmental health (e.g. environmental science, chemistry, physics, engineering, medicine, and many others) of key importance are epidemiology and toxicology, as well as exposure assessment.

Environmental epidemiology is concerned with the distribution and determinants of ill-health effects in human populations at risk from environmental exposures. As workplace exposures have decreased over

time, and environmental exposures have increased, an appreciation of the multiple causation of disease has grown. Various types of study design have been used in environmental epidemiology to assess the nature of the relationship between an exposure and health outcome(s) in a particular setting or population group. These include ecological studies, cross-sectional studies, case–control studies, cohort or follow-up studies, and intervention studies. They can be challenging to conduct due to the complexity of the health risks and exposures involved, and the need to take into account all the potential sources of confounding (extraneous factors associated with the outcome of interest) and bias.

No matter how well designed and executed, however, epidemiological studies suffer from several shortcomings. For a start, they can only disclose health risks after exposures have already occurred. Also, it is sometimes the case that there is too narrow a range of exposure for epidemiological studies to detect health effects in populations. For example, dioxin exposures are difficult to evaluate in the general population because people's dioxin levels occur within a relatively narrow range. In addition, it is difficult to measure exposure at the individual level (air pollution is an example) and exposure measurements made at an area or neighbourhood level may sometimes be (incorrectly) presumed to relate at an individual level, leading to what in epidemiological terms is referred to as the 'ecological fallacy'. This is where inferences about individuals are based on inferences about groups. Thus within an 'exposed' area, owing to micro-variations in exposure and other factors affecting people's exposure (e.g. behaviour patterns), people may not be homogeneously affected, even while assumed to be so.

Toxicological studies, which are experimental studies of the effect of pollutants on human beings or animals under controlled conditions, are also needed in order to identify in advance any adverse effects of substances under investigation. These have the benefit of allowing for a wider range of exposures to be assessed and can take account of the problem of confounding factors in epidemiological studies. However, to be cost-effective and humane, they are designed with as few animals as statistically possible, while dosing animals at high levels. Extrapolation from laboratory animals to humans, at high to low doses, is complex however, with many assumptions involved. It is not usually possible to reproduce all the contributing factors in the laboratory. National and international efforts are being made to substitute more humane methods of assessing toxicity for

animal testing. Such approaches involve employment of structure activity models, coupled with *in vitro* testing, to 'screen' substances for toxicity.

While there exist internationally harmonized guidelines for toxicity testing such as those established by the Organization for Economic Cooperation and Development (OECD), specific testing for toxicity varies by country, and depends on the type of substance and the statute under which it is covered. In the United States, for example, pesticides in food require tests of acute and chronic toxicity, neurotoxicity tests, cancer bioassays, tests of reproductive and developmental toxicity, and others (Goldman and Torres 2009).

Making causal inferences

The concept of risk is linked to that of causation. From the previous discussions it is evident that the relationship between many environmental exposures and health outcomes is complex. Even under optimal conditions and with the best study designs, it is difficult to make definitive assertions regarding causality. Bradford Hill (1965) listed the criteria shown in Box 11.6.2 as being key to assessing whether an observed association is likely to be causal or not.

Risk assessment

While epidemiology and toxicology are used to generate *new* evidence on health effects, risk assessment synthesizes *existing* information and weighs it up with the aim usually of addressing a particular regulatory or policy issue aimed at reducing or eliminating the risk (Bartel 2005). In this respect the National Research Council (NRC) has referred to it as a mixture of 'science and judgement' (NRC 1994).

Risk assessment is used in many fields, including environmental health. It is a science-based process concerned with estimating, usually in quantitative terms, the harm that will result from exposure to an environmental hazard (Fiorino 1995). Risk assessors might, for example, want to analyse the risks associated with being exposed to a factor like indoor air pollution, to a specific agent like lead in paint, or to a suspected contaminant in food or drinking water.

The conceptual framework for risk assessment was set out by the NRC in 1983 (NRC 1983) and divided the process into four key elements: hazard identification, dose–response assessment, exposure assessment, and risk characterization. Risk is a function of hazard and dose. *Hazard identification* concerns the identification of environmental agents and health effects for assessment, based on evidence for causality from epidemiological and toxicological studies.

Dose–response assessment describes the quantitative relationship between exposure and disease based on models that predict the level of response from any dose. Many exposures are considered to have a threshold for non-cancer effects, a point below which no effect is measured. While by default it is assumed that carcinogens have linear dose–response relationships at low doses, this is not true for all mechanisms for carcinogenicity. Risk assessors normally assume a monotonic dose–response relationship (increasing response with increasing dose), unless there is compelling evidence for a different dose–response relationship at low doses (for example between IQ and blood lead levels at low levels). *Exposure assessment* involves estimating or measuring the magnitude, duration, and timing of human exposure to the agent of concern. It necessitates defining the exposed population and the routes of exposure. Direct measures of exposure are rarely available to decision-makers, which consequently often rely on modelling and extrapolations for assessing exposure levels.

The final step is *risk characterization.* Information from the previous three steps is combined and the level of response for the identified health effect(s) at the particular level of exposure to the agent(s) in the defined population is estimated.

Box 11.6.2 Criteria for causality

The strength of the association refers to how large the effect or the size of the association is—a strong association (as measured by a relative risk or odds ratio) is more likely to have a causal component than is a modest association. Absence of a strong association does not, however, rule out a causal association. In environmental epidemiology frequently one is dealing with relative risks in the range of 1–2—since they often apply to the general population, however, the attributable risk or public health impact in terms of the absolute number of cases can be large.

Consistency refers to a relationship that is observed repeatedly in different settings using different methods—for example, in differing groups, places, circumstances, time—by others. Finding an

association consistently using different study designs, methods, and so on reduces the probability that an association is due to an error in the study design.

Specificity refers to an association that is specific for an outcome or group of individuals—that is, altering only the cause would alter the effect. An example would be mesothelioma in relation to asbestos exposure. Due to the multifactorial nature of many environmental diseases, this is not normally the case, however.

Temporality implies that the factor must precede the outcome it is assumed to affect. This is a critical factor in assessing causality.

Biological gradient refers to a dose–response relationship between the exposure and the disease. An increasing amount of exposure increases the risk.

Biological plausibility is concerned with the extent to which the association is consistent with what is already known about the response to the exposure and/or disease—that is, does it make sense?

Coherence of evidence implies that the causal association should not fundamentally contradict present substantive knowledge.

Experimental evidence stresses that causation is more likely if evidence is based on randomized experiments.

Reasoning by analogy implies that for analogous exposures and outcomes an effect has already been shown. For example, is the observed association supported by a similar association?

Tools to aid decision-making

While obtaining knowledge on various risks is fundamental to the practice of environmental health, it is equally necessary to put in place adequate health and environment surveillance and monitoring systems to assess environmental health conditions. In the following sections we deal with the need to develop indicators for health and environment, and with health impact assessment procedures, which have become critical tools to aid decision-making in environmental health.

Indicators

Monitoring systems

Surveillance and monitoring systems of potential hazards, exposures, and diseases are essential to the practice of environmental health. By tracking exposures and diseases, we can identify and respond to different kinds of environmental health problems, and assess the effectiveness of intervention measures implemented. Surveillance systems exist in various settings, and

have been used for differing purposes. Examples include air and water pollution monitoring, blood lead monitoring programmes, poison centre surveillance, and birth defect registries. The blood lead monitoring programme conducted by the US Centers for Disease Control and Prevention (CDC) played an important role in assessing how blood lead levels in the US population fell in association with reductions in the lead content of petrol during the 1980s, at a time in which there was much scepticism in many quarters about the role that lead in petrol played in influencing blood lead levels. This shows how essential it is that information systems are developed that are supportive of policy and decision-making.

It is important to appreciate that environmental health monitoring is not the same as environmental quality monitoring. From the perspective of environmental health, of key importance is that the exposure information collected is relevant to health concerns. Frequently it is the case that exposure information is based on data from high-exposure areas obtained for the purpose of monitoring the effectiveness of environmental control measures, or of assessing compliance with legislated exposure limits. Such compliance-oriented methods are not optimal for accurate estimation of likely exposure levels of the population.

For many pollutants there is a sharp decrease in concentration levels as one moves away from a source. Similarly, significant vertical variations may occur in the concentration level of a pollutant. Knowledge of spatial and temporal variability of concentrations of exposure may therefore be important from a health point of view, and it may also be necessary to take into account that the exposure may be mediated by more than one environmental pathway. In addition, health and environmental data from monitoring programmes are frequently available at differing levels of resolution, making it difficult to determine any associations. The complexity and intersectoral nature of environmental health surveillance can thus prove very challenging, and few routine monitoring systems are set up to assess exposure to potential contaminants comprehensively.

Role of indicators

Increasingly, communities are demanding access to relevant information on the state of the environment and its influence on health, sometimes as part of their ‘right to know’. The development of indicators is of importance in

helping to make scientifically sound and useful information accessible to decision-makers and the public alike. Environmental health practitioners have an important role to play in their design and use.

The Oxford Dictionary defines an indicator as ‘providing specific information on the state or condition of something’ (Oxford Dictionaries n.d.) They are a way of ‘seeing the big picture by looking at a small piece of it’ (Plan Canada 1999). Indicators can play a key role in turning data into useful information, thereby giving it added value, and also, importantly, in simplifying it. They can give a snapshot (synthesis) view of environment and health trends, and can be used to track progress, to help build the evidence base for effective policies, to identify issues and prioritize problems, provide data for the development of interventions, and for their evaluation.

Indicators have been used in many different fields, at the global, regional, national, local, and sectoral levels. The UN system has been actively involved in indicator development for many years, and there exist numerous data sets on indicators of health, environmental health, environment, sustainable development, poverty, housing, urban development, and others (von Schirnding 2002b). Indicators have also been applied and developed in various settings and sectors, and have been used for various purposes, including in ecosystem health, health promotion, healthy cities, and countless other ways (Cheadle et al. 1992; Takano and Nakamura 2001; von Schirnding 2002b).

Types of indicators

Descriptive indicators may be used to highlight what is happening to the environment or to human health, in order to assess trends, and to obtain baseline information on which to formulate subsequent policy options and plans. They may be of use at a local level (pollution concentration levels), at a national level (mortality rates, incidence of food poisoning), or at a global level (temperature increases in relation to climate change). A performance indicator on the other hand is one that is linked to a reference value or policy target, illustrating how far the indicator is from the desired level. Examples would be ‘the proportion of the population living in electrified areas’, ‘the number of children immunized against infectious diseases’ or ‘the proportion of food outlets inspected in an area’.

Composite indicators may be developed, which condense a wide range of information on different but related phenomena into a single measure or index. In the field of health, the DALY is an example of a composite measure of the burden of disease which combines the years of healthy life lost due to premature death, disability, or disease. Gross national product (GNP) is another example of a composite indicator, as is the Human Development Index (HDI) which combines information on life expectancy at birth, education level, and income level.

Indicators have an especially important role to play in the context of the planning process and setting measurable goals and targets. There are many examples of goal setting in the area of environmental health at all levels—global to local. One example at the global level would be the SDGs. Indicators should however be applicable to the users, rather than being merely technically relevant to data providers. In fact, indicators may be derived by community groups and used for community-based monitoring.

Indicator development

Criteria which have been developed to guide the development, selection, and evaluation of indicators include such factors as their general relevance, scientific soundness, and their applicability to users. Ideally, indicators should be credible, unbiased, and representative of the condition of interest, as well as be consistent, comparable in different settings in time and space, and readily understandable, based on information that is easily accessible. The definitions used for the indicators should be clear, and the data sources and methods used for their collection should be specified (Kjellstrom and Corvalan 1995).

In many countries, despite inevitable problems related to data quality and coverage, and the limitations of routine monitoring systems, it is nevertheless usually possible to find some basic data of use, even if rudimentary or incomplete. If data on health outcomes and exposures is truly unavailable/unusable/inaccessible, it may be prudent to focus instead on action indicators. It may also be possible to use proxy measures of actual exposure (e.g. in relation to air pollution) like traffic volume, distance from a road, or proximity to industry.

Indicator frameworks

Several indicator frameworks have been developed for presenting the various linkages between factors under consideration. One of the earliest of these, upon which many others have been subsequently based, is the OECD Pressure-State-Response (P-S-R) Framework (OECD 2001) which looked at the various pressures which impacted on the state of the environment and necessitated various policy responses.

Modifications to this model such as the D-P-S-I-R (driving forces, pressure, state, impact, response) model adopted by the European Environment Agency made provision for broader driving forces to be taken account of, as well as impacts (including on health) deriving from changes to the state of the environment. The WHO's 'DPSEEA' model (driving force, pressure, state, exposure, effect, action) divides the 'impact' component further into exposure and health effects separately (Kjellstrom and Corvalan 1995; von Schirnding 2002b).

Thus, for example, if applied in environmental health, one can think of 'driving forces' as including such indicators as the population growth rate, or the level of economic development, while the resulting 'pressures' which may be exerted on the environment may be in the form of indicators like pollutant emissions. This may in turn cause the 'state' (quality) of the environment to be degraded through the dispersal and accumulation of pollutants in various environmental media like air, soil, water, and food (indicators might include pollutant concentration levels in media). People may then become 'exposed' to these hazards in the environment (an indicator might be people exposed to air pollution levels above standards) and a variety of 'health effects' may subsequently occur (indicators like air pollution-related morbidity and mortality could be useful). Various 'actions' can then be implemented at different points in the framework (indicators might include clean air policies, technical control measures, treatment regimens, or education measures).

While this may be considered a somewhat linear and simplistic model, it can nevertheless be useful for presenting data in a way that shows the linkages between exposures, health effects, and policy actions in a straightforward and readily understandable, actionable way. Nevertheless, when it comes to dealing with complex ecosystems, for example, deciding what to measure, and how to measure it, and how to analyse and present the measurements, can be very challenging (Cole et al. 1998). In the realm of climate change, development of indicators of vulnerability and

preparedness to inform public health adaptation strategies and project the impact of climate change on human health, is an example (English et al. 2009). Various other indicator models and frameworks with complex webs and feedback loops, in the realm of health and sustainability, have been developed (Waheed et al. 2009; Reis et al. 2015).

Environmental health impact assessment

It is critical to conduct research on specific hazards, carry out epidemiological studies, conduct risk assessments, do environmental monitoring and surveillance of risks, and develop indicators. Most importantly, it is necessary to prevent risks to human health occurring from the outset. In many countries relatively little attention has been paid to the health impacts of planned developments. This, however, is a critical aspect of the practice of environmental health. Impact assessment provides a powerful (yet underutilized) tool to institutionalize a holistic, cross-sectoral approach to addressing health in public policy (Bhatia and Wernham 2008).

Key steps

In line with the principle of sustainability, development should minimize negative health impacts and maximize health benefits. Health impact assessment (HIA) is a decision-support tool aimed at adding value to the decision-making process by analysing potential effects of planned policies, programmes, or projects on health (Davenport et al. 2006). A practical way for collaborating with other sectors and promoting intersectoral collaboration (Kang et al. 2011), HIA has been defined as ‘A combination of procedures, methods and tools by which a policy, programme, or project may be judged as to its potential effects on the health of a population, and the distribution of those effects within the population’ **(**Gothenburg Consensus Paper, WHO 1999). It aims to identify and predict the impacts of proposed developments on environmental parameters that have a strong health significance. Using information from epidemiological and toxicological studies, researchers attempt to identify, predict, and evaluate possible changes in health which could occur as a result of the development under consideration. A risk assessment is then undertaken (see Chapter 7.4).

As a planning tool, it is meant to optimize not only health outcomes, but also environmental, social, and economic outcomes, being not only process-oriented (involving intersectoral collaboration and community participation) but also forward looking to future impacts in the longer term, and in this way bearing the hallmarks of sustainability and sustainable development. Indeed Strategic Environmental Assessment has an important role to play in advancing sustainable development, and, despite many barriers that still need to be overcome (White and Noble 2013), is nevertheless recognized by key bodies such as the World Bank as an important tool for promoting sustainable development (World Bank 2013). There have also been efforts to strengthen the health component of strategic environmental assessment (WHO 1999).

HIA is to an extent based on the environmental impact assessment (EIA) process, with a number of procedural steps accompanied by opportunities for stakeholder involvement. Steps to conduct an HIA include *screening* to identify projects or policies for which an HIA would be useful; *scoping* to identify which health impacts should be assessed and which populations are affected; *assessing* the magnitude, direction, and certainty of health impacts; *reporting* results to decision-makers; and *evaluating* the impact of HIA on the decision-making process. Some HIAs focus on biomedical outcomes (e.g. respiratory disease), while some define health holistically to include social, environmental, and economic conditions. Others focus on equity impacts (Dannenberg et al. 2006).

HIA approaches

Some approaches consider HIA independently of EIA while in other cases HIA is integrated with EIA. For example, in some European countries HIA has evolved independently of EIA and is applied in a wide range of public policy decisions not subject to EIA (Kemm et al. 2004). Despite much work done over the past years however, in a majority of countries, health impacts are all too infrequently incorporated into the impact assessment process. In comparison with EIA, HIA is still, in many ways, in a rudimentary phase. This is somewhat surprising given the substantial growth in HIA activity in recent years, as evidenced by the number of publications, training courses, and guidance materials developed (Davenport et al. 2006). Support has grown most rapidly in Canada, Europe, Australia, and New Zealand—countries where health promotion efforts have had a strong environmental

basis (Cole and Fielding 2007). HIA is also increasingly seen as an important tool for promoting Health in All Policies (Robert Wood Johnson Foundation 2011; Leppo et al. 2013).

Indeed it is interesting to note that even in the country where EIA originated (namely the United States with the promulgation of the National Environmental Policy Act of 1969 (NEPA 1969), and which established the foundation for environmental policy in the United States)—health impacts are still infrequently incorporated into the EIA process, although this is gradually changing. While the objectives and regulations of NEPA do indeed provide for the protection of human health and welfare, in practice where health impacts have been considered, these have been narrowly focused on chemicals and toxic exposures. A comprehensive and systematic approach to addressing human health impacts in impact assessment procedures has yet to evolve. A range of institutional, organizational, and disciplinary factors may account for this (Rattle and Kwiatkowski 2003).

It is also a consequence of the complexity of relationships between exposures and health outcomes as discussed earlier. Sometimes there may be inadequate evidence and methodological challenges involved in predicting health outcomes and it is necessary to make decisions at the pace required by political or economic priorities, which may be based on existing evidence, albeit flawed or inadequate, and professional opinion.

Some have contended that a voluntary approach to HIA is preferable to a regulatory approach, where there is more procedural rigidity and stricter rules of evidence required (Cole et al. 2004). That said, it is often the case that causal certainty and quantitative precision are unrealistic and unnecessary standards for impact assessment. What seems likely is that HIA linked to EIA will conform to the limits of EIA, rather than HIA expanding the scope of the EIA (Cole and Fielding 2007), although there is some evidence in Canada that there has been some success with expanding the traditional EIA approach.

Need for capacity building

Whatever the case may be, HIA methodology has been criticized for the lack of rigour in its use of evidence, and improved guidance is needed on the kinds of public health effects to be included in an impact assessment, as well as on the methods for analysing health effects. New analytical tools are needed to translate the impacts presented in an EIA into valid health impact

predictions. The scope of health issues that could be addressed is broad, and includes conditions as diverse as traffic injuries, social cohesion, traditional diets, domestic violence, psychological problems, and so on (Bhatia and Wernham 2008).

Impact assessment training for environmental health practitioners should be included in the curricula of schools of public health as well as in continuing education courses, and countries should advocate for formal guidance on incorporating health into EIA. Examples exist in Australia and Canada, where guidance for social impact assessment contributed to institutionalizing these issues as routine considerations within EIA.

A guide to reviewing available evidence for use in HIA has been developed by the WHO (Mindell et al. 2010). However, in order for HIA to be more effective, environmental health practitioners need to familiarize themselves with the EIA process and they need also to be more involved in community collaboration (Bhatia and Wernham 2008). In practice, there often exists a tension between the need to involve communities in the HIA process but at the same time to give priority to expert- and research-generated evidence (Wright et al. 2005). In the United States, efforts to promote the role of HIA in improving health have been intensifying and the PEW Charitable Trusts has, through their Health Impact Project in collaboration with the Robert Wood Johnson Foundation, developed a national initiative to promote the use of HIA in the United States, including an online searchable directory and interactive map of HIAs (Pew Charitable Trusts and Robert Wood Johnson Foundation, n.d.).

Intersectoral action and partnerships

The previous subsections on indicators for decision-making, and on HIA processes, have highlighted the possibilities for these tools to help institutionalize intersectoral approaches to policy and decision-making. In this section, we discuss the nature of the intersectoral planning process in addressing health and environment concerns at various levels, which is a key aspect of the practice of environmental health.

While governments share the main responsibility for ensuring healthy living environments, they can do so only by working in collaboration and partnership with other groups. Involving stakeholders in all stages of the

decision-making process is an important part of the practice of environmental health. Over recent years there has been an increasing trend towards decentralized government services and more emphasis on health and environmental actions by non-governmental organizations (NGOs) and the community itself. Intersectoral, participatory planning has become more central to the way governments do business in the field of environmental health.

Where partners have been involved in the definition of problems as well as in their solution, there has been a better chance of commitments being met in the long term. There have been a number of collaborative planning initiatives at various levels of government which involve partnerships with NGOs and local communities, whereby health authorities have been able to address problems more effectively. For example, there have been the national environment and health action plans at the national level (NEHAPS), and local health and environment planning initiatives such as local Agenda 21 initiatives, and initiatives like the WHO healthy cities movement, the UN Human Settlements programme, and United Nations Environment Programme's (UNEP) sustainable cities movement (von Schirnding 1997; UNEP n.d.), among others. These initiatives flourished in the context of the UNCED and Agenda 21—the Global Plan of Action on Sustainable Development.

These, and numerous others subsequently, have led to a better understanding of the importance of environment and development issues within health ministries, as well as a better understanding of health issues within environment ministries. In many cases successful intersectoral committees or commissions and fora have been set up, and in the process alliances and linkages formed with various sectors.

On a global basis, approaches to incorporate health and environment issues in national plans and programmes have varied from country to country depending upon priorities and planning mechanisms and the way in which responsibilities are divided. This has led to a wide variety of approaches being adopted. Sometimes health and environment plans have been included in national plans for sustainable development or for economic and social development. Sectoral plans might include health and environment issues or health considerations might be included in national environmental plans and so forth.

Healthy cities

The healthy cities project has been instrumental in helping to address health and environment issues at the local level in many countries and settings. What started as a small-scale initiative of the WHO arising from the Beyond Healthcare conference held in Toronto, Canada in 1984, became a major movement involving thousands of cities throughout the world.

The healthy cities concept and approach has been translated in different ways according to different priorities and emphases of different localities. Importantly, the healthy cities movement emphasizes process—in particular the building of political commitment and a common vision locally to push health higher up the urban policy agenda. Secondly, there is involvement of a wide range of stakeholders including local communities, and emphasizing community empowerment and participation rather than an expert-led health agenda. Thirdly, strategy development within local government, in the form of a city health plan based on intersectoral partnerships and the necessary stakeholder engagement, is important. This goes along with the development of health information systems, the integration of health into other urban policy and planning processes, and the use of tools to assess health effects (Rydin et al. 2012).

According to the commission by *The Lancet*, most cities evaluated are still struggling with the holistic approach, in which health is fully integrated into urban planning. This is no doubt in part due to lack of adequate understanding of the complexity of systems at work in these urban settings, prompting utilization of a systems approach to the analysis of healthy cities in the future (Rydin et al. 2012). Of key importance though, is that the health sector fit in with planning processes in other sectors rather than the other way around. As we have seen in other areas like HIA, the health sector is also frequently lacking the expertise and capacity needed to measure or estimate the health impacts associated with proposed projects or policies. Until it has developed that capacity its ability to meaningfully participate in intersectoral work may be limited.

What is needed is to be able to better characterize the health burden from the perspective of the sector, rather than merely the specific vehicle of exposure—for example, air or water. In all instances though, data challenges remain key. These include gaps in data availability and quality, difficulties in detecting trends (geographical and temporal), difficulty in disaggregating data, poor linkages of health and environmental data, and

sectoral data. Other problems include emphasis on symptoms rather than on causes of problems, little focus on analysis of management structures and capacity, and lack of clarity in priority-setting processes. Many of these issues have been discussed in earlier sections. Environmental health management issues are further elaborated on in the following section.

Environmental health policy and management

While there is more acceptance now of the links between health status and the determinants of health, especially those that arise from the activities of sectors other than health, there are still problems acting on this knowledge. Greater attention needs to be paid to developing institutional, managerial, administrative, and financial capacities to address problems. Definitions of environmental health aside, it has become increasingly complex to define roles and responsibilities in environmental health in light of its inherent intersectoral nature.

The Institute of Medicine (IOM) report *Investing in a Healthier Future* (2012) highlighted the need to develop a detailed description of a basic set of public health services that must be made available in all jurisdictions. They developed the concept of a minimum package of public health services which includes foundational capabilities and basic programmes which no health department can be without. These apply regardless of the specific area of control—for example, whether it be infectious disease control or environmental health. They are capabilities that are needed across all programmes.

Some of these foundational public health capabilities include the following:

Information systems and resources, including surveillance and epidemiology.
Health planning (including community health improvement planning).
Partnership development and community mobilization.
Policy development, analysis, and decision support.
Communication (including health literacy and cultural competence).
Public health research, evaluation, and quality improvement.

Environmental health policy

Environmental health policy is concerned with selecting actions to reduce or eliminate harmful effects of environmental exposures. Some measures may be short term and remedial, while others may be preventive and longer term. Actions can take many forms and involve such factors as regulations and standards, technological control measures, product design, personal or community protection measures, health and environment action plans, housing or transport policies, awareness raising, and education measures. Such policies can take the form of standards that directly regulate the allowable limit of a contaminant, for example, an air pollution or drinking water standard. Other environmental protection measures can benefit health indirectly, for example, via safeguarding biodiversity, or determining which fuels are used, and hence the impact on air quality and health.

We can maximize opportunities for health by better aligning the policies of sectors with the potential to affect health. Health professionals need constantly to motivate support for policies that are beneficial to health—for example, food and agricultural policies that promote integrated vector control over use of toxic pesticides or encouraging substitution of crops that harm health, and that promote consumption of diets balanced in fruits and vegetables. Similarly, energy policies need to support clean energy sources, cleaner and more energy efficient transport, and energy efficient buildings while transportation policies need to encourage use of bicycles and mass transit.

The overall cumulative impact of such policies can be substantial and can help avoid scenarios in which health is sacrificed for short-term sectoral or economic gain. That is not to imply that health and environmental goals always coincide—frequently they do not. DDT is one example where the immediate health gains were used to lobby for its continued use in sub-Saharan Africa despite its longer-term insidious negative impact on the environment.

Some laws and regulations may in turn contain policies embedded in them. For example, NEPA in the United States states that ‘Congress recognizes that . . . each person should enjoy a healthful environment and that each person has a responsibility to contribute to the preservation and enhancement of the environment’ (Johnson 2005).

Federal laws form much of the environmental framework in the United States and many of these have been emulated in many other countries. Examples of such laws include the Safe Drinking Water Act, and the Clean Air Act. A strong science base is normally required for setting standards, and a science-based risk assessment process undertaken to inform risk management policies and strategies, which of necessity also take into account social, economic, and political considerations.

Policies may also span the spectrum of government—from global to local. In general, policy approaches tend to become more specific and targeted as they go from national to state/provincial/regional to local. In the United States, for example, federal statutes and regulations may be issued and states and local governments will issue statutes or ordinances needed to comply with these, or they may develop their own regulations. Policies may be preventive and aim to reduce hazards directly in a prospective manner (e.g. air pollution regulations) or they may be retrospective and require, for example, clean-up of a toxic waste site. Other types of policies may be aimed at awareness raising and education of the public rather than regulatory control (Johnson 2005
).

International policy principles have been adopted as well. For example, as indicated earlier, the UNCED adopted the Precautionary Principle, which states ‘ … Where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environmental degradation’ (UNCED 1992). Another principle adopted was the Polluter Pays Principle—that is, those who cause pollution should pay the price to clean it up. Economic instruments such as pollutant trading systems are also in use which shift the societal cost of pollution to the polluter.

The principle of intergenerational equity states that ‘The right to development must be fulfilled so as to equitably meet developmental and environmental needs of present and future generations’. This principle has particular relevance in regard to chemicals with long-term adverse consequences, and to greenhouse gases and climate change, for example. Another UNCED principle, the principle of integrated decision-making states that ‘In order to achieve sustainable development, environmental protection shall constitute an integral part of the development process and cannot be considered in isolation from it’. Thus, environmental

considerations need to be incorporated into decision-making processes at all levels, global to local, and in all sectors, as alluded to earlier. Environment and HIA processes, and the 'health in all policies' movement, are example of this principle in action.

Impacts originating from a multitude of small sectors rather than from one large obvious source such as a major polluting factory, for example, are often more difficult to control. Smaller enterprises usually have fewer resources at their disposal and are more resistant to change, or may be less knowledgeable about standards which may apply, than large-scale industry. In developing countries, fewer controls are generally applied and control technology may be less well developed. In the absence of local standards (which demand relevant epidemiological and exposure data, which may often not be available), international standards are often applied but may not be appropriate (Goldman and Torres 2009) due to the differing prevailing lifestyles, cultures, climate, demographic attributes, institutional and policy framework, level of economic development, and so on, which differ from country to country.

Environmental standards may be risk based (i.e. based on assessments of environmental or health risks) or technology based (i.e. based on the best available technology) or a combination of both. Pollution prevention is key. Increasingly it has been recognized that controlling pollutants one medium at a time can result in transferring pollutants from one medium to another, for example, from air to water to land. Multimedia approaches are thus preferable. Reduction of pollution at source is optimal, but other strategies include waste minimization, reuse, recycling, emissions control, and, finally, clean-up. Environmental monitoring has an important role to play in evaluating the success or otherwise of the various control measures adopted, and the public may have an important role in advocacy, monitoring, and enforcement of environmental policies.

Financial incentives

As environmental health protection measures inevitably involve costs, cost–benefit analyses may be undertaken to weigh costs and benefits of an action, while cost-effectiveness analyses might be performed to look at alternative solutions to a problem. Attempts may also be made to assess economic inequities in impacts, taking into consideration issues of environmental justice. Economic and fiscal policies can influence the

potential for health gains and their distribution in society. Financial incentives can be established so that they can incentivize a healthier lifestyle and discourage the use of harmful products and substances. When combined with appropriate legislation and health education programmes, many of the negative health trends could be retarded or even reversed.

International regulations

When pollutants cross boundaries, or where there are global impacts and concerns, international agreements and standards come into play. In parallel with the role that international conferences have played in galvanizing action on health and environment issues, so too do international environmental treaties offer the prospect of further advances in public health. Due in part to the WHO's and others' increasing involvement in international conferences and treaty-making processes in recent years, health issues have received increasing recognition and attention. Mechanisms in international environmental law can be used to provide motivations for research aimed at further strengthening the evidence base related to health, and to achieve improved surveillance and monitoring systems concerned with ill-health. Increased efforts are needed to more fully realize the potential of international law to promote global environmental health (von Schirnding et al. 2002).

Many multilateral environmental agreements have health implications, for example, the Montreal Protocol on Protection of the Ozone Layer (1987), the Basel Convention on the Control of Transboundary Movements of Hazardous Wastes and their Disposal (1989), the Convention on Biological Diversity adopted in 1992 (including the Cartagena Protocol on Biosafety), the Kyoto Protocol of the UN Framework on Climate Change (1997), the Rotterdam Convention on the Prior Informed Consent Procedure for Certain Hazardous Chemicals and Pesticides in International Trade (1998), and the Stockholm Convention on Persistent Organic Pollutants (2001).

Environmental agreements in existence today, however, recognize the sovereign right and responsibility of nations to set their own standards. So, for example, the Basel Convention does not cover handling and disposal of wastes within a country, and the Rotterdam Convention does not require prior consent for chemicals manufactured and produced within a country (Goldman and Torres 2009).

Environmental health services

It is complicated to manage environmental health issues which are intersectoral, and whose determinants frequently lie outside the control of the health sector, or outside of jurisdictional boundaries, with different organizations and agencies having differing roles and responsibilities in respect of policy development and implementation, In addition, systems of organization in many government authorities worldwide may be based on concepts of bureaucracy, hierarchy, professional authority, disciplinary specialization, and sectoral analysis that were established for purposes other than the provision of environmental health services (von Schirnding 1997). To facilitate implementation of intersectoral policies and plans there may be a need for institutional restructuring and readjustment in order to overcome barriers and obstacles in coordinating action between sectors.

One approach is to make internal reforms within government departments. Issues that may need to be addressed might include creating mechanisms for interjurisdictional cooperation in implementing policies and plans, decentralizing of structures facilitate community involvement across sectors, and establishing better coordination between and within governance structures. Other types of jurisdictional reform include transferring powers and functions from one department to another or from one tier of government to another, changing geographical boundaries, consolidating multiple jurisdictions, and/or forming various coordinating mechanisms. In any case, increasing mechanisms for sharing power, exchanging information, and aligning financial resources and incentives are all important.

While there is no universal understanding of what precisely constitutes an environmental health service, it is essentially concerned with developing and implementing environment and health policies, largely through monitoring and control activities, but also increasingly through environmental health promotion efforts. Environmental health services worldwide have been established and developed within a complex framework of policies, institutions, and legislation. The concept of environmental health, the problems to be addressed, the way in which services are delivered, and the way in which governments are organized differ considerably throughout the world.

Environmental health activities are carried out in many different settings at various tiers of government, in the private sector, the workplace, healthcare facilities, and so on. In most countries a range of different agencies have responsibility for various aspects of environment and human health at different levels of government. Normally there are separate regulatory agencies dealing with the environment, health, food safety, agriculture, and so on, which have various environmental health responsibilities. Different tiers of government have different responsibilities. Thus, for example, regulatory frameworks and standards (e.g. for air, drinking water, and so on.) may be set at a national level, while implementation and enforcement may occur at a state, regional, or local level. Inspection of food preparation premises, food hygiene, sanitation, vector control, and so on, are normally done at the local level. This requires strong monitoring and enforcement abilities which are sometimes in short supply, especially in some developing countries.

Internationally a shift has occurred towards organizational diversification regarding environmental health services. In the context of the development of primary healthcare services and district health systems in many developing countries, and parallel development outside of the health sector of environmental management systems, the placement of environmental health services within government structures is a fundamental issue in need of addressing. Despite the fact that environmental health is recognized as a major and core function of a public health department, it is also the case that the public health sector has gradually lost organizational responsibility for many aspects of environmental health.

This includes, increasingly, such aspects as air quality, waste management, chemical safety, meat inspection, and many other areas. While it would be unmanageable for the full ambit of environmental health services to be located centrally in one department, in light of its intersectoral nature, what is needed is to develop organizational structures that facilitate the movement of professionals across different departments, sectors, and organizations. Box 11.6.3 gives a case study from the United States, which is typical of the situation in many countries around the world, who face similar challenges in regard to the placement of environmental health functions subsequent to the establishment of environmental departments and new environmental regulations.

Box 11.6.3 Organizational responsibility for environmental health in the United States

In the first part of the twentieth century in the United States, a typical scenario was a health department headed by a physician, with nurses responsible for immunization programmes and sanitarians/sanitary engineers responsible for sanitary inspection, water and sanitation, food safety, vector control, and so on. Sanitarians were generalists trained to respond to a broad array of environmental health issues.

With increasing industrialization and growing public awareness about the widespread contamination of the environment in the 1960s, a number of environmental laws dealing with water and air quality, toxic substances, and other issues were passed, and the US EPA was established. Separate state-level environmental agencies were also established, with responsibility for enforcement of these new environmental laws. At this time many of the traditional environmental health functions falling under health departments were transferred to environmental departments with positive (increased funding and visibility) but also negative (schism in environment and health actions) repercussions. Separate data systems, uncoordinated planning, and loss of oversight of community health and environment issues resulted. With the new environmental 'medium-specific' laws, and the emergence of environmental health specialists in particular areas like water or air quality, environmental health professionals became increasingly disconnected from their public health roots and counterparts in health departments at state or local level and the agencies grew apart too.

Subsequently in the 1970s and 1980s there was a growing public awareness and involvement in environmental health issues and a demand for more accountability and transparency in decision-making. With the advent of environmental impact assessment legislation and requirements for public involvement, watchdog groups, and advocacy organizations were formed with a strong focus on environmental justice, human rights, and equity concerns. Increasing initiatives to reconnect environmental and public health sprang up out of a sense of growing dissatisfaction over the inability of accountable agencies to address these in a coordinated and integrated way.

Environmental health practitioners

In general, environmental health practitioners and professionals have as their main responsibilities the identification, assessment, management, communication, and remediation of health risks resulting from environmental factors. They include people working in a wide range of professions and specialties and include environmental health officers (EHOs), sanitarians, health inspectors, clinicians, epidemiologists, toxicologists, environmental scientists, environmental engineers,

veterinarians, and many others. Examples of specialty areas of environmental health practice are given in Box 11.6.4.

Box 11.6.4 Specialty areas of environmental health practice

- Air quality management
- Consumer safety
- Emergency preparedness
- Environmental epidemiology
- Food safety
- Housing quality
- Noise control
- Outbreak investigation
- Radiation control
- Recreational health and safety
- Risk assessment
- Solid waste management
- Sanitation
- Toxic substances control
- Vector control
- Drinking and recreational water supply and treatment
- Water quality management

Environmental health officers

As stated at the beginning of this chapter, the roots of the environmental health profession today can be found in the sanitary and public health movement of the United Kingdom during the 1800s. The role of the health inspector has steadily changed over the years, and has evolved from a focus on inspection and control, to a broader role that also includes education, health promotion, community development, and indeed sustainable development (Guidotti 2015). Commensurate with the changing role of the health inspector has been a change in title—variously referred to over time and in different settings as sanitarian, inspector of nuisances, sanitary inspector, health inspector/technician/assistant, public health officer, environmental health officer, or environmental health practitioner/specialist/professional.

Notwithstanding changing roles and titles, the theory and conceptual basis of environmental health is firmly based in public health, and the practice of environmental health, as embodied in the day-to-day work of EHOs and others, is closely associated with inspection and environmental control, with EHOs being responsible for administering and enforcing legislation related to environmental health.

Normally an EHO would be a public employee in a health department in local government or at regional/provincial/state level who investigates environmental hazards and public health nuisances with the view to mitigating or eliminating these. EHOs are involved in inspection of housing, food establishments, schools, daycare centres, nursing homes, and many other premises, and are also involved in vector control, pollution control, and health promotion activities. They may also be employed by the military and by the private sector.

It is inevitable that, with the increasing involvement in environmental health of professionals and specialists from a wide variety of fields including environmental chemistry, physics, environmental science, geography, environmental engineering, public health, medicine, and others, the role of the EHO outside of its traditional ambit of inspection, monitoring, and control will continue to evolve. This also has a bearing on their role inside of, and outside of, the health service, and the challenges and constraints faced while working on the broader determinants of health, within the principles of sustainable development, but remaining firmly public health based.

Qualifications and training

Environmental health requires, in many countries, a university degree, with field training and professional certification needed for environmental health officers/practitioners. In the United Kingdom, a degree in environmental health is required, as well as certification and registration with the Chartered Institute of Environmental Health. Many universities in the United Kingdom offer accredited environmental health degrees, including undergraduate and postgraduate degrees. A postgraduate environmental health qualification is required for graduates from other scientific disciplines (Chartered Institute of Environmental Health n.d.). The Chartered Institute of Environmental Health offers training modules in

specialized areas of environmental health as does the Environmental Health Registration Board (n.d.).

In Canada, EHOs are required to hold a bachelor's degree in environmental health or a related field as well as a certificate in public health inspection. A number of universities in Canada offer degree programmes approved by the Canadian Institute of Public Health Inspectors (n.d.). A bachelor's degree and professional licence is also a requirement in parts of the United States and there exists the National Environmental Health Association (NEHA) offering environmental health credentials and registration/certification for practitioners. Interestingly, the premier NEHA credential is referred to as the Registered Environmental Health Specialist/Registered Sanitarian (REHS/RS) (NEHA n.d.).

There exists, as well the International Federation of Environmental Health (n.d.), the initiative to promote cooperation between countries where environmental health issues are cross-boundary. Regional groups exist in Africa, the Americas, Asia and the Pacific, Europe, and the Middle East. Member countries in turn have their own professional institutes and associations of environmental health. These include such bodies as the Environmental Health Workers Association of Uganda, the Public Health Inspectors Union of Sri Lanka, the Malta Association of Environmental Health Officers, the Kenya Association of Public Health Officers, and numerous others, reflecting the variety of names given to those practising environmental health around the world.

In some countries (South Africa for example), degree courses in environmental science or health are offered at universities, and diploma courses (e.g. the National Diploma in Environmental Health) at technical institutions. Degrees in environmental health technology are also offered. Environmental health practitioners are required to complete practical training and registration with the Health Professions Council of South Africa (n.d.). Training programmes have been updated to accommodate the changing role of the environmental health officer in South Africa from law enforcer to community facilitator, in line with changing political and economic realities which make legislation difficult to enforce, especially in the context of rapid urbanization, informal settlements, and a large informal sector.

Clinicians

Clinicians are becoming increasingly involved in the practice of environmental health. The diagnosis of illnesses that are associated with environmental exposures is an important clinical function that expanded from the field of occupational medicine, to a focus on the broader environment outside of the workplace (Laumbach and Kipen 2005). Treating environmentally related diseases is often the same as treating these illnesses from other causes, although in some cases (e.g. lead poisoning), specialized treatments may be required. Clinicians need to be alert to the role that environmental factors may play and adopt a high 'index of suspicion' in assessing underlying signs, symptoms, and diseases in patients —whether adults or children (Laumbach and Kipen 2005).

If an environmental cause is suspected, an environmental history should be taken in order to obtain information on potential sources and pathways of exposure (both current and past), and in the case of a paediatric evaluation the age and development stage of the child. In the case of infants, for example, breastfeeding could be a source of exposure to be considered, and the hand-to-mouth pathway could be of special significance.

Examples of environmental health problems dealt with by clinicians include lead poisoning, asthma associated with air pollution, poisoning by pesticides, hearing loss caused by noise, and cancer associated with excessive radiation. Apart from diagnosing and treating environmental diseases, clinicians also have an important role to play in prevention, including advocacy for protective standards, and patient education to avoid or reduce exposures.

Children's environmental health issues have become of increasing importance to paediatricians. In 1997, an Executive Order on Children's Environmental Health and Safety was signed in the United States and a cabinet-level oversight committee was formed between the US EPA and the Department of Health and Human Services. Since then, children's environmental health has become an increasingly important part of paediatric practice (Landrigan and Etzel 2013). Improved exposure and risk assessment and toxicity testing is needed to more adequately address children's environmental health issues, however (Galvez et al. 2005). As part of the WHO's contribution to the follow-up to the WSSD held in 2002, an international alliance on 'Healthy Environments for Children' (HECA)

was formed to help advocate for worldwide action on environmental health issues affecting children (WHO n.d. 2009).

Conclusion

This chapter has highlighted a number of key issues relating to the nature and practice of environmental health, which is a complex, dynamic, and evolving multidisciplinary field. It is increasingly evident that environmental health practitioners face numerous challenges in addressing the myriad factors influencing health and environment relationships in differing contexts and settings.

The multiplicity and interaction of chemical, physical, and biological risks in the environment, the various media and pathways of exposure, the differing vulnerabilities and susceptibilities of diverse groups, and the changing priorities and capacities for the management of environmental health risks in various parts of the world, all need to be addressed by practitioners of environmental health.

Despite dramatic advances in the recognition and amelioration of environmental health risks worldwide in recent decades, there nevertheless remain significant gaps in knowledge of new and emerging risks, and in approaches needed to more effectively address them. Improved indicators which are reflective of complex health and environment interactions, and health impact and risk assessment procedures which can better predict impacts associated with differing environment and development parameters and scenarios, are needed.

So too are systems approaches needed for addressing the complexity of issues associated with ecosystems, global change, urbanization, and sectors like energy, housing, and transport. Economic development, the environment, and human health are closely intertwined and interconnected, and need to be addressed as such.

As evidenced by the intersectoral health and sustainable development planning processes which have been underway in recent years at all levels —global to local—there will be more of a need for practitioners to work proactively with communities and other stakeholders and partners in addressing the complexity of health and environment issues. While increasing capacity is needed to assess and address intersectoral impacts,

the causes of which frequently lie outside the domain of the health sector, tools like HIA can help to institutionalize intersectoral processes in policymaking and decision-making.

With the continuing development of improved risk assessment procedures and environmental health management tools and policy instruments, and ongoing capacity development of environmental health practitioners and professionals in various settings and tiers of government worldwide, excellence in the practice of environmental health will culminate in increasingly healthier environments for current and future generations to come.

Strategies and structures for public health interventions

Sian Griffiths and Kevin A. Fenton

Introduction

The mantra that public health is everybody's business can be two edged. On the one hand, it implies wide support for interventions which would improve health. On the other, it implies such wide responsibility that no one makes public health interventions their priority. Thus, strategies for improving public health and structures for their implementation are complex and situation dependent. It is not always possible to translate a successful programme in city A to one in city B, country C to country D, or urban area E to rural area F (Rao et al. 2007). However, the knowledge base and evidence for effective interventions are growing and the appreciation of the critical role of cross-sectoral and multilevel approaches is deepening.

The use of evidence underscores the breadth of interventions which improve health. For example, the strongest evidence among the 43 most effective interventions identified for improving dietary habits, increasing physical activity, and reducing smoking were economic incentives to make healthier foods more affordable; improved safer roadsides and land-use design to encourage physical activity as well as smoking bans (American Heart Association 2012).

Thus, public health interventions require a wide range of strategies to translate policies into effective action plans (Kickbusch and Buckett 2010) and structures for their implementation if they are to be effective at producing population-level improvements in health.

Strategies may be global agreements, national plans, or local government or community agreements for action (Department of Health 2011a). To be implemented, they require structures which are both directly and indirectly concerned with health outcomes, evidence-based processes, and outcome

measures of their effectiveness. Strategies may directly involve the health services which make contributions both to improving health as well as to managing disease but, more often than not, strategies are multisectoral, address the broader determinants of health, and involve an ecological perspective which engages politicians, the corporate sector, civil society, local communities, and the public. This chapter will discuss the concept of strategic approaches for improving the public's health and give examples of health-promoting strategies at global, national, local, and individual levels.

Why a strategic approach?

The purpose of public health is to promote and protect health and prevent disease and injury. Improving the health and well-being of communities is a difficult process which takes time and involvement from a range of stakeholders including the public and communities. Having robust strategies to guide public health interventions is critical to guide the improvement of health of the public, to ensure effective use of resources and appropriate investments and to support successful implementation of plans in order that governments and organizations are best able to promote and protect health and prevent disease and injury.

The need for an increasing focus on effective strategies to guide public health interventions is welcome and has been a journey of continuous improvement over the past three decades. This has in part been driven by the understanding of the need to address the systemic causes of ill-health in a more coordinated, resource effective way, which delivers intended results and maintains trust among stakeholders and the community (WHO 2010).

Today, governments recognize that they have the responsibility to translate these calls for change into national health policies, strategies, and plans (WHO 2010). At the same time, they understand the complex systems in which we operate mean that plans must be fit for purpose, inclusive, and ideally integrated into existing assets and infrastructures to ensure success. It is now widely understood that national health policies, strategies, and plans have to go beyond healthcare delivery and address the broad public health agenda; and that they have to go beyond the boundaries of health systems, addressing the social determinants of health and the interaction between the health sector and other sectors in society.

In summary, the need for effective strategy to guide public health interventions is increasingly being driven by a range of other factors including:

Improvements in the understanding of the role of good governance, strong national capacities, and transparency to reap the full benefits of global, regional, and national cooperation and intelligence
A greater focus on accountability and transparency
A realistic assessment of current capacities and how bold vision for the future may be achieved through improved collaboration, coordination, and utilization of assets
The need to harmonize and align financial and technical health sector investments to reduce fragmentation and duplication and maximize health impact.

The need for strategy

Health is created by a complex variety of interacting influences, reflected in the World Health Organization's (WHO's) definition which not only highlights the physical and psychological aspects of good health, but also its socioeconomic and environmental dimensions (WHO 1948). More recently global leadership initiatives on Planetary Health (Whitmee et al. 2015), World Health Organization One Health (WHO 2017b), and the United National Sustainable Development Goals (United Nations n.d. c) provide examples of the global mobilization, engagement, and the strategic approach needed to tackle emerging and urgent public health threats.

Using England as an example, the government's 2010 public health strategy, *Healthy Lives, Healthy People* (HM Government 2010) underscored its commitment to protecting and improving health and reducing health inequalities. It recognized that although people are generally living longer, the overall burden of chronic physical and mental ill-health is increasing, and the poor are worse off than the rich. The strategy was evidence-based and rooted in an approach that engaged and integrated the efforts of national and local government, the National Health Service (NHS), charities, schools, higher education, voluntary groups, businesses, and employers. The strategy accepted a place for government leadership and, albeit when other approaches have failed, for regulation. However, it took

the view that the balance of responsibility and action should shift from central government to local communities, and that people should be ‘nudged’ towards taking on more responsibility for their health by living more healthily. A cabinet subcommittee was established to engage relevant government departments, and the strategy includes an encouraging list of related initiatives.

By 2013, this strategy was updated in the government’s Living Well for Longer: A call to action to reduce avoidable premature mortality strategy (DH 2013) recognizing that if we are to tackle the challenge of rising non-communicable diseases, improvements are needed across the three domains of prevention, early diagnosis, and treatment. Two-thirds of deaths under 75 are avoidable, and around 80% of those are preventable, largely through improved public health. This new strategic approach recognized changes within the health and care system in England where local government has become the major force for improvements in public health as it takes on responsibility for health improvement. This complements local responsibilities for tackling the wider determinants of health, such as air quality, road deaths, transport, noise, violence, housing, fuel poverty, and use of outdoor space. Bringing together lead responsibility for preventative action across this wide spectrum provides a unified approach to tackling the causes of ill-health. The updated strategy also stresses the importance of maximizing opportunities across primary care to reduce premature mortality, as local government roles span prevention, early diagnosis, and treatment. A strategic approach to strengthening primary care was seen as paramount for improving rates of early diagnosis, ensuring that key risk factors, diagnosing illness, and long-term conditions were done as early as possible, along with proper case management of people’s conditions and risks with appropriate and timely referral to secondary care for further treatment.

Strategic development is dynamic and linked to policy. For example, in China, among the first challenges faced by the new People’s Republic of China in 1949 was the need to improve the general health and hygiene of the population (Dai and Jiang 2013). Strategies for tackling inadequate sanitation, communicable diseases, and providing basic care at the community level for mothers and children led to the creation of the ‘barefoot doctor system’, a forerunner for many current models of community-based primary care. In the latter part of the twentieth century, China has become one of the largest forces in the world economy but during the ‘opening up’,

the lack of strategy for the health services meant that market forces dominated, resulting in greater inequity in health and decimation of the public health system. Health was not a priority and economic strategies held sway. As a consequence, the first decade of the twenty-first century brought the urgent need to bridge the gap between China's world-class economy and its poor health service provision in which many people were unable to afford basic care. The inequities between the affluent East Coast and urban areas have grown and China now faces not only the problems of an increasingly ageing population and the growing challenge from non-communicable diseases (NCDs), but the poorer, less-developed parts of the country still remain in greater need of infectious disease surveillance, improvements in maternal health, and implementation of basic primary care programmes, in addition to the challenge of a growing burden of NCDs. The massive movements of migrants from rural to urban communities, estimated to be around 200 million in 2012, add extra challenges for public health (Daar et al. 2007; Jin et al. 2013; Mohammed n.d.). At the national level, in addition to hospital service reform, new policies placing greater emphasis on prevention, a stronger public health system, and new strategies to improve primary care are in development to reduce the growing health burdens resulting from rapid urbanization, growing consumption of tobacco, and the increasing rates of lifestyle-related NCDs (Tan et al. 2018).

The experience of China demonstrates the need for national strategy to be interpreted at local levels according to the needs of the population and the resources available. The wide variations in health status, as well as access to care, underline that the delivery of strategy relies not only on national strategic intent, but on appropriate infrastructures and resources at the local level. This was demonstrated in 2003 by the severe acute respiratory syndrome (SARS) epidemic in Hong Kong.

CASE STUDY 11.7.1 Lessons from SARS in Hong Kong

Among the global lessons learned from the experience of SARS in 2003 was that better strategies and structures were needed across all sectors of the health and political systems to respond to the threat of new emerging infectious diseases and to the possibility of a pandemic. When SARS hit Hong Kong in 2003, its surveillance systems were focused on the possibility of an H5N1 (avian flu) pandemic and influenza-like illnesses, and the authorities were monitoring the hospital system. Local activity on the Hong Kong borders, such as shop shelves empty of white vinegar boiled by local residents to sanitize and protect their homes from a rumoured killer disease over the border, went unremarked. There was no formal exchange of accurate information about this atypical pneumonia outbreak in the Guangdong Province available to Hong Kong or to the

international community. Only when a group of healthcare workers and medical students in Hong Kong were admitted to one of the largest teaching hospitals with an unidentified respiratory illness within a few days in early March was an alarm triggered in the healthcare community (Hong Kong College of Community Medicine n.d.; Hong Kong Academy of Medicine n.d.).

While the story of the spread of the disease to the local community and to the rest of the world is now well known, the Independent Inquiry commissioned by the Hong Kong government (Hong Kong Special Administrative Region Government 2003) provided the opportunity to review what strategies had been in place and how well they had worked. The Inquiry found that while the healthcare staff could be commended for the care they gave the patients, the healthcare system itself had structural deficits and the strategy for action was inadequate. The ability to rapidly legislate to designate the new disease as notifiable was not in place, and interventions were hindered by outdated legislation. The organization of health protection functions, hospital management, and the relationships with central government all needed review. Better collaboration and communication outside Hong Kong, within Hong Kong, and within the healthcare sector was also needed, and it was recognized that to manage workforce capacity for future epidemics, training, and research were all needed. These findings had much in common with the Canadian experience (the country hardest hit by SARS outside of Asia), where it was found that amid the commendable response by public health and healthcare workers to contain SARS, there were still many systematic deficiencies to adequately address outbreak containment, surveillance, information management, and infection control (Naylor et al. 2004).

In response to the SARS epidemic, significant progress to strengthen structures and strategies to combat emerging infectious diseases have been put in place by both affected and unaffected jurisdictions. In Hong Kong, as in many other countries, surveillance information is now available through a real-time system of reporting of data not only across the Pearl River Delta but globally through the network coordinated by the WHO. Active networks not only of government officials responsible for resilience, but also of researchers, are in regular communication. Communication between the hospital and the community has been improved by streamlined systems and the creation of geographical coterminosity between catchment areas. Extensive plans are now in place for all sectors and staff to be trained through ‘drills’ which are intersectoral, and which have clear leadership and chains of command and control. The public and the media are better informed about communicable diseases and about preventive measures, such as hand washing. Efforts are continually being made to ensure that communication is open and transparent with press releases and letters to medical staff to keep them abreast of emergent diseases.

The new improved infrastructure was put to the test in 2008 with the threat of the H1N1 pandemic (Cowling et al. 2010). Unlike the SARS experience of 2003, the media and politicians worked together to ensure public health messages about H1N1 were clear and well communicated to the public, based on up-to-date information regularly provided by the Centre for Health Protection (CHP). The CHP, which was established post-SARS, was able to play its part in the global network of surveillance for communicable diseases acting as the central structure to coordinate local responses, and ensuing global collaboration and communication (Hong Kong Government n.d.).

The experiences of SARS and H1N1, and more recently H7N9 in Asia and the Middle East respiratory syndrome coronavirus (MERS-CoV), have demonstrated the need for cross-sectoral strategy, a clear plan for proposed implementation, as well as identified structures to support its implementation. The experience of H1N1 demonstrated that both strategy and structures had improved with the lessons learned from SARS and, in 2013, the flow of information about H7N9 to the press, various professions, and the public is significantly better, as is the support from the global scientific community.

CASE STUDY 11.7.2 Lessons from Ebola in Congo (WHO 2018)

On 8 May 2018, following the provisions of the International Health Regulations, the Ministry of Health of the Democratic Republic of Congo notified WHO of two confirmed cases of Ebola virus disease (EVD) in the Bikoro health district in Equateur province. The affected areas shared a border with the Republic of Congo. This is the ninth Ebola outbreak in Democratic Republic of the Congo, but the first in the province of Equateur.

The national and local authorities and their partners acted quickly to respond to this outbreak. A National Epidemic Response Coordination Committee was established to coordinate the interventions and partners' efforts following the official declaration of the epidemic as a public health emergency by the Ministry of Health (announced on 8 May 2018). A joint response plan for all partners to support the Ministry of Health was developed. This initial plan covered a 3-month period expiring at the end of July 2018. After this first stage, a consolidation and stabilization phase was necessary to develop resilience at the local and national levels.

By summer 2018, 54 cases were reported, including 38 confirmed cases and 16 probable cases. The last confirmed case of EVD in Equateur Province was reported on 6 June 2018. The last confirmed case admitted to the Ebola treatment centre was discharged on 12 June 2018 and monitoring of all registered contacts was discontinued on 27 June 2018.

A national strategic response plan was developed to guide the work of all stakeholders involved in the response around the Ministry of Health. The first phase of the EVD response was to protect the towns of Bikoro and Mbandaka against an increase in cases that could potentially threaten the country's major cities as well as neighbouring countries along the river. The strategy adopted by the Ministry of Health was to bring laboratory diagnosis of EVD closer to the populations affected by the epidemic. Infection prevention and control measures were strengthened in major hospitals and other health facilities.

Defining strategy

Strategy can be seen as a means of mobilizing an organization to get to its future. It is about giving an organization purpose and direction, motivating trustees, staff, and volunteers to engage meaningfully with the external environment—linking in with funders and beneficiaries (WHO 2010).

Strategy is about determining how an organization will match its diverse capabilities with the needs of stakeholders, now and in the future (in order to maximize impact). An organization's strategy will determine how it relates to the outside world—how it makes the most of opportunities, responds to change, and faces up to threats: opportunities to innovate, improvise, and improve.

A strategy makes it clear what the priorities are, and what the organization's resources should be concentrated on delivering. While most strategies focus on the medium to long term (3 to 5 years), they are often reliant on the short term too, since one cannot often predict when and how

things will change. Consequently, strategic plans need to be flexible and agile. Strategies are often developed ‘top-down’ but increasingly organizations seek to mobilize and motivate everyone in the organization and their strategic partners and key stakeholders by early involvement. Strategy will emerge from the grassroots of an organization—finding ways of creatively integrating top-down from bottom-up is vital.

Experience shows that the process for building comprehensive national health policies, strategies, and plans is as much a political process as a technical one. It requires attention for the inspirational side of defining vision and policy; it also requires attention for operational detail (WHO 2010). The balance between vision, policy, strategic planning, and attention for implementation varies considerably from country to country and between national, regional, and local levels. Given the overarching importance of context, blueprint approaches are unlikely to be of much assistance. Nevertheless, there are ways of going about policy dialogue that are more likely to produce robust policies, strategies, and plans.

Strategies are a necessary step in the translation of policies into plans and action. They create the bridge between policy and practice. Mintzberg (1987) has described five aspects of strategies:

Plan—with purposeful intended action.
Ploy—competitive manoeuvring.
Pattern—signalling a plan in a series of actions.
Position—relevant to the outside world.
Perspective—an organizational personality.

Translating the aspects of strategy into public health practice requires certain features:

Focus on populations rather than individuals.
Address the social determinants of health and their impact on poverty.
Base on values of social justice and equity.
Reflect a global perspective.
Be aware of the dynamic relationship between the environment and health.
Place priority on prevention rather than curative care.
Understand the importance of systems and structures.
Take a transdisciplinary and multisectoral approach.

Ensure decision-making is based on:

Vital statistics (population-based data).
Data, scientific evidence, and good research.
Surveillance and outbreak investigation.
Be committed to advocacy and in tune with politics.

Strategic plans may relate to the health status or needs of a defined group of people or of the population as a whole, and may take various forms, such as laws, rules and regulations, guidelines, recommendations, and mandates (Kawamoto 2004).

Health strategy and health service strategy are both important for delivering better public health interventions. Health services are responsible for dealing with disease, and they do not control the major forces which cause disease. They can, however, play a significant role in prevention both at institutional and individual levels through the services they provide and the institutional influences they exert. Health strategy is, however, conceptually broader and requires engagement at different population levels with a wide variety of forces which impact on health—social, economic, political—and with a wide range of multisectoral stakeholders.

CASE STUDY 11.7.3 The Sustainable Development Goals (WHO 2015)

The 2030 Sustainable Development Agenda is of unprecedented scope and ambition, applicable to all countries, and goes well beyond the previous Millennium Development Goals (MDGs), which came to the end of their term (United Nations n.d. a; United Nations n.d. b), and a post-2015 agenda, comprising 17 Sustainable Development Goals (SDGs), takes their place. While the MDGs were concerned with low and middle-income countries, SDGs are global in their aspiration. Poverty eradication, health, education, and food security, and nutrition remain priorities, but the SDGs importantly comprise a broad range of economic, social, and environmental objectives, and offer the prospect of more peaceful and inclusive societies (WHO n.d. a). Notable among the remaining challenges include acute epidemic diseases, disasters, and conflict situations, the burgeoning epidemic of NCDs and mental health disorders and large inequalities in all parts of the world.

The SDGs address many of these issues head on, setting a new health goal (‘Ensure healthy lives and promote well-being for all at all ages’) with a broad set of targets (WHO 2015). The SDGs also significantly broaden the scope of action with 17 goals and 169 targets, including one specific goal for health with 13 targets, of the new development agenda integrating the three dimensions of sustainable development around people, planet, prosperity, peace, and partnership. The health goal is broad: ‘Ensure healthy lives and promote well-being for all at all ages’. Health has a central place as a major contributor to and beneficiary of sustainable development policies. There are many linkages between the health goal and other goals and targets, reflecting the

integrated approach that is underpinning the SDGs. Universal health coverage (UHC), one of the 13 health goal targets, provides an overall framework for the implementation of a broad and ambitious health agenda in all countries (NHS n.d.).

Fundamental to achieving the SDGs will be the recognition that eradicating poverty and inequality, creating inclusive economic growth, preserving the planet, and improving population health are not just linked but interdependent. This has profound implications for development strategy, many of which will only be revealed as we move forward. But some seem fairly clear at the outset, including the fact that silo-based, vertical approaches to development will have to give way to broader, cross-cutting approaches coordinated around and aligned with countries' needs and priorities.

By taking a more integrated approach to development the SDGs present an opportunity to advance, seizing opportunities to collaborate and exploit synergies. However, there are clearly challenges too. For example, in order to take on cross-cutting issues, it will be necessary to achieve far greater intersectoral coherence and coordination of effort. To achieve that end, a new impetus will have to be given to global and regional partnerships and collaborations, with a focus on country action.

Public health strategy: from global to local

Global public health strategies

Strategies may address needs at multiple population levels and be influenced not only by local factors, but also by global policies, linking both vertically and horizontally. Vertical strategies may be concerned with single programmes, such as those addressing HIV/AIDS in sub-Saharan Africa, whereas horizontal strategies may focus on addressing a wider range of influences such as those creating or alleviating poverty.

Social determinants of health

Poverty and poor health are inextricably linked and strategies to reduce poverty are essential for improving health opportunity. Addressing the root causes of poverty while promoting greater equity are key strategic objectives underpinning the work of the WHO Commission on Social Determinants of Health (2008), an influential global think tank which has raised the profile of the debate on the need for strategic action across four main dimensions—political, economic, social, and cultural.

> Health is a universal aspiration and a basic human need. The development of society, rich or poor, can be judged by the quality of its population's health, how fairly health is distributed across the social spectrum, and the degree of protection provided from disadvantage due to ill-health. Health equity is central to this premise. (Marmot 2007)

Proposed strategies to reduce health inequity include:

Improving the conditions of daily life at home and at work, for women and men, in rural and urban settings, and for all ages.
Addressing the inequitable distribution of power and money, forces that shape the conditions of daily life.
Acting based on knowledge, a professional workforce, alliances with civil society, and evaluation.

The Commission did not stop with making these strategic statements, but has backed them up with a series of papers which provide examples of good practice to support their implementation.

Health promotion

The work of the Commission can be contextualized within a framework of strategic declarations from the WHO, particularly from the Declaration of Alma-Ata (WHO 1978). This declaration, and subsequent iterations, echo public health's historic roots by reflecting the importance of the socio-environmental conditions in which people live and the need for community-based action to improve health. Emphasis is placed on the importance of interactive roles of government, communities, and individuals alongside the healthcare sector to promote good health and prevent disease. While the health sector has a role in promoting health through the services it provides, its role beyond acute medical care is significant with potential for involvement with upstream activity to prevent ill-health in the entire population. This was proposed in the Declaration of Alma-Ata, which called for 'a comprehensive health strategy that not only provided health services but also addressed the underlying social economic and political causes of poor health'. De facto effective prevention would rely on working with, and across, other sectors and, in particular, promoting joined-up government at all its levels including greater community engagement through better primary care.

The conceptual framework of Alma-Ata was further developed by the Ottawa Charter (WHO 1986), which promoted the concept of healthy public policy rather than focusing only on health policy, extending consideration of

health to all policy environments, including the concept of health impact assessment.

The Ottawa Charter defined five key areas for strategic public health action:

Building healthy public policy.
Creating supportive environments.
Strengthening community action.
Developing personal skills.
Reorienting health services towards prevention and a holistic approach (WHO 1986).

The Ottawa Charter stated unequivocally that health is created in the context of everyday life where people live, love, work, and play. It expanded the concept of health determinants to include environmental challenges and people's empowerment. It included not only the basic well-described determinants but broadened the strategic thinking to the need to combine diverse but complementary approaches in order to promote lifestyles conducive to health. These now include, in particular, legislation, fiscal measures, taxation, and organizational change

Subsequently, in 2005, the Bangkok Charter (WHO 2005) further broadened the notion of 'Health in All Policies' (HiAP) by highlighting the need to work across the corporate sector and at a global level, stating that the promotion of health was:

Central to the global development agenda.
A core responsibility for all governments.
A key focus of communities and civil society.
A requirement for good corporate practice.

Underpinning concepts included those of social justice, stressing the importance of the values of gender and health equity, respect for diversity and human dignity, and the search for peace and security.

CASE STUDY 11.7.4 The Shanghai Declaration on Promoting Health (2016)

More recently the Shanghai Declaration on Promoting Health in the 2030 Agenda for Sustainable Development the outcome of the Ninth Global Conference on Health Promotion (Shanghai, 21 to

24 November 2016), which was jointly organized by the Government of China and WHO, under the auspices of a Scientific Advisory Group and Conference Organizing Committee. The concise Shanghai Declaration on Health Promotion was endorsed by the participants of the Conference. The declaration recognizes that that health and well-being are essential to achieving sustainable development and are essential to achieving the United Nations Development Agenda 2030 and its SDGs.

Key among the declaration was the reaffirmation that health remains a universal right, an essential resource for everyday living, a shared social goal, and a political priority for all countries. The United Nations (UN) SDGs establish a duty to invest in health, ensure UHC and reduce health inequities for people of all ages. The declaration committed to promoting health through action on all the SDGs and by engaging the whole of society in the health development process. This means acting decisively on all determinants of health, empowering people to increase control over their health and ensuring people-centred health systems.

The declaration also focused on tackling health inequalities, recognizing that this requires political action across many different sectors and regions. They also require global collective action. The importance of prioritizing good governance, local action through cities and communities, and people's empowerment by promoting health literacy was also stressed along with giving a high priority on innovation and development to support people's enjoyment of a healthy life and give precedence to the health of the most vulnerable (WHO n.d. e).

Finally, the declaration recognized that governments have a fundamental responsibility at national, local, and global level to address the damaging effects of unsustainable production and consumption. This includes offsetting economic policies that create unemployment and unsafe working conditions, and enable marketing, investment, and trade that compromise health. The declaration called on business leaders to demonstrate good corporate governance—profit must not stand above people's health. This is of particular concern in fighting the NCD epidemic.

Tackling non-communicable diseases

NCDs are a long-standing, progressive, and costly threat to healthy populations. Diseases such as diabetes are associated not only with the problems of diminished functional capacity, increased physical and psychosocial morbidity, comorbidities, and complications, but also lead to higher utilization of health services and higher medical costs, as well as opportunity costs that are associated with self-care and disability and shorter life expectancy than those without diabetes (Diabetes UK n.d.). Today, NCDs kill 40 million annually, more than any other cause of death. Of these deaths, 15 million occur prematurely among people aged 30–70 years, and 7 million in low- and low-middle-income countries. Low- and middle-income countries are particularly affected by NCDs with more than 80% of all deaths from NCDs occurring in these countries. Violence and injuries take an overwhelming toll on young people, particularly boys. In 2015, world leaders committed to reduce premature deaths from NCDs by one-third by

2030 as part of the SDGs. Recent WHO reports indicate that the world will struggle to meet that target.

The WHO continues to build on the Global Strategy for the Prevention and Control of NCDs (WHO 2013a), which was first adopted in 2000, and has been followed by strategies to address tobacco control, and lifestyle factors such as diet, exercise, and alcohol consumption. These have so far materialized into the Physical Activity and Health campaign (WHO 2004), the Reduction of Harmful Use of Alcohol campaign (WHO n.d. b), as well as an Action Plan for the Global Strategy for the Prevention and Control of NCDs for 2008–2013 (WHO 2009a). This set of actions also called for high-level political commitment and the concerted involvement of governments, communities, and healthcare providers for successful implementation. The 66th World Health Assembly (WHA) in 2013 concluded with Member States adopting an 'omnibus resolution' on NCDs. This resolution combined major decisions and recommendations in a single, comprehensive resolution, including:

Adopting the global monitoring framework (GMF), including nine targets and 25 indicators.
Endorsing the Global NCD Action Plan 2013–2020 (GAP).
Agreeing to establish a global coordination mechanism (GCM) for NCDs, and to develop terms of reference by November 2013.
Agreeing to establish a set of indicators to measure the implementation of the GAP (The NCD Alliance 2013a, 2013b).

The GAP lays out the vision of a world free of the avoidable burden of NCDs with the goal of reducing the preventable and avoidable burden of morbidity, mortality, and disability due to non-communicable diseases. The means of achievement will be through multisectoral collaboration and cooperation at national, regional, and global levels. The objective is for populations to reach the highest attainable standards of health and productivity at every age so that NCDs are no longer a barrier to well-being or socioeconomic development (WHO 2013b). The principles adopted should be:

Life-course approach
Empowerment of people and communities
Evidence-based strategies
Universal health coverage
Management of real, perceived, or potential conflicts of interest
Human rights approach
Equity-based approach
National action and international cooperation and solidarity
Multisectoral action (WHO 2013b)

The objectives of the plan are to raise the priority given to the prevention and control of NCDs at all levels, through strengthened international cooperation and advocacy; to strengthen national capacity, leadership, governance, multisectoral action, and partnerships to reduce modifiable risk factors and underlying social determinants through creation of health-promoting environments; and to strengthen and orient health systems to people-centred primary healthcare and UHC. This should be underpinned by promoting and supporting national capacity for high-quality research and development as well as monitoring the trends and determinants of NCDs to evaluate progress in their prevention and control.

Progress can be measured by adopting voluntary global targets (Box 11.7.1). By creating a framework and setting targets, emphasis is shifting from analysis of the problem to implementing changes that can make a difference, monitored through a set of measurable outcomes.

Box 11.7.1 Voluntary global targets

- A 25% relative reduction in risk of premature mortality from cardiovascular diseases, cancer, diabetes, or chronic respiratory diseases.
- At least 10% relative reduction in the harmful use of alcohol, as appropriate, within the national context.
- A 10% relative reduction in prevalence of insufficient physical activity.
- A 30% relative reduction in mean population intake of salt/sodium.
- A 30% relative reduction in prevalence of current tobacco use in persons aged 15+ years.
- A 25% relative reduction in the prevalence of raised blood pressure or contain the prevalence of raised blood pressure, according to national circumstances.
- Halt the rise in diabetes and obesity.
- At least 50% of eligible people receive drug therapy and counselling (including glycaemic control) to prevent heart attacks and strokes.
- An 80% availability of the affordable basic technologies and essential medicines, including generics, required to treat major NCD in both public and private facilities.

Reproduced with permission from World Health Organization (WHO), Noncommunicable diseases and mental health: about 9 voluntary global targets, Copyright © WHO 2014, available from: http://www.who.int/nmh/ncd-tools/definition-targets/en/

In 2017, Heads of State and Government and ministers from around the world re-committed to new and bold action to reduce suffering and death from NCDs, primarily heart and lung diseases, cancers and diabetes, the world's leading killers. Governments endorsed the *Montevideo Roadmap 2018–2030 on NCDs as a Sustainable Development Priority* (WHO 2017a) at the opening of the three-day Global Conference on Noncommunicable Diseases in Montevideo, hosted by WHO and the Presidency of Uruguay. The pledge followed agreement by world leaders to reduce 'premature' deaths from NCDs by one-third by 2030 as part of the United Nations' Agenda for Sustainable Development.

The *Montevideo Roadmap* (WHO 2017a) highlights the need for coordinated and coherent action from all sectors and the whole of society, as many of the main drivers of ill-health lie outside the control of health ministries, systems, and professionals. Non-state actors, including civil society and industry, have important roles to play. It also points out that the bulk of NCD deaths could have been prevented by action against tobacco, air pollution, unhealthy diets, physical inactivity, and harmful use of alcohol —as well as by improved disease detection and treatment. The roadmap will guide global preparations for the 2018 United Nations General Assembly Third High-level Meeting on NCDs which will assess countries' progress in meeting the target of reducing premature NCD deaths by 25% by 2025 and then by a third by 2030 (United Nations News Centre 2011). Finally, the plan identifies a range of challenges, including: uneven and insufficient

progress to reduce premature deaths from NCDs; influence of the private sector on governments to prioritize trade over public health goals; and lack of high-level political leadership to ensure that health promotion and NCD prevention and control are part of all areas of government policy.

Regional public health strategies

European region

The European Union (EU) health strategy creates a framework within which jurisdictions take forward their own strategies tailored to national needs. It raises not only the aspirations but also the need for effective implementation and for monitoring progress. Promoting good health is an integral part of Europe 2020, the EU's 10-year economic growth strategy which emphases smart, sustainable, and inclusive growth as way to overcome the structural weaknesses in Europe's economy, improve its competitiveness and productivity, and underpin a sustainable social market economy (Lefebvre and Flora 1988; Evans 2006; World Health Organization Europe Office n.d.). More specifically, health policy is important to Europe 2020's objectives for *smart* and *inclusive* growth because:

keeping people healthy and active for longer has a positive impact on productivity and competitiveness;
innovation can help make the healthcare sector more sustainable and find new cures for health conditions;
the healthcare sector has an important role to play in improving skills and creating jobs as it employs 1 in 10 of the most qualified workers in the EU;
with a projected 45% increase in the number of people aged 65 and over in the next 20 years, financing rising healthcare costs and access to a dignified and independent life for the ageing population will be central to the political debate.

Of the 7 EU2020 *flagship initiatives*, the four most relevant to public health are: Innovation Union; Digital agenda for Europe; Agenda for new skills and jobs; and the European platform against poverty (European Portal for Action on Health Inequalities n.d.).

CASE STUDY 11.7.5 Health in All Policies in the European Union (EU)

Health in All Policies has been adopted by the EU as part of its strategic approach seeking to complement national action on health. The EU health policies aim to: Protect people from health threats and disease; Promote healthy lifestyles; and Help national authorities in the EU cooperate on health issues (European Commission 2007; Leppo et al. 2013).

HiAP is one of the four principles adopted by the EU. The three further principles are:

A strategy based on shared health values: this principle places particular emphasis on reducing poverty and inequities and on the importance of indicators of comparable health data at all levels. Further work on how to reduce inequities in health and how to promote health literacy programmes for different age groups is part of the strategic approach.

Health is the greatest wealth: highlights that spending on health is not just a cost, it is an investment and that although health expenditure may be regarded as an economic burden, the real costs to society are the direct and indirect costs linked to ill-health. The report estimates that the annual economic burden of coronary heart disease can amount to 1% of the gross domestic product (GDP), and the costs of mental disorders to 3–4% of the GDP. It emphasizes that with 97% of spending going on acute care healthcare and treatment, there is an underinvestment in prevention and improving of the population's overall physical and mental health.

Strengthening the EU's voice in global health: the EU's contribution to global health requires interaction of policy areas, such as health, development cooperation, external action, research, and trade linking with the WHO and other relevant UN agencies, the World Bank, the International Labour Organization, the Organisation for Economic Cooperation (OECD), and the Council of Europe, as well as other strategic partners and countries (World Bank 2005, 2011, 2013).

The strategy has three objectives related to its policy priorities, which together culminate in an overarching framework for action at all levels across the population:

Fostering good health in an ageing Europe: promoting health and preventing disease requires efforts throughout the lifespan to tackle key issues including poor nutrition; physical activity; alcohol, drugs, and tobacco consumption; environmental risks; traffic accidents; and accidents in the home. Improving the health of children, adults of working age, and older people will help create a healthy, productive population and support healthy ageing now and in the future.

Protecting citizens from health threats: emphasizing the need for surveillance and mechanisms to respond to health threats, including emerging infections, as well as adaptation to climate change (The Lancet 2010).

Supporting dynamic health systems and new technologies: e-health, genomics, and biotechnologies can improve prevention of illness, delivery of treatment, and support a shift from hospital care to prevention and primary care. New technologies must be evaluated properly, including for cost-effectiveness and equity, and health professionals' training and capacity implications must be considered.

Africa region

Another example of a continent-wide strategy addressing different health needs comes from Africa where significant numbers of low-income countries face different challenges associated with poverty and infectious diseases. The strategy produced by the African Union Ministers of Health

was structured using the framework of Vision and Mission, Principles, Goals, and Objectives (NEPAD n.d.). Its goal is to contribute to Africa's socioeconomic development by improving the health of its people and by ensuring access to essential healthcare for all Africans, especially the poorest and most marginalized. The vision, expressed as working towards 'an integrated and prosperous Africa free of its heavy burden of disease, disability and premature death', was to build an effective, African-driven response to reduce the burden of disease and disability through strengthened health systems, scaled-up health interventions, intersectoral action, and empowered communities.

The strategic principles include health as a human right and a developmental concern requiring a multisectoral response, equity in healthcare as a foundation for all health systems, and effectiveness and efficiency as central to realizing the maximum benefits from available resources. Evidence is proposed as the basis for sound public health policy and practice and more of the same is not enough: 'new initiatives will endeavour to set standards that go beyond those set previously' (NEPAD n.d.). This has been followed more recently with the creation of the Africa Centres for Disease Control as a key driver for regional capacity building, collaboration, and response.

CASE STUDY 11.7.6 Strategic planning by the Africa Centres for Disease Control

More recently, the Africa Centres for Disease Control (CDC) was established and its statute approved by the 26th Assembly of the Heads of State and Government in January 2016 and officially launched on 31st January 2017 in Addis Ababa, Ethiopia (Africa Union and Africa CDC). The Africa CDC Governing Statute anchors the institution in the following guiding principles: Leadership, Credibility, Ownership, Delegated authority, Timely dissemination of information, Transparency, Accountability, and Value-addition. The Africa CDC endeavours to support Member States in improving the health of their people through building the capacity of public health institutes to focus on prevention of infection, surveillance and response to emergencies (including outbreaks, man-made and natural disasters, and public health events of regional and international concern), and building capacity to reduce disease burden on the continent. Building on these guiding principles and mission, the Africa CDC has developed a 5-year strategic plan (2017—2021). This strategic plan describes five strategic pillars, which will help the Africa CDC to achieve its mission and vision. These are: Surveillance & Disease Intelligence; Information Systems; Laboratory Systems and Networks; Emergency Preparedness and Response; and Public Health Research.

From these strategic pillars, several strategic objectives are derived with a defined set of activities and performance measures. Functionality and implementation of these pillars will require the support of cross-cutting enablers (workforce, partnership, innovation, finance and leadership and management) that provide the backbone for the operations of the Africa CDC.

National and subnational public health strategies

Canada

Changing Directions, Changing Lives is the first Canadian mental health strategy and was published in 2012 (Mental Health Commission of Canada 2012). The strategy was produced 'to help to ensure that people who experience mental health problems and illnesses—especially those with the most severe and complex ones—are treated with respect and dignity, and enjoy the same rights as all Canadians'. The strategy provides six strategic directions for change to improve mental healthcare (Box 11.7.2). Change will not be possible without a whole-of-government approach to mental health policy.

Box 11.7.2 Six strategic directions for changes to improve mental health and the mental healthcare system

1. To promote mental health across the lifespan in homes, schools, and workplaces, and prevent mental illness and suicide wherever possible.
2. To foster recovery and well-being for people of all ages living with mental health problems and illnesses, and uphold their rights.
3. To provide access to the right combination of services, treatments, and supports, when and where people need them. A full range of services, treatments, and supports includes primary healthcare, community-based, and specialized mental health services, peer support, and supported housing, education, and employment.
4. To reduce disparities in risk factors and access to mental health services, and strengthen the response to the needs of diverse communities and Northerners.
5. To work with First Nations, Inuit, and Métis to address their mental health needs, acknowledging their distinct circumstances, rights, and cultures.
6. To mobilize leadership, improve knowledge, and foster collaboration at all levels.

England

In England, the mental health strategy published in 2011 followed many of the same themes. No Health Without Mental Health: A Cross-Government Mental Health Outcomes Strategy for People of All Ages sets shared objectives to improve people's mental health and well-being and plans to improve services for people with mental health problems. The strategy set out the policy for how the government, working with all sectors of the community and taking a life-course approach, would improve the mental health and well-being of the population and provide people with high-quality services that are equally accessible to all (Department of Health 2011b). The strategy incorporated the key elements of defining a policy, setting out aims and objectives, and proposing goals and how they will be monitored to ensure the highest quality of mental health for people of all ages, and all backgrounds and cultures (HM Government 2011).

More recently England's national strategic approach to mental health was updated in the *Five Year Forward View on Mental Health* report. This independent report of the Mental Health Taskforce (2016) set out the start of a ten year journey for transformation for mental health services, commissioned on behalf of the NHS. In preparing the report, particular attention was placed on ensuring that the lived experience of people with mental health problems were at the heart of the report and its recommendations. Over 20,000 people participated in sharing the changes they wanted to see in order to fulfil their life ambitions and take their places as equal citizens in society. Key priorities were prevention, access, integration, quality, and a positive experience of care.

The updated mental health strategy included a number of recommendations for the six NHS arm's length bodies to achieve the ambition of parity of esteem between mental and physical health for children, young people, adults, and older people. Recommendations were also included that cover areas where wider action is needed, underscoring that as well as access to good quality mental healthcare wherever they are seen in the NHS, another main ambition was to have a decent place to live, a job or good quality relationships in their local communities. Finally, the strategy placed a particular focus on tackling inequalities given that mental health problems disproportionately affect people living in poverty, minority ethnic groups, those who are unemployed, and who already face discrimination. To truly address these issues, the strategy recommended tackling inequalities at local and national level.

Global to national strategy and action

While at a global level the WHO produces strategies to provide direction for change, action to implement change is needed at a national population level. Examples of national strategies for mental health were given earlier in this chapter—each being country specific. Another approach is the proposal for a common framework for national action, an example of which is the Framework Convention on Tobacco Control (FCTC) (WHO n.d. c), which was the first international treaty negotiated under the auspices of the WHO, adopted by the WHO on 21 May 2003 and entered into force on 27 February 2005. It was developed in response to the threats posed by the globalization of the tobacco epidemic and is an evidence-based treaty that reaffirms the right of all people to the highest standard of health. By mid-2013, 176 jurisdictions had signed up to the Convention, including 90% of the world's population.

Support for national-level implementation has been provided by the WHO MPOWER package (WHO n.d. d), which gives strategic advice on six proven evidence-based policies to reduce tobacco-related harm (see also Chapter 9.1). This is a vertical strategic approach, focusing specifically on one risk factor, tobacco smoking. The recommended headline actions are:

Monitor tobacco use and prevention policies
Protect people from tobacco smoke
Offer help to quit tobacco use
Warn about the dangers of tobacco
Enforce bans on tobacco advertising, promotion, and sponsorship
Raise taxes on tobacco. (WHO n.d. d)

Importantly, MPOWER provides examples of successful initiatives which have reduced the burden of tobacco-related harm. For example, legislation is a key element to achieving the MPOWER measures and many countries have actively legislated to stop smoking in public places through the banning of tobacco smoking indoors in environments such as workplaces, shops, restaurants, bars, and residential care homes. In 2013, additional steps have been taken in Australia to introduce plain packaging of cigarettes and are now being studied by other countries who are deciding whether to follow suit (The Lancet 2013a, 2013b).

But while national legislation can provide environments in which tobacco harm is reduced, local strategies are also necessary particularly to engage the health sector.

Local-level action

Engagement of health services at a local level has been shown to be essential for the translation of the objectives of the FCTC. While health promotion in schools about the harms of tobacco in schools plays an important role in raising awareness, local services also need to provide support such as smoking cessation services in special clinics and within routine services in both public and private sectors. Non-government organizations (NGOs), for example, the Action on Smoking and Health (ASH) in the United Kingdom (ASH UK n.d.) and Australia (ASH Australia n.d.), and the Hong Kong Council on Smoking and Health (COSH) (n.d.) provide invaluable support in both leading and assisting the implementation of strategies. In Hong Kong, COSH advocates with government and also provides additional services and support for smokers who wish to quit, such as manning quitlines, organizing local campaigns, and providing smoking cessation information. Smoking cessation community clinics, such as the Hong Kong's Hospital Authorities' Smoking Cessation and Counselling Centres, are supported by other NGOs, as well as the government, and increase the effectiveness of smoking cessation services by providing nicotine replacement therapy and continuity of care. Among smokers who are aware of the dangers of tobacco, three out of four want to quit. Like people dependent on any addictive drug, it is difficult for most tobacco users to quit on their own, and they benefit from help and support to overcome their dependence from a variety of sources including local clinics, support groups, and advice from helplines.

While MPOWER seeks to provide global guidance that can be translated into local action, other strategies will be jurisdiction specific. Typically such strategies describe the epidemiology of the target population, its demography, the distribution of mortality and morbidity, its health needs, and local characteristics. Since the purpose of a strategy is to bring about change, plans for implementation will be included, as well as a framework for monitoring and evaluation, often promoting targets or objectives to be achieved. Many countries have produced strategies for tackling major health priorities, including strategies for addressing the epidemic of NCDs.

Typically, development of a strategic framework at a local level will analyse needs, priorities, and plans for implementation of a policy and engage stakeholders in its implementation. One example of this approach comes from Hong Kong where, in line with WHO and the Western Pacific Regional Action Plan (WPRO) NCD strategies, the Hong Kong Department of Health has developed a strategic framework for NCDs, revised in 2018 (Hong Kong Government 2013). This framework was produced following a series of processes engaging not only with the health sector but more widely, particularly with the NGO sector which plays a significant role in health promotion and service delivery. The first step was to review international literature as well as local epidemiology and health service information. The plan was then drawn up using a set of strategic principles (Box 11.7.3).

To flesh out the framework, the strategy group engaged other arms of government, professional groups, non-government agencies, representatives of the business sector, and the community to agree on a work programme based on promoting the need for prevention and early intervention, and to ensure that any action was to be evidence based, outcome focused, and addressing broader health determinants to reduce the burden of disease related to NCDs. Particular emphasis was placed on informing the population to promote responsibility for their own health, engagement of public and private sectors, engaged professionals, and a sustainable health system (Hong Kong Government 2013).

Implementing strategy

With frameworks and principles for strategy in place, action to address specific health behaviours and challenges needs to be planned and monitored. The development of a strategy can be a case for change, a new service, or a further development of an existing service and can involve major changes or relatively minor changes. The development of strategies within healthcare can be devised at a local or national level, and encompass a different size of area, or focus upon a specific topic or aspect of health. The strategy can be formulated through individual or cross-departmental /agency or cross-government programme. The majority of government strategies are currently developed following a period of consultation with a wide variety of partners.

Executing a strategy is perceived as more difficult than its development and represents a disciplined process or a logical set of connected activities that enables an organization to take a strategy and make it work (Hrebiniak 2005). Hunter has observed that, 'regardless of the precise nature of a policy or strategy, and the support that exists for it, if the means to implement it are either non-existent or inadequate in terms of capacity or capability, or both, then it will count for little' (Hunter 2007:20). There are key elements and activities that are known to affect the resources required for managing successful change efforts:

motivating change: creating readiness for change and overcoming resistance
creating a vision: mission, valued outcomes and conditions, midpoint goals
developing political support: assessing change agent power, identifying key stakeholders, influencing stakeholders
managing the transition: activity planning, commitment planning management structures
sustaining momentum: providing resources, building support system for change agents, developing new competencies and skills, reinforcing new behaviours

CASE STUDY 11.7.7 Implementing an alcohol harm reduction in strategy in Hong Kong

Having identified reducing alcohol harm as a priority for implementing the NCD strategy, the HK Working Group on Injuries and Alcohol Misuse proposed ten recommendations to address alcohol-related harm (Hong Kong Government 2011; Kim et al. 2013):

Strengthen surveillance of alcohol consumption through collecting data from all sectors.
Strengthen surveillance of alcohol-related harm by collecting data from the healthcare sector.
Promote research to understand drinking patterns, particularly among the young, and assessment of impact of measures taken.
Involve all health professionals through education and practice.
Encourage healthcare professionals to identify at-risk drinkers and explore the development of tools to enable this to happen.
Provide secondary, tertiary, and mental health services for those identified with needs.
Working together of government, NGOs, schools, and employers in partnership to maximize efforts.
Develop evidence-based and culture-relevant advice and information that can be disseminated in all sectors.
Strengthen community awareness and actions through publicity, media, and other means.
Review legislation and consider age restrictions for selling alcohol.

The recommendations were then used to establish process measures for monitoring implementation and various partners, such as NGOs and community groups, were involved in promoting the strategy. Healthcare providers were also included to provide health education and care for individuals and to engage with professional groups (Li et al. 2011).
Source: data from Hong Kong Government, Department of Health, Promoting Health in Hong Kong: A Strategic Framework for Prevention and Control of Non-communicable Diseases, available from http://www.change4health.gov.hk/filemanager/common/image/strategic_framework/promoting_health/promoting_health_e.pdf.

Local strategy implementation

The process of strategy development uses the whole range of public health tools and skills. Much of the focus of the work will be on the process of gaining commitment from partners, patients, and the public, and overcoming the barriers they perceive. Successful implementation relies on clarity of the health challenge, key aims, and objectives, as well as structures which support engaging the right people in the community to create change, and ensure that proposed changes are implemented and sustainable. Some key questions guiding local-level action are shown in Table 11.7.1.

Table 11.7.1 Questions guiding local-level action

How do we make the case?	By doing a local needs assessment, and taking into account local and national strategies
What are we aiming to do?	Expressed by clear aims and objectives with indicators and targets
How do we involve patients and the public?	Be clear about why patients and public need to be involved and how to engage them at all stages of the strategy identifying the barriers to change
How do we engage/communicate with partners?	Make sure all those who are affected by the strategy are involved including clinicians and partner organizations. Identifying who will support and who will oppose and how to deal with this; communicate with all involved as the work is taken forward
How can we make change happen?	Securing change is the core of the work and needs to be addressed in the planning stage. This stage should include a description of the actions that are required, and an assessment of the resource implications, securing adequate resources in order for implementation to be possible and appropriate
How do we know we have done what we wanted to do?	Evaluate the impact to demonstrate achievement against the standards and targets
How can we make change stick?	Change needs to be sustained to ensure that it becomes routine practice. This may require a change in work environment with a process of ongoing monitoring and audit to stop people reverting to old patterns of working

Source: data from Hill, A. et al., Public Health and Primary Care: Partners in Population Health, Volume 1, Oxford University Press, New York, USA, Copyright © 2007, by permission of Oxford University Press USA.

Numerous frameworks exist to guide how strategies are implemented. Once useful structure is the PEOPLE framework. The acronym PEOPLE (Hong Kong Government 2013, pp. xiii–xiv) can be used as a tool to review the structural support for strategy implementation:

Partnership
Environment
Outcome focused
Population-based interventions
Life-course approach
Empowerment

1. Partnership

Partnerships between different sectors of society and at different population levels are essential to maximize the strengths of different knowledge bases and skills. A strategic partnership or an alliance can provide a competitive advantage and an opportunity to access a broader range of resources and expertise. This means that the partnership can offer clients distinctive skill sets and product lines that are different from the competition.

Successful partnerships and alliances rely on the principle that the work involved in maintaining a partnership, and the benefits from the alliance are equally spread, rather than one partner carrying the load while the other reaps the benefits. The best results from a strategic partnership generally occur when each partner delivers excellence in service areas that are different but related to the other partner(s) and where the partners are not adversarial in the marketplace. That way, by partnering up, each partner can focus on its strengths, while having reliable people in other organizations to cover the areas outside its expertise.

CASE STUDY 11.7.8 Creation of Public Health England—emphasis on partnership

As part of the healthcare reform process in England, in 2013, the public health system was restructured by the creation of Public Health England (PHE) to reflect the need for strong central and local partnerships. The main drive for this reform was the recognition that public health is not the product of health service activity, and that addressing upstream broader social and economic determinants are key to promoting better health.

At a central level, the PHE strategy directorate is responsible for ‘a coherent, credible and internationally recognized strategy for the transformation of the public’s health’ (PHE n.d.) providing ‘the leadership for a widely-owned strategic direction for public health that is strongly supported by local authorities, the National Health Service (NHS) and other partners’. Key to its implementation was the repositioning of local directors of public health from the NHS to local government authorities that have duties and powers and promulgate local plans for improving health and well-being and reducing inequalities in their local communities. It is envisaged that there will be a continuous process of strategic assessment and planning involving all sectors to

‘develop local evidence-based priorities to improve the public’s health and reduce inequalities’, and helping determine what actions local authorities, the local NHS and other partners will need to take to meet health and social care needs, and to address the wider determinants that impact on health and well-being (Department of Health 2013a).

How well these structural changes work in delivering their objectives of reducing inequalities and addressing local health needs through joint strategies will need ongoing monitoring and evaluation.

When entering into a strategic partnership or alliance, there is a lot to consider, however the following strategies have been found to be especially helpful in creating positive and productive alliances:

Focus on outcomes. It is important to know what you can, and are prepared to deliver, and what you would like in return from your potential partner.
Commitment. The level of commitment required from each party needs to be considered. The nature of the partnership or alliance will determine how much each party needs to give in order to keep the partnership or alliance healthy.
Collaboration. The extent to which you will be happy to share resources with partners will need to be considered. Generally, the more collaborative the partnership or alliance, the more successful the endeavour is.
Communication. An emphasis on effective communication between partners is essential. Open and effective channels of communication between members of the partnership or alliance will ensure that there are no misaligned expectations between the parties.

2. Environment

Environmental influences play a key role in effective intervention. At a broad level, they may be economic, social, political, and physical. The healthy settings approach, which considers health promotion and disease prevention in the context of broader settings, provides an example of structuring environments to be health promoting.

The WHO defines a setting for health as the place or social context in which people engage in daily activities in which environmental, organization, and personal factors interact to affect health and well-being. Settings are characterized by physical boundaries, a range of people with defined roles, and an organizational structure (WHO n.d. f). Examples of settings include : Schools, Hospitals, Cities/villages, Workplaces. In healthy settings, people can create and solve problems related to health, and actively

use and shape the environment. Different settings provide diverse ways to implement health strategies.

Schools

Schools have an integral responsibility and role in encouraging health promotion as part of a larger social health model. The Healthy Schools movement, promoted by the WHO, has played a key role in developing and sharing experiences across many countries. For example, in India, the school fostering health programme has been emphasizing that a balanced diet, regular physical activity, and lifestyle management play a key role in the prevention and control of many diseases. One of its key programmes has been to work with schools to promote the 'Mid day Meal Program', which encourages healthy eating and hygiene (Mahal et al. 2009; Bangdiwala et al. 2011; Healthy India n.d.; Association of Schools & Programs of Public Health 2012, n.d.). The School Health Foundation of India has established a scheme for 'Healthy School' Certification based on the achievement of ten points of criteria (School Health Foundation of India n.d.). In Mississippi, United States, the state's Department of Education has established an Office of Healthy Schools committed to offering technical assistance and services to enable schools and communities to create programmes, based on CDC guidance, which encourage lifelong healthy behaviours (Etienne et al. 2013; Mississippi Office of Healthy Schools n.d.).

In England, the aims of the National Healthy Schools Programme (NHSP) are to: Support children and young people in developing healthy behaviours; help to raise pupil achievement; help to reduce health inequalities; and help promote social inclusion. Health-promoting schools have been characterized as having six domains for action: the formal curriculum, the school ethos, school policies and practices, school health services, school–home–community interactions, and organizational structures. National Healthy Schools also provide education and support of young peoples' personal and social health (including sex and relationship education), healthy eating, physical activity, and emotional health and well-being. The evidence regarding interventions to improve children's health indicates the value of intersectoral, comprehensive programmes, and these can be developed and implemented through the structure of health-promoting school programmes (Department of Health n.d.).

Hospitals

Hospitals are another example of a setting in which to promote health, as well as provide health services. The promotion of healthy hospitals can be described from two perspectives—through the care they give and through the lens of environmental sustainability. The initial declarations on health-promoting hospitals focused on the former with statements that hospitals should:

Promote human dignity, equity and solidarity, and professional ethics, acknowledging differences in the needs, values, and cultures of different population groups.
Be oriented towards quality improvement, the well-being of patients, relatives and staff, protection of the environment, and a realization of the potential to become learning organizations.
Focus on health with a holistic approach and not only on curative services.
Be centred on people providing health services in the best way possible to patients and their relatives to facilitate the healing process and contribute to the empowerment of patients.
Use resources efficiently and cost-effectively, and allocate resources on the basis of contribution to health improvement, forming as close links as possible with other levels of the healthcare system and the community (WHO Health Promoting Hospitals Network 1997).

The US CDC on Healthy Hospital Choices strategies suggests that hospitals could engage to promote better health where recommended—promoting healthy hospital food, physical activity, breastfeeding and lactation support, and tobacco-free choices (National Center for Chronic Disease Prevention and Health Promotion 2010; Rocco et al. 2011; CDC 2012; United States Global Health n.d.). However, over recent years, the responsibility of hospitals to contribute to sustainability has been a growing theme.

More recently the Global Green and Healthy Hospitals is an international network of hospitals, healthcare facilities, health systems, and health organizations dedicated to reducing their environmental footprint and promoting public and environmental health. The network has more than 1,000 members in 54 countries who represent the interests of over 32,100 hospitals and health centres. Members use innovation, ingenuity, and

investment to transform the health sector and foster a healthy, sustainable future.

The NGO ‘Healthier Hospital Initiative’ has created a network of hospitals committed to improving not only the health of patients and staff, but also to promoting the role hospitals can play in creating a sustainable environment through engaging leadership, healthier food, cleaner energy, less waste, safer chemicals, and smarter purchasing (Healthier Hospitals Initiative 2013).

In England, the NHS has created a Sustainable Development Unit which works across health, public health, and social care to help health and care organizations to fulfil their potential as leading environmentally sustainable and low-carbon organizations (NHS n.d.).

These roles of hospitals and healthcare facilities in civil society as providers of care, as providers of employment, and as influencers of the local environment and the local community are often forgotten.

Cities/villages

Cities/villages are also important healthy settings as they encompass the overarching areas where people live (Yang et al. 2018). The WHO healthy cities project (WHO n.d. g) is a global movement established to create health-supportive environments, which will enable the achievement of good quality life. They focus on ensuring basic sanitation and hygiene needs are met, as well as ensuring access to healthcare. In Europe, the primary aim is to put health high on the social, economic, and political agenda of city governments, and engage all sectors to provide policies and plans to address inequality and urban poverty, and address the needs of vulnerable groups and the social, economic, and environmental determinants of health (WHO Europe Office n.d.).

Workplaces are other important settings where health should be promoted. Just as the younger population spends most of their day at schools, adults usually spend more time at their workplaces than in any other setting. Workplaces can support programmes aimed at improving the health conditions and awareness among workers/employees for mental, as well as physical, well-being:

> Providing a psychologically safe workplace is no longer something that is simply nice to do, it is increasingly becoming a legal imperative. (Mental Health Commission of Canada 2013).

The WHO healthy workplace model suggests a comprehensive way of thinking and acting that addresses:

Work-related physical and psychosocial risks.
Promotion and support of healthy behaviours.
Broader social and environmental determinants (WHO n.d. h).

The programme for Health at Work seeks to ensure a positive approach to health and work which includes training managers to be aware and communicate about well-being and mental ill-health, as well as encouraging a culture of health (mental and physical) at work. This approach highlights the mutual benefits of health and productivity, linking traditional health and safety with well-being initiatives (World Health Organization Regional Office for the Western Pacific 1999; Healthy Workplaces 2011). This positive approach to health is demonstrated by the replacement of sick certificates with 'fit notes' in the United Kingdom. Introduced in April 2010, fit notes are issued to individuals by doctors to provide evidence that they 'may be fit for work' or 'not fit for work' (Department for Work and Pensions n.d. 2008).

3. Outcome focused

Too often, when doing strategic planning, public health practitioners and policymakers end up with global goals that only reflect a set of directions. The best-case scenario here is that they end up going in the 'right direction', but they never reach their community-specific destinations. Another typical result is that their successful areas or localities meet their success, but their needy or unsuccessful localities stagnate and remain the same.

Increasingly, global ambitions need to be met with more detailed locality specific strategies that identify their specific, desired destinations—that is, the objective and measurable outcomes that they want for local residents and communities. If 'outcomes-based' strategic planning is used in place of 'standards-based' strategic planning, localities, and implementers will be able to set their own strategic paths for achieving goals, cognizant of local assets, capacities, and capabilities. The clear result is that they will then have a much better chance of meeting their goals and attaining their outcomes.

A strategy that is outcome focused ensures an optimal investment of available resources with the greatest health gains through the monitoring of

health outcomes. Focusing on outcomes can help programmes measure the successes and failures of what has already been implemented, and allow room for evaluation, adjustment, and improvement.

CASE STUDY 11.7.9 Public health outcomes in England

In England, the Public Health Outcomes Framework *Healthy Lives, Healthy People: Improving Outcomes and Supporting Transparency* sets out a vision for public health, desired outcomes, and the indicators that will help us understand how well public health is being improved and protected. The Public Health Outcomes Framework was refreshed in May 2016, following a consultation in 2015.

The framework concentrates on two high-level outcomes to be achieved across the public health system, and groups further indicators into four 'domains' that cover the full spectrum of public health. The outcomes reflect a focus not only on how long people live, but on how well they live at all stages of life. A list of indicators updated, for the most recent and previous releases, can be found in the Public Health Outcomes Framework Collection within https://www.gov.uk. Data are published as part of a quarterly update cycle in August, November, February, and May each year. This data tool presents data for the indicators in the framework for the most recent period available and accompanying trend data where possible. Inequalities data are provided where these are available.

An example of outcome-focused strategies is the use of health inequality targets in England. These targets and headline indicators were initially promulgated in 2006 as part of a national strategy to promote health and identified 14 areas for measurement (Department of Health 2006). Two health inequalities targets on infant mortality and life expectancy in addition to 12 headline indicators for areas in which evidence suggested actions could lead to a greater emphasis on prevention were proposed. These have subsequently been refined and published as the Public Health Outcomes Framework for England 2013 to 2016 (Department of Health 2013b), which has the outcome targets of increased healthy life expectancy and reduced differences in life expectancy and healthy life expectancy between communities, as well as indicators in four domains: improving the wider determinants of health, health improvement, health protection and healthcare public health, and preventing premature mortality (Fig. 11.7.1).

This framework will guide public health action at the local level and regular monitoring will take place, allowing progress to be tracked and performance to be compared between different geographical areas based on local authority boundaries.

Public Health Outcomes Framework

OUTCOMES

Vision: To improve and protect the nation's health and well-being, and improve the health of the poorest fastest

Outcome 1: **Increased healthy life expectancy**
Taking account of the health quality as well as the length of life

(Note: This measure uses a self-reported health assessment, applied to life expectancy.)

Outcome 2: **Reduced differences in life expectancy and healthy life expectancy between communities**
Through greater improvements in more disadvantaged communities

(Note: These two measures would work as a package covering both morbidity and mortality, addressing within-area differences and between-area differences)

DOMAINS

DOMAIN 1:	DOMAIN 2:	DOMAIN 3:	DOMAIN 4:
Improving the wider determinants of health	Health improvement	Health protection	Healthcare public health and preventing premature mortality
Objective: Improvements against wider factors that affect health and well-being, and health inequalities	Objective: People are helped to live healthy lifestyles, make healthy choices and reduce health inequalities	Objective: The population's health is protected from major incidents and other threats, while reducing health inequalities	Objective: Reduced numbers of people living with preventable ill health and people dying prematurely. while reducing the gap between communities
indicators indicators indicators } *Across the life course*	*indicators indicators indicators* } *Across the life course*	*indicators indicators indicators* } *Across the life course*	*indicators indicators indicators* } *Across the life course*

4. Population-based interventions

There are a broad range of prevention and early intervention strategies. Some prevention strategies target the *whole population*—for example, a mass media antismoking campaign. By their nature, these interventions are a *one size fits all* type, with no allowance for targeting specific populations. While these programmes are usually expensive, they are quite economic when calculated on a cost-per-person basis. Placing emphasis on the whole population produces collective health benefits and can change the patterns of behaviours and disease prevalence by having a small impact on many people. Population-based prevention strategies include legislation; media-based strategies (including mass media campaigns and reduction in the advertising and promotion of alcohol and tobacco), and drug education (including school drug education).

CASE STUDY 11.7.10 Less Salt, More Life campaign in Argentina

In 2011, bread makers in Argentina voluntarily reduced the salt in bread by 40% and restaurants in Buenos Aries removed salt from their tables as part of a campaign to reduce hypertension and reduce heart disease. Discussions also took place with the food industry on reducing the salt content of processed food. Prior to the campaign, the daily salt consumption was estimated to be two to three times that of recommended levels. Population-level salt reduction is considered to be one of the most cost-effective strategies to reduce hypertension and its consequences (He and MacGragor 2009). The government established a national committee with cross-government representation, working with the big food companies and unions to come to voluntary agreements. The coordinated monitoring plan will evaluate progress. It is estimated that with a 3 g salt reduction in each individual's diet, 6,000 cardiovascular deaths, 13,000 myocardial infarctions, and 13,000 strokes could be avoided overall (Laspiur 2012).

CASE STUDY 11.7.11 Sugar reduction and reformulation in England

Childhood obesity is a national crisis in England and a leading cause of ill-health and premature death where one in three children are overweight or obese by the time they leave primary school. Obese or overweight children are more likely to become obese or overweight adults, which increases their risk of developing cardiovascular disease, type 2 diabetes, and some cancers.

Public Health England's prioritization of childhood obesity recognizes that we live in an obesogenic environment that encourages weight gain and obesity, and excess sugar intake has

become the norm. Children and adults are consuming more than double the recommended amount of sugar and this is an underpinning factor of the obesity epidemic.

In 2016, PHE launched the first Sugar Reduction Programme in the world. This was supported by the government's commitment to tackling childhood obesity, and Childhood obesity: a plan for action (HM Government 2016), which included a commitment for PHE to lead a transparently monitored sugar reduction programme. The programme challenges the food industry—from retailers to manufacturers, restaurants, cafés, takeaways, pubs, entertainment chains, and delivery services—to reduce the sugar in the products that contribute most to children's intakes by 20% by 2020 (UK Government n.d.).

PHE determined where to focus efforts on sugar reduction by the food industry by identifying the main foods and drinks that contribute to children's consumption of sugar, and the biggest businesses that make them, using National Diet and Nutrition Survey (NDNS) data and market share analysis.

PHE has committed to engaging with food manufacturers and retailers who manufacture products that come under the high sugar categories to discuss sugar reduction in their products and targets for each category. PHE is also with the 'eating out of home' sector—those that provide food that we both buy and consume out of the home, including restaurants, pubs, takeaways, and fast food restaurants, sandwich, and coffee shops.

From 2017, PHE will work towards setting targets to reduce total calories in a wider range of product categories and across all sectors, including the eating out of home sector. Work on saturated fat will be further reviewed in 2018 onwards.

5. Life-course approach

A life-course approach addresses cumulative adverse effects on people's lives by fostering health from gestation through to old age. The risks of developing disease and disability accumulate with age and are influenced by social and physical factors at all stages of life (Fig. 11.7.2).

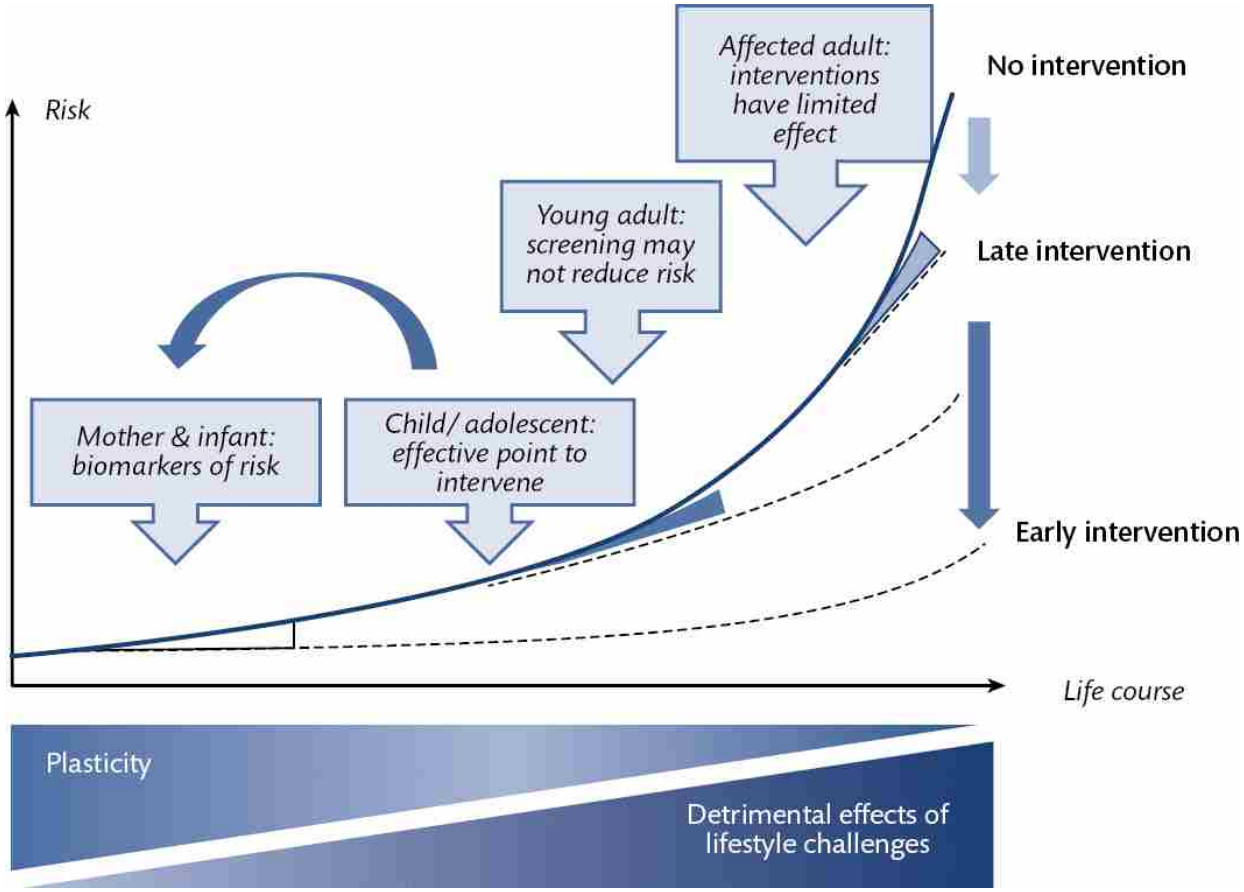

Fig. 11.7.2 Life-course view of NCD.

Reprinted from *Progress in Biophysics and Molecular Biology*, Volume 106, Issue 1, Hanson, M. et al., Developmental plasticity and developmental origins of non-communicable disease: Theoretical considerations and epigenetic mechanisms, pp. 272–80. Copyright © 2011, with permission from Elsevier.

There are critical periods, such as gestation, and early childhood and also adolescence, when environmental exposures do more harm to health and its potential, as well as sensitive developmental stages when social and cognitive factors are more easily acquired, than at other times. Thus, social behavioural and environmental factors impact on the potential for a healthy future and continue to do so throughout the life course to old age (Kuh Ben-Shlomo 1997; WHO n.d. i).

Understanding the importance of the life course has led to different initiatives to develop strategies to promote preconception care, promote optimum care in pregnancy, efforts to ensure safe delivery, a focus on vulnerable children and adolescents, and interventions tailored to promoting and maintaining health in middle and older age.

CASE STUDY 11.7.12 Everybody Active Every Day—promoting physical activity in England

Since the 1960s people in the United Kingdom have become less and less active. We are around 20% less active today, and estimates suggest that by 2030 we will be 35% less active. Half of women and a third of men in England today are not active enough to stay healthy. In October 2014, Public Health England (PHE) published Everybody Active, Every Day as the national physical activity framework for England. It drew on the international evidence base and was co-produced with over 1,000 different individuals and organizations. It set out the need for action across four domains at national and local levels (Active society, Moving Professionals, Active environments, and Moving at scale). The core document was supported by a 'What works—the evidence' document, a toolkit for MPs and a collation of local emerging and promising practice developed with ukactive and the National Centre for Sports and Exercise Medicine (NCSEM).

This vision of 'Everybody active every day' was supported by a practical 'what works' guide, which details promising local practice initiatives that already have strong evidence of success in increasing activity in local areas. In addition, the strategy aimed to promote physical activity through the life course focusing on five key opportunities for local areas:

- teach every child to enjoy, value and have the skills to be active every day
- create safe and attractive environments where everyone can walk or cycle, regardless of age or disability
- make 'every contact count' for professionals and volunteers to encourage active lives
- lead by example in every public sector workspace
- evaluate and share the findings so we are learning more about what works

A 2-year evaluation of the progress made in this strategy (Ahmad et al. 2018) highlighted that there has clearly been significant progress to tackle inactivity since the publication of Everybody Active, Every Day in 2014. The framework has informed local and national strategy and delivery plans and has made a visible difference to the approach across England. While the full impact of these first two years may take time to be reflected in the data, progress has clearly been made to embed the evidence into practice and build the foundations for a healthier future for the nation. International evidence demonstrates the need for continued leadership and coordination over several years to make sustainable change in population levels of physical activity.

6. Empowerment structures for local action—community-based initiatives

Community engagement, also called 'public participation', is the process of involving people in the decisions that affect their lives. It enables good governance and informed decision-making by promoting shared responsibilities for decisions. It supports an open approach to managing risk by providing a strong foundation for understanding decisions and building trust within our community about the decision-making process (Merson and Page 2009). Community engagement can involve a broad variety of activities, best considered as a continuum from informing (reflecting a low

level of engagement) through to active participation (reflecting a high level of engagement).

Informing takes place when a decision has already been made or action is required, and localities need to make sure that those affected are aware of the facts.
Consulting takes place when a project requires some input, feedback, or advice before part of the project or decision is progressed.
Active participation takes place when the locality collaborates with specific stakeholder groups or the community to work out what needs to be done and to develop solutions that are incorporated into decision-making.
All engagement processes need to inform; most will have some level of consultation and some will include active participation.

Engagement and empowerment give everyone in the community the opportunity to achieve their full potential by gaining control over decisions and actions that influence health. There are many levels of involvement when empowering people and their communities (Box 11.7.3).

Box 11.7.3 Principles for involving the public in public health strategy implementation

- The community must be seen as being part of the solution, not the problem.
- Community representatives need mechanisms to link to the wider community.
- Community input must be accountable to the local community. Any strategy has to take into account marginalized minority groups.
- To ensure the public can truly benefit, financial support is necessary.
- The community should raise issues that are of concern to them.
- The community needs to see concrete outcomes from their voluntary involvement, otherwise, they might lose interest.
- Meetings involving the community must avoid jargon.

Source: data from Crowley, P., Community development and primary care groups, pp. 41–2, in Communities Developing for Health, UK Health for All Network, Liverpool, UK, Copyright © 2000.

In addition to directly involving members of the public, the voluntary and community sector organizations also have a key role to play in helping to develop strategy. There is a considerable evidence base on the reasons why

partnership working is needed to address issues of exclusion, area-based disadvantage, and development opportunities, especially but not exclusively from the perspective of the community and voluntary sectors. For example:

It ensures the involvement of residents and excluded groups at different stages and on different issues in the strategy development process;
It enables community and voluntary organizations to highlight the contribution and assets they can bring to implementing solutions;
It can provide a framework for more joined-up approaches to addressing issues of equality, disadvantage, and exclusion;
It makes for better accounting for the impact of the strategy development processes, especially where they involved substantial public sector investment.

An example of the contributions of Diabetes UK to strategy development in England is highlighted in Box 11.7.4 next.

Box 11.7.4 Role of Diabetes UK

- Diabetes UK is the leading charity that cares for, connects with, and campaigns on behalf of every person affected by or at risk of diabetes. We help people manage their diabetes effectively by providing information, advice, and support.
- We campaign with people with diabetes and with healthcare professionals to improve the quality of care across the United Kingdom's health services.
- We fund pioneering research into care, cure, and prevention for all types of diabetes.
- We work to stem the rising tide of Type 2 diabetes—through risk assessment, early diagnosis, and by communicating how healthy lifestyle choices can help many people avoid or delay its onset.

Delivering public health strategy

Political leadership

Undoubtedly, given the political environment in which public health policy development and implementation often sits, it is imperative that due

consideration is given to political context and the potential for this to be either a barrier or facilitator. In addition to having a positive effect on health, effective public health strategies can contribute to societal stability, through attaining health equity, national security, and economic dividends to those who invest in them. These benefits need to be articulated more effectively to Heads of State, government ministers, local politicians as well as civil servants, policy makers, and economists. Helping political leadership to understand that the health system and public health strategies can help to improve its functioning and outcomes, and are a critical source of employment, capital investment, contributes to economic growth via a healthy workforce that is more productive, and to national security.

CASE STUDY 11.7.13 Partners for Mental Health

The Canadian Mental Health strategy emphasizes the need to engage patients and their carers in determining what they want from health services:

The mobilization of the Canadian public to take action on mental health issues is essential in order to ensure that mental health remains a high priority (Mental Health Commission of Canada 2012).

Partners for Mental Health 'has one focused goal … to catalyse a social movement that will empower individuals and organizations to take action to improve mental health' and in particular to engage with the general public to increase engagement in and advocacy for mental health issues (Mental Health Commission of Canada 2012).

Effective strategy implementation also relies on community engagement and the conciliation of top-down directives with bottom-up initiatives. As such, it is important to engage the public and patient groups in implementation as their lack of engagement will result in a failing strategy. Ways of engagement may be through minimum participation, where people are merely passive receivers of information, for example, receiving health education materials or through active partnership, in which patient groups or the public are partners, empowered to play expanded roles and to take responsibility. For example, Diabetes UK plays a pivotal role in providing advocacy and advice for diabetic patients at national and local levels (Box 11.7.4).

Examples of mobilizing political leaders to support public health strategies are found both at global national and local level. Political leadership and engagement in WHO's strategic programmes on climate change, universal healthcare, tackling the HIV/AIDS are well documented and are key achieving consensus and accelerating progress. In England, strong political leadership from the Secretary of State for Health was essential to develop the National Tobacco Control Plan (DH 2017), National Sexual Health Strategy (DH 2013c), and more recently the Childhood Obesity Plans (DHSC 2018). At local levels, where public health strategies may become more challenging due to the resourcing, community concerns

and political mandates, local elected mayors, and councillors have been at the forefront of tackling issues that matter to local communities and promoting greater community engagement and co-production as strategies to promote inclusive policy development.

Politicians at global, national, and local level, have to balance a number of competing concerns and priorities, not just the evidence of effectiveness, before agreeing to champion, support, and fund implementation. Considerations may include alignment with political ideology and manifesto commitments, the need to balance competing interests, mitigating the risk and unintended consequences of public health policies on other sectors, how decisions will play out in the media and public domain, and the threat of loss or alienation of key constituencies including the public, donors, business etc. Recognizing these additional and important perspectives are critical to understand the window of opportunities for developing public health policies, the importance of developing coalitions, working with a diverse range of partners and sectors to demonstrate widespread buy-in and support, and clear demonstration of public support. If one is able to clearly align the policy with the values, priorities, and commitments of politicians then this will help mitigate barriers to implementation. Political leadership is therefore needed:

To establish the national or local public health strategy and business case action, providing support by necessary regulations.
To use it for demanding plans and budgets from public and private educators and employers of health workers.
To use innovative processes and technologies for more effective and efficient services delivered to protect, promote, and restore health at optimal levels.
To negotiate targeted technical and financial assistance from regional and global donors, and to require donor aid to be harmonized and targeted to meet priority health system needs as defined by countries.

One should also remember that this process of political engagement and support may happen quickly, for example spurred on by response to a national or local tragedy, or may happen over a prolonged period as time is taken to change public opinion, educate, engage, and enlist support of coalitions to demonstrate the need and value of the policy change. In England, national leadership for tobacco control in the United Kingdom unfolded over five decades and reflected the time taken to develop a robust

evidence base on the primary and secondary impacts and costs of smoking on individuals and society, strong leadership by the healthcare professions working in partnership with advocacy organizations, creating alliances with key political leadership, running effective antismoking campaigns, and successive development and implementation of national tobacco control strategies with clear commitments, funding, and accountability for progress (Raw and Joossens 2007; Joossens and Raw 2011).

Leadership and governance

The best developed public health strategies will fail if due regard is not given to leadership and governance. All over the world, public health managers and providers face the challenges of producing results in an increasingly complex healthcare environment. Health sector reform, changing donor priorities, shifting client needs, and new technologies require that managers at all levels take on responsibilities previously held by people at higher levels. Moreover, the drain on health systems workforce shortages, financial constraints, and dealing with new and emerging diseases has accelerated the need to learn new ways of leading and managing to achieve results. Through improved leadership, management, and teamwork, managers in public, private, and non-governmental organizations can face these challenges with more confidence and lead their teams to effect significant changes in health.

Appropriate leadership and governance in implementing public health strategy involves ensuring that strategic policy frameworks exist and are combined with effective oversight, coalition-building, regulation, attention to system design, and accountability. Leadership involves strategically developing and implementing plans and policies with accountability and transparency. Good leadership, which requires the ability to face challenges to achieve results in complex conditions, can and should be practised at all levels.

Governance of health systems comprises the actions adopted by a society to organize itself to promote the health of its population. Although governance is the least understood component of health systems, it impacts on all other health system functions. Good governance may result in strengthened performance of a health system, including effective delivery of public health strategies, health services, and improved health outcomes.

Governance has in recent years transitioned to the fore of the international development agenda, indicating a shift from attention to micro level, project specific objectives to macro level issues of policymaking. Governance in public health strategy is a cross-cutting theme, intimately connected with issues surrounding accountability. It is an integral part of the health system strengthening yet they remain inadequately monitored and evaluated.

In England, an Independent Advisory Group was established to oversee the new National HIV/AIDS Strategy (DH 2013c), bringing together advocates, scientists, clinicians, public health experts, and professionals to review progress and drive successful implementation. Within Public Health England the establishment of a delivery board reporting directly to the PHE Executive oversees implementation of major national public health strategies as well as PHE's own NCD prevention strategies. At the local level, oversight of strategy implementation often rests within existing governance structures including the local health and well-being board, providing oversight, challenge, and accountability for delivery.

Critical lessons are now emerging on some of the broad principles which must underpin good governance in the implementation of public health strategies. These include proactive participation and engagement of persons and communities who are the target of the policies to improve programme responsiveness, efficiency, effectiveness, and sustainability, and to strengthen service-user self-determination and satisfaction. There should be robust investment in data to support political momentum, decision-making of policymakers, evaluation, accountability, and equitable allocation of resources. There should be explicit promotion in policies of the importance of tackling inequalities and promoting inclusion, ensuring equitable and accessible services. And finally, linking back to the importance of political leadership, wherever possible there should be robust intersectoral coordination to ensure coherency across governmental departments (national and local) aligned with a commitment to promote programme sustainability by aligning implementation with pre-existing programmes and initiatives.

The public health workforce

Public health has been defined as 'the science and art of promoting and protecting health and well-being, preventing ill-health and prolonging life through the organized efforts of society'. While this means that a broad

range of people and organizations contribute to protecting and improving people's health, the World Health Organization has defined the three core functions of a public health system as:

the assessment and monitoring of the health of communities and populations at risk to identify health problems and priorities
the formulation of public policies designed to solve identified local and national health problems and priorities
to assure that all populations have access to appropriate and cost-effective care, including health promotion and disease prevention services

In the United Kingdom these functions are mainly delivered through a 'core' workforce (Box 11.7.5), including public health professionals such as directors of public health, specialists, academics and practitioners who are trained in all or some of the nine key areas of public health practice, working in a range of commissioning or delivery roles in a variety of organizations. The role of a broader group of people—the wider workforce—in the public health system, is increasingly being recognized. Improving public health requires the combined efforts of people from many professions and disciplinary backgrounds (Sim et al. 2007).

The formal definition of a public health professional is a person educated in public health or a related discipline who is employed to improve health through a population focus (Institute of Medicine 1988). A useful way of considering the workforce, adopted in the United Kingdom, is that there are three main groupings: (1) specialists; (2) those who practise public health as part of their role, such as primary care workers; and (3) those with an interest whose work impinges on the public's health.

However, it is now widely acknowledged that public health really is everyone's business and that our aim must be to influence and improve many aspects of an individual's life including transport, housing, education, and the environment if we are to begin to shift the pendulum towards a healthier, happier country. For example, voluntary NGOs frequently have greater insights into the health needs of disadvantaged groups within communities than do statutory organizations. As such, it is not enough to focus on any one sector or any one activity but to recognize the interactions and different levels at which these influences are working.

Box 11.7.5 The core public health workforce

Specialists—including directors of public health—working as system leaders at strategic or senior management level, with high levels of technical skills and knowledge—employed mainly in local authorities and PHE

Public health nurses, such as school nurses and health visitors, and those working in health protection, screening, and immunization, research, TB, sexual health, infection prevention and control, drugs, and alcohol; they may be employed by NHS trusts, PHE, the voluntary or private sectors

Public health midwives—improving and promoting the health and well-being of women, children, families, and communities throughout pregnancy, birth, and the postnatal period as well as specializing in quality assurance of antenatal screening programmes in PHE

Environmental health officers and practitioners—working to improve, monitor and enforce public health and environmental health standards in local authorities and in PHE health protection teams

Knowledge and intelligence staff—employed in data analytics, knowledge management, informatics and interpretation and presentation of information

Academics—developing the research and evidence base and training new entrants to public health

Scientists—leading the development and delivery of highly technical and specialized scientific functions in support of public health objectives, primarily within PHE, also working in NHS laboratories

Practitioners with a wide range of relevant skills delivering public health services and programmes in a range of settings including local authority public health teams and PHE

Health trainers, stop smoking advisors, weight management advisors, etc—providing advice, motivation, and practical support to individuals in their local communities, often employed in third sector organizations

In the United Kingdom, public health practice is recognized as having three overlapping domains of health protection, health improvement, and health services (HM Government 2010). This structural framework recognizes the interactions between the different aspects of practice and that practice needs to be underpinned by an understanding not only of epidemiology and biostatistics, but of ethical issues within a global context. The capabilities needed for public health practice have been described in the UK-wide skills and knowledge framework, which is currently being updated to reflect today's practice in both the core and the wider workforce. Four key functional areas have been identified:

Behaviours—principles, values, and ethical practice
Technical competence—traditional public health skill sets in which the core workforce will be more specialized
Context—strategic/policy; organizational/collaborative; contractual/commercial; political and democratic
Delivery—leadership, communication, programme management, prioritization, and management of resources

In addition to technical skills in public health, specialists, and particularly directors of public health in local authorities, need skills that enable them to work as system leaders at strategic or senior management level, or a senior level within a particular area of expertise.

Some overseas countries adopt a similar approach and standards including the Hong Kong College of Community Medicine (n.d.), which is part of the Hong Kong Academy of Medicine. The Academy is an overarching medical body representing the professional groups in medicine (Hong Kong Academy of Medicine n.d.). The Colleges within the Academy are professionally led and independent of government or licensing bodies. Their remit is to set professional medical standards and curricula from postgraduate to specialist levels. Licensing bodies, such as the UK General Medical Council (n.d.), Faculty of Health (n.d.), or the Hong Kong Medical Council (n.d.), act as professional regulators and issue the licences to practise.

Health service contribution: the role of primary care

How public health strategies and programmes are delivered is obviously key to their effectiveness not only in dealing with disease, but in promoting better public health. The role of health services and of public health within health services is important for delivering better health outcomes. For example, providing antenatal care, well-baby checks, postnatal support, and immunizations are all part of a public health service delivered in different places by different systems including within a primary care setting or within a government-run maternal or child health clinic. As such, public health services need to be considered within the framework of primary care provision.

That primary care should be the foundation of health services has been recognized by many countries who strive to develop or strengthen their public health and healthcare systems. The need to enhance primary care, based on the principles of Alma-Ata, has been reaffirmed in the World Health Report 2008, Primary Health Care: Now More Than Ever (WHO 2008) and further highlighted in the 2009 WHA's resolution on primary care policies (WHO 2009b).

In comparison with systems based on specialist care, primary care produces better population health outcomes, reduces the rate of avoidable mortality, improves continuity and access to healthcare, results in higher patient satisfaction, and reduces health-related disparities at a lower overall cost for healthcare (Starfield 1998). Primary care health services provide ongoing care at a community level and, as such, they are often closely interrelated with public health services. In many situations, primary care clinicians are indeed the main providers of public health services and increasing attention is being paid to effective and efficient models for integrating personal healthcare and public health, and organizing primary care on the principle of care for individuals in the context of an identified population over time. To quote Van Weel et al. (2008):

> The future of primary care, and health care in general, will depend on how effectively primary practices achieve this community-oriented primary care approach and contribute to equity and social cohesion. Current efforts to revitalize primary health care worldwide should go hand in hand with attention to the social determinants of health. Just as the social determinants' approach to improving health equity must involve health care so must programmes to control priority public health conditions include attention to the social determinants of health.

Now More Than Ever (WHO 2008) emphasizes yet again how implementing primary care strategies needs to be context specific, in particular with reference to income and resources. For example, the Chinese healthcare system is investing significantly in community health centres and community-based systems to provide universal access to primary care, to emphasize prevention, to enable choice between Western and traditional medicines, and to strengthen programmes within local communities.

The primary care strategy of the reforms in China aims to strengthen the establishment of the public health service system by:

Building sound public health networks of disease prevention, health education, maternal and child healthcare, mental health, first aid, blood collection and supply, health supervision, and family planning.
Improving the public health functions of the medical services system based on a basic medical services network.
Setting up an information-sharing and resources-sharing public health services system.
Enhancing the capacity of public health services.
Enhancing the capacity to respond to public health emergencies.
Decreasing the urban–rural inequity in utilization of public health services (Government of China 2009).

Another example of the promotion of the strategic focus for healthcare reform through developing primary care services to deliver public health comes from Chile. In Chile, the health policy has defined a detailed benefit package, which is well publicized among the population as an enforceable right. People are being informed about the kind of services, including access to specialized care, which they can claim from their primary care teams. In combination with sustained investment, such unambiguous entitlements create a powerful dynamic for the development of primary care (WHO 2008, chapter 6).

Research and evaluation

Research plays and important role in strategy development and implementation. It is essential that public health policies are developed on the most robust evidence available including a robust assessment of the need for change, evidence of effectiveness and cost-effectiveness of interventions, and where appropriate a robust evaluation, including the use of mathematical modelling, of potential options for action. Increasingly, we are seeing the importance of qualitative research as a tool to provide deeper insights into the feasibility, acceptability of potential policies from political, provider, and community perspectives.

Strategy design and implementation is a continuous process. Continued communication about key themes and the resulting behavioural changes should be identifiable and will need to be updated as evaluation strategies are embedded into the process. The two basic rules for successful evaluation:

The evaluation process must be thought through from the start, at the same time as developing the strategy's aims, objectives, and targets.
Adequate funding must be set aside for evaluation.

The key areas to evaluate must be agreed among the partners, including participants, to reflect different agendas. Evaluation will include: Measuring indicators of progress, including progress towards targets; Assessing how well various aspects of the strategy were perceived to work from the point of view of professionals from all sectors and by communities; and assessing whether the changes were a result of the intervention. The use of an impact screening tool can encourage a more realistic perception of the likely impacts of the strategic goals upon particular population groups, and can be used during all stages of planning and review, as highlighted to follow.

As discussed in earlier chapters, public health research and evaluation remain underfunded in most jurisdictions despite the importance of the evidence base to guide effective policies and professional practices. High-tech medical proposals with quick returns are often more attractive to funders.

Earlier in the chapter we have stressed the importance of evaluation and monitoring health interventions as key components of the strategic approach. Increasingly, strategies are developed which recognize the inter-relationship between health and health services. For example, in the United Kingdom when launching Investing in Research, Improving Health, the responsible minister wrote:

> We are committed to tackling disease prevention wherever possible and are excited by the emerging understanding of the biological links between inequalities and health. The benefits to health and healthcare are explicit but we are also alert to the potential for economic benefits. The life sciences have a key part to play and a tradition of excellence on which to build. (Chief Scientist Office, NHS Scotland 2009)

In England, the National Institute for Health Research has an arm which focuses on public health. The public health research (PHR) programme commissions research to provide new knowledge on the benefits, costs, acceptability, and wider impact of non-NHS interventions (NHS 2013) (Fig. 11.7.3). However, as in other countries such as Australia, the lion's share of available funding goes to basic sciences and clinical research, with allocations to public health and health services research in single-digit figures (Australian Government National Health and Medical Research

Council 2008; Pitcher et al. 2010; Australian Government Department of Health and Ageing 2012).

CASE STUDY 11.7.14 A strategic approach to public health research in England

Over the coming decades, the UK population will face a wide range of complex health challenges and opportunities, many of which can only be fully addressed through strategies to secure and improve the health of the public as a whole. The Academy's report, *Improving the Health of the Public by 2040* (AMS 2016) explored how to organize our research environment to generate and translate the evidence needed to underpin such strategies.

The report concluded that while PHR has provided fundamental insights into human health, there remains much we do not know about the complex array of interlinking factors that influence the health of the public, and about how to prevent and solve the many health challenges we face as a population. Solving these challenges will require shifting towards a 'health of the public' approach, involving disciplines that would not usually be considered to be within the public health field. This is turn requires six key developments: (1) Rebalancing and enhancing the coordination of research; (2) Harnessing new technologies and the digital revolution; (3) Developing transdisciplinary research capacity; (4) Aligning perspectives and approaches between clinical and public health practice; (5) Working with all sectors of society, including policymakers, practitioners, the commercial sector, and the public; and (6) Engaging globally.

The report emphasizes the need to significantly increase transdisciplinary research capability, in a way that harnesses the changing drivers of health. To contribute to this ambition, the Academy has launched a new grant scheme called Springboard—Health of the Public 2040 to help further the careers of newly independent researchers working in the health social sciences and medical humanities. The Academy's *Improving the Health of the Public by 2040* report also emphasizes that policy decisions should be guided by a robust understanding of how to most effectively support and improve the health of the public. To facilitate improved use of evidence in policymaking, the Academy is currently undertaking a joint project with the Royal Society in evidence synthesis.

Looking to the future, there needs to be closer alignment between PHR and policy. Ensuring programme relevant research is being undertaken to address contemporary and emerging public health problems, a stronger focus on implementation science, addressing the wider determinants of health, clarifying the costs and cost-effectiveness of interventions, and ensuring that efforts to reduce inequalities are addressed. Much of this change in focus will require a new focus on the research workforce and infrastructure as highlighted in the Academy of Medical Science in England's report on *Improving the Health of the Public by 2040* (AMS 2016).

Barriers to implementing strategy

We have already discussed the importance of the political leadership and support for the successful implementation of public health strategies, given the need for political support and advocacy, full engagement of a range of cross-sector partners, engaging the public, and releasee of resources. Failure to adequately consider this political reality (which may also include organizational or community level politics) can have a detrimental impact on implementation.

However, there may be other barriers to strategy implementation. While many organizations produce strategies, many do not achieve their goals. To some extent this is because they are aspirational and at times unrealistic. Management literature suggests that there are four main barriers to effective strategy implementation. These are:

The vision barrier: in the age of the knowledge-based economy, the workforce needs to understand the strategy.
The people barrier: personal incentives need to be tied to the long-term initiatives supporting the strategy, not to short-term (financial) results.
The resource barrier: strategies need to be linked to budgets.
The management barrier: managers need to discuss strategies but often focus on budgets (Kaplan and Norton 2001).

Thus, there may be overattention being paid to the day-to-day duties rather than tackling the projects that have been identified as key to organizational sustainability and success. Important strategies may be perceived as overwhelming and too difficult to tackle. Lack of teamwork can inhibit cooperation across organizational divisions and different players have different priorities. Recommendations for successful implementation of strategic plans include:

Identify, understand, and plan for the political context within which the strategy is being developed and will be implemented.
Ensure the appropriate leadership and governance is in place to drive implementation and to ensure accountability for each step of the process including evaluation and dissemination of results.
Ensure clear discussion and agreement on the resources required for implementation and plans are in place to access those through the entire implementation phase.
Identify your coalition of diverse and inclusive partners for strategy development, implementation, advocacy, and strategic communications.
Focus: having too many priorities means no action and not everything can be or is a priority, so agree on what the top two to three goals are.
Communicate clearly and often, and understand each other's language and contextual background.
Emphasize and reward teamwork which may involve trade-offs, negotiation, and difficult conversations about resource allocation and expectations.
Regular review of progress: provide a framework for ensuring that all stakeholders reach their objectives.
Accountability needs to be clearly defined.
Emphasize implementation of the strategic plan is the most important aspect of planning.

Identifying the barriers to implementation and overcoming them is a key success factor for any organization. Teamwork, accountability, and resolution of conflicting priorities, or hidden agendas, will help ensure the implementation of the top two to three goals (Dane 2010).

Conclusions

This chapter has focused on strategies for promoting public health and structures for their implementation. As the scope of public health broadens and more consideration is given to the wider determinants of health and to the challenges of the future—the NCD epidemic, changing patterns of demography and disease, and climate change and its impact on health—more partners will need to be involved in signing up to strategies to tackle the threats they pose to public health. The example of SARS in 2003 demonstrated the problems that can occur when a strategy is missing. The

experiences of China during its economic transition demonstrate the need to constantly review the impact of broader determinants on equity in health and health services. Different examples of evidence-based and value strategies have been discussed with reference to examples and experiences in different countries and settings. The need for fit-for-purpose structures in the health systems, public health workforce, and research community has been highlighted and barriers to overcome in achieving the strategic goals described. All too often strategies remain merely fine words. The fundamental challenge is their implementation and continuous refinement in the light of delivery.

Strategies for health services

Chien Earn Lee and Fran Baum

Introduction to strategies for health services

Two crucial questions this chapter needs to answer are: firstly, why public health professionals should be interested in health services, which leads to the second question: do health services actually make a meaningful contribution to population health?

Writers such as McKeown (1979) contended that the main drivers of improvements in health had been nutrition, environment, and behaviour rather than healthcare. He showed that three-quarters of the decline in mortality in England and Wales between 1841 and 1971 had been due to a reduction in deaths from infectious disease and that three-quarters of this reduction had preceded the widespread introduction of immunization or antibiotics.

Others such as Illich (1976) argued that instead of improving health, healthcare has a direct and adverse effect on health, for example, side effects of prescribed drugs, hospital-acquired infections, poorly performed surgery, and the consequences of following up spurious abnormalities from the increasing numbers of laboratory investigations.

However, as several commentators have noted, McKeown was describing a period in which healthcare still had relatively little to offer. It was only in the 1960s and 1970s that safe and effective drugs for many chronic diseases became widely available (Nolte and McKee 2004). Contrary to the situation before the 1960s, health services are now making an important contribution to overall improvements in life expectancies in industrialized countries. Many new treatments have been introduced that have been shown, in high-quality evaluative research, to prolong life. Examples include effective

treatment for hypertension and heart failure, secondary prevention following myocardial infarction, and chemotherapy for many childhood cancers.

International differences provide many natural experiments to examine this issue further (McKee and Bojan 1998). For example, prior to 1990 the death rates from causes amenable to medical care (i.e. deaths from causes that are potentially preventable with timely and effective healthcare) were higher in former communist countries of Central and Eastern Europe than in the West (Bojan et al. 1991; Boys et al. 1991). Excluding early neonatal deaths, for which only incomplete data are available, Velkova et al. (1997) estimated that amenable causes accounted for 24% of the East–West gap in male life expectancy between birth and the age of 75 years in 1988. The corresponding figure for females was 39%.

There is now considerable evidence that, unlike the situation prior to the 1970s, health services, although only one of the determinants of health, others being genetic predisposition, individual behaviour and lifestyle, social, economic and commercial determinants (see Section 10) and environmental circumstances, can make a substantial difference to population health (McKee and Figueras 2009).

The Ottawa Charter for Health Promotion (WHO 1986) recommended the reorientation of health services and their resources, beyond its responsibility for providing clinical and curative services, towards the promotion of health. The Charter also emphasized the need to work towards enhancing life skills to increase the options available for people to exercise more control over their own health and over their environments and to make choices conducive to health. More recently, the World Health Organization (WHO) has added to the work of the Charter and argued that government should adopt a Health in All Policies approach (Leppo et al. 2013) which involves all sectors in examining and then seeking to maximize their health input so that they govern for health (Baum 2019).

Public health professionals have a key advocacy role to ensure that resources in hospitals (which invariably receive the lion’s share of the healthcare budget) are used effectively, efficiently, and equitably to optimize outcomes, and that community-based services which are less urgent but no less important than acute services are not neglected. The capabilities of public health professionals in developing systems-based solutions and mobilizing intersectoral action will need to grow to improve population health

The remainder of this chapter explores the changing context of healthcare services, the emerging themes in healthcare services, and strategies for delivering and improving healthcare services

The context for healthcare services

Healthcare services do not exist in a vacuum. While this statement seems self-evident, it has often not been adequately taken into account in developing and evolving healthcare strategies. As a result, strategies have either not taken root (especially those related to 'transplanted' best practices from other systems) or like the proverbial frog being slowly boiled alive, failed to respond in a timely manner to meet new challenges. Contextual factors that need to be considered include societal and professional norms and values as they influence the central principles of the system as well as the desire for reform. Economic factors such as the level of economic development would affect the level of disposable resources available for health services (Maxwell 1981), while the upward pressure on healthcare expenditures has been the key driver for healthcare reforms around the world. Healthcare systems must also be able to respond proactively to factors affecting population health needs such as the changing demographics and patterns of disease as well as the impact of technological change. The role of education in producing sufficient professional and managerial capability will also influence the health system's capacity for serious and sustainable action. These contextual factors are discussed here under the headings of defining norms and values, the reality of macroeconomics, demographic pressures, changing disease patterns, technological changes, the quest for quality and reducing waste, and rising patient expectations.

Norms and beliefs

Healthcare systems act as mirrors that reflect deeply rooted social and cultural expectations of the population that they serve (Contandriopoulos et al. 1998). Although these norms and beliefs are generated outside the formal structure of the healthcare system, they play a major role in defining the system's overall characteristics.

Societies have dominant belief systems where the daily tensions between differing values and beliefs in a society are held in relative stability (Benson

1975). A useful approach to understanding belief systems sees these tensions as grouped around four poles (Habermas 1987): values, understanding of phenomena, definition of jurisdictions and allocation of resources, and logic of regulation.

In this framework, values include the tensions and trade-offs between equity, individual autonomy, and efficiency (Clark 1988). Understanding of phenomena relates to how concepts such as life, death, sickness, health, and pain are interpreted and thus viewed as relating to the objectives of a healthcare system (Gillett 1995). Definition of jurisdictions and allocation of resources comprise the perceptions of the role and functions of those working in the healthcare sector, as well as the allocation of resources between prevention and cure and between healthcare and broader determinants of health. The logic of regulation relates to how society chooses to regulate the delivery of healthcare. This may be technocratic with trained experts guiding the system on the basis of their knowledge and position within the hierarchy; professional self-regulation which has the physician (as the best agent of the patient) at the centre of the system; the market-based model in which regulations reflect supply and demand in a competitive market; or the democratic model, in which the population, either directly or, more often, through elected or appointed representatives, is responsible for setting out the framework for delivery of healthcare.

An understanding of the dominant belief system in a society is important for public health professionals as it contributes to knowledge of why systems are as they are, how they have changed, and the objectives that individuals within the healthcare system are pursuing. It will also influence the choice of strategies that should be adopted to bring about meaningful and sustained change (McKee and Figueras 2009). For example, some societies view healthcare as predominantly a social and collective good. Such societies would more readily accept policies designed to create intentional cross-subsidies, from young to old, rich to poor, and from healthy to sick, than societies that view healthcare as a commodity that can be bought and sold in the market.

Norms and beliefs can and do evolve over time. For example, years of spectacular growth have seen more people pulled from abject poverty in modern Asia than at any other time in history. But as they become more affluent, the region’s citizens want more from their governments. Across the continent, pressure is growing for public pensions, national health insurance,

unemployment benefits, and other hallmarks of social protection. As a result, the world's most vibrant economies are shifting gear, away from simply building wealth towards building states with better and more comprehensive welfare provisions (*The Economist* 2012). In addition, the United Nations have adopted the goal of Universal Health Coverage (UHC) as part of the Sustainable Development Goals designed to be achieved by 2030 (WHO 2020). The current Director General of the WHO Dr Tedros Adhanom Ghebreyesus said that achieving 'Universal health coverage is a political choice' (WHO 2019). While such changes increase the demands on healthcare systems, they also provide opportunities to introduce changes and strategies that may not have been acceptable based on previous norms and beliefs.

Macroeconomic factors

The historically high rates of economic growth seen during the 1960s and 1970s have not been sustained in the 1990s. This has been compounded by economic volatility with shorter boom and bust cycles with globalization. With economies across the world becoming more and more connected to one another, adverse economic conditions in one country can rapidly spread to other countries and escalate to global proportions, as was seen in the global financial crisis in the late 2000s.

At the same time, the expansion of healthcare coverage both in terms of scope of services and population covered is adding significantly to the upward pressures on healthcare expenditure. There are already concerns that the current level of expenditure on healthcare is not sustainable and is adversely affecting other sectors of the economy. For example, the United States spent more than 17% of its gross domestic product on health, raising concerns about the heavy burden placed on companies doing business in the United States which can put them at a substantial competitive disadvantage in the international marketplace.

The macroeconomic environment influences the political decision-making process, in particular, the allocation of resources to competing sectors. The growth in health spending slowed or fell in real terms in 2010 in almost all Organisation for Economic Cooperation and Development (OECD) countries, reversing a long-term trend of rapid increases. Overall, health spending grew by nearly 5% per year in real terms in OECD countries over

the period 2000–2009, but this was followed by zero growth in 2010. Preliminary figures for a limited number of countries suggest little or no growth in 2011. Countries like the United Kingdom that invested heavily in healthcare in 1990s are having to scale back in the face of the tightening economic situation. The UK government aims to deliver £20 billion (4%) efficiency savings in the National Health Service (NHS) by the end of 2014–2015. The challenge at present is how to balance increased demand from patients with the requirement for productivity and efficiency, while maintaining excellent, quality care.

Demographic pressures

Dr Gro Harlem Brundtland, former Director General of the WHO, called ageing one of humanity's great achievements and also one of its greatest challenges. In rich countries, the number of people over 65 who will require medical care, is expected to increase by between 50% and 120% from 1995 to 2025 and the elderly incur disproportionately more healthcare cost than the young. For example, in the United States, the elderly account for less than 15% of the total population but incur more than one-third of healthcare spending (and this is before taking into account social or long-term care costs).

The greatest challenge lies in the developing countries. While developed countries grew affluent before they became old, developing countries are growing old before they get affluent. The demographic shift towards an older population that took place gradually in Europe over a century, is taking place in the developing countries at a pace which far outstrips these countries' socioeconomic development. The impact of ageing on demand for healthcare is often compounded by falling birth rates, leading to an increasing dependency ratio.

It is, however, necessary to enter three caveats. Firstly a study of American Medicare data showed that while estimated lifetime cost increases with age, the cost associated with an additional year of life and the average annual cost over a person's lifetime both decreased as the age at death increased (McGinnis and Foege 1993; Lubitz et al. 1995). This could be due to less intensive treatment the older the patients are in their respective last year of life (Scitovsky 1988). This suggests that healthcare cost will be more

substantially affected by the expected increase in the absolute number of elderly people than increased longevity beyond the age of 65.

Secondly, the health and social profile of the elderly of the future may be different from current elderly. They are likely to be better educated and would have benefited from a lifetime of better nutrition. On the other hand, they are also likely to have adopted a more sedentary lifestyle and have higher expectations of healthcare. For these reasons, we should not make simplistic extrapolations of demand based on current data of the elderly to a future population.

The final caveat is that pessimistic predictions of the costs of ageing are based on the assumption that health services will continue to expand in their current form which is highly hospital centric. The impact of ageing on disease burden and costs can be moderated by greater emphasis on prevention of disease and disability and transforming models of care for the elderly.

Changing healthcare workforce

Specialization in the pursuit of greater knowledge and expertise has characterized scientific progress in medicine for nearly two centuries (Cassel and Reuben 2011). A more recent development is the creation of subspecialties, recognizing that there are some specific populations of patients who would benefit from the highly focused knowledge and skills obtained by additional training and certification beyond that of a ‘general’ specialist. As these tertiary subspecialists require high patient volume to maintain proficiency in their skills, they are usually based at referral centres.

Many new and emerging subspecialties are cross-disciplinary. In the United States, sleep medicine crosses six different specialties, and palliative medicine is a subspecialty option for ten different primary specialties. The proliferation of specialties has led to concerns that medical care would become increasingly fragmented with the concomitant loss or undervaluing of the generalist physician with decreased attractiveness as a career choice for young doctors.

As trade barriers come down, the forces of globalization have increased the movement of all types of professionals throughout the world, and healthcare is no exception. Richer countries are increasingly relying on immigration as a means of coping with domestic shortages of healthcare

professionals. This trend has led to concerns that the outflow of healthcare professionals is adversely affecting the healthcare system in many of these source countries. Insufficient human resources for health in developing countries have been identified as one of the main constraints limiting progress on such initiatives as 3by51 and the Millennium Development Goals (MDGs) (Institute of Medicine (IOM) 2004). Recipient countries on the other hand need to develop the means to effectively assimilate the influx of healthcare professionals from diverse backgrounds and cultures.

Countries are also exploring expanded scope of practice for healthcare professionals as a means of addressing access-to-care problems. Nurse practitioners, physical and occupational therapists, and other allied healthcare professionals are growing in independence from physicians' oversight. For example, several states in the United States have passed legislation allowing pharmacists limited ability to evaluate and manage drug regimens as well as dispense drugs.

Changing burden of disease

The term 'epidemiological transition' refers to the complex changes in patterns of health and disease as societies develop. It describes the interactions between these patterns and their demographic, economic, and sociological determinants and consequences.

In the classical (Western) model, Omran (1971) described the transition from the Age of Pestilence and Famine with its high mortality and low average life expectancy (20–40 years), through the Age of Receding Pandemics, to the Age of Degenerative and Man-Made Diseases with its relatively low levels of mortality (average life expectancy of more than 50 years) and morbidity overshadowing mortality as an index of health.

Although the classical model assumes linear unidirectional change, counter transitions have also been observed where age-specific mortality rates rise rather than fall over time due to causes such as the HIV/AIDS pandemic in sub-Saharan Africa (Gaylin and Kates 1997). There is also an emerging awareness of old problems that never went away resulting in an overlap of eras, often with large disparities emerging between and within countries. On the other hand, although chronic diseases such as diabetes have usually been considered as diseases of affluence, four out of five people with diabetes now live in low- and middle-income countries

(International Diabetes Federation 2012). In short, health systems in these countries must continue to grapple with the unfinished agenda of communicable diseases while addressing the new agenda of non-communicable ones in an ageing population.

As the burden of disease is dynamic (Murray and Lopez 1996), the configuration of health services must evolve accordingly to meet the changing health needs of the population. Health services cannot remain trapped in structures designed for a time when disease patterns were different. For example, the increasing incidence and prevalence of chronic diseases requires health systems to organize health services with greater emphasis on prevention and community-based services instead of the current hospital-centric model which is more suited for acute episodic care.

Current care delivery models are, however, often overly complex and uncoordinated, requiring many steps and patient 'hand-offs' that slow down care delivery and decrease safety. Healthcare organizations, hospitals, and physician groups also typically operate as separate 'silos', acting without the benefit of complete information about the patient's condition, medical history, services provided in other settings, or medications provided by other clinicians (IOM 2001).

Public health professionals have a central role in tracking and explaining trends in diseases (including predicting emerging trends), designing mechanisms to address them, supporting the changes in service delivery that are required, and monitoring responses to these changes. With appropriate interventions, Olshansky and Ault (1986) have postulated the 'Age of Delayed Degenerative Diseases' as the fourth stage of the epidemiological transition.

Technological changes

The pace of change in healthcare is steadily accelerating. Hip replacements have been joined by knees, shoulders, and finger joint replacements. Transplant surgeons have added heart, liver, and pancreas transplants to their initial successes with kidneys. AIDS has been transformed from a rapidly progressive fatal disease to one in which increasing numbers of patients are keeping the disease under control with complex cocktails of antiviral therapy. The list is almost endless.

The growth of healthcare technology is widely held to have contributed substantially to the upward pressure on healthcare expenditure. For example, the rapid growth in cardiology services throughout the developed world is driven more by angioplasty and other technological advances in care than by changes in the prevalence of heart disease (Dash et al. 2009). Although its precise contribution is controversial (Mossialos and Le Grand 1999), a study by the Health Care Financing Administration estimated that approximately half of the growth in real per capita healthcare costs in the United States is attributable to the introduction and diffusion of new medical technology for the 1940–1990 period, within an estimated probable range of 38–62% of growth (Smith et al. 2000).

There are various reasons for this increase. New technologies are often more expensive than the ones they replaced. Even where the actual technology is less expensive, it may lead to increased costs as other aspects of the service are reorganized to reflect changing patterns of treatment. For example, the introduction of new treatments may lead to an expansion in the number of individuals with indications for treatment, either because a previously untreatable condition becomes treatable or, as side effects or contraindications are reduced, the threshold for treatment falls. Finally, the diffusion of technology from tertiary centres, in some cases into primary care, can markedly reduce barriers to access and thus increase uptake.

Since the 1980s, there has also been an unparalleled revolution in the pace and volume of communication. The development of new ways of storing and delivering knowledge has transformed the way healthcare services are delivered and used, bringing benefits but also risks. It enables the separation of assessment from service provision allowing healthcare professionals to seek and provide advice without the need for face-to-face consultation. Telemedicine has led to the expansion of roles and the need for new competencies in healthcare workers. It also provides opportunities to optimize the value of highly trained subspecialists by making their expertise accessible to a wider patient population through physician-to-physician telemedicine approaches.

Quest for quality and reduction of waste

In tandem with the rapid growth in medical science and technology, healthcare is becoming more complex with more to know, more to do, more

to manage, more to watch, and more people involved than ever before (IOM 2001). Healthcare systems have, however, struggled to translate knowledge into practice. For example, it takes an average of 17 years for research evidence to reach clinical practice (Green et al. 2009). Small-area variation studies by Wennberg (1984) showed that decisions by clinicians in different areas regarding patients presenting with identical complaints could vary by as much as 40%.

Geographical variation of expenditure has also been identified. For example, in 2004, per capita spending on health ranged from roughly $4,000 in Utah to $6,700 in Massachusetts in the United States (Congressional Budget Office 2008). Higher spending does not necessarily mean better outcomes. The primary reason for such variations has been previously cited as clinical uncertainty about the most appropriate treatment in any given circumstance (Anderson and Mooney 1990). This position is, however, becoming increasingly untenable as medical knowledge advances and evidence-based practice guidelines are developed for many conditions.

Healthcare systems are also grappling with the consequences of unsafe care. A study in *The New England Journal of Medicine* (Landrigan et al. 2010) reported that 25% of hospitalized patients are harmed by medical errors. IOM's landmark study 'To Err is Human' (1989) estimated that there were 98,000 annual deaths from medical errors in the United States. The IOM's follow-up publication 'Crossing the Quality Chasm' has identified six dimensions where healthcare needs to improve:

Safe—reducing harm to patients.
Effective—providing appropriate care based on scientific knowledge to avoid underuse or overuse of services.
Patient-centred—providing care that is based on what matters to patients taking into account their preferences, needs, and values.
Timely—reducing unnecessary delays that may compromise care outcomes.
Efficient—avoiding waste not just of material resources but also ideas and energy.
Equitable—providing consistent quality of care regardless of personal characteristics such as gender, ethnicity, geographic location, and socioeconomic status.

Inappropriate care and errors waste precious resources. Waste occurs not just at the individual clinician–patient interface but as a result of poor

coordination between providers and across subsectors, inadequate management of capital resources, and operational budgets. The IOM Committee that produced the report 'Best Care at Lower Cost: The Path to Continuously Learning Health Care in America' estimated that there was $750 billion in unnecessary health spending in 2009 in the United States alone. The IOM Committee recommended a more nimble healthcare system that is consistently reliable and that constantly, systematically, and seamlessly improves. Healthcare systems must learn by avoiding past mistakes and adopt newfound successes.

The International Cochrane Collaboration has played a major role in providing evidence of what healthcare interventions can (and cannot) achieve by undertaking systematic reviews of available evidence in the literature using standardized methods, and disseminating the information (Chalmers and Altman 1995). Unfortunately such information is not always translated into daily practice as it challenges traditional models based on clinical autonomy.

Increasing patient expectations

The development of new and more expensive technologies coupled with the ready access to information, particularly with the growth of the internet, has led to higher and growing public expectations which may be difficult to meet.

Increasingly people are also taking over responsibility for their own care aided by online advice and other sources of information. The public increasingly expects healthcare systems to be responsive at all times (24 hours a day, every day) and that access to care should be provided over multiple channels such as the internet, by telephone, and by other means in addition to face-to-face visits. Patients expect healthcare services to make information available to patients and their families that allow them to make informed decisions when selecting a health plan, hospital, or clinical practice, or choosing among alternative treatments.

Through the internet, patients draw on the perspectives not only of physicians but also other sufferers from their condition. However, it comes with risks too. Those searching the web must be aware of its unregulated nature, with posts of views ranging from Nobel laureates to quacks (Eysenbach et al. 1998; Sandvik 1999). Internet prescribing may offer price

savings for some, but it may also circumvent regulatory safeguards designed to reduce risks to patients.

Emerging themes in health services

This section explores some of the themes that are emerging in response to the changing context of health services. The evolving macroeconomic environment coupled with the demand for health services brought about by changing demographics, epidemiology, and patient expectations have led to a reassessment of the relationship between the state and the market as well as the way health services are organized and financed. Developments in technology underpinned by changes in norms and beliefs are challenging traditional hierarchies and stimulating new ways of delivering health services with greater involvement of patients in their own care. These themes will be considered in turn.

State and market

During the 1980s and 1990s, many countries began to re-examine the role of the state in the regulation, funding, and delivery of health services. Countries where the state has played a central role are exploring new pluralistic solutions with involvement of a range of actors at varying distances from the state. Some functions are being devolved to local government or to statutory agencies at arm's length from government or transferred altogether to private ownership. Conversely, countries in which the state has traditionally played a less central role, acting only as a source of regulation between competing private interests, are now reassessing the need to expand their role and intervene more actively (Saltman and Figueras 1997).

It would be quite wrong, however, to see these developments as a process of convergence to some ideal model of a health system. Instead, the situation in each country represents the complex interplay of the economic, social, demographic, epidemiological, managerial, and technological forces described earlier and deep-seated cultural beliefs. The debate is often characterized as a dichotomy between the state and the market but this is a gross oversimplification (Saltman and von Otter 1995). In some instances elements of both have been combined albeit in differing proportions to allow

an increased use of market-style incentives with continued ownership and operation of facilities by the public sector in quasi- or internal markets.

The introduction of market mechanisms into the health sector creates a series of conceptual and practical challenges. Conceptually, healthcare is considered in many societies as a social good, in which the provision of services to each individual is also valuable to the community as a whole, whether because of ideas of self-interest, as in the treatment of dangerous mental illness or contagious disease, or altruism. Such principles have led to the creation of systems to ensure universal coverage and solidarity. In contrast, market incentives are intrinsically based on the assumption that services provided are a commodity, with demand driven by individual preference (McKee and Figueras 2009).

Another difficulty is that the neoclassical concept of a market is based on the relationship between a buyer and a seller. However, healthcare systems typically comprise a more complex set of relationships involving the patient, various health professionals, a provider institution, and a payer, with health professionals acting as both suppliers of services and agents for the patient (Young and Saltman 1985). Finally, the assumption in neoclassical economic theory that cross-subsidies between different patients are inefficient is incompatible with the social function of the healthcare system where there are substantial cross-subsidies between young and old, rich and poor, and healthy and sick.

The key practical challenge in introducing market mechanisms into healthcare is the development of real prices. This is a tedious and expensive process which requires a robust costing system to compute the real cost (including overheads) at the service as well as patient level. Some attempts to implement market mechanisms have floundered as the transaction costs and the costly duplication of facilities to secure a competitive advantage (Saltman and von Otter 1995) outweighed the improvements in operational efficiency. Another reason for the failure of market mechanisms in healthcare is that competition operates at the wrong level. Porter and Teisberg (2006) argue that currently competition is both too broad and too narrow. Competition is too broad because much of the competition now takes place at the level of health plans, networks, hospital groups, physician groups, and clinics. Instead, it should occur in addressing particular medical conditions. Competition is too narrow because it now takes place at the level of discrete interventions or services. Instead it should take place at the

patient level, addressing medical conditions over the full cycle of care, including monitoring and prevention, diagnosis, treatment, and the ongoing management of the condition.

Some other attempts have, however, been more successful. In these systems, the introduction of market principles does not mean that the government intervenes less but it intervenes differently. Even as we are familiar with market failures in healthcare, there can be government failure too—which can occur in a state- or market-based system. The manner of government intervention matters more than the fact of intervention. The purported failure of market mechanisms may at times be due more to poor implementation than the mechanism itself. Oftentimes markets fail in healthcare, because they are allowed to fail. For markets to work, government intervention such as setting the ground rules for competition and providing clear standards for market participants with tight monitoring and evaluation as well as making prices transparent is needed.

A related issue is the changing approach to regulation. Governments need to find the appropriate balance between regulatory and competitive measures —which will change with time—depending on the context in which they are implemented. Regulation is becoming more sophisticated with greater recognition that traditional ‘command and control’ measures need to be complemented by a more extensive regulatory toolkit (which includes ‘softer’ tools such as education and community engagement). Governments also need to be cognizant of the risk of perverse incentives with poorly drafted regulations.

Many countries are beginning to question whether self-regulation of healthcare professionals can retain credibility as a system that serves the best interests of the public. Self-interest of the profession plays out in various ways, at times negatively. For example, one professional group may use the regulatory structure to exercise control and influence over another group, or to keep hold of their monopoly on very profitable services. The key question for policymakers, then, is one of governance: to what extent are healthcare professional regulators sufficiently independent of the groups they regulate —and to what extent do they act in the best interests of patients and the public? Several countries have moved to ‘shared regulation’ whereby the government and other credible experts from outside the regulated profession sit with members of the profession around the table. The proportion of

places around the table is a matter for each country to determine, based on local context (Dzau et al. 2012).

Governments that have successfully incorporated market principles rely on competition and market forces to improve service delivery and efficiency, while retaining the prerogative of the state to intervene directly when the market failed to keep healthcare costs down (Atwal 2010). Markets are necessary to help government work better, and good government is necessary to help markets work better (Menon 2010). In fact some researchers have concluded that governments have to be more competent to supervise contracting and other market-style arrangements than to run services directly (Kettl 1993).

Reorganizing the system: decentralization, recentralization, and privatization

Decentralization has been defined as the transfer of authority from a high, or national, level to a lower, or subnational, level (Rondinelli 1981). Decentralization has multiple meanings, interpretations, and implementation in different countries and different contexts. The common essence of decentralization lies in strengthening local authorities through transfer of power and resources from the central government.

Decentralization has become attractive because of disillusionment with the perceived failings of large centralized, bureaucratic institutions. These include inefficiency, lack of responsiveness, and failure to innovate. Decentralized institutions are seen to have several advantages. Those working in them are better equipped to identify changing circumstances and needs, and thus can respond more flexibly. They can be more innovative than centralized institutions and they can generate higher morale, more commitment, and greater productivity. Decentralization can also facilitate enhanced partnerships with the local population, thus increasing the democratic input into policymaking.

The experience of many countries in recent years demonstrates that there are certain areas where decision-making power should not be decentralized. Four such areas include:

Basic framework for health policy, strategic decisions on the development of health resources such as capital, personnel, expensive equipment.
Research and development as they shape the future of the entire system.
Regulations concerning public safety.
Monitoring, assessment, and analysis of the health of the population and healthcare provision (as these are tools for influencing the behaviour of decentralized units).

Borgenhammer (1993) has also identified certain social and cultural conditions that are necessary for successful decentralization. These include adequate local administrative and managerial capacity, ideological certainty in the implementation of tasks, and readiness to accept several interpretations of a particular problem. Organizations undertaking decentralization must engage in a process of articulation of their mission, create internal cultures around core values, and establish mechanisms to monitor results (Osborne and Gaebler 1993).

With respect to health services, decentralization enables better access with people benefiting from the convenience of having core health services close to where they live. However, decentralization can have negative effects (Collins and Green 1994). These include fragmentation of services, loss of critical mass in services, and unacceptable variations in practice (Borgenhammer 1993). For health services there is substantial clinical evidence that centralizing certain complex conditions and procedures, specialization with co-location of specialist staff and services in facilities to generate a critical volume of cases has led to better clinical outcomes and higher productivity. The aim then is to ‘decentralize where possible, centralize where necessary’ (NHS 2007). This entails the creation of a primary and community care infrastructure that is able to deliver integrated services close to patients’ homes with consolidation of centres that perform only a small number of procedures (Dash et al. 2009).

Privatization requires separate consideration as it is fundamentally different, in several important aspects, from other types of decentralization. Its advocates argue that it brings benefits from the introduction of economic incentives for greater efficiency and higher quality in the management of healthcare (Cabinet Office 1999). It is also attractive to some governments as a means of attracting private capital into the health sector, thus reducing demands on scarce public funds.

These benefits, however, come with considerable risks. Private management and capital investment require financial returns that are consistent with those obtainable in other private markets. The pressures involved in achieving these returns can result in adverse selection (e.g. practices that intentionally discriminate against the poor and other vulnerable groups). Activities that do not generate immediate returns such as primary and secondary prevention activities are likely to be relegated to lower priority (Himmelstein et al. 1999). If privatization is not to undermine wider health policies, privatization must be accompanied by strengthened central regulatory controls. This increases administrative cost for both regulators and providers.

Two broad findings emerge from the debate on decentralization. The first is whether the advantages of decentralization outweigh the disadvantages, such as fragmented and duplicated services and high transaction costs, an issue that must be resolved on a case-by-case basis (Saltman and Figueras 1997). Secondly, a policy of decentralization requires a series of measures to create an appropriate framework, including development of a shared vision and a means of monitoring outcomes.

Ecosystem approach to healthcare

Health status is largely determined by the interaction of four linked factors: genetic susceptibility, behaviour and lifestyle, socioeconomic status, and environmental conditions (Lalonde 1974). Addressing these factors requires the concerted effort of partners outside of the traditional health sector such as in housing, agriculture, and education, as well as improved coordination and continuity of care between hospital and community-based services (including primary healthcare).

Healthcare systems are moving, albeit at different speeds, from an illness to a wellness/health model, shifting the allocation of funds from curative to preventive care. This is, however, a delicate balancing exercise due to the need to maintain current services while preparing for the future. The Institute for Healthcare Improvement in America has developed a framework that seeks to optimize health system performance by simultaneously pursuing three dimensions, the ‘Triple Aim’ of improving the patient experience of care (including quality and satisfaction), improving the health of

populations, and reducing the per capita cost of healthcare (Berwick et al. 2008).

The components of the Triple Aim are not independent of each other. The pursuit of any one goal can result in changes that affect the other two, sometimes negatively and sometimes positively. For example, improving care for individuals can raise costs if the improvements are associated with new, effective, but costly technologies or drugs. Conversely, eliminating overuse or misuse of therapies or diagnostic tests can lead to both reduced costs and improved outcomes.

The balanced pursuit of the Triple Aim is unfortunately not congruent with the current business models of any but a small number of healthcare organizations. Payment dynamics often lead hospitals to focus only on care within their walls, viewing readmissions for chronic diseases such as congestive heart failure as the result of defects outside the hospital and not as their responsibility to avert (Bisognano and Kenney 2012). For hospitals paid based on number of patients treated, averting readmission incurs costs from additional effort such as patient education and post-discharge follow-up (which may not be reimbursed as these occur outside the hospital) and reduces revenue by decreasing the number of patients being admitted. In such instances, rational common interests and rational individual interests are in conflict. Lack of system knowledge among clinicians and organizations leads them to optimize the components of the system with which they are most familiar, at the expense of the whole.

Movement between the various care levels (primary, secondary, tertiary, and community care) typically involves passage across an interface that is governed by rules of varying degrees of formality. Examples include referral to hospital by a primary care physician or discharge from an acute hospital to a long-stay facility. However, these movements are often not seamless, thus hampering efforts to enable patients to be treated in the most cost-effective settings.

The pursuit of the Triple Aim requires health services to move from the current silo-based approach to a more systematic and integrated model of care. Integrated care brings together inputs, delivery, management, and organization of services related to diagnosis, treatment, care, rehabilitation, and health promotion as a means to improve the services in relation to access, quality, user satisfaction, and efficiency (Gröne and Garcia-Barbero 2001).

Measurement drives behaviour. As such, the move towards better integration of care has been accompanied by efforts to measure health status rather than just healthcare. The proposed framework shown in Figure 11.8.1 (Arah et al. 2006) illustrates a measurement system that takes into account non-healthcare determinants of health, health system performance across the various care sectors, and embeds healthcare within the broader economic, social, and political context of a country. A framework that is unduly narrow and clinical in its focus will miss this big-picture perspective.

Patient engagement and empowerment

Very few healthcare delivery models currently view the patient as a resource who can help improve healthcare delivery for themselves and each other. Patients are either viewed as liabilities who consume scarce resources, or as passive vessels into which treatments are poured (Dzau et al. 2012). At times, healthcare services not only fail to take advantage of the patient's capabilities, but they also diminish them: studies have shown that during hospitalization, older people actually lose the ability to function independently (Creditor 1993; Sager et al. 1996).

Patients with chronic diseases can profoundly change the development and progression of their conditions through effective self-care, goal-setting, and adherence to prescribed medication, exercise, and nutrition regimes. A survey by the Commonwealth Fund (Schoen et al. 2011), however, suggests that this opportunity is being lost in many healthcare systems, owing to the professionals' failure to prepare patients for this role by discussing treatment goals/priorities, making treatment plans that patients can carry out in daily life, and giving clear instructions on symptoms and when to seek care.

On the other hand, we have the positive example in Jönköping, Sweden, where patients with kidney failure have been trained to use hospital dialysis machines themselves, thereby improving the efficiency, productivity, convenience, and safety of care delivery. These patients have also been empowered to provide advice to one another on ways of managing their illness (Dzau et al. 2012).

Several important issues need to be addressed in increasing patient participation in healthcare systems (Saltman and Figueras 1997). One is whether choice is equally important in all healthcare decisions. Another is, given the special characteristics of healthcare, do users have access to

enough information and are they able to understand it sufficiently to make an informed choice? Several countries have sought to inform the public by means of publication of rankings of outcomes by hospital or physician. However, these are subject to substantial methodological limitations and also provide scope for opportunistic behaviour by providers, either to exclude patients with higher risks or to manipulate the data that are presented. Finally, enhancing choice risks increasing health inequalities as those with most resources (time, money, and energy) are likely to have the greatest opportunity to make choices.

Cost sharing

Increasingly, the debate about healthcare costs is no longer about 'who pays?' but about the optimal formula for cost sharing, bearing in mind the need to balance efficiency goals against equity concerns (Lim 2004). Proponents of this approach argue that there is 'no free lunch'. Health insurance premiums have to be paid by the insured, employee medical benefits form part of wage costs, and public expenditures on healthcare are ultimately paid for by taxpayers. The key question is how best to structure the healthcare system, and the means of financing it, in order to keep it efficient, while making it accessible to all at rates that are affordable to them (Ministry of Health 1993).

People with the most control over what drugs get prescribed and what procedures get done have little incentive to lower these costs (indeed, to the extent that they get paid for the procedure, their incentives are often quite the opposite). Furthermore in a fee for service system, it is not in the economic interest of doctors and hospitals to put themselves out of business by promoting disease prevention. Likewise, patients often feel little need to control the costs of their own medical care if it is fully covered by insurance or the state. These approaches fuel overconsumption of healthcare services, hence contributing to rising healthcare costs. Some healthcare systems have thus tried to structure their financing system to give the individual maximum incentive to stay healthy, save for his or her medical expenses, and avoid using more medical services than is absolutely required.

Cost sharing for health services can help limit overconsumption of healthcare and could instil greater personal responsibility for health. On the other hand, cost sharing (or patient co-payment) can and has led to access and equity problems in some countries. Hence, cost sharing or co-payment should be one component of a multifaceted, multilayered healthcare financing system (Lim 2004). It is important to achieve an appropriate balance between personal responsibility with sufficient incentives for people to be prudent and to look after their own health, and risk pooling to provide a comprehensive safety net should they fall sick.

Cost sharing also allows governments to target their social spending more carefully. For example, greater subsidies could be directed at financially needier patients through financial means-testing. Social provision should be about protecting the poor more than subsidizing the rich. At the same time, in fast-ageing societies, especially, increased expenditures on the elderly must not squeeze out healthcare investments in the young (*The Economist* 2012).

These emerging themes bring new opportunities for public health practitioners to reorient health services towards the maximization of health gains. The next section will explore strategies for health services to translate these opportunities into reality.

Strategies for health services

In devising strategies for health services, we need to take into account the complex nature of healthcare where reductionist, mechanical, and linear methods of problem-solving tend to flounder against the laws of unforeseen consequences and incomplete information. It is also important to differentiate the means from the ends. For example, while healthcare systems aim for universal coverage to ensure that no one is denied healthcare that they need because of inability to pay, the means they have employed to achieve this can markedly differ.

Another consideration in developing strategies for health services is the mismatch between the lifecycles of different elements in the healthcare system such as major infrastructure (e.g. hospitals), technological advances (including information technology), service models, and government/regulatory policies. This can pose a major problem for planning and coordination, in particular to ensure alignment and timeliness in response to a constantly changing environment.

It is impossible in the space available to provide a comprehensive overview of every strategy that might be employed to enhance health services. Instead, this section focuses on key steps in the strategic planning process for health services where public health professionals have a potentially vital role to play. It starts by looking at the needs assessment and priority-setting process to ensure that the health services provided reflect the health needs of the population that they serve. Following that, it reviews the design and organization of health services to enhance the efficiency with

which services are delivered. It concludes by discussing the enablers that are necessary to implement, sustain, and enhance these services.

Needs assessment and priority setting

‘Need’ may best be defined as the ability to benefit from ‘healthcare’, which depends both on morbidity and on the effectiveness of care. Need should not be confused with supply or demand. The relationship between need and demand is mediated by differing illness behaviours. Demand is what people would be willing to pay for in a market or might wish to use in a system of free healthcare, and supply is what is actually provided. It is misleading to measure existing service provision as though it were an indicator for need. Similarly, the measurement of waiting lists, reflecting as they do demand mediated by doctor as agent, is also misleading (Stevens and Gabbay 1991).

Healthcare needs are those that can benefit from healthcare (health education, disease prevention, diagnosis, treatment, rehabilitation, terminal care). Health needs incorporate the wider social and environmental determinants of health, such as deprivation, housing, diet, education, and employment. This wider definition allows us to look beyond the confines of the medical model based on health services, to the wider influences on health. Health needs of a population will be constantly changing, and many will not be amenable to medical intervention (Wright et al. 1998). Figure 11.8.2 illustrates how need, demand, and supply might overlap or differ. It shows seven fields of services divided into (E) those for which there is a need but no demand and supply, (F) those for which there is a demand but no need or supply, (G) those for which there is a supply but no need or demand, and then (A–D) the various degrees of overlap (NHS Confederation 2008).

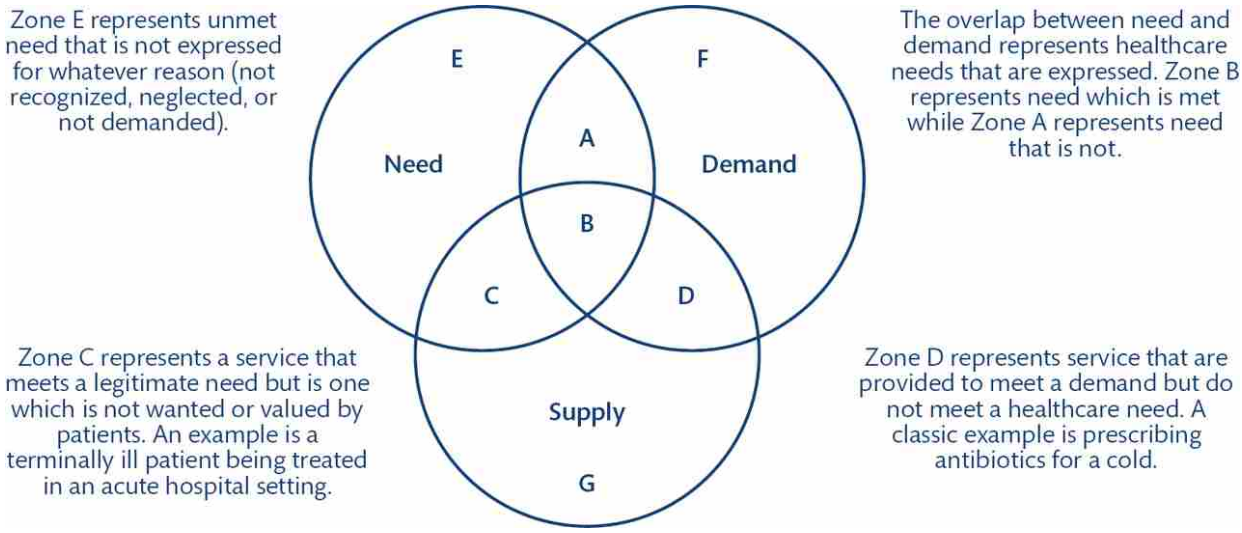

Fig. 11.8.2 Need, demand, and supply of healthcare.

The key challenge is to make the three circles of need, demand, and supply more congruent. This includes demand management and changing supply as well as better definition of need. Demand management may involve curtailing it where it is inappropriate (areas F and D in Fig. 11.8.2) or stimulating it (areas A and B). Varied mechanisms through which demand can be influenced include: the accessibility and organization of services, the provision of health information, education, and financial incentives. Demand can also be induced by supply: geographical variation in hospital admission rates is explained more by the supply of hospital beds than by indicators of mortality (Feldstein 1964); referral rates of general practitioners owe more to the characteristics of individual doctors than to the health of their populations (Wilkin 1992).

Strategies that act on supply of health services include reducing the number of healthcare professionals or facilities, setting global budgets for providers (Schwartz et al. 1996), giving professionals incentives to reduce the amount of care provided, and reducing access to care (Abel-Smith et al. 1995). Even need can be shifted somewhat, with new findings on disease pathology and new treatments that are effective.

Distinguishing between individual needs and the wider needs of the community is important in the planning and provision of local health services. Without a proper need assessment process, the pattern of health services will frequently reflect only what a few people perceive to be the

needs of the population rather than what they actually are and often those whose needs are greatest will receive the least (Hart 1971).

Assessment of health needs is a systematic method of identifying unmet health and healthcare needs of a population and making changes to meet these unmet needs (Wright et al. 1998). The principal activities involved in healthcare needs assessment are the assessment of incidence and prevalence (how many people need the service/intervention), the effectiveness and cost-effectiveness of services (do they confer any benefit, and if so at what cost, i.e. what is the relative benefit?) and baseline services. Changing the provision of healthcare services for the better necessitates knowledge of existing services, both to know which services ought to change and to identify opportunities for the release of resources to enable the change to happen.

Health needs assessment should not just measure ill health, as this assumes that something can be done to tackle it. It should incorporate the concept of a capacity to benefit which requires an assessment of the effectiveness of health interventions and attempts to make explicit what benefits are being pursued, at the level of individuals and the population.

Health needs assessment should include two other objectives. Firstly to improve the spatial allocation of resources so that broadly equal populations receive broadly equal resources. Secondly the accurate targeting of resources so that those who get a service need it, and those who need a service get it.

As the capacity to benefit is always going to be greater than available resources, health needs assessment should also incorporate questions of priority setting (Donaldson and Mooney 1991). Some commentators have argued that rationing should not be necessary if either sufficient funding was made available, typically by redirecting it from other areas of public expenditure or raising taxes, or by ensuring that available resources are used more efficiently.

In reality, some form of rationing has always taken place in all healthcare systems although, in most cases, this was implicit, inextricably linked to clinical judgement. Priority setting or rationing in healthcare continues to be a politically charged topic, but recently its necessity has gained wider recognition as it is impossible to provide everyone with every effective intervention they might need or want (Sabik and Lie 2008). Explicitly addressing priority setting is necessary to develop fairer methods to allocate

scarce healthcare resources (Fleck 1994) through a transparent process that balances clinical, ethical, and economic considerations (Black 1994).

Priority-setting approaches can be broadly grouped into two categories: outlining principles and defining practices. Countries such as Norway, the Netherlands, Sweden, and Denmark decided to develop principles that would guide prioritization efforts. In the Netherlands, the Dunning Committee (Committee on Choices in Health Care 1992) proposed four criteria that any intervention to be funded from social insurance should meet: necessity, effectiveness, efficiency, and individual responsibility. They described these principles as forming a sieve for sifting out services that should not be publicly funded ('Dunning's funnel'). The idea was that one should apply these successively beginning with the principle of necessity, and then limiting the number of services provided. The Committee excluded services that could easily be paid for by the individuals themselves. One example the Committee gave was routine adult dental care. Although such dental care is necessary, effective, and efficient, adults can easily pay for such services out of pocket, and it is therefore best left to an individual's responsibility. The drawback of this approach is that because of their abstractness, government commissions that outlined principles have had little direct impact on their countries' policies.

Other countries, such as the United Kingdom, Israel, New Zealand, and the state of Oregon in the United States established bodies that would actually recommend what services should be provided within the system. Decisions may lead to blanket exclusions of interventions or of condition–intervention combinations, as in the approach taken in Oregon, or production of guidelines, as has been done in New Zealand (The National Advisory Committee on Health and Disability) and by the National Institute of Health and Care Excellence in the United Kingdom. The experience of Oregon has been especially interesting because of the technical and ethical issues it has raised. It was designed to create a list of condition–intervention pairs, ranked on the basis of cost–benefit, with a cut-off point based on available resources below which combinations would not be funded. This initial method was, however, abandoned because of a public outcry over the resulting ranking of services, for example: appendectomy was rated lower than cosmetic dentistry. In response to this public reaction as well as criticism of the methodology, the Commission set out to rank healthcare services based on more broadly defined criteria, where expert knowledge and intuitive

judgements by the Commissioners about appropriateness played a much larger role. The process also raised important ethical questions as the exercise was confined to poor women and children in the Medicaid programme and services denied to them would remain available to others (Rosenbaum 1992).

In the United Kingdom, the National Institute for Clinical Excellence (now the National Institute for Health and Care Excellence (NICE)) was established in 1999 to: appraise new health technologies, develop clinical guidelines, and assess interventional procedures (Rawlins 1999). In conducting these activities, NICE addresses questions including what constitutes necessary and appropriate care, how to incorporate cost-effectiveness considerations, and what interventions should be publicly funded.

The challenge of healthcare prioritization is to identify an appropriate balance between an expert-led process and a process that emphasizes public involvement in decision-making to ensure that decisions reached are legitimate. Ultimately, while public health professionals have an important role in providing the evidence on which any debate on priority setting must be based, priority setting in a publicly funded system is the responsibility of politicians. Decision-making inevitably involves trade-offs between objectives as a balance is sought among universal coverage, comprehensiveness of services, equity, efficiency, cost containment, and broader social values (Sabik and Lie 2008).

Design and organization of health services to ensure efficient service delivery

Conventional service delivery is often based on institutional hospital care and a supply of trained health professionals—all relatively expensive with inpatient care typically consuming 45–75% of resources dedicated to healthcare (Saltman and Figueras 1997). Moreover, different professionals often work in organizational silos, and fail to integrate services to achieve best value and best care. New technologies in fields such as genetics, imaging, miniaturization, pharmaceuticals, and information are changing the mix of preventive, diagnostic, and treatment practices, enabling services to be delivered less expensively to wider populations in their own homes or communities instead of hospitals.

Health systems have adopted several strategies to meet these challenges. They include organizing the network of hospital services to achieve a more efficient and effective configuration through decentralization and centralization initiatives (see 'Reorganizing the system: decentralization, recentralization, and privatization'). Three other strategies are described in the following subsections: improved targeting of interventions, substitution, and integration of services in the hospital and community.

Improved targeting of interventions

Bohmer (2011) identified specification and planning as a common habit of high-value healthcare organization. These organizations specify decisions and activities in advance. Whenever possible, both operational decisions, such as those related to patient flow (admission, discharge, and transfer criteria), and core clinical decisions, such as diagnosis, tests, or treatment selection, are based on explicit criteria. Criteria-based decision-making is manifested in the use of clinical decision support systems and treatment algorithms, severity and risk scores, criteria for initiating a call to a rapid-response team, or triggering the commitment of a future resource (e.g. a discharge planner, pre-procedure checklists, and standardized patient assessments). Specification also applies to separating heterogeneous patient populations into clinically meaningful subgroups—by disease subtype, severity, or risk of complications—each with its own distinct pathway. For example, genomic testing has allowed oncology units to divide patients into separate groups according to their probable response to specific therapies (for instance, Kirsten RNA-associated rat sarcoma 2 virus (*KRAS*) gene testing for cetuximab therapy). And at Intermountain Healthcare in Utah and Idaho, the needs of psychiatric patients are divided into mild (routine care by a primary care physician), moderate (team care), and severe (specialist referral), using a scoring system based on published guidelines (Rathod et al. 2010).

To promote such standardization, we need to accelerate the healthcare evidence base and support the rapid sharing of clinical protocols, best practices, and outcomes data. There is concurrently a need to make effective use of information technologies to automate clinical information and make it readily accessible to patients and all members of the care team (IOM 2001). Excellent information infrastructure and well-thought out and implemented

modes of ongoing communication can reduce the need to craft laborious, case-by-case strategies for coordinating patient care.

A second common characteristic of high-value organizations is infrastructure design. They deliberately design microsystems (Nelson et al. 2011)—including staff, information, and clinical technology, physical space, business processes, and policies and procedures that support patient care—to match their defined subpopulations and pathways. Thus, different conditions or patient groups have different microsystem designs. The various tasks of care are allocated to different members of a clinical team (including the patient), with the skills and training of each staff member matched to the work.

Substitution

Substitution refers to the process of regrouping resources (staff, equipment, information, facilities, etc.) across and within care settings to exploit the best and least costly solutions to achieve better clinical, financial, and patient-related outcomes. A useful typology differentiates substitution into three categories: moving the location at which care is delivered, introducing new technologies, and changing the mix of staff and skills. There may be other substitution types according to different combinations of these three (Warner 1996). For example, moving care from the hospital to community-based care may involve:

Location only such as for physiotherapy.
Location and technology such as for point-of-care laboratory testing and telemedicine that allows remote consultations.
Location and staff and/or skills such as nurse-led home care.
All substitution types such as home dialysis services.

In addition to substitution, the weightage of services across the spectrum of care is also changing with greater emphasis being placed on prevention and self-management to reduce the demand for care. Prevention programmes have historically focused on younger or working-age adults, but there is increasing recognition of the value of prevention programmes aimed at older people with services focused on increasing functionality. These health promotion and primary prevention strategies should ultimately reduce the total demand for healthcare services and healthcare costs. However, the

difficulties in measuring health promotion in terms of cost-effectiveness so that it can be compared with other health services interventions, has meant that health promotion's role has tended to be undervalued. Public health professionals have to develop more and better ways to evaluate health promotion that satisfy the needs of policymakers, managers, and clinicians so the full potential of health promotion can be realized (McKee and Bojan 1998).

Health services should be reoriented from a hospital-centric model to a model with primary healthcare at the core of the healthcare system, and secondary and tertiary care serving as supporting, referral levels. Healthcare systems configured around primary care produce healthier populations at lower cost. In the United States, for example, overall health is better in regions with more primary care physicians and where primary care functions well. By contrast, overall health is worse where specialists predominate (Starfield et al. 2005a, 2005b). An effective primary care system has the following virtues (Oldham et al. 2012):

It can coordinate the care of the many people with multiple, complex health needs, in a way that individual specialists cannot.
It can deliver care closer to people, increasing convenience, especially in areas remote from hospitals.
As a first point of contact for patients it facilitates the early detection of illness, and thereby improves outcomes.

In addition to substitution within healthcare, substitution should also occur between healthcare and other sectors, recognizing the importance of lifestyle and social determinants in improving health outcomes. The importance of broader comprehensive primary healthcare approach has recently been argued as being vital to achieving UHC (Sanders et al. 2019). The upstream cause of ill health has been shown to be social and economic determinants and that these factors also shape the health behaviours people adopt (Baum 2019). The health and social sectors in some countries are thus pooling resources particularly in the provision of services to the elderly to tackle social isolation, engage communities more widely, adapt or develop homes, and make cities more age-friendly places.

Integration of care

The involvement of increasingly more parties in the delivery of healthcare accentuates the need to adopt a systems perspective to foster evolution of care delivery as a whole rather than focusing on single elements. Care processes need to be redesigned to enable coordinated, seamless care across patient conditions, disciplines/specialties, settings, and clinicians, and over time. The key challenge is to match evidence-based, appropriate, and responsive care to patients according to their needs (such as various chronic diseases) across the various stages of their life. Capital investments and operating expenses should encourage thinking across boundaries. As an illustration, questions to be asked might include, 'Might two additional home outreach nurses be better for heart failure patients than another cardiologist?' (Berwick et al. 2008).

One way of achieving this is by designing distinct integrated care platforms (Leape et al. 2009) for conditions that share common work and support requirements, such as chronic disease care, complex acute care, palliative, and end-of-life care. Every care platform must have the following characteristics:

Patient centredness: personnel, facilities, and services are organized to meet all patients' needs efficiently and responsively; to be available when and where needed, and to include the patient and family as partners in care.
Work assignment: work is assigned to the individuals who are responsible for its completion. Assignments strive to maximize the performance capability of each individual while ensuring that work is done by the least expensive qualified caregiver or multidisciplinary team at the location most accessible to the patient. The physician participates when his/her special expertise is required and when patient expectations permit no alternative.
Support: the support framework—people, systems, and tools (e.g. technologies, IT, telecommunications)—is defined by the work and patient participation.
Community linkage: linkages to community advocacy, support, and education groups (especially health literacy) are incorporated into the design as appropriate (e.g. for patients with chronic conditions).
Variation management: ensuring quality and efficiency requires determining whether variations in process are appropriate. Process and outcome measures should thus be incorporated into daily work. Use of such measures makes it possible to understand the degree to which performance is consistent with best practices, and the extent to which patients are being helped. Exception analysis assesses whether variations result from: (1) adaptations to a specific patient requirement, (2) evolution of new evidence (good), (3) lack of training in appropriate care, or (4) poorly defined care pathways (bad).
Transparency: the results of the delivery process and outcomes of care should be shared with all concerned, including patients. This would enable patients, caregivers, organizations, and managers to know the 'state of the system' with respect to its reliability, adherence to evidence, cost, and progress in improvement.

For the integrated platform to work we need an 'integrator' which accepts responsibility for the Triple Aim of improving the patient experience of care, improving the health of populations, and reducing the per capita cost of healthcare for a specified population. The simplest such form, such as Kaiser Permanente, has fully integrated financing and either full ownership of or exclusive relationships with delivery structures which enables it to use those structures to good advantage. A unified financing or a single delivery system is not, however, necessarily a prerequisite for an integrator. That role might be within the reach of a powerful, visionary insurer; a large primary care

group in partnership with payers; or a regional health system that will link healthcare organizations (as well as public health and social service organizations) whose missions overlap across the spectrum of delivery (Berwick et al. 2008). At the patient level, the integrator ensures that members of the population, especially those with chronic illnesses, have someone who can work with them to establish a plan for their ongoing care, guide them through the jungle of health services, and be their advocate.

The integrator has to segment the population according to need such as health status, level of support from family or others, and socioeconomic status, to facilitate efficient and equitable resource allocation (Lynn et al. 2007). In most cases, the integrator would not be a direct provider of all necessary services. Instead, it would need to commission some services from suppliers through business relationships consciously designed to facilitate pursuit of the desired outcomes.

Enablers

Three key enablers are needed to translate strategies into reality: intelligent purchasing, a workforce with the appropriate capacity and capability, and a robust information and knowledge management system.

Intelligent purchasing

All health systems exercise some form of purchasing but the prevailing approach to paying for healthcare, based predominantly on individual services and products, encourages wasteful and ineffective care (IOM 2012). Payment systems that are based on workload tend to disincentivize providers from coordinating care for patients across settings and over time as the benefits of investments (and cost) made by one group of providers are realized by a different group of providers. For example, investments in primary care preventive efforts tend to reduce demand for hospital services rather than primary care services. Hospitals may not be keen on these systems-level savings since their own reimbursement may decline with the decreased workload.

Health systems need to move from passive forms of purchasing—the mere reimbursement of providers—to more proactive and strategic forms of purchasing that consider which interventions should be purchased, how they should be purchased and from whom (Figueras et al. 2005). In an increasing

number of countries intelligent purchasing is seen as an alternative to a traditional command and control approach to implement health policy objectives, including as a means of reorienting the focus of health services, to ensure that they reflect health needs and provide cost-effective care. Its essential characteristic is that it separates purchasers from providers but binds each party by means of contracts to explicit commitments, with creation of the economic motivation to fulfil these commitments (McKee and Figueras 2009).

Payers/purchasers should adopt outcome- and value-oriented payment models where payment systems align financial incentives with the implementation of care processes based on best practices and the achievement of better patient outcomes. Payment systems should also reduce fragmentation of care by supporting high-quality, team-based care focused on patients' needs. Contracts can be used to develop intersectoral responses to health problems and to reorient healthcare providers so that they integrate prevention with curative care.

Contracts should also provide an opportunity for providers to share in the benefits of quality improvement. Substantial improvements in quality are most likely to be obtained when providers are highly motivated and rewarded for carefully designing and fine-tuning care processes to achieve increasingly higher levels of quality and safety. Rewards should thus be located close to the level at which the reengineering and process redesign needed to improve quality are likely to take place (IOM 2001).

Purchasers represent the interests of their populations, in particular the vulnerable and disadvantaged groups as well as underserved communities, by allocating resources and purchasing services in accordance with their needs. There is, however, a need to guard against the risk of providers underemphasizing or phasing out services that are less profitable. Contracts should thus provide fair payment for good clinical management of the types of patients seen. Clinicians should be adequately compensated for taking good care of all types of patients, neither gaining nor losing financially for caring for sicker patients or those with more complicated conditions. The risk of random incidence of disease in the population should reside with a larger risk pool, whether that is large groups of providers, health plans, or insurance companies (IOM 2001).

Purchasing also offers a means for enhancing participation by the population in the organization of healthcare by providing the opportunity for

consumers and purchasers to recognize quality differences in healthcare and direct their decisions accordingly. To do this, consumers need to have good information on quality and the ability to use that information as they see fit to meet their needs.

Implementation of an intelligent purchasing system is a complex process requiring a high level of skills and well-developed information systems. At a minimum, information is required on patient flow, cost, and utilization across specialties or diagnostic groups and demographic and risk groups. Purchasing decisions also need to take into account the reality that medical care is extremely complex. Diagnostic labels are often imprecise and clouded by a degree of legitimate uncertainty. Decisions on clinical management also incorporate values and beliefs relating to factors such as attitude to risk and the utility placed on different health states. It is thus important that expectations of what can be achieved are realistic (McKee and Clarke 1995). Contracts must incorporate sufficient flexibility and reflect the views of all those concerned if they are to retain any credibility. It should also be recognized that purchasing may not be the best option for some services especially where clear specifications in terms of the desired product/service cannot be defined clearly.

While the focus of purchasing should ideally be on outcomes, outcomes are typically more difficult to measure and may only become apparent long after the intervention took place. Some outcomes may also be rare and the sample size required to detect a deviation from what is expected may be very large. For example, Mant and Hicks (1995) have shown, on the basis of knowledge of effective treatment for myocardial infarction, that, in a comparison of two typical hospitals, it would take 73 years of data to detect a significant 3% reduction in mortality whereas the corresponding difference in process measures, relating to uptake of treatments, would emerge after only 4 months. Where process or structure measures are used there should be evidence that they correlate with a good outcome. Measures based on structure can be of some value, based on the assumption that high-quality care cannot be provided in the absence of basic prerequisites, such as adequately trained staff, but this is a necessary rather than a sufficient measure and should normally be supplemented by measures of either process or outcome.

All these activities (e.g. needs assessment, performance analysis, negotiating, and monitoring) incur transaction costs. A substantial increase

in quality and efficiency is required to justify these additional costs. Increasingly, purchasers and providers are entering into long-term contractual relationships that reduce transaction costs (Rosen and McKee 1995). If transaction costs can be minimized without compromising the pursuit of the objectives of equity and health gain, intelligent purchasing can provide a formidable instrument to promote population health.

Workforce

A major challenge in transitioning to the desired models of care described previously is preparing the workforce to acquire new skills and adopt new ways of relating to patients and each other. At least three approaches can be taken to support the workforce in this transition:

Redesign the way health professionals are trained. Healthcare professionals should be taught evidence-based practice and equipped with the skills and tools to access and apply the expanding knowledge base. They should also have sufficient communication and behavioural skills to work effectively with patients, not least in helping to promote treatment adherence and health-enhancing lifestyle changes. In addition they need to acquire the skills to improve the processes and systems of care through proven methods and actions. Furthermore as effective health services will increasingly be delivered by collaborative teams of clinicians, with each member playing a vital role, the training should adopt a multidisciplinary approach and continually advance the effectiveness of teams instead of training health professionals purely by discipline. As almost every country wants more patients to be treated in the community rather than in hospitals, we need to ensure that healthcare professionals spend considerable time during training in the community, not just in hospitals. We also need to review the necessity for the expensive additional years of education for an increasing number of doctors and nurses to be trained in very narrow subspecialties (Emanuel and Fuchs 2012) and its alignment with the wider interests and needs of the population.

Modify the ways in which health professionals are regulated. Regulation of healthcare professionals is designed to protect the public and ensure that patients are kept safe, but providing such protection needs to be balanced against the regulatory burden and the need to retain sufficient freedom for innovators to succeed. Regulation should be focused on the patient and should be independent of professional interests. Scope-of-practice laws and other workforce regulations need to allow for innovation in the use of all types of clinicians to meet patient needs in the most effective and efficient way possible. Statutory regulation should be used to protect the public in areas of high risk, but other processes should be used when the risk is low. Ongoing licensure and certification requirements should also reflect the need for lifelong learning and evaluation of competencies to ensure that healthcare professionals have the specific skills for the time and contexts in which they work (Dzau et al. 2012).

Examine how the *liability system* can constructively support changes in care delivery while remaining part of an overall approach to accountability for healthcare professionals and organizations.

In addition to the professional workforce, it is also important to work on securing the supply of informal care. Care provided by families is the backbone of long-term care. But it is difficult to maintain or increase it in the face of falling support ratios, urbanization, and migration, and changing work patterns. One option is to direct cash and services to support carers. Another is to use technological innovations to provide information and support. Governments can also innovatively incentivize or reinforce traditional family caring responsibilities through the tax system and other regulatory measures (Hope et al. 2012).

Information and knowledge management

The knowledge of how to configure structures and processes to attain the best possible clinical outcomes will become one of the health service's most important assets. Healthcare organizations must thus create, maintain, and disseminate the institutional knowledge required to realize good outcomes.

As healthcare is complex and constantly changing, we need to build healthcare systems that continually learn, in real-time and with new tools, how to better manage problems. Data generated in healthcare delivery—whether clinical, delivery process, or financial—should be collected in digital formats, compiled, and protected as resources for managing care, capturing results, improving processes, strengthening public health, and generating new insights. Decision support tools and knowledge management systems can be included routinely in healthcare delivery to ensure that decisions are informed by the best evidence. The characteristics of a continuous learning healthcare system are summarized in Box 11.8.1 (IOM 2012).

Box 11.8.1 Characteristics of a continuously learning healthcare system

Science and informatics *Real-time access to knowledge*—a learning healthcare system continuously and reliably captures, curates, and delivers the best available evidence to guide, support, tailor, and improve clinical decision-making and care safety and quality. *Digital capture of the care experience*—a learning healthcare system captures the care experience on digital platforms for real-time generation and application of knowledge for care improvement.

Patient–clinician partnerships *Engaged, empowered patients*—a learning healthcare system is anchored on patient needs and perspectives and promotes the inclusion of patients, families, and other caregivers as vital members of the continuously learning care team.

Incentives *Incentives aligned for value*—in a learning healthcare system, incentives are actively aligned to encourage continuous improvement, identify, and reduce waste, and reward high-value care. *Full transparency*—a learning healthcare system systematically monitors the safety, quality, processes, prices, costs, and outcomes of care, and makes information available for care improvement and informed choices and decision-making by clinicians, patients, and their families.

Culture *Leadership-instilled culture of learning*—a learning healthcare system is stewarded by leadership committed to a culture of teamwork, collaboration, and adaptability in support of continuous learning as a core aim. *Supportive system competencies*—in a learning healthcare system, complex care operations and processes are constantly refined through ongoing team training and skill building, systems analysis and information development, and creation of the feedback loops for continuous learning and system improvement.

Regulators have a key role in facilitating this learning process by clarifying and improving rules governing the collection and use of clinical data to safeguard patient privacy while promoting the seamless use of such data for better care coordination and management, improved care, and enhanced knowledge. Legal protections should be put in place to shield individuals from improper use of de-anonymized health data and educational campaigns should be conducted, aimed at providers and public alike, to raise awareness of the rights, responsibilities, risks, and benefits related to health data.

Conclusion

Health services have an important role to play in improving the health status of populations. This chapter has identified mechanisms through which public health can play a major role in maximizing the health gain obtained from health services, in particular in the design of systems that ensure that patients are managed at the level of the healthcare system that is most appropriate, the creation of mechanisms that identify and promote high-quality clinical care, and the reorientation of curative services towards prevention.

Public health professionals, with their emphasis on improving population health, have a key role in ensuring that the pursuit of health gain becomes a central objective of healthcare services, whatever other objectives are being pursued by others (McKee and Figueras 2009). To do so, they must promote the equitable use of interventions that are effective and appropriate for the population in question, reduce interventions that are ineffective or harmful,

and maximize the health gains obtained with the available funding. Much will depend on the ability of the public health profession to adapt and bring its portfolio of tools and skills to bear on rapidly changing health services.

Training of public health professionals in developing countries

San Hone and Roger Detels

Introduction to training of public health professionals in developing countries

Public health and medical systems and training are essential for the health of a country (Heller et al. 2007; Bangdiwala et al. 2010). This is particularly true for developing countries, in which great disparities in wealth exist and there are limited funds to invest in the health of their citizens. Developing countries have being exerting tremendous efforts towards achieving universal health coverage (UHC) through primary health-led approaches for which public health services and medical resources must be made available at national, provincial, subprovincial, and local district levels. The skills and requirements of public health and medical professionals at each of these levels differ and are unique within each level. The mandate of public health is broad, and therefore requires some level of specialization within the profession. Thus, various public health professionals are responsible for assuring access to primary healthcare, as well as maternal and child health services, protection of the environment, including provision of adequate and safe levels of water and safe disposal of human and other waste, implementation of community health programmes such as immunization coverage, prevention, and control of endemic and epidemic health threats from microbial agents, addressing increases in chronic illnesses, and administration/management of the broad and diverse public health workforce at each level. Thus, public health training requires providing training not only in medical sciences, but also in technical fields such as microbiology, chemistry, the physical sciences, management sciences, and behavioural, social, and political sciences, statistics, epidemiology, and research methodologies.

The World Economic Forum launched a 4-year US$100 million fund to support two non-governmental organizations, Last Mile Health and Living Goods, to train 50,000 health workers in six countries, bringing global attention to the need to improve healthcare at the lowest levels (Winters et al. 2018). The focus is to demonstrate how technology can reinvent community healthcare at scale to ensure quality healthcare to marginalized populations in lower-/middle-income countries, using utilitarian but cutting edge strategies to train health workers; e.g. digital education in the implementation of 'M Health' discussed next.

The public health workforce draws individuals from a variety of backgrounds relevant to their intended public health roles, including medicine, nursing, and the behavioural, management, and biological/physical sciences (Beaglehole and Dal Poz 2003). Generally, health training programmes provide training at the certificate level mainly for health professionals and others serving at the local level, which may include health volunteers (who are the core of many health systems and provide service at the village level), specialized training (e.g. midwife), as well as training at the master's level (usually requiring 1–3 years of graduate study) and the doctoral level (requiring 4–6 years of graduate study) for those who become leaders of public health programmes and research. Training at the graduate level also includes specialized training in specific fields for those who focus on environmental, social, behavioural, and healthcare issues of public health essential for a broad mandate of public health. Although most public health training programmes provide basic initial training in public health, there is also an important need to provide postgraduate and refresher training to ensure that the public health workforce continues to utilize the most modern strategies and resources.

In the opinion of some public health professionals, including the authors, there is too often a mismatch between the roles and responsibilities of public health professionals at each level and the training that they receive. Too often, public health curricula in developing countries were developed by the European colonialists based on the European system, and do not adequately address current health problems of the country. This mismatch reflects both the content of the training programmes and the strategies/content of the country's public health system itself. Public health planners, managers, and administrators are confronted by a range of barriers to achieving optimal public health, including funding constraints, politics, and the scarcity of

qualified personnel and public health leaders. It is the responsibility of public health trainers to develop strategies and curricula to overcome these barriers and to ensure that the training of public health professionals is appropriate and has the flexibility to provide trainees with the ability to devise new strategies to address constantly changing public health issues and problems. In some instances, this requires reconsideration of the current public health structure to ensure maximum effectiveness. Public health programmes need to ensure that health professionals in training see a clear career path for themselves, that there is an optimal distribution of health professionals, particularly to rural and remote areas, and that the system provides both monetary and non-monetary incentives to motivate them. In this chapter, we address each of these issues in greater depth and make suggestions for improvement and enhancement of health training in developing countries.

Typical public health structures in developing countries—health system structure in developing countries

Typically, government health systems in developing countries have a tiered system for providing health, comprising the national, provincial, subprovincial, and local levels. In addition, in most developing countries there are private healthcare sectors that provide services primarily to the wealthy, and national and international non-governmental organizations that also provide public health services through community volunteers and clinical services. Sometimes these operate outside the purview of the government public health system which can create problems (see chapter 11.12). In this chapter we will focus on training relevant for the government-sponsored public health system.

The greatest number of health personnel work at the lowest level, with decreasing numbers at the subprovincial, provincial, and national levels. The highest levels of training and responsibility focus on the national level. The duration and intensity of training for health workers increase with greater levels of responsibility for programme leadership.

The public health systems in developing countries are usually divided into three levels: (1) the central administrative level that develops health policies, recommends strategies for the entire country and administers national

programmes, national training institutions, and national hospitals that provide complicated tertiary care; (2) the middle level comprised of provincial and subprovincial health departments that are responsible for implementing national policies and programmes, and provincial hospitals that often see referrals from the local healthcare facilities and conduct regional training programmes for local health professionals and volunteer health workers; and (3) the local or district level that implements national and provincial programmes such as primary healthcare, maternal and child health programmes, and immunization campaigns (Fig. 11.9.1).

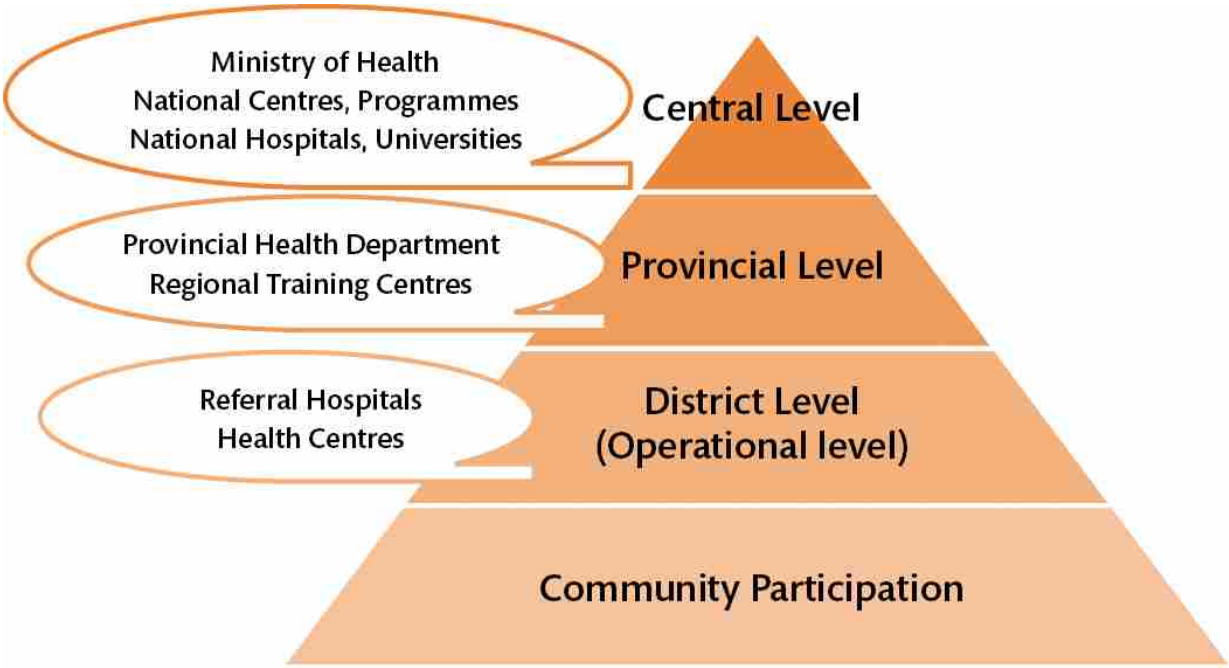

Fig. 11.9.1 The health system.
Reproduced by kind permission of Dr Lo Veasnakiry.

The district level (health centres or health posts) usually provides a minimum package of primary healthcare and public health activities to a population of approximately 5,000–30,000 each and a referral hospital for low-level uncomplicated health problems. The health force at the village health centre includes primary/community healthcare workers, nurses and/or nurse midwives who receive training for one or more years and are responsible for primary healthcare services, including maternal and child, family planning, childhood immunizations, and delivery of treatment for

non-communicable diseases, HIV and tuberculosis which required daily observed treatment. With the recent trend of moving towards the global elimination of certain communicable diseases such as malaria, vaccine-preventable childhood diseases (polio, measles), and elimination of mother to child transmission of HIV and syphilis, etc., the role of the primary health care providers has expanded.

In some countries, these primary care providers are assisted by public health staff who receive about six or more months of training focusing on health education for the endemic and epidemic diseases and environmental sanitation activities. At the village or commune level, there are often volunteer health workers who are selected by the local population and provide minimal first aid and referral to the district health centre or hospital, and who assure directly observed therapy for tuberculosis and other diseases. They also help organize immunization sessions, give oral vaccinations (e.g. polio) and high-dose vitamin A to children, but are not allowed to give injections. In addition, they promote health education activities, including promoting environmental sanitation. The position carries with it a level of prestige that is its main reward, although some level of remuneration is usually advisable. Volunteer health workers usually receive training for several weeks. The characteristics of an ideal volunteer health worker have been outlined by Taylor et al. (2018), and include knowledge of the local population and culture, good interpersonal and communication skills, the ability to see the world from others' perspectives, a non-judgemental attitude, 'imbeddedness' within the community, shared demographic characteristics, and a desire to assist people.

Responsibilities/roles of public health professionals at each level in developing countries

Levels of training and duration vary, depending on the role that the graduate is expected to play in the health system. At the highest level, usually for bachelor's or master's programmes, the trainees receive instruction in administration of health programmes (although care is usually taught through the medical education system), content and strategies for health education, and behavioural modification to achieve a healthy lifestyle, strategies for assuring a safe water supply, appropriate disposal of human

and other waste products, oral health, systems of health financing, control strategies for the major infectious diseases affecting the country (which usually include tuberculosis, malaria, parasite infections, and HIV, as well as any locally endemic diseases), and administration and strategies for immunization programmes. Some developing countries require a medical degree or other health science or technical degree as a prerequisite for entering into a master of public health (MPH) programme. Graduates of these programmes are expected to lead public health programmes. Programmes at this level usually require the trainee to complete an internship in the field at the local or rural level to ensure their understanding of the system and the culture of the populace at the point of delivery. Research methodologies, if available, are usually taught in the relatively few PhD/doctoral programmes in medical and public health institutions. However, many developing countries are only recently investing in schools of public health, and in most, research is not conducted. Recently there has been a movement to use the internet to provide distance learning for public health workers at the MPH level and for postgraduate/refresher courses that target developing countries, which are offered through various universities and government agencies (Mokwena et al. 2007). Although these programmes are probably quite useful for teaching methodology and public health strategies, they may have difficulties in training relevant to practising at the local level in different countries, as they cannot offer hands-on field experience. One strategy to overcome this difficulty is to have discussion sessions on specific topics through the web, which include practitioners from the local level. Because most developing countries do not have the resources to invest in research programmes, most public health programmes are not evidence-based.

At the village level, many countries employ volunteer health workers who have had only a few weeks of training and perform very routine functions, such as tending to minor wounds, routine first aid, and encouraging villagers to take their medications as recommended by physicians and allied health workers at the district or higher levels. The role of the volunteer health worker may include home visits, first aid, treatment of simple and common ailments, health education, nutrition and surveillance, family planning, referrals, collection of data on vital events (births, deaths), and assisting more highly trained health professionals such as the nurse midwives. They usually have the best knowledge of the village and the villagers in terms of

health status and needs, and are often selected by the communities themselves. To be successful they need to be an integral part of their community and have the support of that community. It is important that they receive some reward from the villages, as they are not usually paid by the government.

A typical health structure at the district/township level is presented in Figure 11.9.2.

Health professionals at the village health post include nurse midwives and allied health personnel and health workers who usually have one to three years of training. Nurse midwives are responsible for encouraging and implementing enrolment in prenatal programmes, staffing antenatal clinics, delivering babies, and providing postnatal guidance. They need to be able to recognize difficult pregnancies that will require more highly trained medical personnel to ensure safe delivery. These problem pregnancies are usually referred to a higher-level facility. Transportation to the hospital, particularly for emergency and complicated deliveries, can be a serious problem. Allied health personnel with nurse midwives usually perform the other medical, sanitation, and health education roles, and direct and facilitate health campaigns such as polio immunizations days. In some countries, nurse midwives perform both roles, although they may be assisted by assistant nurse midwives and/or public health staff who have had less but some training. Nurse midwives may be responsible for as many as 10–15 villages. The rural and urban health centres may have facilities for care of patients, including injuries requiring more than simple first aid. Patients with complicated illnesses, however, are referred to higher-level health facilities, and are diagnosed and treated by physicians.

With the trend towards UHC, many countries are striving to identify feasible and cost-effective strategies for providing health services. Major strategies include decentralization of some services that were previously not available at the village health level; for example, performing HIV screening tests and introducing a package of disease reduction services for primary healthcare workers. Under these schemes, primary healthcare providers, nurse midwives, and lower-level health workers are also responsible for conducting packages of activities to target communicable diseases for which the government has pledged to achieve elimination by a specific time. These usually include active case surveillance, implementing appropriate screening

tests, implementing immunization campaigns, introducing standardized treatment, and implementing timely reporting.

The district hospitals may have a laboratory to perform routine procedures, but are usually not able to do more sophisticated biochemical and microbiological assays, which are usually done at the provincial level. One problem with the laboratories at each of the different levels is that quality control procedures are often not implemented and standardized. Few of these laboratories participate in quality control programmes, although some wealthier developing countries (e.g. China) have implemented quality control programmes at the county and provincial levels. Thus, there is a problem with achieving valid test results and safety in many of these laboratories (Callaway 2012). A second problem is staffing these laboratories with well-trained, competent technicians who need to periodically update their laboratory skills to ensure valid results and safe procedures.

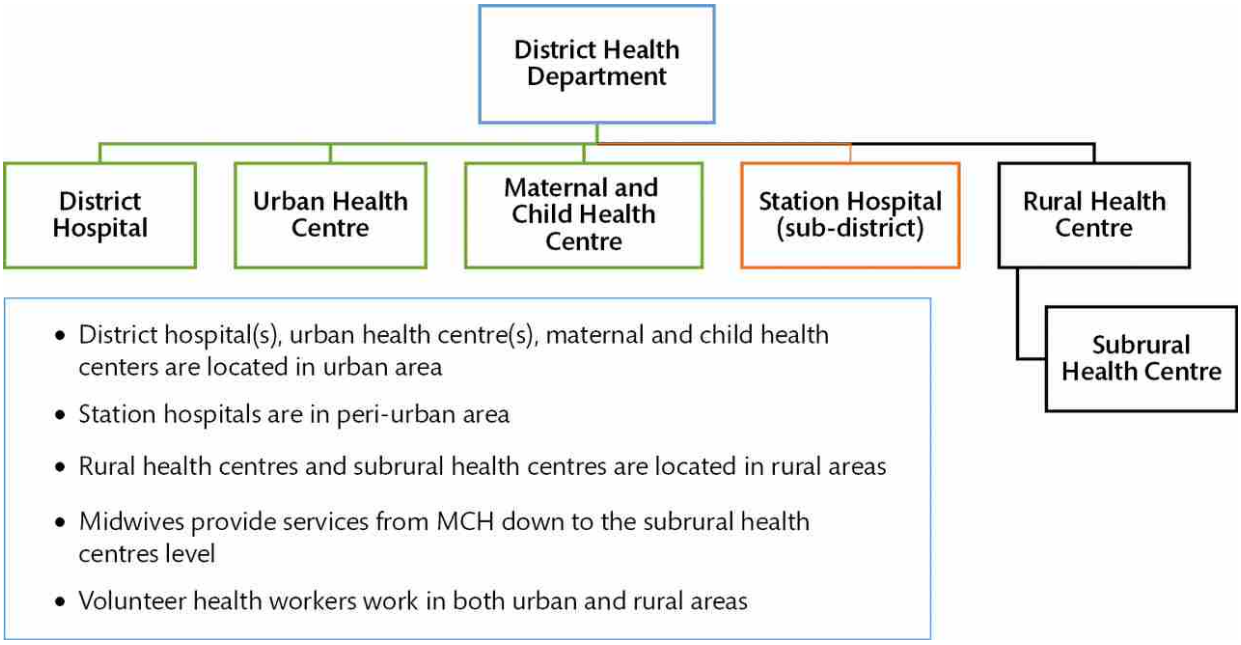

Fig. 11.9.2 Health structure/system at the district level.

Complicated surgical procedures and medical management of serious health problems are usually performed only at the provincial and national/tertiary levels. A serious problem in developing countries with

limited resources and populations residing in remote areas is diagnosis and timely transport of patients to tertiary care facilities to ensure successful treatment.

Training of health workers may occur at each of the levels of the public health system, although training of higher levels of health professionals is usually limited to universities, medical schools, and schools of public health, dentistry, health sciences, and nursing.

Education for health professionals in developing countries

In all developing countries, completion of medical school is required for healthcare professionals working in the various healthcare facilities at the national, provincial and district level hospitals. Many developing countries require graduating physicians to work a minimum number of years at the district level as a strategy for providing healthcare at the peripheral levels of the health system. A medical degree or a master's degree in public health is often also required at the national and provincial levels for staff responsible for administering national programmes. Specialized and advanced medical training is usually only required at the national level healthcare facilities, and sometimes at provincial-level health facilities. Specialized training is usually required for health professionals conducting dental care and pharmaceutical services.

Advanced training is required for health professionals who will design and direct health information systems such as disease surveillance, and who will design and conduct health research to inform policy decisions and evaluate health programmes. These activities are usually directed at the national level, although they may involve staff at the provincial, district, and local levels.

Nurses usually require bachelor's degree level training. However, midwives who work at the local level may receive an associate midwife degree, which may require only 1–2 years of certificate-level training, depending on the country. Some countries also have midwife assistants who receive shorter periods of training. Staff providing lower-level nursing, medical imaging, sanitary services, low-level laboratory services, and physical therapy usually have limited training.

Problems with providing public health training in developing countries

Health professionals at the district level, who often have had only 1–3 years of training, are expected to assist in planning and management of public health programmes, recognition of the need for and initial conduct of outbreak investigations; implementation and monitoring of immunization programmes; prevention, treatment, and monitoring of tuberculosis and HIV programmes (e.g. directly observed therapy); implementing specific communicable disease elimination strategies (e.g. active case investigation for malaria elimination); and basic health education in strategies to prevent disease and promote healthy lifestyles. Their training may include the various skills and knowledge required to carry out these responsibilities, including the need for collection of accurate data that can be used to plan and support effective health systems (International Institute for Viral Registration and Statistics 1989). Thus, there is a need for congruency in the training of public health professionals and the responsibilities they will assume (Sudhinaraset et al. 2013). A major barrier to achieving proper training at all levels of public health training is the scarcity of qualified faculties in these programmes. Refresher training for health workers is important to ensure that they keep up with current and changing strategies and policies. The training of health professionals at the local level is often not integrated, so staff members know only their own responsibilities but do not have a holistic understanding of where their efforts fit into the broad public health system.

Funding for public health programmes and training is often a low priority for political leaders and decision-makers. The majority of health programmes in developing countries are subsidized by international donors who have their own health agendas, which may differ from those of the country (see chapter 11.12).

Clear public health career tracks are often not apparent for qualified individuals who wish to choose a career in public health. Complicating recruitment of public health professionals at every level is the low level of remuneration. Often physicians who are willing to work in public health must also have private practices to generate enough income to support their families (Chomitz et al. 1998; Ferrinho et al. 2004). Thus, they are not able to dedicate their full efforts to their public health responsibilities. Physicians

are often reluctant to work in remote rural areas (WHO 2010a). Public health workers at the peripheral level are usually paid low wages or are expected to volunteer their services. In these situations, other reward structures must be created to motivate volunteers and low-level workers (Henderson and Tulloch 2008; Mangham and Hanson 2008).

Strategies to overcome barriers to optimal public health training

The fundamental principles for designing public health training involve both academic and practical components. For training programmes to be responsive to needs, the needs must be clearly delineated. It is important that the tasks and responsibilities of health professionals at every level of the public health system be designed to meet the needs of the constituency and the level of responsibility expected at that level. A first step is to conduct needs assessments at each level, from the local and provincial levels to the national level, and from primary health care providers to researchers and policy-makers (Bangdiwala et al. 2010). The assessment should involve members of the community or constituency at that level. Formulation of the responsibilities and tasks at each level can then be clearly defined, and documentation of formal job descriptions provided so that an appropriate training curriculum may be developed for health workers expected to perform the required tasks at that level of the system. Training resources should then be identified and/or developed for the required training at each level of the public health system. At each level, the curriculum should be designed and evaluated for responsiveness to the job descriptions of the positions that graduates are intended to fill. The faculty of the training programmes at each level should include individuals who have had experience in delivering services at that level. The training should include providing an understanding of where the responsibilities of the health professional being trained fit into the public health system of the country.

Incorporating new technologies

Development and widespread use of hand-held computers/phones, global positioning systems, and increasingly sophisticated communications

systems, called ‘M Health’, provide opportunities for monitoring, mentoring, and enhancing health activities, particularly at the local level. Implementation of ‘M Health’ strategies can lower costs, while enhancing the quality of the health service delivered, and the completeness and ease of real-time events and disease reporting and transparency and accountability for both funders and donors. For example ‘M Health’ strategies can be used for training and updating of skills via videos sent to mobile devices for: connecting the primary health care providers with supervisory staff for assistance in health and logistic problems that they encounter in the field; accessing higher-level health personnel for advice about care; linking individuals with serious health problems to a higher level of care; reporting health activities such as immunizations and community outbreaks in real time; facilitating rapid public health responses; and increasing the confidence of local health workers because their mobile devices give them access to a higher level of support. Mobile phones used in conjunction with global positioning systems can be used to monitor primary health care providers performance by assuring that they are where they report being and having them check in and out for each home visit, etc. These low-cost strategies are particularly relevant for developing countries with limited budgets and many disease problems. It is important to deploy mobile devices (technology) to facilitate the global goal of UHC, which is dependent on the performance of community-based public health professionals. Updated mobile devices can serve as a platform for practise-based education, training and mentoring through which knowledge and skills for clinical service delivery can be transferred from super-tertiary centres to the community level, and thus ultimately ensure not only the quality of services but also the sustainability and feasibility of UHC (Project-ECHO 2017). In addition, the strategies of using mobile devices can be configured according to specific needs, such as a referencing job aids providing standardized health messages and guiding stepwise procedures for service delivery, a trigger point for initiating case investigation, and to advance the response for effective disease surveillance, etc. The use of these emerging strategies and technology to enhance the performance of health workers and meet the needs of villagers at low costs need to become part of health systems and part of the curriculum for training at every level (Rotheram-Boris et al. 2012; Tomlinson et al. 2013; Taylor et al. 2018).

It is important for those designing public health systems to delineate clear career paths for health professionals at each level, which will inform and, if done well, attract potential students to pursue those careers. An important component of defining career paths is to include incentives for individuals in these career paths (Calcutta Declaration 1999). A problem in many developing countries is the high attrition rate of trained health volunteers, in part due to a lack of monetary incentive. In some developing countries, training, especially for nurses, may better prepare trainees for work in developed countries. Thus, migration of health professionals whose training was funded by the developing countries, particularly doctors and nurses, to better working conditions and pay in developed countries reduces the potential workforce (Stilwell et al. 2004; Naicker et al. 2009; WHO 2010b). In these situations, developing countries may be considered to be subsidizing healthcare in developed countries!

Incentives for health workers should include monetary rewards, but it is important that they also include recognition of the importance of the health professionals at every level in the entire system for advancing the health of their constituencies. This recognition is particularly important at the lowest and least financially rewarding levels. Prestige and recognition of worth are powerful incentives!

Assuring that the public health system remains responsive to changing needs

Finally, it is important to monitor and periodically evaluate the performance of the health system at each level. Over time, specific needs change due to a range of factors and new technologies are developed; therefore, training programmes at every level must adapt their curricula to meet current needs and rapidly emerging technologies. Previously trained health workers need to update their skills. Thus, it is important to also include continuing training at all levels for health workers that will assure that they can continue to meet the changing demands of the health system.

Transformative learning for health professional in the twenty-first century for the future health workforce

Wanicha Chuenkongkaew and Suwit Wibulpolprasert

Why transforming health professionals learning?

Since the 1910 Flexnor report, a set of studies of health professional education system has been proposed for a continuous reform. The empirical experiential apprenticeship was replaced by a science-based curricula at non-commercial and university-based medical schools. The reforms equipped health professionals with the knowledge and skills that doubled life expectancy during the twentieth century (Frenk et al. 2010).

At the start of the twenty-first century, new complex challenges emerged that affect worldwide healthcare services systems. Inequities in term of healthcare access and quality underscore failure to share health advances both domestically and internationally. An unprecedented rate of technology development, rapid demographic transition towards aged and urban populations with increasing chronic noncommunicable diseases (NCD) and disability, rapid globalization favours easy spread of emerging such as COVID19- coronavirus pandemic and re-emerging infectious diseases, have moved the world into a situation of VUCA (Volatility, Uncertainty, Complexity, and Ambiguity). All these emerging challenges, together with the top political commitments to achieve Sustainable Development Goals (SDGs) by 2030, require a totally new type of health professionals.

The current health professional education systems have not been well adapted to address the global challenges. This is mainly caused by outdated, static and fragmented curricula, institutes, and faculty members. The graduates are thus equipped with insufficient knowledge, attitude, and competencies to match the present and future healthcare systems (Wasi 2000). There are many challenges including:

Poor teamwork and inadequate collaboration among health professionals
Gender inequity of professional status
Narrow attention on technique without understanding the broader context
Episodic encounters with patient illnesses rather than holistic continuous care
Emphasizing hospital-based care rather than community and home-based, primary care and disease prevention
Inadequate understanding of social determinants of health
Quantitative, qualitative imbalances, inequitable distribution, and inappropriate skill-mix in the professional labour market
Poor leadership in health system development

Thus, the need to transform the health professional education systems is imminent. The movements must ensure that the new graduates fit well with the changing health challenges and health systems development.

Health challenges and future healthcare delivery system

Global emerging challenges including rapid globalization, technologies development, demographic, and epidemiological transition have been affecting the healthcare delivery system. We can envisage more chronic diseases, both Communicable (CD) and Non-Communicable Diseases (NCD), and Public Health Emergencies, linked to social determinants of health (SDH). We see the rapid increases in health expense and equity. Socio-economic development has also resulted in changing demand and provider-patient relationships.

The World Bank and the World Health Organization (WHO) reported in 2017 that half of the world's population lacked access to essential healthcare. Moreover, almost 100 million people were pushed into extreme poverty, forcing them to survive on only $1.90 or less a day (Tracking Universal Health Coverage 2017). To end people's extreme poverty, which is the greatest challenge and ambitious goal of SDGs, inclusive and sustainable economic growth is needed. This can be achieved through policy coherence of economic, social, and environmental sectors.

Universal Health Coverage (UHC) is an effective social measure to tackle health disparity and medical impoverishment at the same time. The United Nation SDGs 3.8 aims to achieve UHC in 2030.

UHC is defined as ‘all people can access the health services they need without incurring financial hardship. It includes the access to essential comprehensive health promotion, disease prevention, treatment, rehabilitation, long-term, and palliative care services and technologies, without financial barriers’.
To achieve UHC, five criteria must be met.

First, the *availability* of essential health services. This includes an adequate number of skilled Health Work Force (HWF) employed with decent working conditions.
Second, *affordability* to ensure no financial hardship through minimizing out-of-pocket (OOP) payments at point of services.
Third, *accessibility* with equitable geographical distribution and near home primary and community-based healthcare.
Fourth, *acceptability* with culturally appropriate, gender sensitive, non-discriminatory and responsive to special needs of specific populations,
Fifth *quality and accountability*, including quality of care, patient safety, and responsiveness to patients’ demand, as well as people’s engagement.

Public health (PH) is defined as ‘… the science and art of preventing disease, prolonging life and promoting health and efficiency through organized community effort’ (Grant 2012).

Essential PH functions include strengthening primary and community-based healthcare; increasing capability, accessibility, and quality of individual and people-based healthcare services; reinforcing evidence informed policy decision processes through Health Systems Researches; strengthening qualified and equitable HWF; protecting health and safety both in normal and crisis situations and creating social innovation for PH problems. With emerging threats from health in crisis, including man-made, natural disasters, and pandemics, PH capacity is even more essential to ‘prevent, detect, and respond’ to protect health and humanity.

Thus, UHC and PH are closely linked and should be developed in parallel with good integration.

Investing on HWF is the key to achieve health-related SDGs

To achieve SDG targets in 67 low- and middle-income countries (LMIC), more investment on health is needed. A prospective investment of $41-$57 per person, per year on health by 2030 could provide a 9:1 return of global economic growth. The International Labour Organization (ILO) determines a threshold of 41.1 HWF per 10,000 population to achieve UHC. The strategic investment should focus more in the frontline HWF (potentially for women) in rural and underserved communities.

Currently, the world's urbanized population is projected to double from 30% in 1950 to 66% in 2050. Despite the rapid urbanization projected for the next two decades, African and Asian rural populations are estimated to be almost 90% of the global rural population, mostly in India, China, and Nigeria (United Nations 2014), (Fig. 11.10.1). Only 22% of the global urban population has limited healthcare access, whereas 56% of the rural population lacks access to essential healthcare services (International Labour Office 2015) (Fig. 11.10.2). The rural dwellers in Africa are the most deprived group in healthcare access. The challenge to achieve health-related SDGs is to focus to a greater degree in the LMIC where small city growth becomes urbanized rapidly.

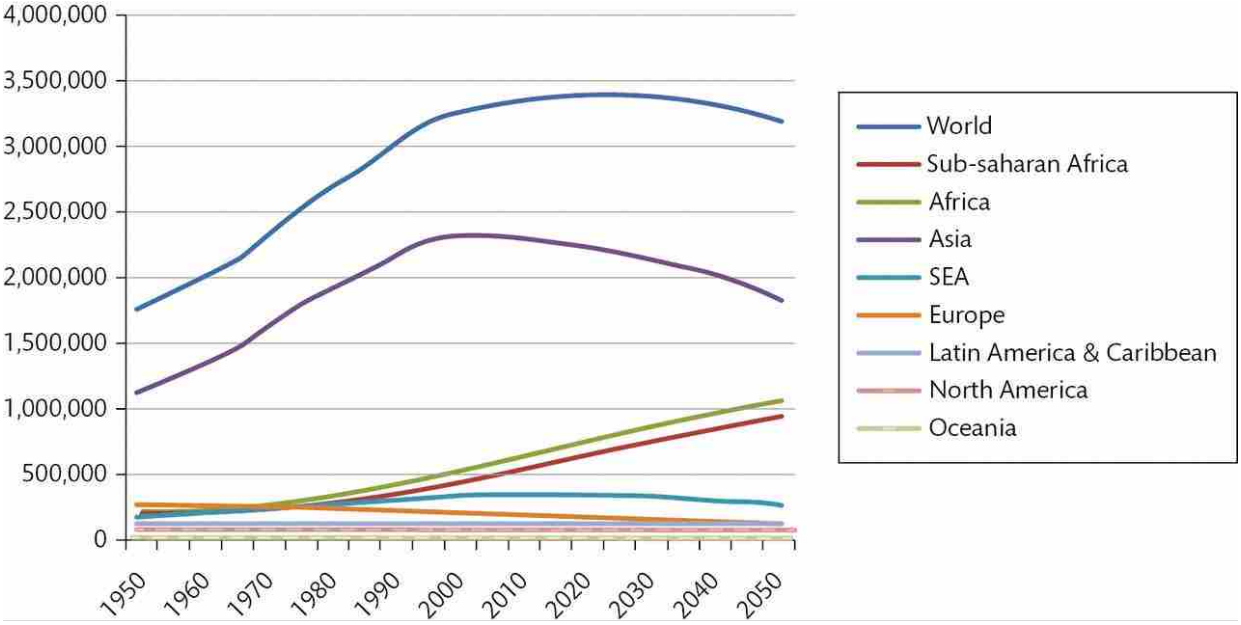

Fig. 11.10.1 Annual rural population at mid-year (thousands).

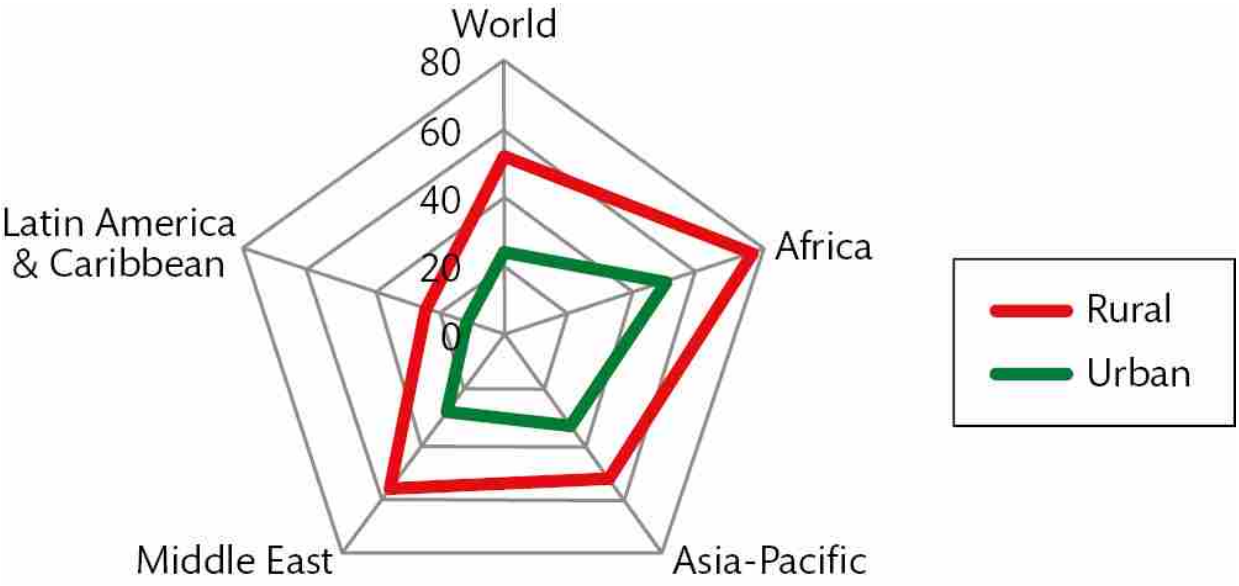

Fig. 11.10.2 Rural/urban population with lack of health coverage due to HWF shortages, 2015 (ILO HWF lack of access to healthcare services, percentages) The 'urban' population is defined as the definition using in each country. The definitions are applied by national statistical offices in completion of the latest available census.

Accessibility, availability, financial protection of efficient healthcare services, OOP expenditure and maternal mortality ratios (MMR) are five indicators for measurement of key dimensions of healthcare coverage and access (Fig. 11.10.3).

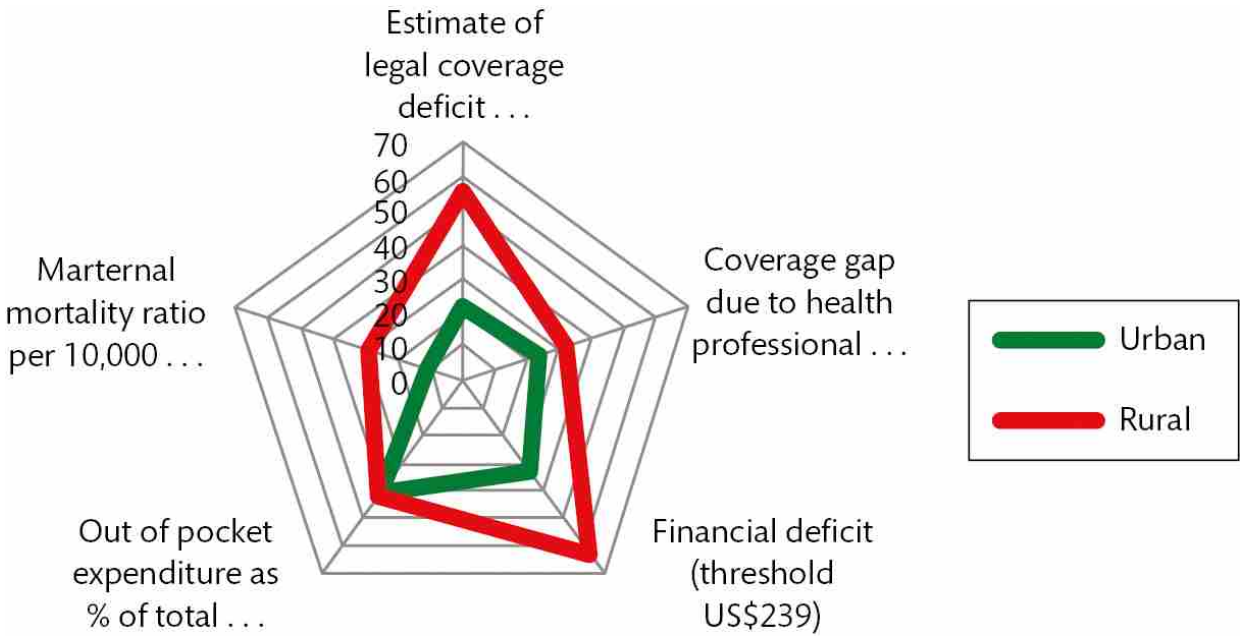

Fig. 11.10.3 The global inadequacy in access to quality healthcare service: rural/urban population 2015 (percentage) Regional averages weighted by rural and urban dwellers except for MMR, by skilled birth attendants.

Source: ILO estimates, 2015.

Although we are facing rapid urbanization, more than 50% of the world population is in the rural underserved areas (Fig. 11.10.2), where severe shortage of HWF is a major challenge (Table 11.10.1). Strengthening primary and community-based healthcare and mobilizing community partnerships are essential to address the urban/rural divide. It requires strong basic primary healthcare (PHC)-based health systems manned by qualified committed health volunteers and professionals. Its success depends on active engagement of families, local government, community leaders, and intersectoral collaboration. Empowering HWF through transforming learning and practice in the community is a key contribution to address the disparity in UHC.

Table 11.10.1 A mismatch in the global and national health labour market

	Stock			Needs-based shortage			Labour market demand	
	2013	2030	Change (%)	2013	2030	Change (%)	2013	2030

A priority approach is community-engaged health professional learning, a mechanism to envision learners how to work in and with communities, in other words, learning how to involve the people that live in community with local redevelopment. It is a key component to produce health professionals with skills and spirit to the community for the reduction of geographical inequities. An engagement of learning develops when the community and academic partnership sustainably collaborate on the design, delivery, and

programme evaluation with equal value to empower the community by training qualified and motivated health professionals to provide community-based service for health equity.

Transformative learning for effective community engagement needs socially accountable values including honesty, respect, authenticity, openness and transparency, and trustworthiness.

Global movement on transformative learning for health professional in the twenty-first century

In 2010, the Global Commission on Health Professionals Education for the twenty-first century was launched, on the 100th anniversary of the Flexner Report. The Global Commission report strongly proposed a system-based approach to replace scientific based curricula in health professional learning. The report triggered global movements to promote transformation, for instance:

The Southeast Asia Regional Committee resolution, SEA/RC/R6 on ‘Strengthening health workforce education and training in the region’ (WHO 2012).

World Health Assembly resolution, WHA 66.23 on Transforming health workforce education in support of UHC (WHA 2013).

The WHO recommendations 2013 for transforming and scaling up health professional education and training (WHO 2013). Eleven recommendations include faculty development in term of continuous professional development (CPD); accreditation; and recruitment process for faculty and teaching staff, curriculum development, simulation method, direct entry of graduates, admission procedures, streamlined educational pathways and ladder programmes, interprofessional education, accreditation, and CPD. The global recommendations provide a guide for transformative learning which include policy and technical guidelines for establishing undergraduate and graduate programmes It gives guidance on how best to produce graduates in response to health needs of the populations.

In the Prince Mahidol Award Conference (2014) ‘Transformative learning for health equity’, several new movements to tackle the current inadequacies of health professional learning have been gathering pace across a range of different constituencies (WHO 2006).

In 2015, as replacement to ‘unfinished’ health-related MDGs, a SDG 3.C on substantially increasing health financing and the recruitment, development, training and retention of the HWF in developing countries is a primary aim for the attainment of UHC (SDG 2015). To achieve UHC, all people must have access to an essential national package of healthcare services and essential, safe, effective, and good-quality medicines without financial barriers.

In 2016, the Global Strategy on Human Resources for Health: Workforce 2030 (GSHRH 2030), reiterates and revisits through a contemporary lens the agenda to adopt transformative strategies in the scale-up of HWF learning. The strategy outlined a set of milestone and key indicators on HWF learning. These include the establishment of an accreditation mechanism for health training institutions by 2020, progress towards halving current levels of disparity in HWF distribution (disaggregated by place of employment, for instance subnational and/or urban/rural/remote) and reduction of the prequalification attrition rates in medical, nursing and allied health professional schools to 20% or less by 2030.

Education strategies should focus on investment in trainers who have a high potential of social return as a priority. It should prioritize regulating curricula to balance on producing graduates in response to local needs and to international markets. A coordinated approach is essential to create close linkage between health professional planning, learning, and motivating interprofessional education (IPE) and interprofessional practice (IPP). National policies should include setting and monitoring the education standards and sufficient financial support. The collaboration between higher education and health sector should be implemented by the integration between health systems and competency-based learning.

Health professionals should be equipped with knowledge, skills, values, and attitudes in term of SDH and public health systems to build the most collaborative and effective interprofessional team. Building PH capabilities on epidemic preparedness and the global health security agenda to prevent, detect, and respond to emerging threats is a priority in current education strategies. The high quality of health training institutes should be regulated through accreditation mechanisms.

The United Nation Secretary General appointed a High-Level Commission on Health Employment and Economic Growth (HEEG 2016) which reported 10 concrete recommendations. The commission brought in the active involvement, at the top level relevant Intergovernmental Organizations including the ILO, the Organization for Economic Co-operation and Development (OECD), and the WHO. The commission recommends stimulation of the health and social sector jobs to drive inclusive economic growth for greater economic stability and security. The achievement can also make gains across SDG 1 (poverty elimination), SDG 3 (good health and well-being), SDG 4 (quality education), SDG 5 (gender equality) and SDG 8 (decent work and economic growth). The report also shows that between 2000 and 2014, in OECD countries, there was a 48% increase in health and social sector employment while the industrial and agriculture sector declined.

The commission recommended an increase of at more than 40 million new jobs in health and social sectors to reduce projected shortage of 18 million HWF, especially in LMIC and LIC by 2030. More health demand will create more jobs. The global economic return on health investment is 9:1 and one extra year of life raises gross domestic product (GDP) by 4%.

More than 70% of the global health and social service workforce are women, compared with less than 40% of those across all employment sectors.

The commission also recommended 10 specific actions. Six actions are on health system and HWF reform, including job creation; gender and woman's right; education, training, and skills; health service delivery and organization; technology; crisis management and humanitarian setting. The remaining four recommendations on enabling actions include financing and fiscal space; partnership and cooperation; international migration; data and information and accountability.

Transforming and scaling up high-quality learning should shift away from narrow specializations to general practice. It should highlight more on lifelong learning to build highly competent HWF. It has to generate motivated HWF in response to local and global health needs. Furthermore, reduction of unnecessary entry barriers is needed. These include addressing geographical inequities, strengthening youth education for better chance of employment, and reinforcing the effectiveness of community-based health workers.

New skills for the future health professionals and leaders

Addressing global emerging challenges, health professionals need to move towards better health promotion, health protection, disease prevention, people-centred care, and community-based and primary healthcare based health systems with extensive geographical coverage.

In the twenty-first century, competency-based curricula and team-based learning will replace traditional time-based learning. As defined by OECD, 'competency' is not only 'knowledge and skills' but the ability to meet complex needs by making use of psychosocial resources in a particular context. Effective health promotion needs to integrate health literacy, communication skill, and personal attitude. A competency-based approach is tailored to identify learner's outcome or performance to align learning and training with health needs of populations in different settings (Gruppen et al. 2012).

Increasing social and economic development allow increasing and timely access to healthcare and knowledge. The patient–doctor relationship has gradually shifted from vertical patron–client, to contractual relationship with reducing trust and increasing cost. To bring back trust-based relationship, the

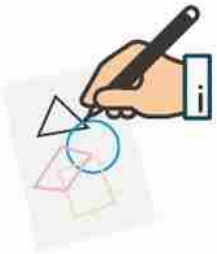
communitarian relationship based of community family doctors would be the new direction.

In the twenty-first century, basic skills should include learning, literacy, and life skills (Fig. 11.10.4) in the training process. In addition, health professionals are also required to understand the high intrinsic value of social justice; ethics; morality; human rights; equity in health; altruism and social accountability. These will facilitate their communication with patients and work with other professionals, families, and community reflecting a mutual respect. They need the skills to enquire, search, interpret, and use evidence for appropriate decision-making. They also need to comprehensively understand the influence of social, political, and economic effects on health status including a concept of Health in All Policies and the SDH.

21st CENTURY SKILLS

learning Skills

CRITICAL THINKING



CREATIVITY

COLLABORATION

TECHNOLOGY

Life Skills

FLEXIBILITY

LEADERSHIP

INITIATIVE

PRODUCTIVITY

SOCIAL

Fig. 11.10.4 Twenty-first century skills: learning, literacy and life skills.

New health professional leaders need five key soft skills for change as illustrated in Table 11.10.2 (Piirto 2010).

Table 11.10.2 Five ‘soft skills’ for changes

Intelligent	A good understanding or a high mental capacity; comprehend quickly
Imagination	A capacity to create a solution that is both novel and appropriate, divergent thinking, being a good critical thinker and problem solver
Inspiration	A sudden arrival of a novel idea, a ‘leap’
Insight	An ability to clearly understand the inner nature of things, particularly by intuition An insight manifests itself suddenly, requires preparation of hard work, believe in reconceptualization, connects old and new information, and applies to ill-structured problems
Intuition	An immediate and effortless knowing from the collective unconscious (a dark or wild animal side and a social mask to get along with other people) of prototypes of the deep human experience Many people do not trust intuition despite their presence but creative people trust and prefer using it. An intuitive person is more likely to operate the tasks by using trial and error instead of using an instruction

Transformative learning for health professional

Transformative learning for health professional is the sustainable expansion and reform of health professionals’ learning to achieve required new skills. It aims to reduce health inequity and improve quality of care as well as addressing issues of health professionals’ competencies for the country health systems. Achieving this will ensure improvement of population health and health equity.

Transformative learning theory was outlined by Jack Mezirow in 1978 (Jack Mezirow 2014). It comprises three dimensions:

psychological (changes in understanding of the self)
convictional (revision of belief systems)
behavioural (changes in lifestyle)

The learning of health professionals is shifting from ‘informative’ to ‘formative’ and on to ‘transformative’.

The ‘informative’ learning is the fundamental level of fact memorization and skill building to become *experts*.

The ‘formative’ learning focuses at the higher level of critical reasoning and systematic thinking to produce *professionals*.

The ‘transformative’ learning aims at the highest level of analysis, synthesis, and enlightenment to be *leader for changes*.

Transformative learning requires reform of the health professional educational system. Reform includes both institutional and instructional reforms. The institutional reform focuses at reforming the structural and functional education system. The instructional reform specifies curricular design, learning process development, and outcome.

Institutional reform (structure and function)

See Box 11.10.1.

Box 11.10.1 Transformative health professional learning

Institutional reform (structure and function)

- Professional reform
- Leadership development and management reform
- Collaboration among stakeholders
- Legal and regulatory reform
- Expenditure and financing reform

Instructional reform (process and outcome)

- Recruitment reform
- Curricula reform
- Learning process reform, including Interprofessional education (IPE), application of IT and authentic learning

Professional reform that focus on faculty development

Faculty development includes academic and career development, teaching improvement, research capacity, and leadership development to ensure teaching, research, and service congruence (Steinert 2012). Effective faculty development is a crucial component in promoting individual and organizational change for its 'grounded in growth' perspective.

Parker Palmer addressed that 'growth of any craft depends on shared practice and honest dialogue among the people who do it' (Palmer 1998). One of the key components of faculty development is to share 'community of practice' dialogue. This would allow collective reflection on human issues of the profession rather than only technical ones. Among others, faculty development help to create values or merits as 'role models' or 'inspirational teachers', rewards system, and attempts for excellence.

Leadership development and management reform

Leadership is critically significant to guide, direct, and influence others to bring about fundamental changes to the health systems. The institutional mechanism is empirically applied to: (1) emphasize fostering leadership development through transformative learning for health professional education and research at all levels; (2) connecting health professional development to evolving local health needs, national priorities and the SDGs; (3) building health equity and eliminating health disparity (WHO 2016) through collaborative institutional and instructional reforms; (4) generating and interpreting data with appropriate stakeholder input to inform evidence-based policy and evaluate innovative practice for education and training; and (5) developing a national HWF plan that harnesses market forces towards development of a workforce with adequate skill-mix for delivery of comprehensive PHC.

Management reform of the education system is collectively pointing to decentralizing the educational administration to shift from central to local control in terms of authority and decision-making power based on good governance and social accountability.

Collaboration among stakeholders

Synergy and coherence among multisectoral key stakeholders from professional educational institutions and councils and the systems that are collaboratively responsible for healthcare services is a necessary component to bring about transformative change and leadership through collective action in developing future health professionals who have a commitment to work in underserved areas where health inequities and inequalities remain. Such collaboration includes public-private partnerships for an inclusive and sustainable healthcare system.

Legal and regulatory reform

In terms of legal and regulatory reform, quality assurance, accreditation and re-accreditation of training institute\ions and curriculum are key instruments to ensure quality and competency of graduates while national licensing examination, re-licensing process, and CPD are instruments are necessary to ensure continuity of health professionals' competency. Accreditation of health professional learning should be introduced and strengthened. It can be achieved through implementation of accreditation procedures. The procedures should emphasize continuous improvement of quality educational processes and outcome, with inclusion of social accountability. Mutual learning with gradual movement towards mutual recognition among countries should be supported, for example the Mutual Recognition Arrangements on the medical, nursing, dental, and pharmacy professions among the South-East Asia Nations.

Finally, with the increasing number of private health professional education institutes, the accreditation and licensing systems should be applied equally in both public and private institutions.

Reform of financing systems

Health professional education requires big investment. Producing a medical doctor in Thailand, for example, costs around US$60,000. Most public institutes are highly subsidized. Students in the private schools may take publicly subsidized loans. The challenge is equity in access and efficiency in using the public resources. Students from low socio-economic families,

especially in the rural settings, find it difficult to compete with those from urban better off families.

‘Rural recruitment, local training and hometown placement’ is an important measure to ensure better equity both in the access to education and the distribution of the graduates.

In some instances, local communities recruit and support their own students with the condition that students must return to work in their communities.

An education financing reform should aim to restructure and reallocate resources to cover local communities through public-private partnerships.

Demand-side financing schemes, where funds are channelled directly to the local communities or students, will empower them and create greater community responsiveness among the supply side.

Instructional reform

See Box 11.10.1.

Recruitment reform

Student enrolment and admission policies should focus more on increasing the socio-economic, demographic, psycho-physiologic, ethnic, and geographical diversity of students. It would reflect local population diversity and ensure their social return. As such, special systems should be in place to increase inclusion of students from disadvantaged, underserved populations, and marginalized groups. These systems should also align with the requisite academic standards and other desirable characteristics. In addition, special training programmes should be implemented to support underserved population groups to achieve admissions requirements and to reduce dropouts before completion of their training.

Curricula reform

The existing conventional, and fragmented curricula should be transformed. They should focus on population health needs, new models of service delivery and health team skill-mix to support UHC for health equity. The

‘silo’ competencies across different relevant curricula have to be reviewed to ensure better alignment across different professionals.

Essential new issues should include:

Broader and deeper competency-based learning with emphasis on social and contextual determinants of health in situ
Broader understanding of overall integrated people-centred health systems and roles of different health professionals
Continuous leadership development to be active ‘change agents’
Home-based comprehensive primary care, health promotion and disease prevention
Community engagement, inter- or transprofessional health teams, and immersion education experiences
Inclusion of community leaders, health service managers, and users from heath facilities on curriculum planning committees

Interprofessional education (IPE)

WHO defines IPE as ‘Learning “With”, “From” and “About” different professions, for collaborative practice to improve healthcare quality’ (WHO 2010). It is one of the 11 WHO’s key recommendations. It supports and enhances the performance of community health systems. It deepens mutual understanding among different professions to bring about an effective collaboration and improve health outcomes in the community.

In order to scale-up IPE, all health professions should be incrementally focusing on IPP in the real-life services (de Villiers and Naidoo 2011; IOM 2013).

To optimize health professional learning, the transformation should also focus on team-based education in addition to the competency-based learning.

The key challenges are:

Personal barriers, including failure to appreciate other professionals
Misunderstanding and miscommunication
Fear of change
Differences in income
Different power in the systems
Language or gender
Institutional barriers such as practice setting, structure, and priority

Information and communication technology (ICT) for transformative learning

Digitalized Information Technology (IT) and social media skills are key elements of twenty-first century teaching and learning. It can provide a common platform for knowledge exchange and sharing. However, this platform does require substantial infrastructure support to connect all the basic facilities, services, and information together.

ICT for Transformative learning has five objectives:

Fostering and deepening the learner-centred learning system and learning environment
Diminishing costs by mobilizing and sharing resources
Increasing the application of ICT in learning settings and sharing knowledge on informatics
Strengthening teachers' and learners' confidence, competency, and capacity in ICT utilization
Developing an online course from the existing course

The four strategies for applying ICT in transformative learning include:

Fostering ICT across all disciplines
Increasing the use of technology platform s in courses
Promoting learner utilization of mobile devices
Implementing a comprehensive learning management system to achieve learning outcome improvement

The key successful indicators are:

Percentage of teaching and technical support staff with ICT literacy
The number of electronic resources on learning, educational research studies, and innovations that can be applied to improve the learning process and achieve better learning outcomes
The number of ICT skilful faculty members

In the technology-rich digitalized innovative environment, shortfalls in soft skills development can occur. To overcome such challenges, a few measures should be addressed:

Social interaction by means of communicating through dialogue
Encouraging
Explaining
Hugging and thanking

We should always emphasize that 'The digitalized technologies are helpful but artificial, the real health services depend on the *ten digits* of the health professionals that touch on the patients and people'.

'Appropriate Technology with High Human Touch' is the most favoured service, not the 'High Technology with Low Touch' (Gade and Chari 2013).

Authentic learning

Authentic learning or experiential based learning will engage learners to actually participate in solving real health challenges. The learners' skills and attitude gained from experience and practice will keep them motivated to enhance their lifelong learning. This is to ensure sustainable quality of care and ultimately achieve community satisfaction. The key challenge is to create learning experiences to effectively provoke deep reflective thinking.

Authentic learning should be supported by the effective and appropriate application of ICT.

Networks on transformative learning for health professional

A number of global and regional transformative learning networks to actively enrich its momentum have been established, including:

The Joint Learning Initiative (2004)
The Global Health Workforce Alliance (GHWA)
The Asia Pacific Action Alliance on HRH (AAAH)
THEnet
The President's Emergency Plan for AIDS Relief (PEPFAR) supported Medical and Nursing Education Partnership Initiative (MEPI and NEPI) or AFREhealth
The Asia-Pacific Network on Health Professional Education Reform (ANHER)
The Pacific Open Learning Health Net (POLHN)

The Joint Learning Initiative (2004)

The Joint Learning Initiative (2004) is a network of more than 100 great healthcare leaders who are determined to confront the global health system crisis by mobilizing and strengthening HWF primarily in low-income countries. Reflecting their initiative, the HWF shortage has become a common concern and the collective action to tackle the HWF crisis is needed.

The Global Health Workforce Alliance (GHWA)

When the Rockefeller supported Joint Learning Initiative ended in 2005, one of its recommendations was to establish global and regional networks on HWF.

In 2006, the GHWA was launched and hosted by WHO in response to the HWF crisis. It is a global network of various agencies including civil society, financing sectors, workers, national governments, international, academic, and professional organizations. In 2016, GHWA transitioned to the Global Health Workforce Network (GHWN), operated by WHO to support the national actions on the Global Strategies on HRH 2016–2030 and the recommendations of the UN High-Level Commission on Health Employment and Economic Growth.

The Asia-Pacific Action Alliance on Human Resources for Health (AAAH)

At more or less the same time as the GHWA, the HWF leaders in Asia and Pacific established the AAAH. It is a regional partnership mechanism to strengthen country health workforce planning and development actions. AAAH's prominent roles are to advocate HRH policy; monitor information system; strengthen capacity; generate, manage, and share knowledge; and coordinate technical issues. AAAH has convened annual conference, since 2006 and biennial since 2014. Network activities of 18 countries, in WHO SEAR and Western Pacific Regions (WPR), include training workshops and study visits. Intersession research workshops to drive national agenda by country partners through evidence generation and capacity building activities.

Training for Health Equity Network (THEnet)

In 2008, Training for Health Equity Network (THEnet) aims to increase the impact of academic institutions on community health and develop more equitable health systems. The identification of successful strategies to indicate health workforce shortages is primary goal, THEnet is located in outreach areas worldwide and steps forward to convince schools and policymakers that socially accountable education can increase quantity and quality of HWF practising in rural and underserved areas.

The Medical Education Partnership Initiative (MEPI) and the Nursing Education Partnership Initiative (NEPI)

In 2010, the United States (US) PEPFAR, supported the MEPI administered by the National Institutes of Health (NIH) and the NEPI administered by the Health Resources and Services Administration (HRSA). These two networks have together strengthened innovative evidence-based strategies for transformative health professional learning, training, and research in support of HIV epidemic control and achievement of UHC in Africa. Both MEPI and NEPI were a response to the critical shortage of HWF in sub-Saharan

Africa by increasing the quantity, quality, and capacity of physicians, nurses, and midwives. From these two multicounty initiatives, a new African designed and led African Forum for Health Research and Education in Health (AFREhealth) has emerged which embraces interprofessional collaboration since 2016.

Asian Network on Health Professional Education Reform (ANHER)

To envision the 2010 Global Commission's report on Transformative Learning, Bangladesh, China, India, Thailand, and Vietnam, committed to implement and conduct distinct and suitable health professionals' education reform. The strategies will be flexible with respect to the nation's socio-economic and cultural situation and trends, as well as its domestic health service system. In 2011 at a meeting in Hanoi, they initiated ANHER. The network has agreed on joint actions including joint surveys on health professional learning, information sharing, and learning in medical nurse and public health professional reform, plus other internationally collaborative activities. The situation analysis survey focused on the introduction of innovative institutional and instructional reforms. The reforms aimed to improve quality, enhance teamwork among students, schools, and networks, improved curricula, and practicum to prepare health workers for the new challenges. The innovations are introduced into the learning systems such as e-learning methods and introduction of new skills in the curricula such as public health and management training. Articles on cross-country analysis and country experiences were published for experience learning and sharing and drive the reform (Chuenkongkaew et al. 2016; Pudpong et al. 2017; Zodpey et al. 2018).

The Pacific Open Learning Health Net (POLHN)

The POLHN is a key programme of the WHO in collaboration with the Pacific Ministries of Health to increase health professional standards and quality by offering free, online, and blended courses. The network cooperates through 47 learning centres and a team of dedicated focal points in 15 countries. POLHN offers different specialized online accredited

programmes from Fiji National University, Pacific Paramedical Training Centre, and Penn Foster Dental School. Since Internet access in the Pacific is getting better and an increasing number of online courses are available globally, online continuing education will be increasingly important in the Pacific. In this regard, POLHN needs to reinforce its role in overall CPD, including better regional coordination with more countries.

Conclusion

The successes of health-related SDGs depend on the successes of the health system reform towards primary care-based, patient-centred health service. These reforms, in turn, depend on the successes of the Health Professional Education reform.

The reforms will ensure adequate numbers and equitable distribution of competent, inspired, and motivated HWF with leadership capacity.

Transformative health professional learning is a set of essential reforms, from hospital-based to health systems and community-based and authentic learning. The reforms focus on building skills and attitude on rationalizing appropriate technology with a high human touch. It moves from individual silo-based practice to integrated team-based practice. It also ensures the effective and constructive collaboration between the producers and users of HWF in the health systems.

11.11

Humanitarian emergencies

Craig Spencer and Les Roberts

A challenging moment in history: more people in need, more money, and more difficult tasks

In recent years the humanitarian sector has been the target of intense criticism. The humanitarian community has been seen as driven by wealthy country agendas, inadequately developing and listening to local actors, and not being adequately accountable to international law and humanitarian principals (Agenda for Humanity n.d.). While all of these criticisms have a solid basis of complaint, they do not stem from a humanitarianism in decline. The lack of clarity of purpose of many humanitarian players has arisen in part as a result of the spectacular success of the humanitarian community.

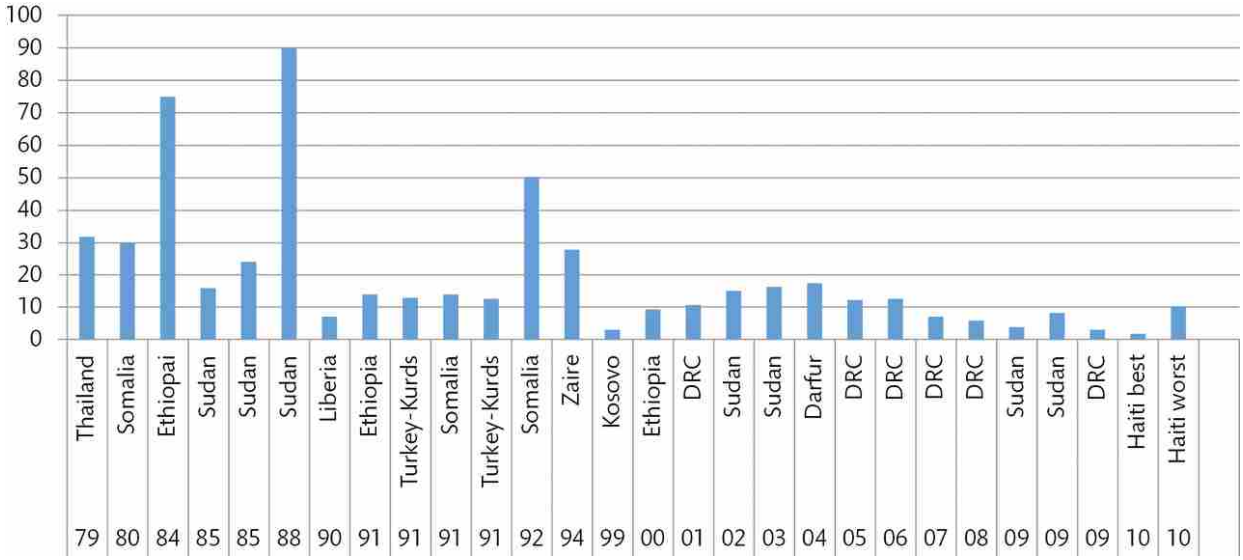

Fig. 11.11.1 Highest mortality periodically recorded over the last 30 years in >100,000 people lasting >1mo. Deaths/1,000/mo.
Source: data from Centre for Research on the Epidemiology of Disasters (CRED) database.

This may partially be explained by a 75% decline in the fraction of people living in poverty since 1981 when current World Bank measures began (Roser and Ortiz-Ospina 2018). Yet perhaps most of the decline is because of the near ubiquitous presence of humanitarian actors during the most acute of crises and their improvement in the science of keeping people alive.

Our present moment in history also involves higher numbers of displaced people than have ever been recorded. The United Nations High Commissioner for Refugees (UNHCR) estimates that more than 60 million people are displaced, with two-thirds of them still in their home country and therefore the responsibility of that government (UNHCR n.d.). One-quarter of today's refugees have fled Syria, a middle income and highly educated country not similar to most of the origins of last century's most acute crises shown in Figure 11.11.1. Those who do manage to cross borders now are not returning for longer periods than those in recent decades (Fig. 11.11.2).

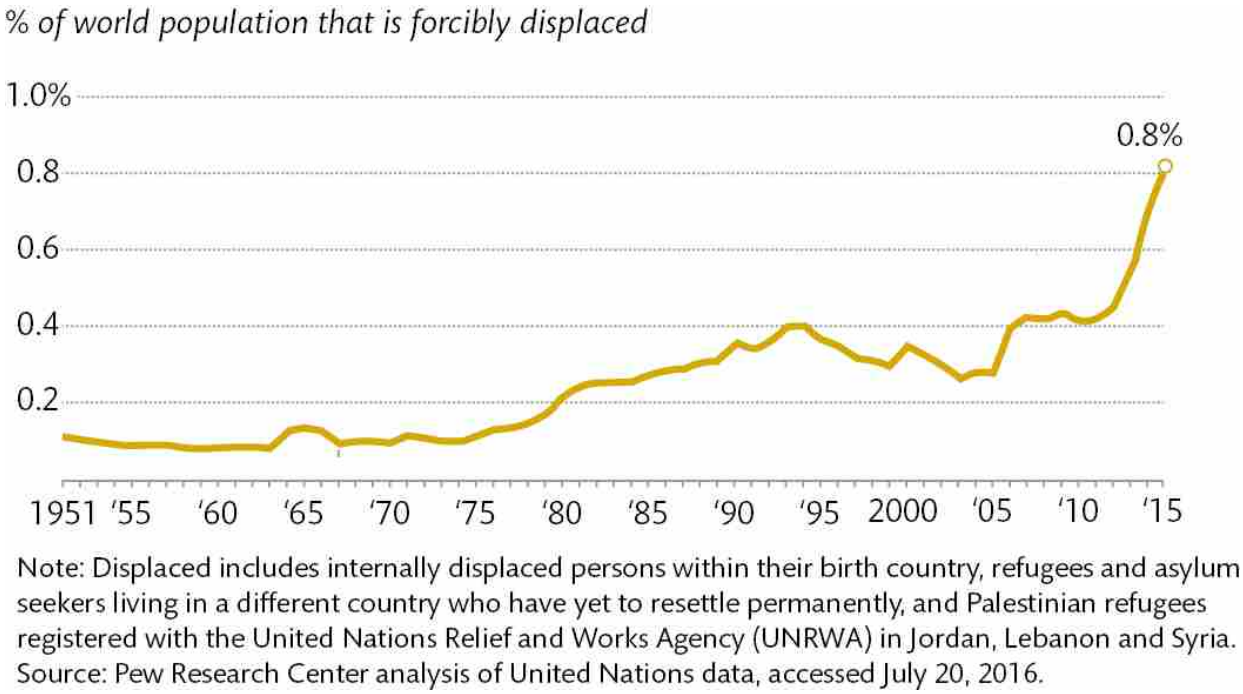

Fig. 11.11.2 Estimate of the percentage of the global population displaced over time. Reprinted with permission from the Pew Research Center 2016. http://www.pewresearch.org/fact-tank/2016/08/03/nearly-1-in-100-worldwide-are-now-displaced-from-their-homes/ft_16-07-28_displaced_world/

Making this time period more complex is the fact that more money is being spent on humanitarian assistance. The 2017 Global Humanitarian Assistance Report suggests that $27.3 US billion was spent in 2016 on humanitarian assistance, more than on development. This is in stark contrast to the 1970s–1990s when OECD countries typically spent more than ten times as much on development aid as on humanitarian assistance (Global Humanitarian Assistance 2000).

Figure 11.11.3 shows the dramatic increase in violent deaths in the WHO Middle East and Northern Africa (MENA) region since 1990 (GBD 2018). In this region, violent deaths have increased in every demographic group, increasing 450% from 1990 to 2015.

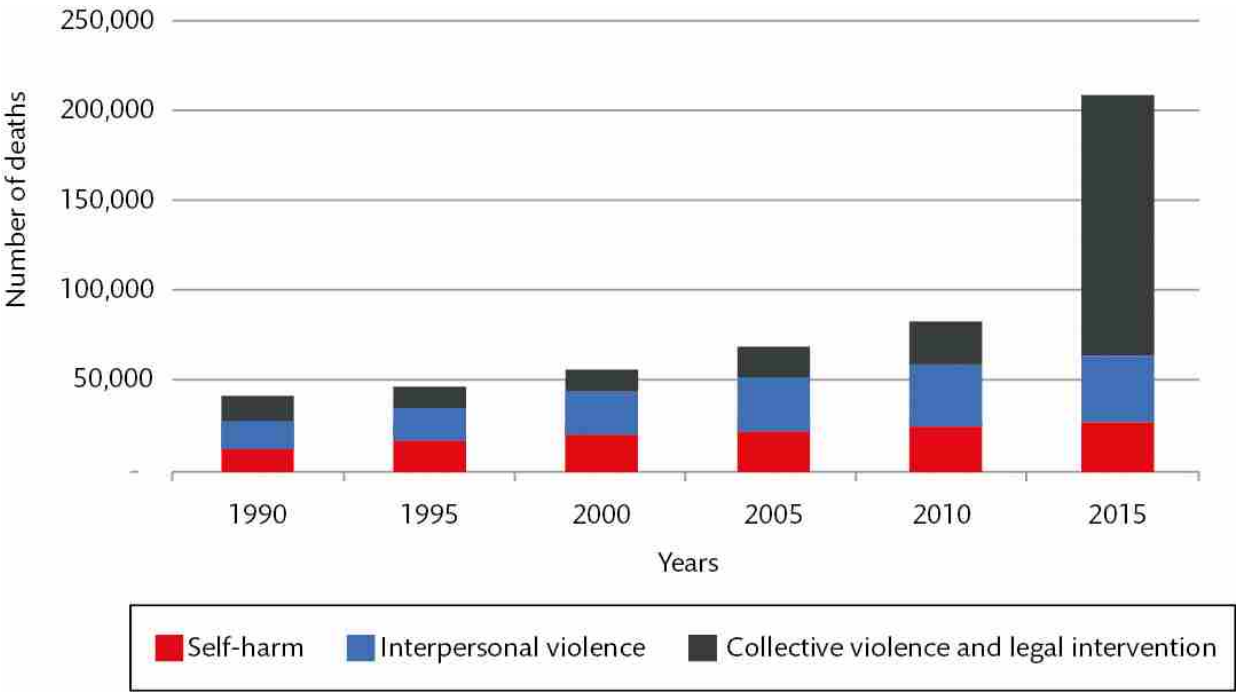

Fig. 11.11.3 Increased numbers of violent deaths MENA region, 1990–2015.
Reprinted from GBD 2015 Eastern Mediterranean Region Intentional Injuries Collaborators (2018) 'Intentional injuries in the Eastern Mediterranean Region, 1990–2015: findings from the Global Burden of Disease 2015 study'. *Int J Public Health*. 2018; 63(Suppl 1): 39–46, under a CC BY 4.0 license.

During this time, violence has become the number one cause of death for children 10 to 19 years old. Thus, the core causes of morbidity and mortality in this region are not easily fixed by non-state actors like humanitarian aid workers. Adding insult to injury, violence against aid workers has become more common and expectations of neutrality and safety for health workers and aid workers has diminished (Jackson 2012). Over 1,000 hospitals and clinics have been attacked during the war in Syria, a level of attacks out of step with historical norms (Briody et al.). On one day in July of 2016, the last four remaining hospitals in the besieged city of Aleppo were bombed, presumably by Russian aircraft (Al-Jazeera 2016a). No United Nations (UN) condemnation or International Criminal Court (ICC) action was taken, and no apology form the Russians was offered. This event, like the invasion of Iraq as a pre-emptive war or the rise of anti-immigrant sentiment across the globe, implies that the humanitarian community is living in an era of incivility that adds significant barriers to their work.

This period involving lower mortality crises means humanitarian assistance in the twenty-first century is less focused on the relatively easy to

treat killers of measles, ARI, diarrhoea, and malaria deaths. Today, aid is more often being provided to more people from middle income countries who want long-term support and have health priorities that involve addressing issues like violence, depression, and unemployment. The Oxford Dictionary defines ‘humanitarian’ as ‘Concerned with or seeking to promote human welfare’. Thus, addressing whatever the most acute needs of a population are is innately the mandate of the humanitarian endeavour. But, the UN, church groups, and non-governmental organizations (NGOs) who tend to lead major humanitarian efforts are innately better suited to preventing measles and malaria deaths than they are to addressing issues that require ongoing engagement and social change.

To summarize, the twenty-first century will be a challenging era for the humanitarian community. There are more people in need, not only for food, water, and medicine to stay alive, but who are also experiencing more complicated and difficult needs in a period of rising expectations. While this sounds difficult, this is in many ways the apex of civilization. The challenges are vast because the expectations of service and compassion are now projected to more than just those at risk of death. The challenges are difficult because we are now expected to operate in environments where aid workers are targeted and where host governments responsible for those at risk are often the source of that risk. The challenges are complex because depression and domestic violence and many of the relief priorities today are issues not easily solved even in the wealthiest of countries. This chapter will review where the humanitarian community has been and will lay out some of the new efforts for dealing with these challenges.

Introduction to emergency public health and humanitarian assistance: where we have been

During the Biafran War (1967–1970) perhaps half of the 2,000,000 population inside the shrinking breakaway enclave died of malnutrition and disease by the end of the conflict (Western 1972). During this crisis, profound advances in modern humanitarian relief arose. Unable to determine which children were starving and which children were just skinny or small, the Friends Overseas Service Committee triggered the development of the Quaker Upper Arm Circumference (QUAC) Stick, the first scheme for

assessing nutritional anthropometry. The Centers for Disease Control and Prevention (CDC) tested the universally accepted theory that malnourished children could not produce an immunological response to being vaccinated by using intervention and control groups. They vaccinated some very malnourished children and followed up weeks later by drawing blood from the study children to see if immunity had developed. In this first known controlled trial in an emergency, it turned out that malnourished children could indeed be effectively vaccinated (Ifekwunigwe et al. 1980). Other developments included the first known public health adaptation of capture-recapture methodologies from wildlife biology in order to estimate the number of deaths (and thus the first real-time conflict mortality measurement), the first guidelines for such things as running feeding centres, and the creation of the medical relief organization Médecins Sans Frontières (MSF).

In the crises that followed, more and more central insights into the science of keeping vulnerable people alive and healthy accumulated at an ever-increasing rate. The East Pakistan Crisis, by chance arising where an international diarrhoeal research centre was based, brought the advent of oral rehydration therapy (ORT) (Sack et al. 1970). Relief for Cambodians on the Thai border demonstrated the value of surveillance and rapid assessments (Glass et al. 1980). The famine and conflict in the Horn of Africa in the early 1980s provided the rationale for the caloric content of rations, a two-stage measles vaccination strategy for children less than 9 months, and a variety of other ‘best practices’ (Toole et al. 1988, 1989). By the 1990s, comprehensive outlines of priorities and best practices were in place based on the accumulation of these various lessons learned and documented (Toole 1990; CDC 1992; MSF 1997).

Most of these guidelines were developed based on experiences in settings of extreme poverty and high mortality, where the excess (above the normal) mortality profiles were dominated by infectious diseases, primarily diarrhoea, respiratory infections, and malaria. While acute respiratory infections are often the leading cause of death in emergencies, it is relatively difficult to prevent infections and emergency response efforts usually focus on getting effective medical treatment to cases. In contrast, the next three major killers in emergencies in decades past, namely malaria, measles, and diarrhoea, can all be prevented by interventions commonly provided as part of humanitarian relief efforts. Figure 11.11.4 next shows the global rate of

death from these three diseases from 1985 to 2015. Data are compiled from multiple sources (Rodolfo et al. 1993; Kosek et al. 2003; Boschi-Pinto et al. 2008; WHO n.d. 2011).

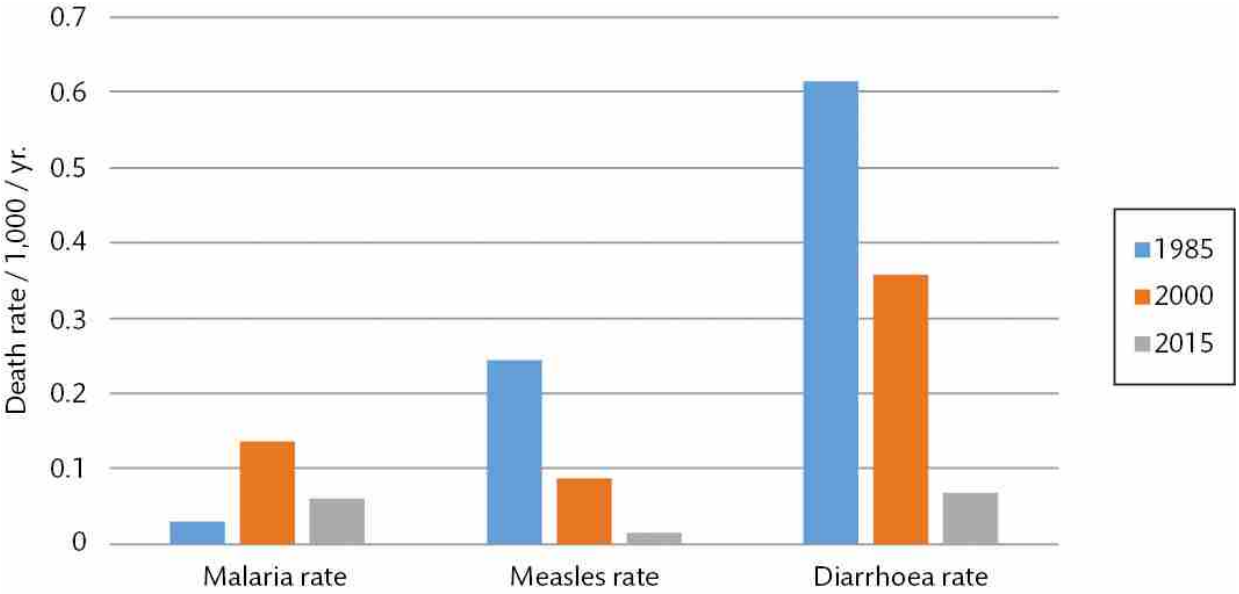

Fig. 11.11.4 Global death rates for malaria, measles, and diarrhoea.
Sources: data from (WHO n.d., 2011, Boschi-Pinto et al. 2008, Kosek et al., 2003, Rodolfo et al., 1993).

In assessing why these dramatic reductions occurred, it is hard to separate what influence the reduced fraction of the global population in poverty has had compared to focused programmes like measles vaccinations and oral rehydration solution (ORS) promotion or newly available technologies like long-lasting insecticide impregnated bednets. It is most likely that all these factors are at work and simultaneously interacting with other improvements such as higher rates of literacy and improving function of health related institutions. In emergencies, people tend to die of the same causes that they die of in stable times, just at a higher rate. Therefore, when compared to the Cold War era, the lower mortality widely seen today may be in part a reflection that our global population is less vulnerable to death in general. The Cold War era crises often continued for many years with large numbers of people displaced and supported in camps for a variety of geopolitical and economic reasons. Crowded camps are ideal environments for spreading

disease. Today, few of the world's displaced stay in camps further diminishing the emphasis on infectious disease control.

To summarize this overview of humanitarian relief evolution over the past half century, the world of humanitarian response today has little in common with the Biafran era. Today, most of the world's displaced have not crossed a border and are displaced within their own country. Many and perhaps most of the world's most vulnerable displaced persons are in urban settings. Finally, likely as a result of the developments of the relief community and greater global wealth, few crises in the twenty-first century to date have been associated with extended periods of high mortality, as were seen in Cambodia, Mozambique, Sudan, Somalia, Biafra, the Democratic Republic of Congo (DR Congo), and elsewhere in the last century. Rising international expectations of support have resulted in expanding humanitarian efforts focused more on issues of suffering, often from chronic or mental health-related disorders.

To address these new realities, this chapter will look at those areas where the twenty-first-century humanitarian endeavour is likely to differ dramatically from the twentieth century, including: preparedness and planning, changing institutional structures and architecture, the growing international attention of disease outbreaks, the evolving public health profile of emergency relief needs, and the role of new and innovative technologies. The roles of emergency planning and relief workers have grown, professionalized, and become politicized at a dramatic rate in recent years and we attempt here to create a framework for understanding these transitions.

Definitions and classification

There are few terms used more divergently in society today than the word 'humanitarian'. Merriam Webster defines humanitarian as: 'a person promoting human welfare and social reform, philanthropist—recognized as a great humanitarian for her work to end world hunger.' The Oxford Online Dictionary says: 'humanitarian (adjective) (1) Concerned with or seeking to promote human welfare. (2) Denoting an event or situation which causes or involves widespread human suffering, especially one which requires the large-scale provision of aid'. In this chapter, and with most humanitarian employers, humanitarian will signify seeking to promote human welfare

while adhering to the Red Cross Code of Conduct, a set of 10 rules designed to promote indiscriminate compassion, impartiality, neutrality, and accountability (ICRC n.d.).

There is currently no universally accepted definition of the term ‘disaster’. This lack of standardization can be attributed in part to the broad range of disciplines involved in disaster management. Nonetheless, common to most definitions is the concept of large-scale loss that exceeds a community’s own capacity to respond effectively, requiring some form of external assistance.

The United Nations International Strategy for Disaster Reduction (UNISDR) defines a disaster as ‘a serious disruption of the functioning of a community or a society involving widespread human, material, economic or environmental losses and impacts, which exceeds the ability of the affected community or society to cope using its own resources’ (UNISDR 2010). This definition is also one of several recognized by the World Health Organization (WHO).

Similarly, there is no standard classification system for disasters, although numerous have been proposed. Generally, disasters are associated with the hazards that cause them. They can be classified as either natural or human generated, with subclassifications of each. Natural disasters are often subclassified according to whether they are acute onset or slow/gradual onset, human-generated disasters as intentional or non-intentional. Generally there are not widely accepted definitions of these subclassifications. Moreover, military, political, and public health professionals have evolved to use words like emergency, disasters, and humanitarian with little functional criteria in common. Further undermining the utility of disaster classifications is the fact that often scholars from different disciplines understand the same crises in different ways. For example, while the 2011 Syrian war is largely painted as politically triggered over a short period by an Arab Spring uprising and a brutal government crackdown, Selby describes the conflict as a slow onset consequence of years of abnormally low rainfall creating migration and political instability (Al-Jazeera 2016b; Selby et al. 2017). Thus, we shall emphasize here epidemiologically based definitions and interpretations, as that will likely be the most useful approach for health professionals.

Epidemiology

The epidemiology of manmade crises (war and most famines) differ dramatically from natural and technological disasters, which aside from drought, tend to have a rapid onset. We shall refer to the latter as disasters and data about their occurrence and mortality effects are far better than with manmade crises. Earthquakes and tsunamis are the deadliest of natural disasters followed by extreme temperature events and floods.

According to the Centre for Research on the Epidemiology of Disasters, during the period from 1996 and 2015, on average approximately 600 natural and technological disasters occurred globally each year resulting in 67,000 annual fatalities (CRED 2017). Over these two decades, the number of annual events has gone up slightly while the annual death toll has not. The most severely affected region was Asia, followed by Africa and the Americas.

Those most vulnerable to the public health impacts of disasters are the poor. While 27% of disasters occurred in countries categorized as having low human development, they accounted for 47% of deaths, because of their limited capacities to mitigate, prepare for, and respond to disasters. Moreover, the economic costs run into billions of dollars and a single disaster can set back a nation's development many years with obvious implications for public health programming and health outcomes. A CDC report cites World Bank estimates that the 2014 Ebola outbreak in Sierra Leone cost the country $2.2 billion in lost gross domestic product (GDP) from 2014 to 2016, roughly a 20% drop (CDC 2016).

Globally, the most frequent types of disasters are transport accidents, followed by floods, windstorms, industrial accidents, earthquakes, and droughts/food insecurity (Table 1). Climate change is expected to affect the frequency and severity of floods, windstorms, and droughts, with their associated public health impacts (World Health Organization and World Meteorological Organization 2012). For example, severe droughts and associated food insecurity have occurred at more frequent intervals over the past decade in the Sahel and Horn of Africa. Monsoon-associated floods in Pakistan in 2010 and 2012 were among the most severe ever recorded.

Table 11.11.1 Frequency, impact, and geographic distribution of major types of disasters, 2006–2015

Disaster	Frequency per year	Average deaths per year	Average number of people affected	Average cost of damage (millions of dollars)	Region with highest frequency	Region with highest deaths
Droughts/food insecurity	24	2025	58,790,500	6,783	Africa	Africa
Earthquakes/tsunamis	25	35,709	8,500,100	47,103	Asia	Americas

While such events are usually recorded well and seen as non-controversial, natural disasters have long-term effects such as inducing migration or prolonged interruptions of public services and the actual health effects may be more complex in nature and go unrecorded. An extreme example of this arose when Hurricane Maria struck Puerto Rico in September 2017. Official government estimates placed the death toll at 64 deaths, a number repeated consistently by government officials in the months that followed (Shugarmen 2017). An examination of death certificates by the New York Times three months later placed the death toll at 2,000 and a population-based survey months later conservatively placed the death toll at about 4,600 (Kishore et al. 2018). This is the exception

rather than the rule as acute disasters like transport accidents and earthquakes typically cause trauma deaths over seconds or hours.

There is a growing body of evidence that climate change is interacting with a variety of factors to make populations more vulnerable. Thus it is difficult to distinguish which deaths are associated with climate change, overpopulation, or simply associated with natural disasters. Weather extremes and climate changes interact with other important global trends that threaten to increase the frequency and impact of disasters. Increasing urbanization, poor urban planning, poor land use, unregulated industrialization, new and emerging infectious diseases, and terrorism all have the potential to expose greater numbers of people to hazards (United Nations International Strategy for Disaster Reduction 2010; WHO 2011a; Bhui et al. 2012). The Christchurch earthquake of 2011, Bangkok floods of 2011, and Superstorm Sandy in New York City in 2012 all demonstrated that disasters striking densely populated urban areas have the potential for substantial public health and economic impact. The Nigeria floods of 2012 and on the Indian Subcontinent in 2017 that forced millions from their homes have brought attention to the issues of poor urban planning and settlements in flood-prone zones. The severe acute respiratory syndrome epidemic of 2003 and the H1N1 pandemic of 2009 have demonstrated the need for stronger public health surveillance and response mechanisms. Terrorist attacks across a range of countries have revealed security threats that need to be addressed in disaster planning and mass casualty response plans (WHO 2007). In spite of these complicating factors, because deaths tolls from disasters tend to be collected consistently, evidence suggests that since the 1920s there has been over an 80% reduction in the annual deaths from natural disasters (Richie et al. n.d.). Over this past century, deaths from droughts have dramatically declined while earthquakes have evolved to become the dominant cause of natural disaster deaths. Thus, the relatively consistent documentation of disaster death tolls has recorded the beneficial effects of the world's efforts to attenuate drought and famine effects.

In contrast, the impacts of armed conflicts are far more difficult to quantify. The World Bank estimated that 1.5 billion people live in countries affected by repeated cycles of political and criminal violence, and fragility (World Bank 2011). Most modern-day conflicts are protracted civil wars, in which civilians are often deliberately targeted and frequently displaced from

their communities. Often called ‘complex emergencies’, they are associated with high rates of morbidity and mortality.

In such conflicts, large numbers of deaths can result from violent injury, as in the Rwandan genocide, the Balkan conflicts of the 1990s, and the recent war in Syria. But in many instances, most deaths are due to the so-called indirect health consequences of conflict—increased rates of infectious diseases, acute malnutrition, and complications of chronic diseases that arise due to societal disruption, population displacement, and breakdown in health services. This has been well described in crises in DR Congo, Ethiopia, Somalia, and Sudan (Toole 1997; Coghlan et al. 2006).

The number of ongoing conflicts can be difficult to quantify, as definitions vary. The Uppsala Conflict Database defines a conflict as a ‘contested incompatibility that concerns government or territory or both where the use of armed force between two parties results in at least 25 battle-related deaths in a year. Of these two parties, at least one has to be the government of a state’. Based on this definition there were 52 ongoing conflicts in 2016, of which 2/3rds were intrastate or civil wars (Uppsala Conflict Data Program n.d.). Since the Second World War, there has been a strong tendency for conflicts to become longer in duration and less intense in terms of rates of violence (Garfield et al. 2012). Passive efforts to monitor conflicts are almost always incomplete but tend to be more incomplete in the least socially networked countries. For example, a survey from MSF found that at least 9,400 Rohingya died over a one-month period of ethnic cleansing from August to September 2017 in Myanmar (MSF 2018). Virtually none of those deaths were recorded in the news of by social media. In contrast, five civil society groups in Syria are believed to have recorded the vast majority of violent deaths in that conflict (Price et al. 2014).

Perhaps the most robust and standardized of systems for monitoring deaths from conflict is the previously mentioned Uppsala Conflict Database which attempts to evaluate press, relief agency, and expert opinion to make annual death toll estimates (see ucdp.uu.se). Population-based estimates based on surveys or multiple systems estimations have shown the Uppsala system to be relatively complete in highly networked countries (Our World Data 2017). For example, the Human Rights Data Analysis Group (HRDAG) estimate suggests that the system is 60% complete in Syria (Price et al. 2014 vs. UNDP 2010). Likewise, looking at Algeria from 1997 to 2016 suggests that UCDP is 100% sensitive when compared to the Armed

Conflict Location and Event Data Project (ACLED) Excel database. In contrast, a 2011 comparison of death toll in South Sudan with the exact same ACLED database suggests a sensitivity of only 35%. In the violent and moderately connected setting of Iraq 2003–2010, a comparison of the conflict related deaths recorded in a household survey suggested the Uppsala data set was 12–17% complete (Burnham et al. 2006; Hagopian et al. 2013 vs. UCDP 2010). Further, surveys in CAR in 2009 suggest the UCDP was less than 2% complete there (Vinck and Pham 2011). This suggests that our global data and understanding of deaths from wars is likely of lower quality than our understanding of deaths from natural disasters.

Garfield looked at both the major natural and manmade disasters from 2002 to 2006 (Garfield 2007) and found that while natural disasters tended to affect far more people, conflicts tended to kill far more people. These results are presented in Figure 11.11.5, next.

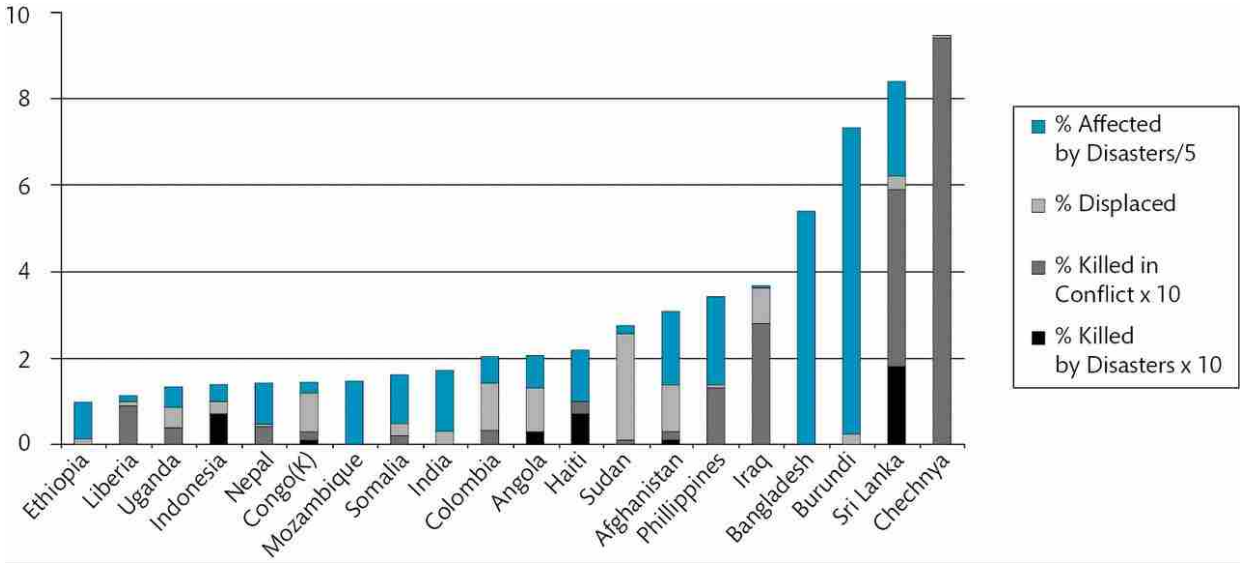

Fig. 11.11.5 Relative measures of populations affected and killed in major emergencies 2002–2006. Reprinted from Garfield R (2007) 'Measuring Humanitarian Emergencies' *Disaster Medicine and Public Health Preparedness* 1(2):110–116, with permission from Cambridge University Press.

In terms of the demands on local societies and the humanitarian community, elevations in mortality rates can persist for years after the formal end of conflict, as documented in Angola, DR Congo, and South Sudan. An important aspect of crises that can expose the affected populations to

increased public health risks is forced displacement. The United Nations Development Program (UNDP) has developed a Human Development Index, in an attempt to articulate how well a society is doing. The index is a composite of life expectancy at birth, an education index, and income. According to the Human Development Index for 2016, nine of the 10 least developed countries on the planet experienced significant levels of armed conflict in recent years. The only one of these countries that has not experienced major conflict, Guinea, is surrounded by conflict-affected countries. Similarly, of the ten countries with the highest maternal mortality, nine have recently endured conflict. According to the World Bank, no low-income fragile or conflict-affected country achieved even one of the eight Millennium Development Goals—three of which are health related.

The process of displacement can increase the risk of infectious diseases (e.g. through housing in unsanitary conditions or exposure to disease-carrying vectors), food scarcity and malnutrition, physical violence, sexual abuse, and psychological trauma. Thus, the disruption associated with crises usually disproportionately affects the health and survival of small children. Access to health services is often limited and ongoing health programmes (e.g. vaccinations) disrupted. Higher disease rates are often documented among internally displaced persons (IDPs), as the well-developed mechanisms to provide protection and humanitarian assistance to refugees do not always apply directly in IDP settings (Salama et al. 2001).

Thus, our knowledge and use of data is rather contrasting between disasters and conflicts. Wars induce far more deaths, and often involve protracted periods of crisis where outside support can be essential for averting deaths. Disasters, in contrast, affect far more people, and tend of create crises of shorter duration. Disaster related epidemiological data is most useful for making preventative plans and policies. This last concept leads us to the topic of disaster planning.

Preparing and planning for disasters

Following the 2010 earthquake in Haiti, the Centre for Research on the Epidemiology of Disasters (CRED) produced an assessment contrasting the previous 10 natural disaster events that struck the island of Hispaniola. Of note, the two countries that comprise this island each had similar populations

of approximately 10 million people. Table 11.11.2 next shows the number of deaths and affected people per event in each country.

Table 11.11.2 Contrast in death rates between the same storms hitting the Haiti and Dominican Republic

Date	Event	Haiti deaths	Haiti affected	DR deaths	DR affected
Sept. 2008	Hurricane Hanna	529	48,000	1	10,745
Aug. 2008	Hurricane Gustav	85	73,006	8	6,257
Aug. 2008	Trop. Storm Fey	10	220	4	20
Dec. 2007	Trop. Storm Olga	3	2,090	33	61,605
Oct. 2007	Trop. Storm Noel	90	108,763	129	79,728
Aug. 2007	Hurricane Storm Dean	9	3,966	1	1,600
May 2007	Flood	2	12,500	9	16,000
March 2007	Flood	14	15.014	3	3,830
Oct. 2005	Trop. Storm Alpha	12	2,192	9	1,000
Sept. 2004	Hurricane Jean	2,754	315,594	11	14,009
Totals		3,508	581,345	208	194,794

Source: data from CRED 2010.

What is striking is that 10 storms hitting the same island by chance affected 2.5 times as many people in Haiti but induced 17 times more deaths in Haiti. There are likely many factors such as crowding and deforestation that work against the safety of the less wealthy Haitian population. But some factors, like construction quality, zoning codes and compliance, and government response plans also likely influenced the sevenfold risk of mortality associated with these storms for residents in Haiti.

Preparing for disasters—health emergency risk management

The most effective means of reducing the public health risks and impacts of disasters is to employ a comprehensive emergency risk management approach. Emergency risk management (ERM) consists of a continuum of synergistic steps that can reduce the risks and consequences of disasters, including prevention (risk reduction and mitigation), preparedness, response, and recovery. These steps are so closely interconnected that for all practical purposes they should not be considered in isolation from each other. Risk assessments and risk reduction activities directly inform disaster preparedness and response, for example. Moreover, the manner by which agencies respond to an emergency will directly impact the recovery process (WHO 2011b).

ERM for health draws on the disciplines of risk management, disaster management, and health systems. The approach emphasizes managing the risks prior to a disaster occurring so that potential public health consequences may be prevented or minimized. Specifically, ERM entails identifying and reducing hazards and associated vulnerabilities, preparing for and responding effectively to disasters, and recovering, rehabilitating, and reconstructing after a disaster has occurred. Experience has demonstrated that countries and communities that have invested sufficient resources in ERM have responded more effectively and have been more resilient to the effects of disasters. Strengthened ERM also has the potential to contribute to sustainable development.

Bangladesh is one of the most natural disaster-prone countries on the planet. Large numbers of people live on a low, flat alluvial delta vulnerable to floodwater coming from the Brahmaputra basin to the north and the typhoon-prone Indian Ocean to the south. A typhoon in 1970 resulted in approximately a quarter of a million deaths (Bern et al. 1993). Over the next decades, the people of Bangladesh built 311 elevated typhoon and flood shelters that could hold 350,000 people and implemented community-based response strategies. A similar 1991 typhoon affecting a far larger population resulted in 138,000 deaths (Mallick et al. 2005). During the 1991 storm, seeking a storm shelter early and being in an official shelter were highly protective against death although only 17% of the affected populations sought shelter in response to the storm warning sirens. Since then, advances in storm warning, public communications and community response have resulted in Southern Bangladesh being held up as an example of disaster preparedness (UNDP 2010).

Guiding principles

In addition to the emphasis on managing risks, ERM is guided by the following key principles (Brennan et al. 2009):

Addressing all hazards. Many of the key functions required to manage risks are common across all hazards, for example, assessments, communications, logistics, etc. Moreover, it is neither efficient nor cost-effective to develop separate plans, procedures, trainings, rosters, and response mechanisms for each individual hazard. While some hazard-specific considerations will rarely be required (e.g. radio-nuclear), an all-hazards approach allows for more efficient management of risks and responses.
Multisectoral approach. Many activities required to protect and preserve health are managed primarily by non-health sectors, for example, water and sanitation, shelter, food security, law and order, etc. Effective mechanisms for multisectoral collaboration and coordination are therefore necessary to ensure optimized ERM in the health sector. These should be established at national and local levels, wherever possible.
Prepared community. Communities are always the first to respond to disasters and can play a critical role in meeting emergent health needs. Community resilience can be strengthened by building their capacity to prevent, mitigate, prepare for, respond to, and recover from disasters. Local governments, civil society organizations, and individual citizens all have the potential of contributing to ERM.

Key components of emergency risk management

Prevention, risk reduction, and mitigation come first.

Table 11.11.2 regarding the impact of the 10 storms on the Dominican Republic vs. Haiti highlights the value of robust building zoning codes, urban planning, flood plain buffer zones, utility repair plans, evacuation plans, pre-recorded radio messages, and all of those things that prevent people from risk exposure which are planned years and months ahead of any disaster. The highest priority of disaster planning should be to keep people and potentially harmful exposures apart. While that statement is very broad (including evacuation orders and do not travel orders and hazardous waste

regulations), it needs to be kept in the forefront of the disaster planner's priorities.

Disaster risk assessments are the lens through which prevention and risk reduction can happen.

In 1993, a truck bomb was exploded in the parking lot under the World Trade Center killing 6 and injuring over 1,000 people (Lambert n.d.). In the aftermath of this explosion, electricity went out and smoke filled the vertical structure. With the electricity out, the elevators did not work. Because the stairwells had no windows and were dark and filled with smoke, it took many hours for people to go down those stairwells in the dark. The CDC sent a team to assess what had gone right and wrong during the event and the team's top recommendation was that battery powered lights be placed in the stairwells in case the power was ever cut off again. In 2001 when the World Trade Center was struck by two airliners 8 years later, thousands and thousands of people were likely saved because those lights were in those stairwells in the minutes after the electricity went out and before the buildings collapsed. This is a particularly dramatic example of the value of a disaster risk assessment.

Ideally, a disaster risk assessment should be multisectorial, multidisciplinary, and attempt to identify risks in advance to develop clear strategies to manage them (International Federation of the Red Cross 2006). The health component of a multisectoral risk assessment aims to determine the likelihood and potential public health impact of future disasters. Possible health consequences include direct impacts on people (e.g. injury, disease) or health facilities, and/or secondary effects due to damaged infrastructure (e.g. water and sanitation systems), population displacement, environmental damage, etc.

A coastal community will have greater vulnerabilities to hurricanes than communities located at a distance from the shoreline. A community on a steep hillside will have different earthquake risks than a nearby village on the flat valley bottomland. Thus, the most important lessons and ideas that will help shape a community's preparation for a disaster will often come from locals and will need to vary from place to place. The task of a disaster planner is to separate out those lessons that are universal (e.g. never drive a car into moving floodwaters, always assume electrical lines are 'hot' even if the electricity has stopped working) and those that are site-specific (e.g. when a tornado comes, go to the church basement).

Strategies and programmes should be based on evidence and endorsed or formed on the level of the implementers.

Disaster risk assessments, based on assessing past disasters, inspecting the environment, and speaking with key partners should be used to develop strategies and programmes to reduce the potential impact on public health by the identified hazards. These may include general health system strengthening measures to improve the coverage and effectiveness of existing health services (e.g. vaccinations, training and supervision of staff, improved drug management). They may also include specific health sector interventions that can mitigate the effects of disasters, such as the successful safe hospital programme in Latin America (Pan American Health Organization 2000, 2002) and early warning alert and response systems for outbreak control. In some places, radio messages or alarms are important to establish. In some situations such as the recent Latin American Zika outbreak, focusing support and efforts to key groups like health workers and pregnant women, may be appropriate. Once a strategy or programme is established, drills or simulations can be an invaluable tool to understand what parts of the response procedure are not working optimally.

Get prepared. The UNISDR definition of preparedness is 'the knowledge and capacities developed by governments, professional response and recovery organizations, communities, and individuals to effectively anticipate, respond to, and recover from, the impacts of likely, imminent or current hazard events or conditions' (UNISDR 2009). Many emergency organizations also use the related term 'readiness' to describe their ability to rapidly and appropriately respond to a disaster. In those cases where emergencies are likely to be predicted or recur (e.g. hurricanes, floods, wildfires), preparedness plans need to be in places on the household level, as well as on the local governance and national levels.

Sound preparedness clearly arises from an effective risk assessment and is linked to early warning systems. It should ensure the required resources and capacities can be rapidly deployed following the onset of a disaster. Clear emergency functions should be specified in advance and rosters of qualified and experienced staff developed. Stockpiles of essential drugs, equipment, and supplies should be established and maintained, including strong logistics procedures. All emergency staff should be trained in the relevant technical standards, performance standards, and response procedures (Sphere Project 2011). Standard operating procedures should address key administrative,

financial, procurement, and communications functions. Coordination mechanisms should be developed in advance, both for improved health sector and intersectoral functioning. Contingency planning may take into account possible scenarios and triggers for response, and further strengthen coordination.

Response is what gets noticed. When Ebola struck in DRC in 2018, WHO was more than 100 times more responsive than they had been during the 2013–2015 outbreak in West Africa in terms of person days delay in responding. WHO had prepared staff, a vaccine had been developed that was utilized in the field within a month of initial reports, and they had protective clothing and materials in stock. It is not by chance that WHO received scathing reviews for years after the 2013 outbreak and almost exclusively good press in 2018. This, in spite of the fact that over both periods responding to Ebola was likely much less than 10% of all that WHO was doing. This is nearly universal: governments and agencies are publicly evaluated on their response to crises more than for the crises they averted or non-emergency related good they do.

This implies that the things needed to respond (knowledge, messages, materials, and people) need to be in place long before a crisis hits. Having preparedness plans, documented operating procedures, a flexible emergency funding strategy, and a rooster of workers are all tasks best achieved far in advance of a crisis, but will usually be what most influences the quality of response.

Recovery is often neglected. Many organizations adhere to the so-called build back better approach. Recovery programmes are increasingly informed by post-disaster needs assessments (PDNA), which provide a measure of loss within each sector and a prioritized plan for recovery and reconstruction (World Bank Global Facility for Disaster Reduction and Recovery 2011). In reality, emergency responders are poorly suited to doing this and local players often do not have the resources. Most emergency funding lasts for months or a year at the longest and reconstruction rarely happens so quickly. While this is widely known and agencies and offices have attempted to address the void between emergency response and reconstruction, this remains a very problematic issue.

In 1993, the US government created a funding office to fill the void between emergency response and development called the Office of Transition Initiatives (OTI). Critics have pointed out how this institution has

done little to end the dropping of health supporting programmes when an acute crisis has passed. In the case of OTI, critics point out how it seems to spend much of its funding on civil society activities like democracy building (Blum 2013). For example, Wikileaks reported that in a 2006 cable, then-Ambassador William Brownfield, outlined a strategy to 'penetrating Chavez's political base', 'dividing Chavismo', 'protecting vital US business', and 'isolating Chavez internationally' and OTI funding was a central part of this (Hart 2013). While this example is from the US, many other countries have interwoven political and humanitarian agendas and it is inevitable that ambassadors and funders will not be able to operate with the humanitarian tenants of impartiality and neutrality. Thus, when recovery and developments get together for a 'Do Development Differently' conference, they conclude that locals are not sufficiently engaged and empowered and that true recovery is often neglected (DDD n.d.). When the UN held a Humanitarian Summit in Istanbul in 2016, they conclude that locals are not sufficiently engaged and empowered and recovery is underfunded or neglected (Agenda for Humanity 2016). Thus, in spite of widespread understanding of the problem and good intent, for the foreseeable future there will be a tendency to provide funding when a crisis is underway; but, in the poorest of settings, for competing priorities to shift the focus from rebuilding post-crisis.

Coordination of response

The coordination of responses occurs by a wide variety of mechanisms that vary widely. There is a tendency for natural disasters to be coordinated by a national emergency response mechanism. Sometimes this coordination is housed in the military, sometimes it is a permanent cabinet level office like in the UK and Japan, and sometimes it is a self-standing office like in Peru and Ghana. In such settings, assistance from abroad is typically coordinated by that entity. In some cases, the coordination structures can evolve or be complex. For example, during the 2014 Ebola outbreak in Sierra Leone, initially, the Ministry of Health directed the focus of response efforts through a National Ebola Response Committee (NERC) which met daily and coordinated most overseas assistance with the WHO. After 3 months, the military took over the national Coordination and the NERC, but the Ministry

of Health continued coordinating the foreign assistance (LR personal observation).

In complex emergencies and including wars, it is often difficult for the host government to play a coordinating role either because it is overstretched or weak, or because humanitarian actors are wedded to their concept of neutrality and are reluctant to cooperate with a warring party. In such settings the UN Cluster System is often established. Figure 11.11.6 is a visual display of this system.

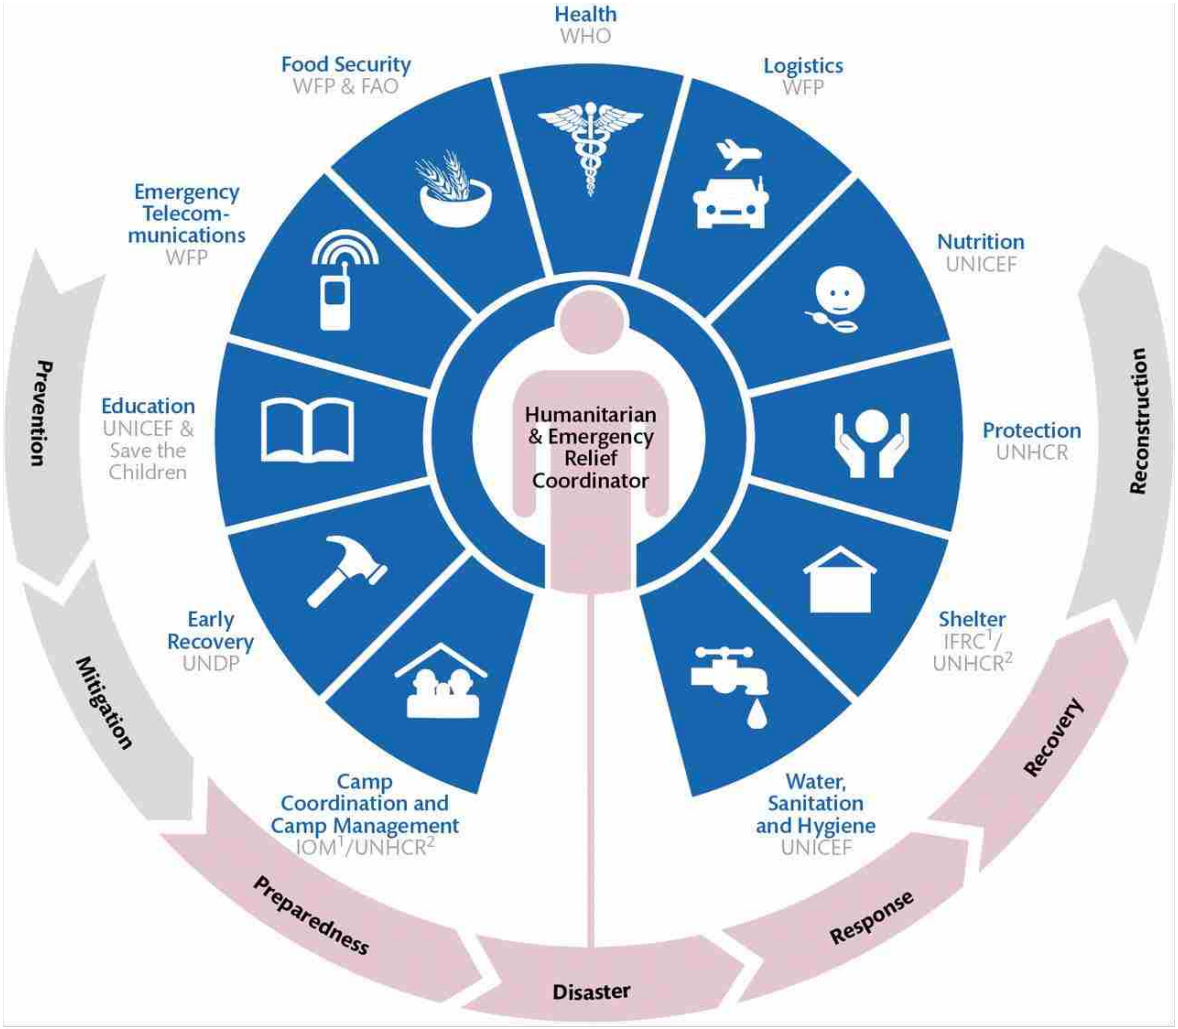

Fig. 11.11.6 UNOCHA depiction of the Cluster System.
Reprinted under a Creative Commons Attribution 4.0 license.

The Cluster System is typically coordinated by the United Nations Office for Coordination of Humanitarian Affairs (UNOCHA n.d.) and operates as a constellation of coordinating bodies. There are 11 sectors that each have a coordination lead, usually a UN agency that attempts to share information, resources and optimize the distribution of assets. In some settings where needed, there are subclusters that attempt to coordinate for a subset of a sector's activities. Typically, members of the humanitarian community gather for regular meetings, often with government agencies present. For a variety of reasons, some humanitarian actors such as MSF tend not to formally participate in Cluster processes. In 2018, 27 countries have 'Health Clusters' operating all led by the WHO. While the success of these clusters is widely debated, they are almost certainly going to be a mainstay of humanitarian coordination for the foreseeable future

Public health needs

Oxygen, water, and food remain the essential priority human needs in almost all settings including the most acute of hardships. The initial handbooks overviewing the public health priorities in high-mortality, low-resource settings remain as relevant today as when they were written (CDC 1992; MSF 1997). Most were lacking in some areas now better appreciated, with obstetric care being perhaps the most dramatic example. Usually those handbooks defined an emergency in terms of a doubling or quadrupling of the baseline mortality rate. In settings of extreme hardship, those displaced and whose livelihoods and social order are disrupted will generally continue to die and suffer from the same ailments they experienced before the crisis but at a higher rate. In some categories of disasters such as natural disasters like earthquakes and floods, death profiles are briefly but dramatically altered but prolonged elevated mortality as seen in the 2017 Puerto Rico example earlier is rare. Thus, in the most typical disruption and displacement scenarios, acute respiratory infections, diarrhoea, and in some places malaria, dominate the prevention and treatment priorities. Yet, these kinds of crises, with mortality rates elevated fourfold or more, are accounting for a smaller and smaller fraction of all humanitarian aid.

Most aid workers today can work an entire lifetime and never see the dramatically elevated mortality of ten or 20 times the baseline rates seen repeatedly in the 1960s through the Rwandan Crisis of 1994. For example, if

we use the threshold of 2% of the population dying each month (ten times the highest of baselines) in a population over 100,000 people to define a humanitarian catastrophe, a review of both published and unpublished mortality reports suggests that from 1979 to 1994, as shown in Figure 11.11.1, there was such a catastrophe on average every 2 years, but none have been reported since that time (Roberts 2013). The camp-based relief setting has also become rare, forcing relief agencies to work in cities and with existing government institutions.

This change away from relief typified by water and food delivery and life-saving primary healthcare approaches is being driven by four forces: the global transition from a disease burden profile typified by acute infectious illness to one dominated by chronic diseases, more aid funding and a downward trend in conflict inducing a lower threshold of what is considered a humanitarian crisis, changing motivations, and the rise of the rights-based framework within humanitarian relief.

Transition from acute infectious diseases to chronic conditions

In recent years, international health crises like the 2013–2016 West Africa Ebola outbreak and the 2015–2016 Zika epidemic have dominated the headlines. In both of these events, the WHO declared a ‘public health emergency of international concern’ to mobilize international support and governments and NGOs led a global response to increase preparedness and funding for these diseases that seemed to threaten global health security.

Yet despite the outsized media coverage and financial contributions to combat them, outbreaks of acute infectious diseases are now responsible for a small proportion of global deaths. Lopez et al. have documented how globally, between 1990 and 2005 the human species transitioned from experiencing disability-adjusted life years (DALYs) lost primarily to infectious diseases to losing DALYs primarily from chronic and non-infectious causes (Lopez et al. 2006). In fact, globally more people will die in the next 3 hours from NCDs than the total number who died from Ebola in the 3-year-long West Africa epidemic (WHO 2018). Yet despite the fact that NCDs are responsible for 60% of all DALYs and 70% of all deaths, they currently receive only 2% of overseas development assistance for health (Allen 2017).

The epidemiological transition occurring in developing countries from infectious diseases to non-communicable diseases as a greater contributor to mortality has been well documented. For example, Lopez et al. contrast the causes of death among adults in various regions based on 1990 and 2001 data respectively (Lopez et al. 2006). Over those 11 years, the non-HIV infectious disease adult death rates declined markedly in Latin America and the Caribbean, the Middle East and North Africa, East Asia and the Pacific, and South Asia. In each locality, this reduction in infectious disease death rates corresponded with lower overall adult mortality. Only in the post-Soviet Europe and Central Asia region and Africa did adult mortality rise over this period; in the former, primarily from cardiovascular diseases and unintentional injuries, and in Africa primarily from HIV. In Africa, overall mortality still decreased over this period because of dramatic reductions in infant and child mortality.

The impact of this epidemiological transition was evident in crises in Bosnia, Kosovo, and Iraq, where Ministries of Health and aid agencies were confronted with morbidity profiles dominated by non-infectious diseases. More recently, the high prevalence of NCDs in Syrians displaced by the ongoing civil war has challenged aid groups and health systems in neighbouring countries. Prior to the Syrian civil war, a 2007 survey found that cardiovascular disease was responsible for 45% of overall mortality in Aleppo, and a situational analysis conducted by the WHO Eastern Mediterranean Regional Office (EMRO) demonstrated that 79% of mortality among Syrians nationally was related to NCDs (Gardemann 2002; Rahim 2014). Providing NCD care for the millions displaced by the conflict has been complicated by the difficulties in humanitarian relief coordination within Syria and by the lack of access to primary healthcare in neighbouring countries where many Syrians have sought refuge.

The growing prevalence of non-communicable diseases in humanitarian settings highlights the disconnect between the health needs of those impacted by crisis and a humanitarian system that has been built to respond to crises characterized by high-mortality from communicable diseases.

Adding to this need to transition medical preparedness for emergencies is the growing appreciation of HIV as a non-fatal chronic condition. An estimated 10.3 million Africans regularly received antiretroviral drugs (ARVs) in 2015, double that of 2011, covering 54% of the total number of Africans who are HIV positive 2011 (WHO et al. 2011; WHO 2016). As a

disproportionate number of humanitarian operations occur in Africa, planning for the chronic disease support aspects of HIV needs to be part of the humanitarian public health portfolio (O'Brien et al. 2010).

The future success of the humanitarian community will depend in part on how well it can develop the capacity to provide quality care for NCDs in humanitarian crises while simultaneously maintaining the ability to respond to outbreaks of acute infectious diseases that will undoubtedly continue to plague our increasingly connected world.

More aid, more in need, and longer armed conflicts

Spending on humanitarian assistance has increased dramatically in recent decades. According to Global Humanitarian Assistance, formal humanitarian assistance spending increased fourfold from 1990 to 2010 (United Nations Children's Fund 2013). Unfortunately, however, more aid is being taken up by the increasing numbers of people displaced by conflict, requiring relief after natural disasters, and to a lesser extent, technological disasters such as the Fukushima nuclear meltdown in 2011. This has the effect of lowering the mortality prioritization with regard to what is considered a humanitarian crisis. It also means since much humanitarian spending is in post-conflict settings, that humanitarian assistance is now inseparable from development work.

At the same time, there was a downward trend in the number of armed conflicts in the world since the end of the Cold War, although this number has been on the rise since 2013, driven largely by ongoing conflict in the Middle East (Gleditsch et al. 2002; PRIO 2017). Although many of the ongoing conflicts are internalized within a state, a growing proportion are internationalized indicating the involvement of external states, which is significant because internationalized conflicts tend to last longer and more difficult to resolve (PRIO 2017). Further complicating the issue, conflict has become more protracted with the average conflict increasing from 19 years in 1990 to 37 years in 2013. Garfield et al. documented how the number of people living in conflict has increased over the past half century but a smaller and smaller portion of those people are in high-intensity conflict settings (Garfield 2012). With prolonged conflicts taking place in multiple geographic regions, the international community faces serious challenges.

Changing motivations and the rights-based framework

Aid meant to induce development may be different in nature from humanitarian aid designed to prevent deaths and suffering in the short term. Donors are continuing to place increasing emphasis on sustainability of humanitarian interventions and demanding local participation and empowerment. These are natural changes in perspective that match a transition from death aversion to priorities involving improved quality of life. A few NGOs such as MSF maintain a philosophy that they work primarily to reduce death and suffering but most others now hold long-term impact and sustainability as central objectives. This creates several new conditions for relief work. Many relief efforts in the 1980s and 1990s defined success by the lowering of the crude mortality rate (CDC 1992). This is rare today. Sustainability efforts usually require training and supporting local officials and institutions, committing to multiyear engagements, and monitoring changes in behaviours. These require different skills from those prevalent in relief agencies in the twentieth century. Reconstruction activities following earthquakes and tsunamis often employ many times more construction and economic experts than health professionals and epidemiologists.

In tandem with this shift in focus from just averting deaths, has been the rise of a rights-based approach to programming. The United Nations Children's Fund (UNICEF) defines a human rights-based approach as ‘a conceptual framework for the process of human development that is normatively based on international human rights standards and operationally directed to promoting and protecting human rights’ (UNICEF 2013). This framework, while not fundamentally contradictory, is very different in focus and in programme implications from the ‘public health’ approach of the last century’s relief operations (CDC 1992; MSF 1997). This public health approach, sometimes called a cost-effectiveness approach, concentrated on how the relief community could reduce the most deaths and suffering with the assets available. This manifested in specific interventions like measles immunization, latrine construction, or primary healthcare clinics which brought broader benefits at low costs.

The rights-based approach has the advantage that it more readily encompasses issues like psychological suffering which are harder to measure, and can project values such as that girls should have equal chances for advancement as boys. But the term ‘normatively based’ in the UNICEF

definition is not well defined or constant. For example, UN resolutions or agency position statements often stress the need to have child re-unification programmes where benefit is difficult to demonstrate (Ager and Metzler 2012). In the public health approach the benefits and the cost-effectiveness of programmes are more readily established, and new ideas can be compared with established programmes. Rights-based programming, in contrast, has no equivalent incentive to demonstrate cost-effectiveness and in fact is more driven by the strength of resolutions or declarations. Thus, if one wants to advocate for the value of counselling rape victims, in a rights-based framework it would be more efficient to attempt to pass a UN resolution than to evaluate the effectiveness of programmes in the field. With the public health approach, the opposite would be true.

In summary, humanitarian public health needs have broadened as the clientele served has begun to span a broader range of development levels, as the need to support people with chronic conditions including HIV has become more important. This may be an indication that the humanitarian endeavour has worked over the past half century. A Biafra-like scenario, where half the population died in a 4-year period, is rare today. Thus, the world's growing sources of compassion and aid can serve more than just those on the verge of death.

New developments for the twenty-first century

A host of new developments make it likely that relief work in the middle of the twenty-first century will look little like efforts in Biafra and South East Asia the century before. The advances of the past decades that will likely expand in the future can be considered in three broad categories: political trends, new approaches, and new technical advances. These categories interact with and influence each other, with technical advances often creating the potential for new orderings of social organization. While not comprehensive, this section seeks to imagine the likely changes to come in the field of humanitarian response.

Political trends

The melding of political and humanitarian agendas

National governmental political agendas and humanitarian relief have never been completely independent. In 1919, the US Congress formed the American Relief Administration (ARA), supposedly an independent NGO-like entity, headed by future President Herbert Hoover, to act as an independent famine relief mechanism in Europe in the years following the First World War (Fisher 1927). Oxfam, among the most famous of NGOs for its politically neutral funding sources, was formed in large part to lobby the British government to loosen the Allied blockade of occupied Europe (Oxfam n.d.). MSF co-founder Bernard Kouchner later became the French Minister of Humanitarian Affairs and the Foreign Minister, allotting funding for his creation, MSF. That humanitarian and political interests overlap is not completely unhealthy if in a democracy the populace is privately choosing to fund humanitarian ventures while simultaneously influencing the priorities of their government to do the same. On the other hand, countries are often in open competition with each other, and the linking of aid to enhance economic, military, or political competitiveness would be antithetical to the humanitarian endeavour. Two documents have attempted to keep humanitarian aid 'neutral' in the eyes of combatants and beneficiaries over the last part of the twentieth century.

Both the Third Geneva Convention of 1949 and the Red Cross Code of Conduct, to which most NGOs and the UN aspire to adhere, actively encourage the separation of humanitarian endeavours and self-interested agendas of individual states. The fourth tenet of the non-binding Red Cross Code of Conduct explicitly states, 'We shall endeavour not to act as instruments of government foreign policy' (International Federation of Red Cross and Red Crescent Societies n.d.). The ICRC and MSF are particularly famous for keeping political and military forces at arm's length even during the acute phases of crises. For example, during the 1992 crisis when Kurds fled northern Iraq but were not allowed into Turkey, MSF refused to move in public or cooperate with any military personnel carrying a weapon. Many military personnel, including the British and American forces who had just invaded Iraq and were thus belligerents in this conflict, operated within the displaced community without weapons so as to work with MSF and other NGO personnel. Thus, until 2001, while funding influenced where relief went and what kinds of relief efforts were funded, an honest effort was made on the part of most donors and most international NGOs to not undertake patently political activities to advance the agenda of one country.

Nonetheless, a remarkable change in the landscape of humanitarian assistance has been the melding of political and humanitarian agendas after the terrorist attacks on New York City on 11 September 2001. Beginning with the invasion of Afghanistan, this narrowing separation of political and humanitarian ventures was often ignored or blurred. In October 2001, US Secretary of State Colin Powell addressed leaders of the American NGO community referring to their organizations as 'force multipliers' (International Federation of Red Cross and Red Crescent Societies n.d.). In Afghanistan, US humanitarian aid was openly discussed as a military tool for winning hearts and minds. In May of 2003, USAID Administrator Andrew Ntasios told the American NGOs that they needed to do a better job of advertising that the goods and services they provide to the Afghan people were coming from the US government. He told the American NGOs that they were an 'arm of the US government' (Klien 2003). Military activities such as distributions and school construction often made it unclear what was being done by combatants and what was being done by NGOs (Falconer 2009). MSF, who had been working in Afghanistan for 33 years, was forced to pull out there and in Iraq after their aid workers were targeted for assassination (Katz and Wright 2004). This blurring of aid and political agendas was again demonstrated when the Central Intelligence Agency hired a physician to conduct a sham vaccination campaign in Pakistan as part of the hunt for Osama Bin Laden in 2011 (Roberts and VanRooyen 2013; Rubenstein 2013). Subsequent to this ploy, the Aid Worker Security Database demonstrated a drastic increase in the number of vaccinators attacked and killed as shown in Figure 11.11.7 next.

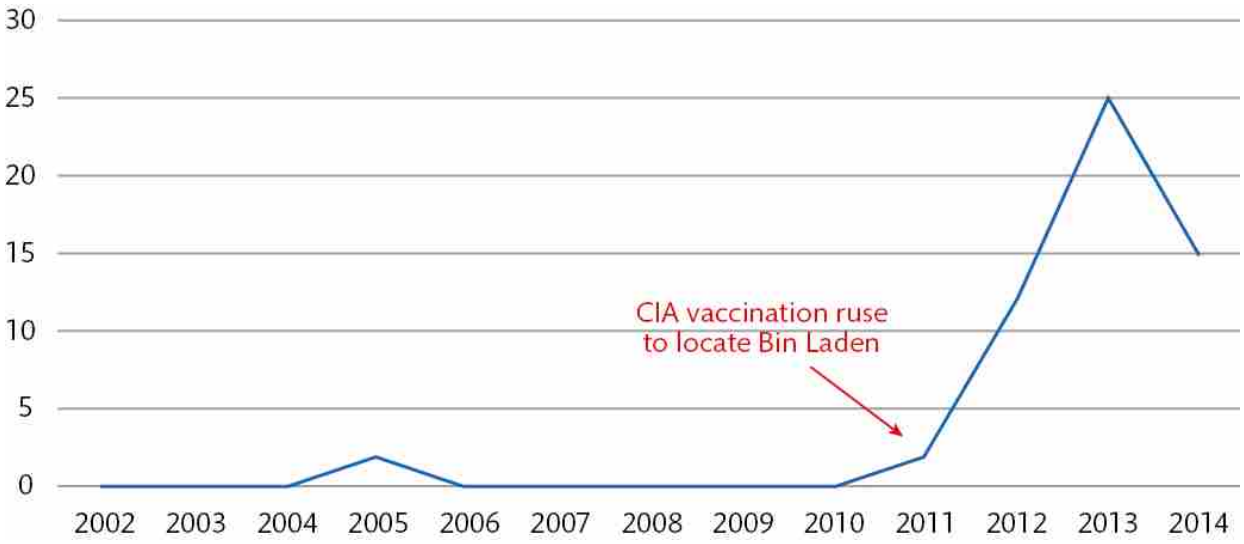

Fig. 11.11.7 Vaccinators attached, 2002–14.
Source: data from Humanitarian Outcomes (2015), Aid Worker Security Database, https://aidworkersecurity.org/Graphic provided courtesy of A. Stoddard.

The responses to natural disasters are not devoid of political overtones or agendas either. Following the 2005 tsunami in a largely Muslim area of the Pacific, the US Secretary of State called the disaster a 'wonderful opportunity' for the United States (Anonymous 2005). Preferential responses to former colonies and near neighbours appear to be an inevitable aspect of bilateral giving following natural calamities.

Attacks on healthcare

As a likely consequence of the blending of political and humanitarian agendas discussed earlier, there is growing worry within the humanitarian community that attacks on healthcare—including workers, structures, and transport—are occurring at an unprecedented rate.

During armed conflicts, international humanitarian law protects healthcare facilities and personnel from being the targets of attack. This protection is enshrined in the Geneva Conventions and was re-iterated by the United Nations Security Council Resolution 2286 as recently as 2016 (UN 2016). Certain high-profile attacks—such as the destruction of MSF's hospital in Kunduz, Afghanistan in 2015 by a US Air Force gunship—have provoked widespread concern among aid workers. Although there have long been documented attacks on healthcare—including Italian attacks on the

Ethiopian Red Cross, and even attacks on Red Cross that incensed Henri Durant in the Franco Prussian War—there is a perception among aid workers of an increase in attacks on healthcare workers and facilities (International Crisis Group 2005; Verma 2017). While anecdotal evidence, especially in Syria suggest an increase, a historical lack of standardized data documenting these attacks makes it difficult to quantify any trends (Briody 2018).

In response numerous organizations have established advocacy campaigns —including ICRC's Health Care in Danger and MSF's Medical Care Under Fire—to raise awareness and document such attacks while comprehensive databases have been established by independent research organizations like the Aid Worker Security Database of Humanitarian Outcomes to record attacks on healthcare workers (WHO 2015).

The WHO-led trauma response during the 2016 Mosul offensive in Iraq provides an example of how healthcare is being provided in potentially more dangerous conditions that may expose aid workers to a greater risk of attack. A coalition of Iraqi and international forces launched military operations to retake the city of Mosul from ISIS but abdicated its responsibility under international humanitarian law to provide medical care to war-wounded combatants. Anticipating a high number of patients with complex trauma, the WHO assumed control of the trauma response and contracted medical NGOs and private medical actors to 'co-locate' or embed within military units on the frontlines of conflict to provide medical stabilization and coordinate a trauma referral system (Fox et al. 2018). Although there were no reported attacks on healthcare workers, there was concern in the humanitarian community that directly working with military forces on the frontlines of a conflict increases the risk to aid workers and compromises the principles of independence and neutrality.

Migration—a record number on the move

An unprecedented 65.6 million people around the world have been forced from their home, and 20 more people are displaced every minute while fleeing violence, poverty, and persecution (Pew Research Center 2016).

Most people on the move today are internally displaced, indicating they have not crossed a border and are still within their home country. Using the example of those displaced by the Syrian civil war, nearly half of the nearly 12 million Syrians on the move are still within that country. The majority of

the rest are living in neighbouring countries—including Turkey (3.4 million), Lebanon (1 million), Jordan (660,000), and Iraq (125,000) (Pew Research Center 2018). Despite the increasingly anti-immigrant and nationalistic rhetoric of politicians in the Western world, relatively few on the people on the move are being hosted in the United States or Europe.

In addition to the large displacement of Syrians since 2011, there are multiple other large populations on the move throughout the world. In Central America, violence in Honduras and El Salvador in 2016 caused 388,000 to flee the region to seek refuge further north in Mexico and the US. Beginning in 2017, nearly 700,000 of Rohingya—a stateless minority group living in Myanmar—fled across the border to Bangladesh to escape persecution. Across sub-Saharan Africa, hundreds of thousands of men, women, and children—primarily from West Africa—have travelled through the Sahel to reach Libya from which many try to reach Europe via the dangerous sea route.

In the course of their journeys and regardless of whether they cross a border, displaced people are subject to numerous challenges, including human rights abuses, lack of access to healthcare, and restricted movement. For example, in Libya countless thousands are held in official and unofficial detention centres where rape, torture and abuse in an attempt to extract ransom are common (Amnesty International 2018). Similarly, many Rohingya report having been the victim of rape and indiscriminate attacks while in Myanmar or while fleeing across the border into Bangladesh.

One aspect of the migration experience that is disturbingly underdocumented is the number who die while on the move. Efforts such as the ‘Missing Migrants’ project by the International Organization for Migration have attempted to quantify the mortality experience of migrants in different contexts, but these are limited by incomplete and unstandardized data collection, limited political funding and support, and the difficult physical environments through which many migrate. Using the Mediterranean Sea route as an example, the Missing Migrant’s Project reports that 6,869 people have died attempting this crossing between 2014 and 2017, making it the most dangerous sea journey in the world (IOM 2018). However, the number is undoubtedly much higher given that this estimate doesn’t include the untold number of people who drowned but whose bodies were never found.

Humanitarian accountability

While aid agencies and the Red Cross Code of Conduct have always purported to support local empowerment and accountability of aid deliverers to beneficiaries and donors alike, many new developments have made that aspiration more common. The third edition of the Sphere Standards (Sphere Project 2011), perhaps the most widely followed guidelines for humanitarian practice, has an expanded emphasis on local participation and accountability to beneficiaries. In 2010, the UN passed an 'Accountability Framework' which may or may not result in more cost-efficient services on the ground, but certainly contributes to an international focus on recording transparently what is achieved by aid efforts and at what cost (UN 2010). Likewise, in 2011, the Inter-Agency Standing Committee (IASC) developed an operational framework on how to ensure accountability to affected populations in humanitarian emergencies which is widely cited among humanitarian players (IASC 2011). Thirdly, the rise of wealthy, highly functional governments in all regions of the world raises the expectations of aid delivery procedures. For example, in 2003, India became a net creditor to the International Monetary Fund (IMF) and the World Food Programme (WFP) (Bijoy 2011). The rise of local NGOs as a primary international delivery mechanism, the prevalence of social networking, and the economic downturn in post-2008 Europe and North America all point towards a future where local and more players have a larger role in what aid is provided and how it will be disbursed.

Growing participation of 'non-traditional' actors in humanitarian response

At its root, today's humanitarian system is fundamentally a Western construct based on European Enlightenment ideals of charity and limitations on the conduct of war. Although some form of the humanitarian impulse is likely as old as mankind, the formal structure we know today was first established in the late nineteenth century and was greatly expanded in the aftermath of World War II with programmes primarily targeted to provide assistance to Europeans displaced by war. The humanitarian community gradually extended its programmes globally to nearly all populations affected by crisis, and its core principles have largely remained unchanged

since their beginnings, despite substantial global geopolitical and financial changes.

However, there are indications that within the global aid community a number of 'non-traditional' actors—including China, Saudi Arabia, and Turkey—are playing a larger role in the humanitarian endeavour. While the majority of funding for humanitarian emergency response comes from 'traditional' government and intergovernmental sources—the US, European Commission and United Kingdom alone contribute more than 50% of the total government humanitarian contributions—recent years have shown greater contributions from outside the rich Western nations. Between 2012 and 2014, the largest increases came from Saudi Arabia and the Gulf States of Kuwait and Qatar (ALNAP 2015) and as shown in Figure 11.11.8, between 2004 and 2016 humanitarian contributions from China have increased fivefold (Hirono 2018).

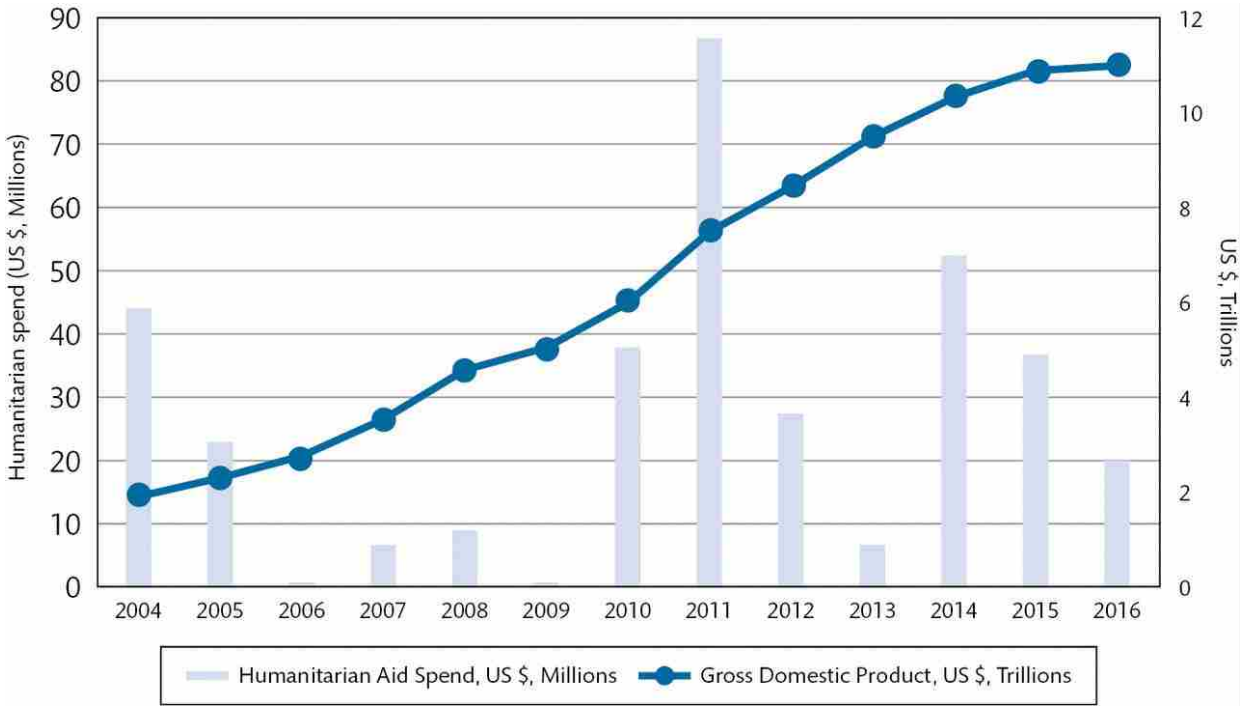

Fig. 11.11.8 Chinese GDP in trillions and humanitarian spending in millions 2004–2015. Sources: UNOCHA FTS, World Bank.

In addition to their growing financial presence, non-traditional actors are also playing a bigger political role in the global humanitarian system. Turkey

has used its growing economic influence and its strategic position between Europe and the conflicts in the Middle East to position itself as a significant contributor to humanitarian assistance worldwide. In recognition of its involvement in Somalia, its role in hosting millions displaced in the Syrian civil war, and its deal with the EU to reduce the number of asylum seekers entering Europe, Turkey was selected to host the first ever World Humanitarian Summit in 2016.

Humanitarian response has largely been shaped by Western ideas and actors since its inception, yet that is currently changing as non-traditional actors constitute a larger part of the financial and political leadership of the humanitarian endeavour. It remains to be seen what impact this growing involvement of non-Western donors will have on the future of humanitarian action.

New approaches

The growing appreciation of local capacities to provide exacting technical services combined with technical advances and greater emphasis on accountability, have paved the way in the past decade for exciting new ways of delivering aid. Among these are the following:

Home-based treatments

In the 1980s, the promotion of ORT was championed aggressively by the UN and aligned agencies because it was seen as a way to overcome the primary barrier to successful treatment of acute illness, namely early detection and treatment. The logic was that if people did not have to go through the effort of transporting the patient and their things to a medical facility, far more people would get treated. This was partially the logic behind the barefoot doctors' programme in post-revolution China and a variety of other initiatives such as mobile clinics (Gish and Walker 1977).

Over the past decade, ambitions to provide antiretroviral treatments in areas of modest medical infrastructure and limited resources have resulted in a variety of models for drug distribution and patient monitoring using community or patient volunteers, or paid community health workers. The evidence suggests that patient management and monitoring schemes that are not physician based, where the monitoring occurs closer to the community level, are associated with better patient retention and survival (Callaghan et

al. 2010). In focused settings of high malaria transmission, home-based treatment of fever has been shown to be an effective life-saving approach (Kidane and Morrow 2000).

In emergency settings, no home treatment strategies have received more attention or inspired as much enthusiasm as home therapeutic feeding. Home therapeutic feeding usually involves training and equipping mothers of malnourished children to cure the child at home with a nutritious ready-to-use food such as eeZeePaste™NUT or Plumpy'Nut® which come precooked and are resistant to bacterial growth. These ready-to-use home treatment products cut down on attrition in feeding centres, are a less expensive means for treating moderately malnourished children, and have been shown to be highly effective in field trials (Patel et al. 2005).

Crowd sourcing and mobile phones

The widespread availability of mobile phones and social media has made it possible to have the whole population participate in the monitoring of crises. One of the most well-known of these efforts is the Ushahidi platform, formed during the violent period following the 2008 Kenyan elections (Ushahidi n.d.).

Perhaps the most dramatic application of the Ushahidi platform was in the February 2010 Chilean earthquake. The 8.8 magnitude quake was followed by a series of aftershocks that damaged thousands of buildings and ultimately killed an estimated 521 people. Within 48 hours of the initial quake, an Ushahidi–Chile platform was established and a team of graduate students in New York began mapping press reports and text messages to create a picture of damage and where people were trapped. One hundred 'incidents' were mapped in the first day of operation and 700 were mapped by the end of 3 days. In the weeks that followed, the Ushahidi platform updated local press members and the general public about food distributions, dangerous buildings, the occurrence of looting, and the progress of children re-attending school (Carlsen et al. 2011). Crowd sourcing strategies have also been used to inform Chinese authorities about acute situations in the aftermath of the Szechuan earthquake, to map the occurrence of sexual violence in Syria, and to map unsafe areas following the Japanese tsunami of 2011.

Mobile phones by themselves are allowing for some exciting innovations. Somalis affected by conflict have received humanitarian aid in the form of

phone credits which can be used to purchase goods in local shops (Global Communities n.d.). After the earthquake in Haiti, the largest mobile phone carrier used cellular networks to compare the movement of people before and after the earthquake to show that 630,000 people in Port-au-Prince left the capital in the 19 days following the earthquake (Bengtsson et al. 2011). In the Democratic Republic of Congo, community members in North Kivu were provided mobile phones to monitor trends in the number of children separated from their families and caregivers in emergencies (Guinote 2012; Rubenstein 2015). Many of these initiatives are exploratory and controlled trials will be needed to establish such procedures as effective protective investments. It is likely mobile-phones will be increasingly utilized by the humanitarian and health community in the years to come.

Monetary aid

As part of the promotion of local and beneficiary empowerment, providing aid that allows beneficiaries to set their own priorities has become increasingly popular. The example of giving displaced Somalis mobile phone credit was discussed earlier. But, giving cash directly to beneficiaries in lieu of rations or material goods has several advantages. People are more likely to end up with what they want and the transfer costs are far lower. It has the potential to support the local economy including creating incentives for future increased local food production. It potentially has downsides such as driving local inflationary pressures and exposing people to increased risks of exploitation and extortion. A recent comprehensive review generally weighs the upsides as being greater than the downsides but suggests that implementers will need to choose the contexts carefully and develop methods for monitoring the success of direct cash assistance (Harvey 2007).

Closely related to monetary aid is the distribution of credit vouchers or coupons. Sometimes these have a specific purpose such as paying for school fees or uniforms. The most common flexible distribution is non-food item (NFI) or food item fairs where a select collection of vendors selling at predetermined prices gather in one place and beneficiaries with coupons spend their coupons at this one place and time. This system has the advantages of giving beneficiaries choice over the aid items they receive, it supports local markets, and leaves beneficiaries less open to local extortion. A recent analysis of such a NFI fair aimed at recently displaced populations in South Kivu Province, DR Congo found that local authorities missed most

IDPs when constructing vulnerable lists and included many locals. At the end of the NFI distribution process, the NFI 'vulnerability score' as defined by UNICEF was unchanged by the distributions (O'Keeffe and Zadravecz 2012). As with so many new practices, implementation and evaluation procedures will need to be developed locally to match each context in order to maximize the efficiency of distributions via fairs and similar voucher systems.

New technical advances

A host of new technical advances or tools also create the potential for transformative advances in humanitarian relief in this century (Interagency Standing Committee 2013). Some technologies, such as the Global Positioning System (GPS), are so essential to relief efforts at present that it is hard to realize that the technology was almost non-existent 20 years ago. It is likely to evolve as a tracking tool for people, goods, and vehicles. One-dollar GPS transmitters will likely result in the tracking of individual cases of vaccines and drugs, and curb looting of warehouses by armed groups. Eye and fingerprint scanning technologies are reducing ration theft and false registrations across the globe. Advances in medicine, in diagnostic techniques, or protective devices such as long-lasting impregnated bednets, are constantly changing the practice of humanitarian relief. Some of the more promising new technical and medical breakthroughs are highlighted here.

Satellite imagery and remote sensing has already changed humanitarian practice. UNHCR has used satellite images to count people moving from Darfur into Chad. For years, remote sensing has been used to predict crop failure and crop yields. The destruction of villages in Darfur and DRC has been documented with before and after remote images. But lately, satellite imagery has been used to undermine the impunity brought by national sovereignty. For example, during the 2017 period government violence against the Rohingya in Rakhine State in Myanmar, Human Rights Watch made extraordinarily detailed and timely documentation of village destruction by remote imagery (HRW 2017).

Cloud computing and internet collaboration hold potential for a host of new ideas and innovations that may assist those responding to emergencies. Groups like Hackers for Humanity attempt to channel the efforts of internet

talents to charities (Hackers for Humanity n.d.). A variety of efforts to solve 'humanitarian problems' have been addressed by crowdsourcing for a solution. A notable example is the use of open-source survey (OpenDataKit) and navigation (OpenStreetMap) software in the 2013–2016 West Africa Ebola outbreak. Using local people with self-owned smartphones, surveyors were able to quickly update geographic and village information used by medical surveillance and response teams at a cost of €3.80 per village surveyed (Nic Lochlainn et al. 2018).

Internet accountability mechanists: Google Earth and the internet are allowing for greater accountability of aid from the perspective of small private donors. A model held up as innovative but already being reproduced is that of Charity Water. Charity Water does not directly implement water supply and sanitation projects, but instead subcontracts with local operational partners to turn Western private donations into water and sanitation infrastructure (Charity Water n.d.). Charity Water provides donors with the latitude and longitude of the specific things people have paid to have built so that over time they can see if indeed a well was built or public tap installed, and they can monitor if it continues to be used over time. They even install monitors so that donors to a specific project can see at any given moment if water is flowing from it. While not all aid is remotely visible, this process of linking donors to beneficiaries visually or by social media will likely grow over time and the process of humanitarian assistance will be better for it (Srinivasan et al. 2012).

Unmanned aerial vehicles: Although unmanned aerial vehicles (UAV) —'drones'- are known primarily for their military uses, there has been increasing recognition of their potential to improve humanitarian and disaster response. UAVs have already delivered small packages to camps in Port-au-Prince after the 2010 Haiti earthquake and helped assess the damage caused by Typhoon Haiyan in the Philippines in 2013 (Oxfam 2013; Reuters 2014). Zipline, a US-based drone manufacturer and operator, has partnered with the Ministry of Health in Rwanda to trial delivery of blood for transfusion to remote areas throughout the country, and other countries have used UAVs to deliver emergency vaccines, HIV medication and antimalarial medication to difficult-to-access areas (Reliefweb n.d.). Confronted by high tuberculosis burden in a very remote location, Doctors Without Borders recently began using an unmanned maritime vehicles (UMV) to transport tuberculosis samples in Papua New Guinea (MSF 2018). Although they may

face challenges from regulatory requirements and local opposition, UAVs may likely play a larger role in future humanitarian and disaster response.

Telemedicine: Telemedicine—medical care provided from a distance—is being increasingly used in developed settings to remotely connect patients and healthcare providers. MSF has been using telemedicine since 2010 to connect field staff with experts based in Europe or the US who can provide advice from afar (Walji 2015). Although its use is still limited, the increasing presence of cellular and wireless connections and the lack of specialized healthcare providers in the most remote areas means telemedicine has promise for greater use in humanitarian response.

Conclusion

The twenty-first century is likely to see an ever growing humanitarian movement that will become more focused on economic, emergency preparedness, and developmental issues. Aid will be more politicized, while simultaneously more locally controlled and with greater accountability for implementation. The post-Biafra humanitarian endeavour has been associated with a dramatic decline in extreme episodes of excess deaths associated with crises and the new face of humanitarian relief, which often looks a lot like development work of old, has largely been built on the successes of twentieth-century humanitarian relief.

11.12

Principles of public health emergency response for acute environmental, chemical, and radiation incidents

Virginia Murray, Thomas Waite, and Paul Sutton

Introduction to principles of public health emergency preparation, resilience, and response

Acute environmental, chemical, and radiation incidents and emergencies can have significant effects on people's health, including loss of life. New threats reveal new challenges for managing the health risks and effects of emergencies. Deaths, injuries, diseases, disabilities, psychosocial problems, and other health impacts can be avoided or reduced by skilled disaster management involving health and other sectors.

This chapter considers the various stages of an emergency response and the role of public health at each stage. Case studies are used to illustrate the principles described. Of note is the importance of emergency responders at the scene to save life and protect people (including the emergency responders). This chapter addresses the following:

Incident management arrangements for emergency response including international obligations: including the local emergency response arrangements and how they interact with international obligations such as the International Health Regulations from the World Health Organization (WHO) (see Chapter 11.10).

Public health risk assessment: in any incident response it is essential to assess exposure, as soon as possible, to members of the public, workers, and responders using biological or environmental monitoring or modelling. This will allow assessment of health risks to exposed people and define further environmental and people sampling and modelling to refine risk assessments. There are significant differences in exposure assessment methods between chemical and radiation incidents.

Public Health risk management techniques and countermeasures are important to ensure that advice that is given early enough to be effective to reduce exposure, even at the early stages of an incident when little is known. Countermeasures are broadly similar for all hazards and include decontamination, sheltering, evacuation, specific antidotes, and medical treatments. The chapter touches on mechanisms of recovery and return to normal. Follow-up of affected populations is often essential. Approaches on how to undertake appropriate follow-up of affected populations including ongoing care and epidemiological follow-up are discussed

Public reassurance in emergencies and incidents: it is essential to have clear messages for information and reassurance to cover both affected and unaffected members of the public. These need to build trust in the systems that have been invoked to protect the public.

Identify and publish the lessons and examine the importance of sharing and disseminating learning to decrease the chance of an incident reoccurring and to identify lessons to improve emergency preparedness, response, and recovery.

The chapter offers a conclusion which includes a need for further evidence identifying some of the research gaps and future challenges.

Incident management arrangements for emergency response including international obligations

Incident and emergency risk management for health refers to the systematic analysis and management of health risks, posed by incidents and

emergencies, through a combination of:

Hazard and vulnerability reduction to prevent and mitigate risks
Preparedness
Response
Recovery measures

This is summarized in Figure. 11.12.1.

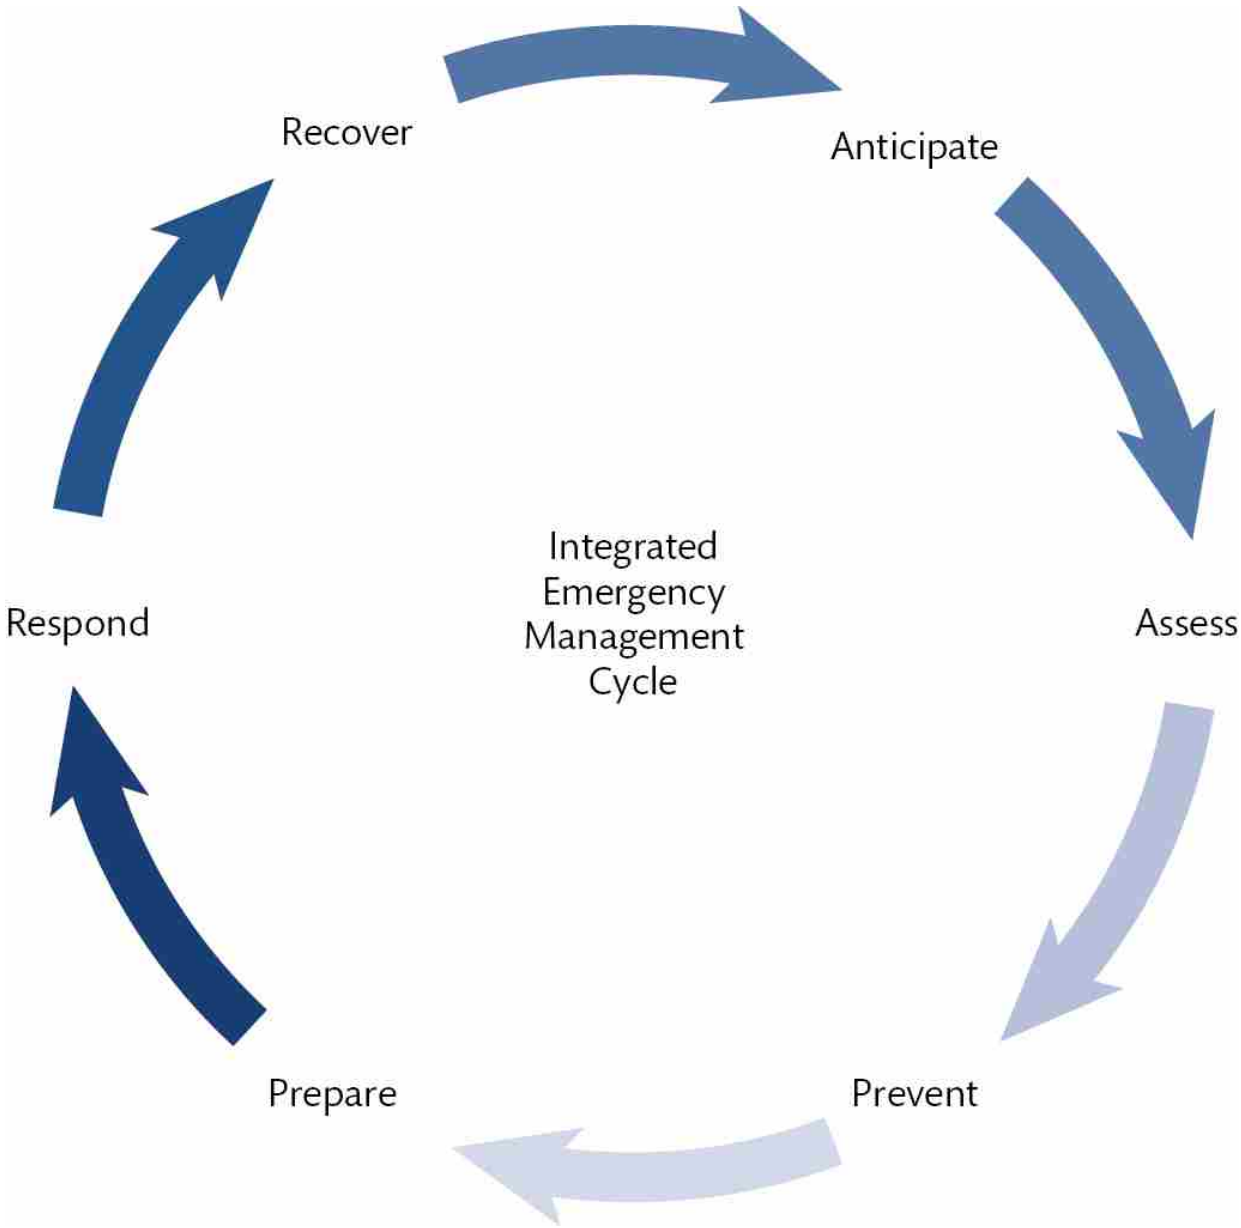

Fig. 11.12.1 The integrated emergency management cycle.

Reproduced with permission from National Health Service (NHS), NHS Commissioning Board Emergency Preparedness Framework 2013, Copyright © 2013, available from https://www.england.nhs.uk/wp-content/uploads/2015/11/eprr-framework.pdf, under the Open Government Licence v3.0.

Public health expertise has a vital role in reducing harm and saving life at every stage in this cycle. The traditional focus of the health sector has been on emergency response however increasingly the challenge is to broaden the focus of incident and emergency risk management to a more proactive approach emphasizing risk identification, reduction, prevention and

mitigation, and the development of community and country capacities to provide timely and effective response and recovery including learning. Resilient health systems based on primary healthcare at community level can reduce underlying vulnerability, protect health facilities and services, and help to scale-up the response to meet the wide-ranging health needs.

Emergencies and other crises may cause ill health directly or through the disruption of health services, leaving people without access to healthcare in times of emergency. They also affect basic infrastructure such as water supplies and safe shelter which are essential for public health.

World Health Organization Emergency Response Framework

The World Health Organization approach to emergency preparation and response is outlined in its Emergency Response Framework 2017 (WHO ERF), an all hazards approach which provides a structured framework for Member States (WHO 2017). The first step of the framework is risk assessment and situation analysis, including the importance of early identification and detection to prevent events from developing into public health emergencies where possible.

The framework then moves to rapid risk assessment and characterization to arrive at a risk level based on the likelihood of the event potential impact on public health. A standard approach to grading incidents and emergencies assists in determining the level of response required from the WHO; three grades are outlined for acute responses and three for incidents which are considered ‘protracted’ or to last beyond six months. Importantly, the initial operational response to any incident should not be delayed by this grading process, as the WHO adopts an important principle of ‘no regrets’ which supports over-resourcing rather than the risk of under-resourcing in the initial stages of a response.

From here the WHO Incident Management Process describes the various components of the WHO response which are common to all emergencies regardless of the underlying nature of the incident. This highlights the move towards structured and predictable response methods for emergency management systems in order to minimize variation and maximize the opportunities for interoperability and standardization. The WHO Incident Management Process is based on what it considers international best practice and is increasingly influencing the development of emergency response

plans for systems around the world. The framework concludes with detailed descriptions of the performance standards and key performance indicators for emergencies which monitor 'process' and output/outcome indicators respectively.

The UK Civil Contingencies Act 2004 (Box 11.12.1) provides an example of the implementation of the framework.

Box 11.12.1 UK Civil Contingencies Act 2004

The UK Civil Contingencies Act and supporting guidance establishes clear roles and responsibilities for emergency preparedness and response for its two categories of responder and imposes legal duties on them (Cabinet Office 2011, 2017). Category 1 responders are those organizations primarily involved in the response to the emergency such as emergency services and local authorities, Category 2 responders are those organizations which are needed to co-operate with Category 1 responders such as the Health and Safety Executive. These categories of responder come together in Local Resilience Forums to prepare, plan, exercise, and review emergency response within their areas. The guidance describes a cycle of emergency preparedness and response as an evolutionary and systematic process by which organizations should prepare for and respond to emergencies.

The cycle starts with direction being set by a risk assessment process. The steps which follow reiterate the importance of the risk assessment phase since the cycle moves on to objective setting, determining actions, and assigning responsibilities. It is the risk identification and assessment phase therefore, which drives the process from here. The process then moves through dissemination and training phases before seeking to validate plans through both actual responses and emergency. The crucial stage of identifying lessons and implementing learning from responses and exercises is followed by review and revision of plans, completing the evolutionary cycle.

UK HM Government guidance (2013) describes six activities within its Integrated Emergency Management approach which set the context for the cycle just described:

- Anticipation
- Assessment
- Prevention
- Preparation
- Response
- Recovery management

This approach provides a comprehensive approach to emergency preparedness and response for the United Kingdom.

It is of note that the importance of anticipation and systematic risk identification, followed by exercising and identifying learning and improving plans, provides a continuous improvement approach to preparing for and responding to public health emergencies.

International consensus views disasters as barriers to progress on health-related development as they often set back hard-earned development gains in

health and other sectors. However the recent synchronous adoption of landmark UN agreements the Sendai Framework for Disaster Risk Reduction, Sustainable Development Goals (SDGs), COP21's Paris Climate Conference, World Humanitarian Summit and Habitat III has created a rare but significant opportunity to build coherence across different but overlapping policy areas to reduce the impacts of disasters on health. The three key 2015 UN landmark agreements are briefly summarized next:

The **Sendai Framework for Disaster Risk Reduction 2015–2030** was endorsed by the UN General Assembly in June 2015 (UNISDR 2015). It puts health at the centre of global disaster risk reduction policy and advocates for action to reduce disaster risks for the next 15 years. It is a voluntary, non-binding agreement with seven global targets, aimed at the reduction of disaster risk and losses in lives, livelihoods and health and links to the critical implementation of the International Health Regulations (2008). It identifies four priorities for action:

- Understanding disaster risk
- Strengthening disaster risk governance to manage disaster risk
- Investing in disaster risk reduction for resilience
- Enhancing disaster preparedness for effective response and to 'Build Back Better' in recovery, rehabilitation, and reconstruction

The **UN Sustainable Development Goals** represent 17 aspirational 'Global Goals' with 169 targets between them, including the universal call to action to end poverty, protect the planet from climate change and ensure that all people enjoy peace and prosperity (UN General Assembly 2015). Target 3d of the health goal is to 'strengthen the capacity of all countries, in particular developing countries, for early warning, risk reduction and management of national and global health risks'.
The international political response to climate change that began at the Rio Earth Summit in 1992 was complemented with the adoption of the Paris Climate Conference in November 2015 (UNFCCC 2015). The **Paris Climate Change Agreement** aims to achieve a legally binding and universal agreement on climate and keeping global warming below 2°C.

Health risks can be understood in terms of hazards, people's exposure and vulnerability to that hazard and the capacity to manage the risk (Cardona et al. 2012). Human vulnerability to emergencies is a complex mix of issues

that includes socioeconomic, health, and cultural factors. In many situations it is not the hazard itself that necessarily leads to an emergency, but the vulnerability and inability of the population to anticipate, cope with, respond to, and recover from its effects. Populations and their health are put at risk from many hazards and the Sendai Framework identifies an all hazards approach, which includes natural, biological, technological, and societal hazards:

Natural: earthquake, landslide, tsunami, cyclones, extreme temperatures, floods, and droughts
Biological: disease outbreaks including human, animal, and plant epidemics and pandemics
Technological: chemical and radiological agent release, explosions, transport, and infrastructure failures
Societal: conflict, stampedes, acts of terrorism, migration, and humanitarian emergencies

Progress has been made at global, regional, national, and community levels, but countries' capacity for risk reduction, emergency preparedness, response, and recovery remains extremely variable.

The burden of emergencies falls disproportionately on vulnerable populations, namely the poor, ethnic minorities, old people, and people with disabilities. Worldwide, the loss of life from climate related emergencies is far higher among the less-developed nations than it is in developed nations (Cardona et al. 2012). Within each nation, including developed nations; poor people are the most affected. Poverty reduction is an essential component to reducing vulnerability to emergencies. High-risk populations must be prioritized in targeted efforts to mitigate human vulnerability including emergency- and disaster-related health outcomes, such as death, injury, illness, and disability.

In the context of emergency risk management, public health programmes build capacities and resilience of individuals and communities to risks, to reduce the impact, to cope with, and to recover from the effects of adversity. They address issues related to disparities in health outcome that arise between the general population and the most vulnerable groups.

International Health Regulations

The International Health Regulations (IHR), agreed by the World Health Assembly in 2005 and revised in 2007 (WHO 2008), were introduced to protect the world from global health threats. The need for such an internationally binding instrument was identified following the emergence of severe acute respiratory syndrome in 2003, which demonstrated how quickly a new disease could spread. As a result, 196 countries acknowledged a responsibility for collective action against infectious diseases, and food and environmental contamination, deemed to be public health emergencies of international concern. Member states are responsible for developing, strengthening, and maintaining the capacity to detect, assess the risks of, and respond to public health emergencies. Furthermore, countries are required to notify the WHO of these threats through their designated National IHR Focal Point within 24 hours. The regulations mandate countries to assess their capacities for disease surveillance and response and report whether these are sufficient to meet their obligations.

Implementation of the IHR and the WHO Emergency Response Framework has resulted in a number of high-risk countries having strengthened their disaster prevention, preparedness, and response systems; in some countries, the health sector has led initiatives developing multisectoral approaches to emergency risk management (WHO/PHE/UNISDR 2017). Multisectoral working is needed to protect the health of the population during and after a major incident or emergency. Wider determinants of health such as water, sanitation, nutrition, and security also need to be adequately addressed. In addition, essential infrastructure such as communications, logistics, energy and water supplies, emergency services, and banking facilities need to be protected through multisectoral working to ensure the continuity of health services.

Public health risk assessment

Risk identification and assessment are the first components of the public health risk management process. The risk assessment stage will take into account the probability of an event occurring and the magnitude of the consequences of the event. In the early stages of an incident, the risk assessment will be subjective but will be refined and quantified as more information is gathered.

Single risk assessment involves four stages: hazard identification, assessing the consequences, assessing their probabilities, and characterizing the risks and uncertainties (Gormley et al. 2011). In an emergency situation, the public health risk assessment can be done through a combination of qualitative and quantitative methods.

One of the greatest challenges of public health—and disaster—risk assessment is prioritization of risks arising among all the hazards in a given geographical location. This is further complicated by the use of different assessment techniques and metrics for understanding risks in different hazard types and thus common, multirisk frameworks are needed. Furthermore, public health emergency planning and response for acute environmental, chemical, and radiation incidents must be cognisant of the frequent and often complex interactions between such hazards.

Such multihazard approaches to understanding risk must start from single-hazard risk assessments and we thus start by outlining this process in generic terms. Natural hazards, such as extremes of rainfall or temperature, or landslides and floods, are particularly prone to cascade or interaction, increasing total risk. Examples include the tsunami in Japan of 2011, or the hurricanes in the Caribbean region of 2017.

In many environmental, chemical, and radiation incidents it is helpful to break down risks by considering the source, pathway, and receptors. (Box 11.12.2)

The source

Information about the source can be weather specific with naturally occurring environmental exposures, such as extremes of temperature, being understood through meteorological assessment, forecasting, or modelling. Chemical data on the source can usually be obtained from the site operator for industrial accidents. Where available, specialized fire and rescue hazardous materials and environmental protection officers can provide invaluable, on-the-scene information in the early phase of a chemical incident. The key requirement is to identify the chemical(s) released and its/their physical form. The chemical’s physico-chemical properties will provide information on its ease of spread throughout the environment. Understanding its toxicological properties and the quantities released is also key to successful risk assessment.

Box 11.12.2 Example of source–pathway–receptor model

Source: chemical release due to road traffic accident involving a tanker.
Pathway: dispersion of the chemical through the air.
Receptor: residents (children and adults).

Most incidents involving chemicals and radiation will require access to specialist advice to interpret the information gathered. It is important to remember that the substances contained in a product inventory are not always those of most public health concern. For example, a fire may lead to the formation of more toxic chemicals and can result in other hazards depending on the temperature and oxygen availability.

The pathway

The pathway describes how the exposure spreads in the environment. If a polluting gas, the main pathway will be through the air and dispersion modelling can be used to predict how it will move spatially and temporally. Liquids, depending on their volatility, may disperse through the soil, water, and air. Solids will disperse more slowly; however, fine solids will form dusts that can disperse quickly in the right conditions. Exposure to a substance can be assessed through a combination of methods: by sampling or monitoring the external environment, by modelling the external environment, or by measuring the substance in the body.

Food can also be part of a complex exposure pathway, for example, some chemicals and even radioactive ones travelling in the air can be deposited on crops which are later ingested leading to exposure.

Exposure to meteorological data may be routinely collected by relevant national agencies, such as the Met Office in the United Kingdom.

Timely information on the type, concentration, and environmental distribution of the pollutants is needed for public health risk assessment. Where available and applicable the concentration of a substance in the environment can be monitored and/or modelled with varying degrees of accuracy and precision depending on time and resources. Unless arrangements have been made at the planning stage for rapid deployment of sampling and measurement equipment, information may be received too late to inform the risk assessment.

A UK example of a planned monitoring system is the Radioactive Incident Monitoring Network (RIMNET), set up in 1988 to monitor the consequences of nuclear incidents abroad. RIMNET comprises 96 monitoring stations around the United Kingdom. A range of organizations can submit monitoring data to RIMNET. Public Health England advises government departments on the public health interpretation of radiation monitoring data.

Environmental matrices containing the substance of interest (e.g. air, food, water, dust, or soils) can be used to aid public health risk assessment. In certain circumstances, real-time measurements can be made, for example, for chemicals in air or monitoring of levels of radiation. Monitoring should be planned as soon as possible. The monitoring strategy should ensure that the samples taken are representative of the general bulk material as substances are rarely homogeneously dispersed in the environmental media. The methods used to take and store the samples should not degrade the substance of interest. The analytical techniques used must be appropriately sensitive, accurate, and reproducible. For direct measurements, monitoring over the right time interval allows comparison with any predefined health-based standards.

Modelling external exposure involves computer simulation to estimate the pollutants' concentration and predict their behaviour through one or more environmental media. Air dispersion models are often used during large-scale incidents. A number of data sources are required, depending on the sophistication of the model, for example, source term, weather data, and topography.

Monitoring and modelling should be considered together in a multiagency group attended by specialist scientific staff as information gained from monitoring could be used to inform the model and model outputs can predict areas to monitor for effective exposure assessments. The uncertainties for this type of external exposure assessment include the accuracy, completeness, and relevance of the data.

The receptors

For the purpose of a health risk assessment, the receptors are the people potentially exposed to environmental, chemical, and radiation incidents. Some population groups exhibit adverse health effects when exposed to extreme temperatures or at lower pollutant levels and may react more quickly than the general population. These are called 'sensitive receptors'.

Children, the elderly, people with pre-existing diseases, and pregnant women may be sensitive receptors, depending on the hazard involved.

The primary exposure routes for chemicals are absorption (contact between the chemical and the skin or eyes), inhalation (breathed into the lungs), ingestion (through contaminated food and/or water), and injection (through breaks in the skin). For radioactive materials, an additional exposure route is external irradiation, where gamma and/or beta radiation particles emitted by materials outside the body penetrate the skin and deposit their energy inside. Alpha particles are a risk to human health only when taken into the body by inhalation, ingestion, or through open wounds as they are easily stopped by the dead layers of the skin.

The duration of exposure is important to assess and estimate health risks. Single or short-term exposures to some chemicals at a sufficient concentration can trigger adverse health effects (e.g. carbon monoxide). Other chemicals require exposure for days and months to cause lasting health effects (e.g. some respiratory irritants).

Once inside the body, chemicals move through the metabolic pathways, are transformed, and either stored or eliminated. Biological markers of exposure can be used to enhance the risk assessment and measure the internal dose. However, the right study design, including the choice of the most appropriate body fluid or tissue to be tested, collection, storage, processing, and analytical protocols require a thorough understanding of the exposure route, absorption, and metabolism of the chemical of interest. Specialist scientific advice should be sought before considering human bio-monitoring to assess exposure.

Risk characterization

This step of the public health risk assessment is usually a quantitative assessment involving a comparison of the environmental, chemical, and radiation incident exposures or concentrations measured against health-based values, where they exist. These values are different for different types of events and even with chemical exposure the same chemicals in different environmental matrices. For example, health guidelines have been set for lead in air, water, and in blood. Health-based values are derived at levels below which adverse health effects are considered unlikely for so-called threshold chemicals. Exposure to some chemicals can lead to health effects

at any level of exposure, these chemicals are called ‘non-threshold chemicals’ and health-based concentrations are set for tolerable risks.

Radiation has both threshold and non-threshold effects. Acute injuries occur above a threshold high dose. At lower doses there are stochastic risks, mainly of cancer induction that are assumed to have a linear no-threshold dose–response function. Public and occupational exposures to radiation aim to be as low as reasonably achievable within the context of specific dose limits to aid emergency planning. Strenuous efforts should be made to avoid acute radiation injuries in emergency situations.

Characterization of the risk posed by natural hazards depends not only on the probability of the event, but also the complex interlinkage with both the infrastructure of modern day living and increasing population vulnerability due to climate change, urbanization communication, and transportation. The knock on consequences of a disaster in a single population or financial centre may have consequences in cities and economies across the world; similarly the victims to a disaster such as the Indian Ocean tsunami in 2004 will not be limited to the countries affected but may carry the individual and public health impacts with them when they return home, potentially many thousands of miles away.

Multirisk assessment methods

The Sendai Framework for Disaster Risk Reduction (UNISDR 2015) promotes the development of multihazard risk assessment of natural hazards. One of four priority actions in the Framework is to better understand disaster risk, with the development of guidelines for regional and national multihazard risk assessments, mapping, and risk profiles recorded as a key deliverable.

In order to prioritize hazards and risks in a given location or region, their quantitative and qualitative characterization must be comparable with one another. Since such characteristics inherently differ by hazard, such as return period, nature, impacts and intensity, and their measurements are necessarily in different units (wind speed, water depth, temperature) this results in great complexity when compiling hazards for a region in order to assess the total public health risk for the population.

Harmonization of risk assessment processes is thus an important first step to overcoming these difficulties. The use of matrices and indices for hazards, risks, and vulnerability have been proposed as a means to address this,

although such approaches do not allow assessment of interacting or cascading risk.

Matrices seek to classify hazards on more than one scale, often impact and intensity or frequency. These characteristics are then grouped categorically (either qualitatively or quantitatively) to allow graphic display and hence comparison of their relative importance.

An example of this is the UK National Risk Assessment (see Box 11.12.3).

Box 11.12.3 The UK National Risk Register of Civil Emergencies 2017 as an example of multirisk assessment methods implementation

The National Risk Register 2017 explains the risks of major emergencies that could affect the United Kingdom in the next 5 years and provides resilience advice and guidance and has been used by UNISDR as a model (UNISDR 2017).

The National Risk Register of Civil Emergencies 2017 edition provides an updated government assessment of the likelihood and potential impact of a range of different civil emergency risks (including naturally and accidentally occurring hazards and malicious threats) that may directly affect the United Kingdom over the next 5 years. Figure 11.12.2 provides some of the assessments used to inform the register.

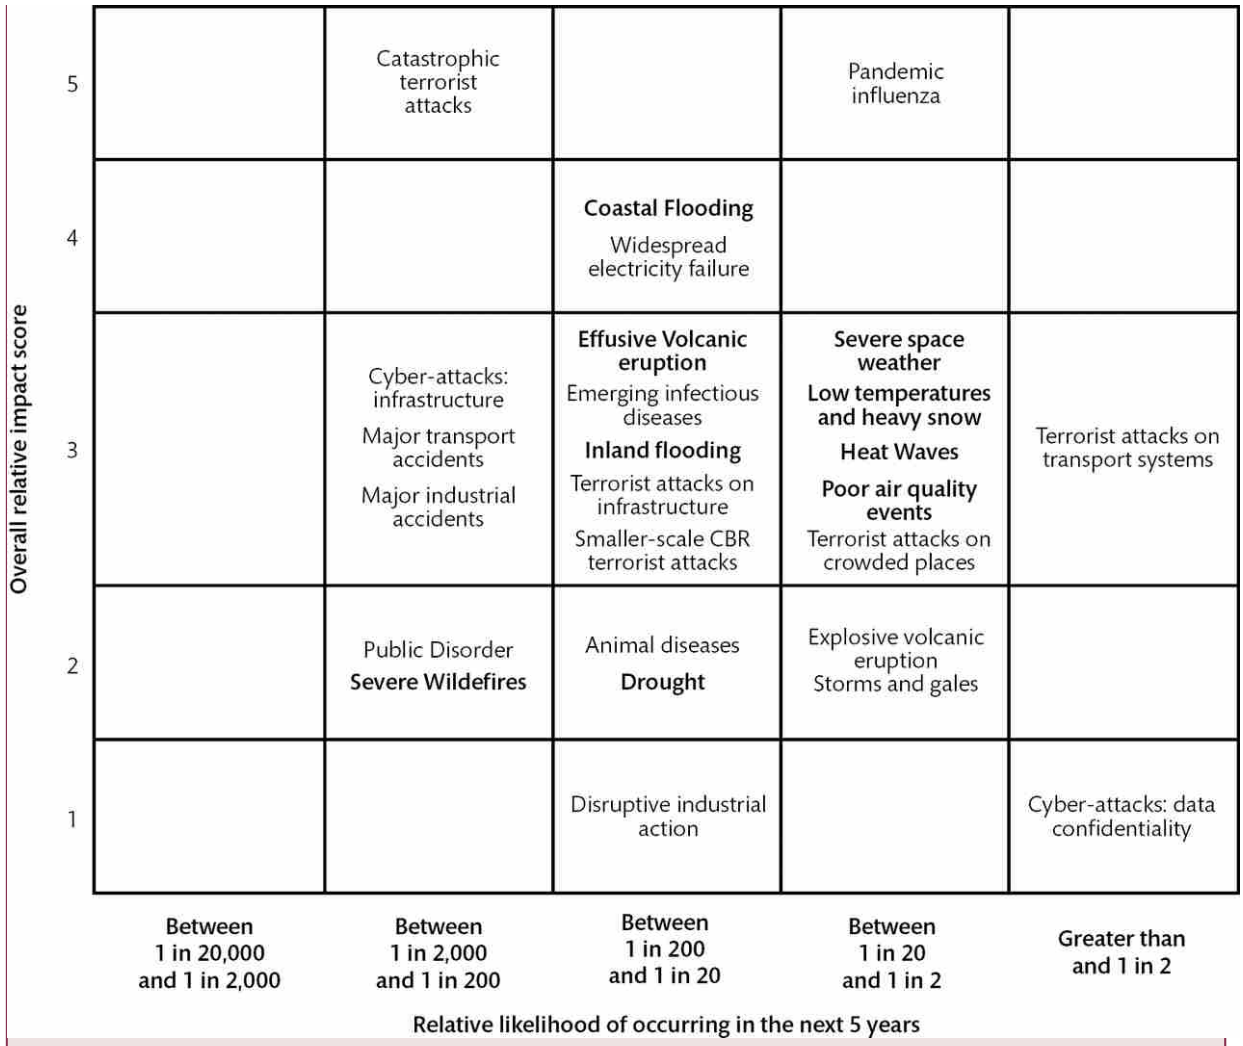

Fig. 11.12.2 Key civil emergency risks published in the 2015 National Risk Register (NRR) from UK NRR).

Reproduced from Hemingway R and Gunawan O. (2018) The Natural Hazards Partnership: A public-sector collaboration across the UK for natural hazard disaster risk reduction International Journal of Disaster Risk Reduction 27 (2018) 499–511, with permission from Elsevier.

In addition to providing information on how the UK government and local responders manage these emergencies, the National Risk Register also signposts advice and guidance on what members of the public can do to prepare for these events. As an open access document regularly updated the Risk Register allows the public to find links and information about how to find the local Community Risk Register.

Indices, or index-based approaches, also seek to allow comparison between diverse risks and hazards. Their composition depends on the selection of indicators—usually composite indicators on the basis of an underlying model of the multidimensional concept that is being measured—

which result in a meaningful, overall quantitative measure. The availability of useful and useable data is often a determining factor in such indices. Sociodemographic data, such as population level metrics of age, income, or sex as well as measures of social disadvantage (such as unemployment) and vulnerability (such as disability or pregnancy) are routinely collected in many countries at census. Composite variables of such data can thus be calculated at different geographic scales, from country level down to small administrative units. Environmental and meteorological data may be available at very different geographies, or with far less precision and thus the age old problem of assigning area level information to individuals or groups must be navigated with great care.

Multiple risk assessments by such means can simply be totalled to obtain an overall hazard level in a geographic location, but this approach overlooks the interaction and cascade between hazards which frequently result in more significant and widespread public health impacts than had the individual hazards occurred at separate points in time. These interactions have been classified into five relationship types (Gill and Malamud 2016):

Triggering relationships (such as rainfall triggering landslides)
Increased probability relationships (such as wildfire leaving an area at risk of landslides should rainfall occur)
Decreased probability relationships (such as rainfall reducing the risk of drought)
Coincidence relationships
Catalysis and impedance relationships (such as volcanic eruption triggering wildfire but impeded by tropical storms)

Qualitative multiple risk assessment methods seek to describe and classify hazard relationships to allow decision makers to select the most important relationships in their region. Semi quantitative methods use matrices to characterize interactions between hazards by the inclusion of multiple hazards in a single matrix, with interactions assigned a score based on judgement of the strength and direction of the interaction (Zschau 2017). Quantitative methods seek to use event or decision trees with underlying Bayesian probability distribution functions to weight particular branches and nodes. This approach has been used in the modelling of scenarios around volcanoes including Mount Vesuvius in Italy (Neri et al. 2008) and the

Kanlaon volcano in the Philippines (Neri et al. 2013) to analyse the risk of eruptions and the consequential hazards they may trigger.

Public health risk management techniques and countermeasures

The next stage of the process considers the options available to prevent or control the risks. It is likely that more than one possible risk management strategy will be available.

For environmental, chemical, and radiation incidents, countermeasures fall into two categories, preventative countermeasures to avoid or reduce people's exposure (sheltering, evacuation, and decontamination) and those used to treat casualties once exposure has occurred (antidotes and medical treatment). It is important to stress that lifesaving treatment should always take priority. Health plans should include arrangements for ambulance transport of casualties, be they contaminated by chemicals or radioactive material with serious injuries, without exposing ambulance crews to significant risk.

A combination of countermeasures can be used depending on the type, scale, and severity of the incident. This should be continuously re-evaluated as the incident evolves and more information is collated to inform the risk assessment. For all of this to happen effectively, multiagency plans need to be developed and exercised so that organizations understand their roles, how they will communicate with each other and members of the public, and the pros and cons of specific countermeasures. The plans should allow responders to scale the response up or down depending on the severity of the release and the outcome of the risk assessment.

For high-risk fixed sites industrial and nuclear installations, plans usually include local sheltering and evacuation strategies based on maps dividing a geographical area into zones, taking into account local infrastructure (e.g. availability of local transport systems, location of rest centres) and effective warning and informing of residents within a certain emergency zone (e.g. using sirens).

For all risk management techniques and countermeasures, vulnerable sections of the community need to be identified early as they may require assistance (e.g. people with special educational needs/disabilities, requiring

medical support, the elderly, the frail, and children) or not be able to understand the messages. Some population groups may be particularly sensitive extreme temperatures or to the substance released; for example, consideration should be given to minimize the exposure of pregnant women in a radiation incident.

Sheltering, shelter in place

Shelter in place (also called shelter *in situ*) is invoked when the safest place to take refuge or cover from an actual or perceived danger is indoors (e.g. in a house, business place, or school). Most buildings can provide significant protection against short-lived environmental, chemical, and radiation releases. In the United Kingdom, the message used by the emergency services, usually through the local media, is ‘go in, stay in, and tune in’ and was developed by an independent National Steering Committee on Warning and Informing the Public (HM Government 2004).

Vehicles, boats, and caravans offer a lower level of protection than residential building, so sheltering in these conditions should be a last resort and for short periods. Closing windows, air conditioning, and vents will help reduce airborne exposures.

Evacuation

Evacuation can range from small-scale, locally managed and coordinated evacuation (one or two streets) to mass (or wide-area) evacuations requiring national coordination (e.g. for wide-area flooding) (HM Government 2014). Evacuation should be conducted in a controlled, systematic way to minimize potential exposure and other risks. Mass evacuation is a complex undertaking as transport, support for vulnerable groups, and the availability of shelter in a designated local authority rest centre (e.g. a school or leisure centre) will be necessary. Longer-term psychological impacts of unscheduled evacuations among vulnerable populations must not be underestimated.

Evacuation may be preferred for longer-lived incidents, especially when it can be implemented before people are exposed (e.g. before a release reaches a community), or before an incident happens.

The fire and rescue services will activate pre-existing plans for evacuation of members of the public and non-essential personnel to a safe distance for defined scenarios, for example, where there is an explosive risk.

Decontamination

Decontamination usually refers to external decontamination of people to reduce further exposure or avoid secondary contamination. As an example of how decontamination can work see Box 11.12.4

Box 11.12.4 Decontamination planning in England and Wales

The management of public mass decontamination is the joint responsibility of the fire and rescue services and the Department of Health. The fire and rescue services are equipped with mobile mass decontamination units including disrobe and re-robe packs. Following the terrorist attacks in the United States on 11 September 2001, new equipment and training procedures, particularly focusing on mass decontamination in public places in the event of a chemical, biological, radiological, or nuclear (CBRN) attack, have been provided (Health Protection Agency 2009).

The UK Department of Health has developed Hazardous Area Response Teams (HART) within ambulance services (NARU 2018). These resources enable specially trained and equipped ambulance professionals to be able to care for patients in the event of major or catastrophic incidents where previously it may not have been safe for them to do so. This includes a CBRN capability, to be able to provide interim decontamination as well as full wet decontamination of casualties.

Where at risk contaminated casualties should be evacuated to a safe environment and individual or mass decontamination should be carried out as soon as possible, preferably within 15 minutes of exposure for maximum benefit. Casualties are usually asked to remove their clothes from head to foot to reduce the risk of inhalation of any contaminant. Recent research in decontamination techniques shows that, in the initial phase of an incident involving non-caustic chemicals, the blotting and rubbing of exposed skin surfaces with dry absorbent material, that is, dry decontamination, is most effective unless the use of water is recommended by expert advisors.

The water decontamination method is the rinse–wipe–rinse method and at its most simple may be just washing hands after any contact with flood water. After removal of chemically or radioactively contaminated clothing, casualties are asked to drench themselves under a lukewarm shower to remove water soluble material and dusts (rinse), apply a detergent solution

using a soft brush to remove organic matter (wipe), and drench again to remove the detergent (rinse).

Non-ambulant casualties and those with open wounds should be decontaminated by trained personnel.

Research continues into decontamination techniques and there are a number of ongoing studies comparing the merits of wet and dry decontamination as well as decontamination of other aspects such as hair, latest guidance and advice should always be sought in this area.

Non-invasive screening of the public for radioactive contamination can be used to triage large numbers of people and assess the need for medication intervention, decontamination, and/or further contamination monitoring. Depending on the radionuclides, walk-through portals and hand-held equipment can be used to detect internal or external contamination. Portable or transportable whole-body monitors should be used to detect the presence of internal contamination and for dose assessment following decontamination.

Antidotes

Treatment for chemical and radiation exposure is mostly symptomatic and supportive. Very few antidotes for individual toxins exist and where they do, they should be administered under medical supervision.

For nuclear reactor accidents where iodine usually forms a significant part of the release, the administration of stable iodine before or in the few hours after exposure, in conjunction with sheltering can form a very effective countermeasure strategy.

Depending on the chemical, antidotes can be used to form an inert complex with the poison, speed up detoxification, reduce the rate of conversion to a more toxic compound, and so on. For example, chelating agents such as dicobalt edetate are recommended to treat moderate to severe cyanide poisoning in adults and 2,3 dimercaptosuccinic acid (DMSA) has been recommended for lead poisoning. Prussian blue (ferric hexacyanoferrate) is used to increase the faecal excretion of caesium and thallium from the body, thus reducing the internal dose. Advice can be obtained in many countries on how to manage chemical and radiation exposure via local agencies such as poisons control centres.

Recovery

Recovery is the process of restoring and rebuilding the community in the aftermath of an incident; this can take years or decades for the most serious events. The recovery from an incident needs to be considered from the outset and most successful recovery strategies begin during the emergency phase of the incident by addressing the environmental, health, infrastructure, and economic impact of the incident. Recovery roles and responsibilities should be planned and rehearsed in a multiagency setting. The appropriate local level of government will usually lead the recovery phase of the incident; in the UK comprehensive recovery handbooks containing guidance have been developed to support evidence-based decision-making (Public Health England 2013, 2015a, 2015b).

Follow-up of affected populations

There are two main reasons to undertake follow-up of populations affected by chemical, radiological, or environmental incidents: part of the long-term response to help and provide services for affected people, and to gather scientific information about the health effects of the exposures that they may have received. In most cases, the decision to set up a follow-up study is done for elements of both reasons. A case study is outlined in Box 11.12.5.

The former may be particularly useful if there is to be ongoing treatment of or compensation for affected people. Compensation usually takes many years to organize, by which time the affected people may have moved away from the local area or died.

There are two major problems with emergency response follow-up studies that distinguish them from other epidemiological research. Firstly, the decision to set up the study may need to be taken very early on in the incident, in order to capture, as fully as possible, the cohort of participants for the study. Secondly, it may be more difficult than in a planned study to determine each individual’s exposure to the noxious agent.

It is not straightforward to decide if a follow-up study is needed in each incident. Done properly, the work will be resource intensive in all but the smallest of incidents. If the cohort does not accurately reflect all those who may have been harmed, then its scientific power and usefulness as a tool to

help patient care may be limited in the long term. Paranthaman et al. (2012) have proposed a decision framework to help responders decide if a follow-up health register study is indicated based on a Delphi consensus study of emergency responders and epidemiologists. The study presented participants with four scenarios and asked responders whether a follow-up study should be set up and why. Although there was a spectrum of views from the range of responders, 11 factors were defined by the participants as important in making the decision about setting up a health register. The factors are not mutually exclusive and their relevance needs to be debated by the team setting up the follow-up study.

Measuring individual or group ‘doses’ to noxious agents may be difficult in emergency situations as resources are rightly focused on more urgent aspects of the response. For some agents, for example intakes of radionuclides, there are accurate biodosimetry methods that can be used in the weeks and months following an incident to retrospectively assess exposure. However, for other agents there is no measurable signal after the event, or the signal decays very quickly. This poses real logistical problems if large numbers of people need to be measured and may well swamp national capability to perform such measurements. Triage arrangements may be needed to ensure that people with the highest clinical need for testing have priority.

In other situations, environmental measurements, combined with information about where people were at the time of the incident, what they were doing, and what injuries they may have suffered allow post hoc assessment of likely ‘doses’. These can be calibrated by actual measurements taken in smaller numbers of people with similar locations and behaviours at the time of the release.

Some of the work to set up a follow-up study is needed in the acute phase of the incident. Therefore emergency plans need to specify how the decision to set up a follow-up study will be taken and plan for the resource and practical implications of this work. Exercising these plans will help to spot rate-limiting steps and identify actions that can be done in advance, for example, detailed understanding of how to collect patient data from hospitals, community services, and rest centres, developing generic data collection, and patient information forms that can be adapted when an incident occurs.

Box 11.12.5 Understanding the impact of flooding and associated disruption on psychological morbidity

After widespread flooding in England in 2013/14, a multiyear National Study of Flooding and Health was established to examine the long-term impact of flooding on the mental health of people living in flood-affected areas.

There are methodological complexities in measuring the mental health impacts of flooding so collecting data on a range of personal factors was essential. Twelve months after flooding, the prevalence of probable psychological morbidity was found to be elevated among both flooded participants (depression 20.1%, anxiety 28.3%, post-traumatic stress disorder (PTSD) 36.2%) and among those who were disrupted but had no floodwater entering their homes (depression 9.6%, anxiety 10.7% PTSD 15.2%) (Waite et al. 2017).

Flooded participants who reported disruption to domestic utilities (such as electricity, gas, or water) or to healthcare had higher odds of all mental disorders than did other flooded participants, as did those displaced from their homes. For example, after adjusting for the depth and duration of floodwater in the home, the odds of probable depression were 1.7 times higher for participants who were displaced compared with those who were not (Munro et al. 2017). The amount of warning received appeared to be a protective factor among those who were displaced: those receiving no warning before flooding tended to report more symptoms of depression and PTSD than those who were forewarned.

Public reassurance in emergencies and incidents

The scientific basis of accurate public risk communication is mature. There is also a considerable literature on the need to build trust in the systems that will be used in an emergency to protect casualties, the public, and emergency responders.

Environmental, radiation and chemical exposures can provoke all of the ‘fright factors’ that are known to be most feared by the public (Slovic 1987; Meara 2002). WHO guidance exists to help risk communicators in emergency situations (WHO 2018a). A case study is presented in Box 11.12.6.

Regulators and organizations with responsibilities for health protection have been criticized for taking a low media profile during emergencies (House of Commons Science and Technology Committee 2012). Scientific organizations can find it difficult to communicate in high-pressure situations where the facts are not known and the uncertainties about what may occur are extensive.

Box 11.12.6 Case study: public risk communication during the polonium contamination in London 2006

In 2006, following enquiries relating to an unexpected death, radioactive polonium was found to have contaminated many public places in London (Rubin et al. 2007; Morgan et al. 2008). Detailed investigation eventually revealed that the public health risks were low, but this was not known at the start of the incident. The investigation needed clear objectives and a prioritized approach to make best use of the environmental and people-monitoring facilities that were available.

During the emergency response, researchers carried out a random telephone survey of 1,000 Londoners and more than 100 potentially exposed people. The survey showed that health protection communications, including media interviews and a daily press release, were generally successful as only 11.7% of those who replied perceived their health to be at risk because of the incident. The number of visitors to London did not decrease.

Daily health protection press releases were considered important to keep people informed. Seventy-one per cent (71%) of responders understood that they could not be contaminated if they had not been in the relevant venues. Fifty-eight per cent (58%) of responders understood that polonium is only dangerous if it enters the body.

The authors suggested that the factors contributing to this effective public communication were:

- The incident was linked to espionage rather than terrorism in the public consciousness. People who thought the motive was terrorism (15% of the sample) were significantly more likely to feel that their health was at risk than the people who attributed the incident to espionage, criminal activity, or spying.
- The public perception was that one person had been targeted. People who thought the incident was intended to harm the general public (14% of the sample) were significantly more likely to feel that their health was at risk than those who thought that it was intended to harm one person only.

Despite these positive outcomes, people who had been in contaminated areas and had been offered urine testing tended not to be happy with the information they received. Some of this displeasure was inevitable because they wanted details related to the criminal investigation that could not be made public. Other people wanted more numerical information about their test results. Uniquely for polonium in urine testing, this was difficult to provide because the same amount of urinary excretion can be associated with a radiation dose that varies by a factor of ten, depending on the assumptions made. For the lowest category of risk, there were insufficient resources to undertake detailed dose assessments, using individual-specific assumptions so people were only told that their results were ‘of no concern’. These complexities are not easy to put across in the midst of an emergency incident.

A small number of people (seven out of 3,837) who contacted the telephone helpline that was set up for the incident failed to be reassured by direct discussion with specialist health protection staff, even if they had not been at any of the contaminated venues (Morgan et al. 2008). Of these, four were contacted by a psychiatrist who found evidence of pre-existing psychological stressors and a history of health-related anxiety. The authors concluded that access to psychiatric help may be useful in incidents such as the polonium contamination in London.

Identify and publish lessons

Identifying lessons from both incidents and exercises is an integral part of the emergency preparedness and response cycle, in order that learning can take place. This requires a structured debrief process to capture learning at various stages of emergency response and recovery. The WHO After Action Review process (WHO 2018b) is a good example of a structured approach to identifying potential learning which is integrated with the response and recovery stages of an emergency. Implementing learning, altering plans, and disseminating the lessons are key responsibilities of responding organizations. Understandably, repetition of lessons identified in previous incidents or exercises, in subsequent emergencies, is increasingly seen as avoidable and the learning component of the planning and response cycle is as critical as the response itself.

This means that plans should be updated where necessary following incidents or exercises and learning should also be disseminated. Reporting incidents is vital to share learning, decrease the chance of the incident reoccurring, and to improve emergency response. However, many incidents and emergencies are very poorly documented. Incident reports may also be useful for members of the public who have been placed at risk, colleagues who are responding to similar incidents, and public health professionals who are called to give evidence in public or legislative inquiries into the incident. Only with detailed documentation can lessons be identified that can then change policy and practice.

A process to ensure consensus on what information will be gathered and how data collection will be organized during and after an incident or emergency should be established as part of the pre-incident emergency planning. Collation of data for reporting should start as soon as possible during the crisis event with plans for continuous updating as more data become available from the multidisciplinary (or potentially international) response.

Organizations, including public health partners, performing incident or emergency responses should jointly develop and document how the quality and validity of information are assured. This needs documented procedures and training for incident responders, including administrative staff, in the methods for information gathering, analysis, and quality assurance.

Kulling et al. (2011) set out a summary of the requirements for reports on health crises and critical health events and recommended issues that should be managed actively at an early stage in a response. These include:

The mandate for the emergency report and that of the respective authority/organization.
Early identification of the authors and their responsibilities.
Ethical approval and quality assurance statements for the report if required.
A summary of the pre-event status if needed, such as baseline disease patterns and user patterns of hospitals and health facilities as well as other relevant previous incidents or disasters described as well as preparedness plans.
A summary of the incident or emergency.
A method statement to include descriptions of hazard and exposure assessments, decision flow, and information management.
A description of the interventions and how they were evaluated in terms of effects, outcomes, and impacts balanced against the goal(s) and objectives of the interventions. It may be useful to distinguish between immediate-, medium-, and long-term impacts.
Coordination and collaboration between organizations from health and other sectors.
Adverse health effects in the responders.
Identify interventions that restore normality to the pre-event level, including how responding organizations intervened to provide resilience and reduce vulnerability in people at risk.
Consider summarizing the lessons identified by describing:

- What went well.
- What went badly.
- What could be done better.

The final task is to publish the report in an appropriate peer-review publication for all to share and learn from and how these can be used to reduce further impacts (Box 11.12.7).

Box 11.12.7 Chemical incident lessons and the Seveso Directives

Since the onset of the industrial revolution, incidents involving chemicals and industry have led to significant loss of life worldwide. Many incidents have occurred and publication of the lessons and learning has resulted in clearer and more implementable legislation (Rees and Waite 2015).

An accident at Flixborough, United Kingdom in 1974, in which a vapour cloud explosion killed 26 people and injured many more almost triggered a ‘domino-effect’ incident at a neighbouring site. In

1976 at Seveso, Italy a chemical plant producing pesticides and herbicides released a large cloud of dioxins. While no fatalities were immediately reported at Seveso, dioxins are known to be lethal in man, even in very small doses. A large area of land was contaminated, 600 people had to leave their homes and up to 2000 were treated for dioxin poisoning. The AZF factory in Toulouse, 2001, had a catastrophic explosion, annihilating the entire compound and instantly killing 29 people. The official investigation indicated that the explosion was the result of mislabelling, which led to compounds reacting that should never have been mixed. Research indicated that better management and improved land use surrounding the plant would have limited the extent of the disaster substantially. In 2005 the Buncefield explosion and fire at an oil storage depot in the United Kingdom was unprecedented at the time, and was the result of an unrecognized explosive mechanism where a spill allowed the formation of a vapour cloud that was confined in such a way by the plant layout. This exploded in a characteristic way; an Open Flammable Cloud Explosion. Within the European Commission the Seveso Directive which addresses Technological Disaster Risk Reduction led to changes in policies included inspections (European Commission 2017). Checks were made to ensure that the policies were being thoroughly implemented, and to broaden and tighten legislation around storage sites to help prevent future unprecedented disasters by effective and flexible planning involving both private and public entities. As these incidents were documented action was taken to introduce a subsequent series of Seveso Directives by the European Commission leading to a significant reduction in the number of chemical accidents in the region, saving potential costs in lives, environment, and finance.

Conclusion

This chapter on the principles of public health emergency response for acute environmental, chemical, and radiation incidents summarizes the stages of response to emergencies using a generic ‘all hazards’ framework and a ‘source–pathway–receptor’ risk assessment model which is adaptable to any situation and conforms with international obligations.

In recent years there have been many environmental, chemical, and radiation disasters that have challenged the emergency preparedness of countries around the globe. Adequate resources for response and pre-planning are vital to deliver a professional, and proportionate response and to define the important factors to consider when establishing follow-up studies after a major incident. The knowledge gained by careful evaluation of emergency actions can greatly improve the efficiency of emergency preparedness and safety of subsequent responses. However, there are great challenges in doing research under such circumstances. A significant number of evidence gaps remain and so detailed documentation and follow-up of

future incidents will continue to be needed to fill those gaps and improve emergency preparedness and response in the future.

ACKNOWLEDGEMENT

With thanks to both Dr Naima Bradley and Dr Jill Meara, Public Health England.

Private support of public health

Quarraisha Abdool Karim and Roger Detels

Introduction to private support of public health

Private support for public good may be understood as the cooperation between private individuals, foundations, and/or the commercial sector and the public sector in order to more effectively meet the needs of society locally and globally (Buse and Waxman 2001). This relationship is not necessarily unidirectional, and in several instances, also benefits the giver through increases in positive product demand from company branding through positive media coverage that accompanies giving (Broadbent and Laughlin 2003). The World Health Organization (WHO) defines public–private partnerships (PPPs) in the health sector as the bringing together of a set of actors for the common goal of improving the health of populations based on mutually agreed roles and principles (Kickbusch and Quick 1998). While these principles are based on the founding ideas and values of human ethics such as beneficence, non-maleficence, autonomy, and equity (Buse and Walt 2000a) the reality is that the relationship between giver and recipient is not an equal one.

Over time, while anonymous individual giving has continued, some of these ad hoc institutional contributions have evolved into more defined and legally recognized structures also referred to as philanthropic organizations and includes giving by more wealthy individuals and families, including the Gates and Zuckerbergs, as well as corporate institutions. Giving, particularly by North Americans, dates back to the formation of ‘foundations’ in the earliest years of the twentieth century as a result of wealth acquired through industrialization. In the United States, this idea was incentivized by a ‘tax break’ provided by the US government to private companies and citizens who donated a certain proportion of their wealth to

federal or state government projects or priority initiatives (Butler 2001). Private entities had the autonomy to choose which government or global projects or priorities they would support, and the extent thereof, while deriving the benefit of reduced taxation.

This type of charitable tax deduction by the US government, has allowed foundations to reduce their tax burden by as much as 25% (Strom 2007). *The New York Times* has estimated that charitable deductions cost the US government US$40 billion in lost tax revenue in 2006 (Strom 2007). In effect, this substantial private philanthropic support means that the foundations, and not the US government, are determining where significant public funds are spent and, thus, are having considerable influence over everything from medical research to social policy and politics. Their giving reflects their personal interests and biases. Some of the larger foundations and philanthropists have larger resources than international agencies such as the World Health Organization and the governments of many smaller countries. Philanthropists and foundations take pride in their autonomy in determining what to invest in and traditionally have identified areas that minimize overlap and define their giving identity. Eli Broad, one of the major donors, summarizes the essence and impetus for private giving by asserting that smart philanthropists get more for their money than governments because they know how to invest wisely (Strom 2007).

However, it is important to recognize that foundations often determine their targets and objectives on personally identified and defined priorities rather than an objective assessment of international and national need. Foundations are likely to invest in areas that governments may be reluctant to for political or moral reasons, for example, sexuality education, gender-based violence, fertility control, and harm reduction programmes. Some, such as the Soros Foundation and the Koch Brothers, even invest in promotion of political ideologies which have significant impacts on social issues and public health.

History of giving

One of the earliest known foundations in the United States was the Russell Sage Foundation that was founded in 1906 with a focus on working women and poverty-related illnesses (Hammack and Wheeler 1994). The

establishment of larger and more encompassing foundations began with the founding of the Carnegie Foundation by Andrew Carnegie in 1911 ‘to do real and permanent good in this world’ (Carnegie Corporation of New York n.d.), followed by The Rockefeller Foundation in 1913 (Menasha and Hsig 1915).

These early gifts had a significant impact on institution creation to support and build public health capacity. Public health provided the optimal mechanism through which Rockefeller philanthropy was able to apply scientific findings for the public good (Birn and Fee 2013). The Rockefeller Foundation established the International Health Commission in its first year (Rockefeller Foundation 2013a). This was the first allocation of funds from private sources for international public health activities and had a wide sphere of influence—52 countries on six continents and 29 islands to improve their public health systems. The Rockefeller Foundation simultaneously initiated a 20-year programme to support the Bureau of Social Hygiene which focused on research and education on fertility control, maternal health, and sex education. This foundation played a key role in founding the world’s first schools of public health, first at Johns Hopkins, then at Harvard, and later in other parts of the United States, as well as in 21 other countries that included establishment of the London School of Tropical Medicine and Hygiene in 1921, the China Medical Board in 1914, and the Peking Union Medical College in 1921. The last two institutions have played a pivotal role in the development of public health in China (Rockefeller Foundation 2013b).

The Wellcome Trust, which was established in 1936 in the United Kingdom, is dedicated to supporting research to improve human and animal health. At the time of writing, it is one of the wealthiest foundations in the world (Wellcome Trust n.d.), following the Gates Foundation, the Chan-Zuckerberg Foundation, and the Dutch Stichting INGKA Foundation (Table 11.13.1).

Table 11.13.1 Wealthiest charitable foundations

Organization	Worth
Chan-Zuckerberg Foundation	$58 billion
Bill and Melinda Gates Foundation	$42.3 billion
Stichting INGKA Foundation	$36.0 billion
Wellcome Trust	$25.9 billion
Howard Hughes Medical Institute	$16.9 billion
Ford Foundation	$11.2 billion
J. Paul Getty Trust	$10.5 billion
Kamehameha Schools	$10.1 billion
Mohammed bin Rashid Al Maktoum Fdn	$10.0 billion
Azim Premji Foundation	$9.8 billion

Source: data from Wikipedia https://en.wikipedia.org/wiki/List_of_wealthiest_organizations

A hallmark of this type of giving was the insightfulness of individuals in anticipating, prioritizing, and filling an important gap and creating a strong foundation for others, including governments, to build on. This type of nimble, risk-taking investment is in keeping with the business model based on entrepreneurship that sees and seizes opportunities. These are the principles on which the foundation wealth was created—unfettered by ponderous, risk-averse decision-making, never-ending procedures, and systems that are the hallmark of most government and public sector bureaucracies.

Current giving

Since those early years of giving, private support for public health has increased in magnitude and scale, particularly in the past decade. Today, the Bill & Melinda Gates Foundation, one of the largest private grant-making foundations in the world at the time of writing, supports major programmes worldwide that include a US-based programme to enhance secondary and

post-secondary education, a global development programme which focuses on the alleviation of hunger and poverty, and a global health programme that includes increasing access to childhood immunization programmes, prevention and research in major infectious diseases such as tuberculosis (TB), malaria, and HIV (McCoy et al. 2009b). This foundation has single-handedly redefined the concept of individual social responsibility and has inspired similar giving trends across the globe, including recruiting wealthy individuals in developing countries in support of public health.

In, 2015, Priscilla Chan and Mark Zuckerberg, aged 31, new billionaires from social media, pledged to spend 99% all of their fortune within their lifetimes to 'cure, prevent, or manage all diseases by the end of the century'. In South Africa the Motsepe Foundation was established in 2013 by Patrice Motsepe, one of the country's wealthiest individuals, and listed on the Fortune 500's top ten wealthiest people, committed 50% of his family wealth to philanthropy and $US10 million over the next five years towards several health, education, and job creation efforts (Morvaridi 2012).

Globally, there are now over 40 major foundations, as well as countless smaller ones (Robert Wood Johnson Foundation 2012; Foundation Center 2013) (Table 11.13.1). This increase can be attributed in part to at least three phenomena: substantial growth in personal wealth among a few, global solidarity around the AIDS epidemic and other health threats, and the rise in citizen pressure for corporate accountability/social responsibility. Corporate social responsibility programmes are a new form of giving that adopt a more entrepreneurial approach for product branding, creating brand loyalty and increasing product sales but are not the focus of this chapter.

Globalization of health threats, global solidarity, and the emergence of public–private partnerships

The global burden of disease, especially infectious diseases, disproportionately affects populations in developing countries, due to poverty, weak healthcare delivery systems, inadequate investment in health, and inadequate access to pharmaceuticals, vaccines, and medications (Widdus 2001). Post-industrial revolution eradication of these diseases in developed countries and the growth of a for-profit pharmaceutical industry

have resulted in neglect of research and development in drugs and other medical products for ‘diseases of poverty’, since such products are perceived as being not likely to generate significant return on their investment.

The rise of multi- and extremely drug-resistant strains of TB (MDR- and XDR-TB), outbreaks of emerging diseases causing a severe acute respiratory syndrome, swine flu, avian flu, etc., and the growing antibiotic resistance of previously controlled infections, have served as sharp reminders of the continuing threat posed by these neglected tropical diseases, as well as emerging and re-emerging infectious diseases, regardless of geographical location, in our increasingly globalized world.

Interventions that reduce costs, provide market incentives, and create infrastructure that will allow for product access (Widdus 2001) require the private sector, such as pharmaceutical companies, to collaborate and work with public and not-for-profit entities to ensure a fast and efficient response (Widdus 2001, 2005). The proliferation of global PPPs (Croft 2005) reflects this approach and is rapidly reconfiguring the global public health landscape (Buse and Walt 2000a).

Other examples of private support

Private support of public health given by foundations, industry, pharmaceutical companies, and professional organizations has been directed towards disease control and treatment, poverty alleviation, education, training of health workers, infrastructure development, research, improved agricultural practices, health information dissemination, and sponsorship of the many global health alliances.

Specific examples include the provision of drugs and the reduction of drug prices for developing countries, the earliest example being the Mectizan Donation Program by Merck & Co. Inc. for treatment for onchocerciasis (river blindness) in West Africa in 1988. In 1998, GlaxoSmithKline provided albendazole for treatment of lymphatic filariasis as part of the Mectizan programme. To date, this ongoing programme has reached more than 80 million people (Mectizan Donation Program 2012).

The development, manufacture, and dissemination of the Sanchol oral cholera vaccine is a notable example of the joining together of foundations,

research institutions, governments, and pharmaceutical companies. Contributors to this PPP included Sweden, Vietnam, Korea, and India, the National Institute for Child Health and Human Development (USA), the Gates Foundation, the Global Vaccine Initiative, the National Institute for Cholera and Enteric Diseases (India), the International Center for Diarrheal Disease Research, Bangladesh, Shantha Biotechnica (India), Eubiologics (Korea)m, and VaBiotech (Vietnam) (Human Vaccines 6:9763–66, September 2010, Landes Bioscience; WHO Weekly Epidemiologic Record no. 13, March 26, 2010).

Another important contribution of private agencies has been research. The Howard Hughes Medical Institute, for example, was established by Hughes Aviation to conduct research into human illness (Howard Hughes Medical Institute n.d.), and has established and funded research centres (Howard Hughes Research Institutions) within major academic medical centres in the United States, as well as in Kwa-Zulu Natal in South Africa. There are also the very significant contributions made by pharmaceutical companies to research and development of vaccines and treatments, both independently and in PPPs.

Activism

The role of activism in advancing the scientific agenda and public access to product advances is most apparent in HIV/AIDS. Since the first reported cases of AIDS in the early 1980s in the United States and the discovery of the causative organism, HIV has spread rapidly across the globe, resulting in several million deaths prior to the discovery of effective antiretroviral therapy (Curran and Jaffe 2011; Sharp and Hahn 2011). The transformation of AIDS from a uniformly lethal disease to a chronic, manageable condition has resulted in rapid and phenomenal declines in mortality rates in industrialized countries, and is having an increasing impact on reducing HIV deaths in developing countries, thanks to the support of the Gates and Clinton Foundations and the support of the US government (President’s Emergency Plan for AIDS Relief (PEPFAR)).

The hosting of the XIIIth International AIDS Conference in Durban, South Africa in 2000 was the first time that many in industrialized countries came face-to-face with the plight of the millions of people infected with

HIV in developing countries, who were continuing to die because they were unable to access antiretroviral treatment and high costs were posing a major barrier. While the inequities and disparities in terms of access to life-saving drugs and healthcare between industrialized and developing countries are not new, this conference was a sharp reminder, and catalysed a whole new approach to public giving in healthcare provision and novel partnerships.

The creation of the Global Fund for AIDS, Tuberculosis and Malaria (GFATM) in 2007 addressed three diseases that, in combination, are major contributors to high rates of morbidity and mortality in resource-constrained settings, and which contribute disproportionately to the global burden of disease (Vitoria et al. 2009). Funding from the Bill & Melinda Gates Foundation stimulated additional large donations by Warren Buffett and the William Clinton Foundation.

The GFATM model builds on the emergence of formalized PPPs to address specific public health challenges, including product development stimulated by The Rockefeller Foundation in the late 1990s with their investment in HIV vaccine development through support for the International AIDS Vaccine Initiative (IAVI) at a time when most had given up on a vaccine. IAVI energized the quest for an HIV vaccine through its intramural programme, expanded the numbers of academic institutions engaged in this quest, and encouraged some pharmaceutical companies to invest in vaccine development.

This model was used subsequently by The Rockefeller Foundation to leverage and harmonize resources to increase access to drugs to reduce mother-to-child transmission (MTCT) of HIV through the MTCT+ initiative coordinated by the Elizabeth Glaser Foundation, and access to antiretroviral treatment for AIDS patients in resource-constrained settings (Barr 2007). The disease-and/or product-specific PPP approach builds on the Bayh-Dole Act that was passed by the US Congress in 1980 (Barr 2007) to promote collaboration in the United States between the federal government, universities, and private pharmaceutical companies for development and marketing of new pharmaceutical products.

Public–private partnerships (PPPs)

PPPs may be classified or described according to purpose, organizational structure, scope of activity, or approach. Three categories are described as follows (Buse and Walt 2000b):

Product-based partnerships that enable access: this includes drug or product donation programmes; bulk purchase of products for low-income countries, for example, the albendazole donation programme; and childhood immunization programme vaccine purchases.
Product-development partnerships that enable and incentivize partnerships for discovery and/or commercialization, for example, the Malaria Vaccine Initiative (MVI) established in 1999, the IAVI described earlier, the International Partnership for Microbicides, the development of the Sanchol cholera vaccine and the Tuberculosis Vaccine Initiative.
Systems-based partnerships that support government efforts to strengthen health service delivery through health systems strengthening.

A PPP can involve financing from various sources such as equity contributions, debt contributions, bank guarantees/letters of credit/performance guarantees, bond/capital market financing, mezzanine/subordinated contributions, and intercreditor agreements in some combination of equity and debt (World Bank Group 2011). Sources may include governments, private foundations, individuals, and the business/corporate sector (McCoy et al. 2009a). The wealthiest non-profit charitable foundations globally are the Bill & Melinda Gates Foundation (Vogel 2006), the Chan-Zuckerberg Initiative, the Stichting INGKA Foundation, the Wellcome Trust, and the Howard Hughes Medical Institute (Table 11.13.1). While in previous years giving was largely unregulated, in the light of the post-2009 global financial and economic crisis, much has changed. Countries such as the United States have called for more strict regulations regarding tax credits for charitable giving by private companies. This would cover federal taxes, but the individual states have their own regulations regarding state-controlled taxes. The government of China regulates which non-governmental organizations can operate in their country. The increase in giving to resource-constrained settings by wealthier governments and private donors has elevated health to diplomatic status, wherein good health is viewed as a basic human right and essential for economic development and social stability at a country level. This goal

of ensuring good governance and sustainable societies is facilitated through bi- and multilateral partnerships between those who have and those who do not through the establishment of a global civil society (Vogel 2006) that redefines the meaning of globalization.

Since the inception of PPPs in the United Kingdom (Spackman 2002), over £56 billion has been contributed to over 800 projects, including car parks, schools, tolled highways, and power plants (Garvin and Bosso 2008). Globally, much attention has been given to healthcare, education, social housing (Flinders 2005), and disaster control. Healthcare in particular remains one of the major recipients of PPP funding (Howard 1983, 1991; Novignon et al. 2012). PPP initiatives in health include infectious disease control (Ardian et al. 2007; Kane et al. 2010; Sinanovic and Kumaranayake 2010; Lal et al. 2011; Sturchio and Cohen 2012), drug and vaccine development (Wheeler and Berkley 2001; Nwaka and Ridley 2003; Nwaka 2005; Sanhai et al. 2008), management of hospitals (Goldman et al. 1992; DeVol et al. 2007; Lester 2012), and building of hospitals (Weiner and Alexander 1998; McKee et al. 2006) and institutes of health.

PPPs can function at a global or country level and imply a mutually beneficial, synergistic alliance between the private and public sectors towards a common goal that is shaped by good governance, equity, and efficiency (Goldman et al. 1992). While the benefits of PPPs include mobilization of funds, technology transfer, strengthened delivery systems (Kraak et al. 2012), greater efficiency in terms of time, scope, and improved options, there are also risks involved. PPPs are not the solution to all health challenges, and may not be the most effective or efficient approach in several instances (UK Parliament 2011). For example, the UK Parliament's Treasury Select Committee's review of the PFI scheme in August 2011 concluded that: 'Private Finance Initiative (PFI) funding for new infrastructures such as schools and hospitals does not provide taxpayers with good value for money, and calls for stricter criteria to govern its use'. Careful thought and planning need to be given to evaluate the appropriateness of external funding in each case to ensure it is not counterproductive.

In the health sector, a significant PPP exists between the WHO and the corporate sector (Buse and Waxman 2001). This partnership builds on the United Nations (UN) idea of a 'Global Compact' (Williams 2008) that encourages corporate responsibility in the areas of labour, human rights,

and the environment in response to globalization (Buse and Waxman 2001). What is distinctive in this partnership is the commitment to health and the principles inculcated in its mission and accountability to its constituency, namely its member states (Buse and Waxman 2001). The corporate partnership with WHO has been met with mixed reactions. Some board members have expressed concerns that commercial interests would mean compromising the integrity of the WHO in terms of subordination of its values, re-orientation of its mission, weakened capacity to promote and monitor international regulations, displacement of priorities, and self-censorship (Buse and Waxman 2001). A number of examples cited for this threat of 'institutional capture' include: (1) guidelines for management of hypertension that were unduly influenced by a pharmaceutical company that had stood to benefit from the drugs prescribed, and (2) deliberations on breastfeeding that were considered to have been censored in favour of the WHO's new set of commercial constituencies (Buse and Waxman 2001).

At a country level, delays in procurement processes or changing needs of communities (Fussel and Beresford 2009) can reduce the efficiency and nimbleness of private partners (Hodge 2004; Fussel and Beresford 2009), and rigid commitments can undermine existing government policies and infrastructure, resulting in coexisting government projects being jeopardized and government priorities and agendas being undermined in developing countries.

There were more than 90 international partnerships in health in 2004 (Nishtar 2004). The majority addressed infectious diseases, notably AIDS, TB, and malaria. Some involved individual governments, non-governmental organizations, or both, forming an alliance with the for-profit sector. For example, Sanofi-Aventis has an extensive international programme of humanitarian sponsorship, including a partnership with the Nelson Mandela Foundation and the South African Department of Health to provide free TB treatment in severely affected areas within South Africa (Sanofi-Aventis 2007).

Other notable partnerships are the global health alliances, such as the Global Alliance for Vaccines and Immunizations, Roll Back Malaria, the Stop TB Partnership, and the Global Polio Eradication Program. They may be principally driven by a company, be legally independent, or be hosted by a civil society organization (Nishtar 2004). The Stop TB Partnership, for example, comprises a network of more than 500 partners, including

governments of both developed and developing countries, research and technical health institutes, multilateral organizations, civil society, pharmaceutical companies and other industry partners, and is housed within the WHO (Stop TB Partnership n.d.).

Prioritization of need: competing candidates

One of the major issues facing PPPs is the correct distribution of funds based on the degree of perceived need. Depending on the period in question, as well as the global climate in terms of crisis management, funds are generally distributed according to urgency and magnitude of need. In the healthcare sector, much attention has been given to the global HIV/AIDS pandemic, but recent literature cites a need for a more balanced and better-rounded approach (Bygbjerg 2012). Furthermore, over and above the current agenda of infectious diseases, particularly in low-and middle-income countries, there are issues of economic development, industrialization, urbanization, investment, and ageing, which in turn drive the rising prevalence of non-communicable diseases (NCDs), the majority of which now occur in developing countries (Bygbjerg 2012). Malnutrition, including undernutrition, increased obesity associated with increased economic status, and infection in early life tend to increase the incidence of NCDs in later life (Bygbjerg 2012). In addition, the presence of infectious diseases and NCDs together (Boutayeb 2006) can result in adverse interactions (Bygbjerg 2012). Therefore, attempts to fund each health initiative separately are likely to exacerbate the overall situation and distort the countries' health priorities (Bygbjerg 2012). Joint approaches that target improving the healthcare system as a whole are preferable (Bygbjerg 2012). Towards this end, the United Nations identified 17 sustainable development goals in 2015.

Challenges

While the concept of PPPs might be conceptually appealing, they are associated with many challenges (Hodge and Greve 2005; Asante and Zwi 2007) such as prioritization, sustainability; collaboration between donors,

governments, health departments, and civil society; corruption; and numerous ethical and moral dilemmas. Other existing challenges include balancing private commercial interests with public health interests, managing conflicts of interest, assessing partnership compatibility, and evaluating partnership outcomes (Kraak et al. 2012). In addition, money borrowed from the private sector is often more expensive than money borrowed by governments, and these costs are passed along to the public, although the private sector would assert that they can save money in the end because they can operate with greater efficiency. Others argue that the initial capital outlay required may counter the efficiencies gained. Moreover, these expenditures need to be translated into the correct and most effective set of approaches, strategies, and investments for improving the health of the poor (McCoy et al. 2009a). There are also issues of transparency and government oversight (Fussel and Beresford 2009). Commercial considerations may limit public oversight during procurement (Fussel and Beresford 2009). Contract provisions may limit changes that are necessary later on in the project in order to safeguard public interests as new public policies and challenges evolve (Fussel and Beresford 2009).

Private investments and global health—at a crossroads?

Private giving in all its forms has enormously benefited individuals, institutions in the United States and outside, the recipient countries, and global health has achieved goals which otherwise would have been impossible to attain and importantly within a relatively short timeline. There is no question that the recent surge in giving has reduced health disparities and changed the global landscape in select diseases, and is at an important crossroads. In contrast to private giving in public health in the early twentieth century that was modest, catalytic, and individually determined, the giver today is much more visible, contributions much more substantial, and there is active involvement by more players in shaping the global agenda, national agendas, and in decision-making on setting priorities and resource allocation in international bodies and at a country level. The magnitude of the budgets of a few foundations has in some instances overshadowed the capacity of international organizations such as WHO and individual countries to achieve their own agendas, as well as the

contributions/priorities of smaller philanthropic organizations. Differing priorities of these different players can, in some cases, create uncertainties as to their added value. Thus, skewing by philanthropic giving of the priority setting and investment process globally and nationally has associated costs that may sometimes outweigh the benefits. For example, some perceive a conflict of interest when a foundation or industry plays a pivotal role at this level of decision-making, particularly where there may be some vested interest in the products used or in determining what proportion of the budget goes to which country or health need. The recent founding for a Smoke-Free World supported by the tobacco industry raises some of these issues. Other concerns include the imposition of unduly onerous conditions on the disbursement and use of the funds. While there is a need for accountability in use of funds for their intended purposes, that accountability should enable the desired outcomes to be reached effectively and efficiently, while respecting national sovereignty and avoiding excessive micromanagement.

Corporate social responsibility programmes have a different set of issues compared to foundations (Shah 2011). For example, while Rio Tinto, one of the largest global mining firms, is justifiably proud of its success in confronting malaria in Equatorial Africa, it has at the same time dumped billions of tonnes of toxic waste in Papua New Guinea. Similarly, Coca Cola's global distribution system has enabled more effective distribution of oral rehydration salts for diarrhoea, a major killer of children, particularly in Africa. On the other hand, Coca Cola and other producers of modified, unhealthy fast foods are also contributing to the burgeoning increase in obesity and NCDs in developing countries.

Foundations have always based their giving on the personal perspectives of their founders and subsequent leaders. They too often do not consult public health leaders in determining these goals. With the influx of large sums of money by a few foundations, this approach can very easily distort the public health agenda globally and nationally, as well as the roles of smaller foundations.

Large donations by private industry to international organizations like the WHO create an inherent dilemma for the latter. With over 80% of its budget coming from industry, the WHO has limited flexibility to focus funds on its own priorities. For example, in 2004–2005, WHO ended up spending 61%

of its budget on illnesses that accounted for only 11% of global mortality because of designations of the donated funds.

At a national level, large donations can dwarf the total budget of the recipient country and cannot be matched by the local government in many resource-constrained settings. The concern is that the local public health agenda could end up being determined by external agencies, which is a particular problem when the donor's agenda is not aligned with the country's priorities and diverts scarce resources, such as trained personnel and infrastructure, to lower priorities. Donor programmes often offer higher salaries that draw staff out of the public sector, leaving fewer staff within government to work on other health priorities, which results in deterioration of other important public health programmes and exacerbation of the existing public health human resource crisis extant in most developing countries. For example, in Haiti, the dramatically improved HIV/AIDS situation, facilitated by huge private funding that consumed most of the health workforce, resulted in a concurrent decline in other measures of the population's health, including infant mortality rates (Farmer and Garrett 2007).

In many settings, local government funding typically is less than 5% of total government expenditures. External funding can therefore perpetuate underfunding of health and undermine the responsibility that the government takes for healthcare delivery in their country. In countries with entrenched non-functioning bureaucracies and corruption, donor funds could exacerbate corruption, as funds are diverted from their intended purpose to benefit some government officials.

There are clear advantages to private funding being directed to specific public health challenges and emergencies. This has enabled eradication of smallpox, substantial increases in childhood immunization coverage, and stimulated improved responses in natural disasters and emergency situations. This type of funding works well when there are mutually agreed upon priorities among the various stakeholders, and quick and nimble investments for a short duration while the responsible parties work on plans and systems to address longer-term sustainability issues.

In relation to long-term sustainability in this context, there are at least four inter-related concerns. Firstly, when private donations are not synchronized with global or local priority setting and are targeted at chronic conditions that require a long-term investment, such as AIDS, withdrawal

of funding could result in a sharp worsening of the situation. In the case of AIDS, for example, an interruption in medication supplies could lead to treatment interruptions and promote the emergence of drug-resistant strains of HIV. Hence, significant private funding initiatives with a specific long-term focus, for example, eradication of poliomyelitis or development of a new drug or vaccine, need to be sustained until the goal is achieved for such investments to be effective.

A second area where issues of sustainability are a concern with private funding relates to a foundation having a diverse portfolio. Specifically, the concern here relates to the withdrawal of funding before the goal is achieved or the shifting of funds from one incomplete initiative to a new one. While in the corporate world this type of continuing prioritization and re-prioritization is typical, such an approach could be counterproductive when addressing a multitude of public health challenges that are often different than those confronting corporations. As an illustration, the Gates Foundation provides significant funds to eradicate poliomyelitis, support childhood immunization programmes, develop an AIDS vaccine and microbicides, and pre-exposure prophylaxis studies. In addition, its funds support the Grameen Foundation that uses microfinance loans to empower women in Bangladesh. In partnership with The Rockefeller Foundation, the Gates Foundation supports novel agricultural practices in developing countries to enhance food security. All of these initiatives are important long-term projects with uncertain outcomes. When and how decisions will be made to continue or stop investments will have a critical and wide-ranging impact on countries receiving this aid.

A third area of concern relates to who and how priorities are identified, particularly in settings with multiple challenges. For example, some express concern that the substantial funding in AIDS treatment is at the expense of other health priorities that may have a greater impact on morbidity and mortality, such as diarrhoea and respiratory disease. Others view it as an opportunity to concurrently strengthen healthcare delivery systems and integrate services, notably for TB, maternal health, and infant health, resulting in an overall benefit to all health services.

With the global efforts to treat AIDS patients, a new and major partner has been the pharmaceutical industry. The unprecedented price cuts and negotiation of intellectual property rights have been laudable and quoted as an example for extension to other diseases and products. Capacity building

and technology transfer to less developed countries is viewed as a major opportunity to enable national governments in developing countries to meet the needs of their populations, as opposed to medication donations that meet short-term needs but create longer-term dependence.

A fourth level of concern is the lack of harmonization among donors at the country level. In some countries, there are so many donors, each with their own agenda, that coordination and alignment to national priorities becomes very difficult. The disparity is further exacerbated if corruption is rife. A more critical issue relates to the diversion of critical human resource capacity away from government-identified priorities to donor priorities. The duplication of services by multiple funders also creates redundancy and inefficiencies.

External investment in a country's health should prioritize partnering with improving and supporting existing public health infrastructure, and should recognize that a country's government would generally be in a better position to judge its health priorities than an external organization based in a rich country (Widdus 2003). This of course assumes that the national government is well functioning and capable of determining its priorities.

In some developing countries, in the absence of local acceptable leadership, the UN agencies have assumed a leadership role, and private funding and non-governmental aid is structured to bypass the appropriate governmental agencies, thus creating a situation where the government may retaliate by blocking access to the targets of these charitable organizations.

HIV/AIDS provides another example of harmonization at a country level. All the UN agencies are part of the 'Three Ones' agreement: *one* agreed-upon HIV/AIDS action framework that provides the basis for coordinating the work of all partners; *one* national AIDS coordinating authority with a broad based multisector mandate; and *one* consensus for country-level monitoring and evaluation system (WHO 2004). Similar agreements are needed for donor-supported health projects in general.

China provides a unique example of how government authoritarianism has helped achieve this kind of coordination. Although it was motivated by a different purpose, China insists that large donor agencies have government approval before being allowed to work in-country, and thus, the relevant officials have been able to have a direct role in deciding where and how donor money should be channelled. In South Africa, in contrast, during the Mbeki AIDS denialist era, it was private and donor funding channelled

through non-governmental and academic institutions that ensured access to antiretroviral treatment for the millions dying from AIDS.

Moving forward

The generous giving of the foundations, industry, and private donors has benefited public health greatly, but they have sometimes also had unintended negative consequences. How can the positive impact of private giving be maximized? A few suggestions for strategies that may contribute to this goal include:

Objective assessment of priorities utilizing defined and objective criteria.
Transparency, communication, and coordination with key stakeholders (e.g. local health ministries).
Consideration of the long—as well as the short-term impact of investments.
Building capacity at a national level for sustainability of investments.
Ongoing internal monitoring of progress and periodic evaluation of the impact of the programme by an external group.
Establishment of advisory committees that include both international and local experts.
Coordination of multiple donors and key stakeholders to ensure harmonization and synergy.
Development of transparent governance mechanisms, policies, and procedural frameworks.
Sustained funding commitment for long-term health issues.

Many of these recommendations have already been incorporated into the GFATM. As we move forward and the roles and contributors to private funding continue to grow, it is important that the strengths of private giving, such as focus, nimbleness, innovation, risk-taking, and efficiencies do not get lost in massive, ineffective, and paralysing bureaucratic structures. To achieve the full potential of private giving, it is critical that it is structured to produce the maximum good with the fewest negative consequences.

Global health in the era of sustainable development

Fiona Fleck

Introduction: from millennial to sustainable development goals

The world is experiencing demographic and epidemiological transitions that have resulted in a larger human population living much longer lives. In response to these changes, the World Health Organization (WHO) has expanded its initial focus on infectious causes of death to a much broader agenda, including noncommunicable diseases, violence and injuries, nutrition, antimicrobial resistance, health worker shortages, increasing pollution and decreasing biodiversity, climate change, mass migration and inequitable access to basic medicines and services (Vujicic et al. 2004; WHO 2010b).

The WHO works through national governments and with many other agencies, initiatives, and public–private partnerships to improve human health. The final scorecard of the Millennium Development Goals summarizes the cumulative progress made in recent decades (UN 2000, 2015, 2017; PATH 2017; UNAIDS 2018).

For example, from 1990 to 2015, the maternal mortality ratio declined by 45% and the percentage of births assisted by skilled health personnel increased from 59 to 71% (UN 2015). By 2017, the global under-5 mortality rate had declined to 39 deaths per 1,000 live births from a 1990 rate of 90 deaths per 1,000 live births (UN 2015; UN Inter-Agency Group for Child Mortality Estimation 2018). In 2017, about 85% of children worldwide received at least one dose of measles vaccine, an increase from 73% in 2000 (UN 2015; WHO 2018a).

New human immunodeficiency virus (HIV) infections fell from an estimated 3.5 million cases in 2000 to 1.8 million in 2017 (Jordan et al. 2017). In 2003, 800,000 people living with HIV were receiving

antiretroviral therapy, compared to 21.7 million in 2017 (UN 2015; UNAIDS 2018). Between 1990 and 2015, global malaria incidence fell by an estimated 37% and mortality by 58%, however WHO estimates show that no further progress was made between 2015 and 2017 (WHO 2016a, 2018j). Tuberculosis mortality fell by 42% over between 2000 and 2017 (WHO 2018i).

The WHO's efforts to further improve health outcomes, described in its thirteenth general programme of work 2019−2023 (GPW 13), are closely aligned with the *2030 Agenda for Sustainable Development*. In adopting this agenda, Member States of the United Nations committed to meeting 17 goals and 169 targets, measured by 250 indicators (UN 2015a). Sustainable development is defined as a process that 'meets present needs without compromising the ability of future generations to meet their own needs' (World Commission on Environment and Development 1987).

In the 2030 Agenda, governments agree to reconcile three conflicting demands: improved human welfare, environmental protection, and economic growth. Most high-income countries have tended to fare better on measures of human well-being (Sen 1999), but advances in each dimension of the human development index; life expectancy, education, and gross national income per capita, are associated with a large environmental footprint (Sneddon et al. 2006; Steffen et al. 2015).

The mutually conflicting goals of industrialization (Sustainable Development Goal (SDG) 9, industry, innovation and infrastructure) and climate change mitigation (Goal 13, climate action) and between biodiversity (Goal 14, life below water; Goal 15, life on land) and human welfare (Goal 1, no poverty) are clearly outlined, confronting policy makers with many interactions between and within the different goals. These can be divided into positive interactions (i.e. synergies), in which progress towards one goal contributes towards progress in another, or trade-offs, when progress towards one goal hinders progress in another. A few goals have no demonstrable association in either direction and are thereby unclassified (Worm et al. 2006; Pradhan et al. 2017). The 2030 Agenda challenges governments to uncouple the relationship between economic growth and environmental damage, at a time when most countries will experience a rapid increase in population.

The WHO's focus, Goal 3 (good health and well-being), is synergistic with Goal 1 (no poverty), Goal 5 (gender equality), Goal 10 (reduced

inequalities) and Goal 6 (clean water and sanitation). The health goal has 13 targets, including some of the areas that were covered by the Millennium Development Goals—maternal, newborn, and child deaths, HIV, tuberculosis, and malaria. The new targets are for neglected tropical diseases, hepatitis, water-borne and other communicable diseases, non-communicable diseases and mental health, narcotic drug abuse and the harmful use of alcohol, road traffic deaths and injuries, sexual and reproductive health services, hazardous chemicals, air, water and soil pollution and contamination, tobacco control, research and development on vaccines and medicines, health financing and workforce, and early warning of national and global health risks. The WHO and other health organizations have mapped their respective mandates and set mid-term milestones for targets of SDG 3 in the *Global Action Plan for Healthy Lives and Well-being for All* (WHO 2013a, 2018k).

The WHO constitution established 'the enjoyment of the highest attainable standard of health' as 'one of the fundamental rights of every human being without distinction of race, religion, political belief, economic or social condition' (WHO 1948). The right to health underpins all SDG 3 targets, particularly 3.8: to 'achieve universal health coverage, including financial risk protection, access to quality essential health-care services and access to safe, effective, quality and affordable essential medicines and vaccines for all'.

Based on the 2030 Agenda, the WHO's current five-year strategy presents a vision of: one billion more people benefitting from universal health coverage, one billion more people better protected from health emergencies, and one billion more people enjoying better health and well-being (WHO 2018).

Towards universal health coverage

Universal health coverage (UHC)—defined as ensuring that all people have access to needed health services of sufficient quality without incurring financial hardship—is the subject of sustainable development target 3.8. As a step towards this target, the WHO envisions an expansion of such coverage to an additional one billion people by 2023. In the absence of financial protection, an estimated 800 million people spend at least 10% of

their household budgets on health expenses. For almost 100 million people each year, these expenses are high enough to push them into extreme poverty (WHO/World Bank 2017). At least half of the world's population still lacks access to essential health services.

Progress towards UHC is tracked by measures of coverage of health services, and by the impact that out-of-pocket expenditure on those services has on people's living standards and their ability to spend on other basic needs. These measures reflect the twin imperatives of UHC: that people receive the health services they need without facing financial hardship (Sachs 2012; Wagstaff et al. 2017, 2018).

The WHO and the World Bank evaluate the overall level and the extent to which UHC is equitable because national averages can mask low levels of coverage in disadvantaged groups. For example, only 17% of mothers and children in the poorest fifth of households in low- and lower-middle-income countries received at least six of seven basic maternal and child health interventions, compared to 74% for the wealthiest fifth of households (World Bank 2004; WHO/IBRD 2017).

The International Health Partnership for UHC 2030 has 118 signatories —governments and multilateral, civil society, and philanthropic organizations—to its Global Compact. They have committed to building and expanding equitable, resilient, and sustainable health systems, funded primarily by public finance, and based on primary healthcare, that deliver integrated, comprehensive people-centred and quality health services for all, while taking necessary measures to protect households from financial hazards due to health expenditures.

The WHO defines quality of care as the degree to which health services increase the likelihood of desired health outcomes and are consistent with current professional knowledge (Kieny et al. 2018). The components of services comprise financing, workforce, governance, service delivery, information, medicines, technologies, and infrastructure.

Primary healthcare is an essential component of national health systems that is needed to move countries closer towards UHC. Strong primary healthcare is vital for making progress on the unfinished agendas of communicable diseases, and maternal, newborn, child, and adolescent health, as well as for the growing burden of non-communicable diseases.

Digital health approaches and other system innovations are also playing an important role in strengthening these services.

Each national health system has scope to improve upon the components of its health services. For example, essential medicines and health technologies are often poorly distributed and unfairly priced (FAO 2018a). Repeated shortages continue to affect critical products, including insulin, antihypertensives, intravenous fluid, oral rehydration solution, analgesics, oral antidiabetics, and opioids for palliative care.

Antiretrovirals for HIV, direct-acting antivirals for hepatitis C and second-line treatments for drug-resistant tuberculosis when first marketed were too expensive for many countries. However, some countries have since negotiated price reductions, following voluntary licensing agreements and production of quality-assured generics (Andrieux-Meyer et al. 2015) and UN procurement has brought these medicines within reach of millions of patients.

In some countries, the costs of caring for diabetes alone consume nearly 25% of the national health budget (Zhang et al. 2010). Globally, insulin can be accessed reliably by only half of the 100 million people who need it (Basu et al. 2019). In the United States of America, out-of-pocket expenses for insulin increased by 89% between 2000 and 2010. The US$21-billion global market in insulin is divided between three companies that together account for 99% in terms of value and 96% in terms of volume. Although more than 90 of 132 countries have no tariffs for insulin, the combination of taxes, steep mark-ups, and other supply chain costs have pushed up the drug price and hurt affordability (Health Action International 2015).

The WHO has revised the methods used to measure pricing and affordability of essential medicines—particularly those used for primary care—in the context of the SDG monitoring. The WHO promotes policies and builds technical capacities in low-resourced health systems, develops international standards for the manufacturing and regulation of health products and provides guidance for health systems on how to deliver them safely and cost-effectively.

Better access to medical products is pursued by negotiating price reductions for existing products and incentivizing product development for markets with limited purchasing power. Generic medicines, which do not need to recoup the investment needed for drug discovery, development, and marketing approval, are sold at prices closer to the costs of manufacturing, offering a significant means to reduce healthcare costs in all countries. A

national policy that encourages the use of generic medicines can save an estimated 60% of the costs of medicines (WHO 2010, 2010a).

In 1977, the WHO introduced the first *Model List of Essential Medicines*, its selection of the most effective and affordable medicines available at the time. The model list is intended to be adapted for use in any health system, especially those in low- and middle-income countries. The current list contains 433 products and is used by about 150 countries. In 2007, WHO developed the first *Model List of Essential Medicines* for children under 12 years of age. These lists are updated every two years (WHO 2013b).

The WHO prequalification programme stimulates the supply of quality-assured medicines, including generics, and encourages competition between manufacturers (WHO 2013c). The programme was established in 2001 as a quality-assurance mechanism for products procured by UN agencies, the GAVI Alliance, and the Global Fund. Prequalification has resulted in more reliable supplies, better forecasting, and often substantial price reductions (WHO n.d.). Compliance measures include on-site inspections to ensure adherence to good manufacturing practices. Products can become de-listed if quality is not maintained; the prospect of de-listing has proven to be an incentive for manufacturers to maintain standards.

In addition to financing, infrastructure, and medicines, UHC requires a health workforce of adequate size and skills. However, countries at all levels of socioeconomic development face difficulties in education and training, deployment, retention, and performance of their health workforce (Anand and Barnighausen 2004, 2007; Mullan et al. 2011).

The WHO and the World Bank have developed an ‘SDG index threshold’ of 4.45 doctors, nurses, and midwives per 1,000 population as an indicative minimum density for health workers. In 2016 the global health workforce was over 43 million. The supply projections point out that despite significant growth leading to an aggregate number by 2030 of 67.3 million health workers, the projected global shortage of healthcare workers in 2030 will be more than 14.5 million (WHO 2016).

Disabilities

The WHO estimates that over a billion people, about 15% of the world's current population, have some form of disability. Its *International Classification of Functioning, Disability and Health* defines disability as an

umbrella term for impairments, activity limitations and participation restrictions as the result of interaction between individuals with a health condition and personal and environmental factors. Therefore, the disability experienced by a person with lower limb paralysis in a setting where wheelchairs are available, and where homes, pavements, public transport, and the workplace are adapted to wheelchair access, is very different from the disability experienced by a person who has the same physical condition but who lives in an environment with none of these adaptations.

People with disabilities report seeking more healthcare than people without disabilities and have greater unmet needs. However, all people with disabilities also develop the same health problems that affect the general population, and therefore need access to mainstream healthcare services. Article 25 of the UN Convention on the Rights of Persons with Disabilities reinforces the right of persons with disabilities to attain the highest standard of healthcare, without discrimination. The WHO also provides guidance to policy makers on mental health programmes. Of particular concern are the health services available to people with severe mental disorders; moderate to severe depression, bipolar disorder, and schizophrenia and other psychotic disorders. People with these conditions generally have a life expectancy that is 10–20 years less than the general population. Most of these premature deaths are due to physical health conditions. For the minority who can access healthcare, the care received is often of poor quality and physical health conditions are often overlooked.

Emergency preparedness and response

Since its inception, WHO has coordinated the international response to outbreaks and other cross-border heath threats. Its International Health Regulations oblige Member States to report infectious disease outbreaks and other health incidents such as chemical spills and nuclear incidents, as well as to build core capacities for surveillance and response (WHO 2008a; Heymann et al. 2013). These reports are assessed, and responses are mounted in function of the severity, potential for spread, number of people affected, and the causative event or agent. The strongest rating is a ‘Public Health Event of International Concern’ defined as, ‘an extraordinary event which is determined to constitute a public health risk to other States through

the international spread of disease and to potentially require a coordinated international response' (WHO 2008a, 2018b, 2018c). Since the 2005 revision of the Regulations, there have been four such events: H1N1 influenza (2009), Ebola (2014), polio (2014), and Zika (2016).

This approach to health emergencies was severely tested during the 2013–2016 Ebola virus disease outbreak in West Africa. Problems with the international response have been well documented (WHO 2015a; The Ebola Outbreak Epidemiology Team 2018). There were concerns that neither the affected countries nor the WHO sounded the alarm early enough; and that the rating of the outbreak as a public health event of international concern was overdue. Coordination between the WHO, Ministries of Health, United Nations agencies, and non-governmental partners was weak on many levels. The WHO lacked sufficient staff on location to respond adequately and the dynamics of transmission across the borders of Guinea, Liberia and Sierra Leone highlighted the need to strengthen health security (Moon et al. 2015; WHO 2015a, 2015b; Gostin and Katz 2016).

The International Health Regulations require countries to avoid disruption to travel and trade, but during the 2013–2016 Ebola outbreak more than 40 countries implemented measures that significantly interfered with international traffic, outside the scope of the temporary recommendations issued by WHO. As a result, Guinea, Liberia, and Sierra Leone faced severe political, economic, and social consequences, as well as barriers to receiving necessary personnel and supplies (WHO 2015a).

The lessons learnt from the 2013–2016 outbreak catalysed the establishment of the WHO's Health Emergencies Programme. A more effective response to outbreaks and emergencies is made possible by a unified structure and one line of accountability from headquarters through the WHO's Regional Offices. Administrative and financial adjustments were made, including the creation of a contingency fund for emergencies. An incident management system is used to structure and manage response activities, as a core component of the Emergency Response Framework (WHO 2017a).

The WHO now coordinates more closely with United Nations Office for the Coordination of Humanitarian Affairs, joining other agencies that provide support for humanitarian crises in the field, such as the United Nations Refugee Agency, the World Food Programme, and the United Nations Children's Fund (Nabarro 2015).

As of February 2019, the WHO was responding to 41 graded health emergencies around the world and leading the health cluster in United Nations Inter-Agency Standing Committee cluster system in responses to outbreaks, emergencies, protracted conflicts, and natural disasters in 27 countries and territories.

There are three WHO grades for emergencies, signifying the level of operational response required: Grade 1 (limited response); Grade 2 (moderate response); Grade 3 (major/maximal response) (Inter-Agency Standing Committee 2016). A graded emergency that persists for more than six months becomes a protracted emergency, which is an environment in which a significant proportion of the population is vulnerable to prolonged disruption of livelihoods, disease, and death.

The WHO provides technical assistance to countries to help build their capacity to detect, report, and contain infectious disease outbreaks and other health events in line with the International Health Regulations. This assistance covers early warning alert and response systems, laboratory and surveillance, burden of disease, regulatory capacity building, risk communications, and planning for pandemic product deployment.

The WHO has also developed standardized approaches that countries can take to respond to major epidemic-prone diseases, such as meningitis, yellow fever, and cholera. In 2016, the WHO launched a plan to immunize 1.4 billion people against yellow fever in 40 countries by 2026. In 2018, the World Health Assembly endorsed a goal to reduce cholera deaths by 90% in 47 countries (G20 2018).

The WHO Emergency Medical Teams Initiative assists organizations and Member States to build capacity of clinical response teams and to better coordinate deployment of quality-assured medical teams in emergencies. The WHO also helps to identify dangerous and re-emerging pathogens and provides countries with the technical support they need to strengthen their biosafety, biosecurity, and readiness for outbreaks (Bermingham et al. 2012). To prevent epidemics, countries need resilient and inclusive health systems that extend to rural areas, a sensitive early warning system along with rapid response capacity, and informed communities that trust their health service providers. They also need effective and affordable vaccines, diagnostics, and treatments, reliable laboratory and logistics capacity, and safe treatment facilities, properly distributed, staffed, and equipped.

Preventing epidemics and pandemics

During the 2013–2016 Ebola outbreak, the WHO coordinated field trials for candidate vaccines. In December 2016, the Ebola vaccine rVSV-ZEBOV was shown to confer nearly 100% protection for clinical trial participants in Guinea (Henão-Restrepo et al. 2017). To better anticipate the need for vaccines, diagnostics, and therapeutics, the WHO collects inputs to its R&D Blueprint (WHO 2016b). In 2018, the priority diseases were: Crimean-Congo haemorrhagic fever, Ebola virus disease, Marburg virus disease, Lassa fever, Middle East respiratory syndrome, severe acute respiratory syndrome, Nipah and henipaviral diseases, Rift Valley fever, and Zika. The list also contains 'Disease X', representing the epidemic potential of an unknown pathogen (WHO 2018h). For each of the epidemic-prone diseases, research and development roadmaps, target product profiles, and generic protocols are developed. At the same time, the WHO works to strengthen national regulatory and ethics bodies so that research can be conducted during public health emergencies (WHO 2014).

It is clearly preferable that Member States lead the response and coordination of health emergencies, drawing on the support from international partners as required. Increasingly, the WHO is assisting Member States to establish Emergency Operations Centres and develop their capacities for emergency management and coordination. Partnerships such as the Global Outbreak Alert and Response Network and the Global Health Cluster are vital to effective preparedness and response.

Monitoring and evaluation are difficult in emergency situations but are needed for the improvement and adjustment of public health interventions (Roberts and Brennan 2015). Another challenge for emergency healthcare provision is security, as many outbreaks occur in a conflict setting. WHO is monitoring and compiling data on attacks on health facilities, transport, and staff, as well as engaging in campaigns such as #NotATarget, with Médecins Sans Frontières and the International Committee of the Red Cross (WHO n.d.).

A century after the 1918 influenza pandemic—which killed an estimated 30–50 million people—the WHO is still responding to media coverage, public perception, and government policy on influenza. In 2011, the World Health Assembly approved the Pandemic Influenza Preparedness Framework (WHO 2011). The framework sets out obligations for the

sharing of information and materials relating to influenza viruses, and of medicines and vaccines, once a pandemic is underway. The framework stipulates obligations for the WHO, its Member States, and WHO-appointed influenza laboratories, and the pharmaceutical industry (Gao et al. 2013; CDC 2018).

In 2018, thirty-five countries had the systems needed to detect unusual respiratory disease events, a fivefold increase since 2014. In addition, 34 priority countries had functioning inpatient influenza surveillance: this doubled from 16 countries in 2014 and 29 priority countries have a human–animal interagency coordination mechanism (CDC 2018; WHO 2018l). Moreover, 91 countries shared epidemiological data on influenza, compared to 55 countries in 2014.

However, the continued building of national, regional, and global capacities to prevent, prepare for, respond to, and recover from, health emergencies remains a vital international priority. With the sole exception of disease eradication, gains against infectious diseases are always fragile (Packard 1997). Reductions in transmission can be undone by complacency, diminished control efforts, changes in vector habitats or human behaviour, or by the spread of resistant pathogens.

Antimicrobial resistance prevents effective treatment of a range of infections caused by bacteria, parasites, viruses, and fungi. Without effective antibiotics, trauma, surgery, organ transplants, childbirth, and immunosuppression can become life-threatening events. The high cost of healthcare for patients with resistant infections is due to a longer duration of illness, complications, additional tests, and the need to use more expensive drugs.

Antimicrobial resistance occurs naturally over time, through genetic changes in pathogens. However, the misuse of antimicrobials in medicine and in agriculture is accelerating this process. Antimicrobial resistant-microbes are found in people, animals, food, and the environment. They can spread between people and animals, including from food of animal origin, and from person to person (Ong and Heymann 2007). Poor infection control, inadequate sanitary conditions, and inappropriate food-handling encourage the spread of antimicrobial resistance. Multidrug resistance is a particular concern for major health programmes focused on the control of malaria, tuberculosis, and HIV infection.

The Global Action Plan on antimicrobial resistance was adopted by the World Health Assembly in 2015 and its objectives guide the WHO in supporting Member States to develop and implement national action plans on antimicrobial resistance (WHO 2015b).

The WHO also works with the Food and Agriculture Organization of the United Nations (FAO) and the World Organisation for Animal Health (OIE) in a tripartite 'One Health' approach to promote best practices to avoid the emergence and spread of antibiotic resistance, including optimal use of antibiotics in humans, animals, and the environment.

In 2016, the United Nations General Assembly signalled the world's commitment to taking a coordinated approach to address the root causes of antimicrobial resistance across multiple sectors, especially human health, animal health, and agriculture.

Better health and well-being

In 1800, the global population was less than one billion. Rapid population growth, peaking at 2.6% in 1962, resulted in the global population increasing from 1.5 billion in 1900 to 6.1 billion in 2000. That growth has now slowed, reducing by half since 1960. Life expectancy has risen globally for both men and women, a gain of more than 10 years since 1970, to a global average of 72 years in 2016. The WHO South East Asian region has seen a gain of more than 8 years in the past two decades alone. By 2100, average global fertility is predicted to decline to two live births per woman of reproductive age, average life expectancy to level out at 83 years for men and 85 for women and the global population to therefore stabilize at about 11.2 billion (UN 2017).

Worldwide, the proportion of older people in the total population is increasing at more than three times the overall population growth rate. With some exceptions, populations are now ageing fastest in low- and middle-income countries. A transition towards an older society, which took place over more than a century in Europe, is now taking place in less than 25 years in countries like Brazil, China, and Thailand.

By 2030, for the first time in history, the population of people aged 65 and older are expected to outnumber children under age 10 (1.41 billion versus 1.35 billion). By 2050, older persons are expected to account for

35% of the population in Europe, 28% in North America, 25% in Latin America and the Caribbean, 24% in Asia, 23% in Oceania, and 9% in Africa. These trends have major implications for healthcare, as most people will die from the complications of noncommunicable diseases.

The health impacts of climate change

Quantifiable targets are required because the unprecedented improvements in health outcomes seen at the beginning of the century are fragile and easily reversed, including by the effects of climate change and environmental degradation (WHO 2008b). The WHO expects approximately 250,000 additional deaths per year between 2030 and 2050 to be attributed to the health effects of climate change; 38,000 due to heat exposure in elderly people, 48,000 due to diarrhoea, 60,000 due to malaria, and 95,000 due to childhood undernutrition. The direct costs to health are estimated to be between US$2–4 billion per year by 2030 (GBD 2016 Risk Factors Collaborators 2017; Postigo et al. 2007; WHO 2014, 2018g).

Climate change affects human health directly through extreme weather events and in a more chronic fashion through changes in precipitation, crop yields, and sea levels. More than half of the world's population lives within 60 km of the sea. Rising sea levels and storms destroy homes, medical facilities, and other essential services. Deaths in Europe alone from extreme weather events—heatwaves and cold waves, wildfires, droughts, river and coastal floods, and windstorms—are projected to increase from about 3,000 to about 150,000 per year by 2100 (Forzieri et al. 2017).

Variable rainfall patterns affect the supply of fresh water, a shortage of which compromises hygiene and increases the risk of diarrhoeal disease. Floods contaminate freshwater supplies, heighten the risk of water-borne diseases, and create breeding grounds for insect vectors. They also cause drownings and physical injuries, damage homes, and disrupt health services. Rising temperatures and variable precipitation are likely to decrease the production of staple foods in many of the poorest regions. Crop failures are likely to increase the prevalence of malnutrition and undernutrition, which currently cause 3.1 million deaths every year (USFDA 2013; UNICEF 2018).

Climatic conditions also affect water-borne and vector-borne diseases by lengthening their transmission seasons and altering the geographic range of

vectors. As mosquito habitats change, more people are likely to be exposed to arboviral diseases such as yellow fever, dengue, chikungunya, and Zika, as well as to malaria. After years of declining incidence and deaths, progress in malaria control stalled in 2015, with an estimated 219 million cases and 435,000 related deaths in 2017 (Nayyar et al. 2012; WHO 2018f).

People living near the coast are particularly vulnerable to climate change. Small island states and low-lying coastal countries, home to an estimated 65 million people, are already experiencing the adverse effects of climate change. With one-third of their population living on land that is less than 5 metres above sea level, the threat of sea-level rise, storm surges, and coastal destruction pose existential risks (UNDP 2017). Some small island states may eventually disappear with sea-level rise.

At the 2017 United Nations Climate Change Conference, the WHO and the UN Climate Change secretariat launched a special initiative to protect people living in small island developing states from the health impacts of climate change (Ghebreyesus and Espinosa 2018).

Adaptation measures on these islands are complicated by their unique and fragile biodiversity and their dependence on imported fuels and food. While contributing less than 1% to the world's greenhouse gas emissions, these countries are among the first to experience the worst and most devastating impacts of climate change. Despite the lack of commensurate resources, some small island states are already improving population and health system resilience by diversifying crops, building cyclone-resistant health facilities, and using solar energy to power medical services (UNDP 2017).

Air pollution and a multisectoral approach

Affecting a much larger proportion of the world's population, air pollution is another factor mediating the health impacts of climate change. The WHO estimates that more than 90% of the world's population lives in places where the air quality does not meet the recommended concentrations levels of major pollutants, of which particulate matter is a common proxy indicator. WHO air quality guidelines set limits for particulate matter, nitric dioxide, ozone, and sulphur dioxide—pollutants for which a revision is due in 2020—and other air pollutants. The WHO estimates that 4.2 million deaths from ambient air pollution and 3.8 million deaths from household air

pollution are caused by the contribution of these pollutants to stroke, heart disease, chronic obstructive pulmonary disease, lung cancer, and acute respiratory infections (Prüss-Üstün et al. 2016).

Multisectoral action is vital to global health efforts and central to the SDG agenda because of the many determinants acting upon people's health, such as socioeconomic status, gender, and other social determinants. Such action is thus essential for tackling the various sources of air pollution. For example, when the Olympic Games were held in Beijing in 2008, stringent policies to reduce local and regional emissions were enacted: traffic was reduced, factories were closed, construction halted, and emission standards revised (Su et al. 2015). Air quality improved dramatically in Beijing and adjacent co-hosting Chinese cities. Observational studies showed significantly decreased cardiovascular deaths in the cities affected by the 6-month implementation period and researchers estimated that sustained improvements, consistent with WHO air quality standards, could avert almost 1.57 million premature deaths in China each year (Guojun et al. 2016).

Ambient and household air pollution can be reduced by expanding access to clean household fuels and technologies to meet the domestic energy needs of cooking, heating, and lighting. Ambient air quality can be rapidly improved by the expansion of urban public transit networks, energy-efficient buildings, optimal waste management, and by producing electricity from clean, renewable energy. Policies to reduce air pollution can thus be beneficial for both climate and health, lowering the burden of disease attributable to air pollution, as well as contributing to climate change mitigation. These mutually beneficial policies, akin to the synergistic SDGs, are known as health co-benefits. For example, policies that favour electric vehicles and that promote public and active transport can reduce carbon emissions and traffic congestion, impermeabilization of urban land and noise exposure, while improving the urban environment, people's physical fitness, and ambient air quality (UNEP 2013).

Noncommunicable diseases: determinants and risk factors

The transition from infectious to noncommunicable causes of deaths is indicated by current estimates attributing 71% of all deaths to noncommunicable diseases, 15 million of which occur between the ages of

30 and 69 years. Deaths in adults occurring before the age of 70 are considered premature. In total, cardiovascular diseases account for 17.9 million deaths annually, cancers 9 million, respiratory diseases 3.9 million, and diabetes 1.6 million. These four groups of diseases account for over 80% of premature deaths due to noncommunicable diseases (WHO 2016). Road traffic crashes cause 1.35 million deaths per year and have become the leading cause of death of people aged 5 to 29. Approximately half of the people killed on the roads are pedestrians, cyclists, or motorcyclists (WHO 2018e).

Four risk factors are associated with 70% of the premature deaths due to cardiovascular diseases, cancer, respiratory diseases, and diabetes: tobacco use; the harmful use of alcohol; energy-dense, nutrient-poor diets; and inadequate physical activity. In each area, the WHO gathers data, recommends evidence-based policies, provides technical support, and monitors the impact of interventions. In 2011, 'best buy' interventions were proposed to governments for the prevention and control of noncommunicable diseases, ranging from antihypertensives and antilipidemiants for cardiovascular disease to vaccines for human papillomavirus to prevent cervical cancer. These are interventions that have significant public health impact, and are cost-effective, inexpensive, and feasible to implement (WHO and the World Economic Forum 2011).

To support countries in tackling the increasing burden of road traffic crashes that claim over 1.35 million lives each year, the WHO recommends passing laws to reduce speed and drink-driving, to make seat-belts and helmet mandatory, as well improving road infrastructure with safe pedestrian crossings and cycle lanes, making vehicles safer, improving post-crash care, and investing in public transport.

Recent estimates show that 1.4 billion people worldwide do not meet the WHO recommendations on physical activity (Guthold et al. 2018). A large proportion of this inactivity is a result of the same road traffic conditions that cause the deaths of 351,000 cyclists and pedestrians per year. The WHO therefore recommends the provision of infrastructure, facilities, and public open spaces for walking, cycling, and other physical activity (WHO 2018e).

Nutrition—optimal quantity and quality

Everyone has the right to adequate food and nutrition; however, this human right is continually violated as nearly one in three people suffer from at least one form of malnutrition. In 2017, 462 million adults worldwide were underweight while more than 1.9 billion were overweight, of whom more than 600 million were obese. In the same year, 38.3 million children under the age of 5 years were overweight or obese and 150.8 million were affected by stunting (low height-for-age) and 50.5 million were affected by wasting (low weight-for-height) (FAO 2014, 2018b; WHO 2018).

By 2030, the global community has committed to 'end all forms of malnutrition, including achieving, by 2025, the internationally-agreed targets on stunting and wasting in children under 5 years of age, and address the nutritional needs of adolescent girls, pregnant and lactating women and older persons'.

Poor nutrition continues to cause nearly half of deaths in children under 5, while malnutrition and unhealthy diets are key risk factors for non-communicable diseases such as cardiovascular disease, type 2 diabetes, and certain cancers in adults (Petemadi et al. 2017). People are consuming more processed foods high in calories, fats, sugars, and salt. Nearly two out of three infants under 6 months of age are not exclusively breastfed (Yang et al. 2014).

Many diets are low in whole grains, in fruits, nuts and seeds, or vegetables. Diets are the result of personal factors such as gender, culture, knowledge, skills, and preferences. Diets are also determined by economic, political, and environmental factors including cost and availability of food, marketing, labelling, poverty levels, urbanization, geography, and climate change.

To tackle malnutrition and prevent and control diet-related noncommunicable diseases everyone needs access to safe, affordable, and healthy diets. The Second International Conference on Nutrition Framework for Action provides a set of 60 policy actions and recommendations that governments, can use to improve nutrition (FAO/WHO 2014).

These policy actions need to be translated into concrete actions such as restricting marketing of unhealthy foods to children, taxing sugar-sweetened drinks or banning industrial trans fats, mandating simplified front-of-pack nutrition labelling and introducing nutrition standards for food served or sold in schools, hospitals, and other public institutions

(Hastings et al. 2003; McGinnis et al. 2006; Cairns et al. 2009; De Ruyter et al. 2012; Ebbeling et al. 2012; Qibin et al. 2012; WHO 2015, 2017).

In this 2016–2025 Decade of Action on Nutrition, the response by governments is accelerating; but more action, consistent with the WHO's recommendations, is needed (WHO 2017b).

Minimizing harms from tobacco and alcohol

Tobacco use kills around 8 million people every year, accounting for 17% of adult deaths (GBD 2017). Since 2000, the prevalence of smoking has decreased from a global average of 27% to 20% in 2016. Currently 34% of men and 6% of women smoke, totalling 1.1 billion smokers aged 15 or more globally. While smoking rates have declined since 2000, the number of smokers has not. Over 24 million young people aged 13–15 smoke cigarettes. The number of smokeless tobacco users in 2016 stands at 367 million adults and 13 million young people aged 13–15 (WHO 2013, 2018).

The epidemics of smoking-related diseases—lung cancer, chronic obstructive pulmonary disease, and other respiratory conditions—are decreasing in countries where tobacco control measures have taken effect and the burden of disease is shifting to low- and middle-income countries.

The World Health Assembly adopted its first resolution on tobacco control in 1970. Building on decades of progress, SDG target 3.4, calls upon countries to strengthen their implementation of the WHO Framework Convention on Tobacco Control (WHO FCTC). The WHO FCTC was the first treaty negotiated under the auspices of the WHO and one of the most rapidly ratified treaties in the history of the United Nations (WHO 2012). Provisions in the treaty govern the production, sale, distribution, advertisement, and taxation of tobacco products as minimum requirements for tobacco control (WHO 2013d).

To reduce demand for tobacco, many countries have passed tobacco control legislation restricting tobacco sales by age and type of outlet as well as by increasing taxes. Australia, France, Ireland, Russia, Turkey, the United Kingdom have introduced indoor smoking bans and other measures. In 2012, Australia became the first country to introduce plain packaging (Australian Bureau of Statistics 2012; National Health and Medical Research Council 2013). Plain packaging prohibits the use of logos, colours, brand images, and promotional information on tobacco products

and packaging, other than brand and product names in a prescribed colour and font. Six other countries have since implemented plain packaging laws: France, Hungary, Ireland, New Zealand, Norway, and the United Kingdom. Australia and later France, Norway, and the United Kingdom successfully fought legal challenges to their plain packaging laws. Several other countries are enacting legislation, developing regulations, or approving plain packaging policies.

The development of electronic cigarettes and heated tobacco products has raised a new set of issues for tobacco control, shifting the emphasis to building the scientific evidence and the regulatory capacity needed to quantify the harms of various tobacco and nicotine delivery devices and updating regulations as required. In addition, while many countries have stringent regulations concerning traditional marketing and advertising, many of these activities have shifted to unregulated online channels. The unfinished public health agenda includes building capacity in each country to counter the tactics of the tobacco industry, treating the diseases caused by tobacco use, finding sustainable alternatives to tobacco-growing and educating people about the health risks of smoking and other nicotine delivery devices.

The harmful use of alcohol contributes to 3 million deaths globally every year and over 5% of the burden of disease and injury (WHO 2018d). It has a direct impact on many health-related targets of the SDGs, including those for maternal and child health, infectious diseases (HIV, viral hepatitis, lower respiratory infections, tuberculosis), noncommunicable diseases (cancer, cardiovascular diseases and diabetes), digestive diseases, mental health, violence, injuries, and poisonings. Alcohol per capita consumption per year in litres of pure alcohol is one of two indicators for SDG health target 3.5 —'Strengthen the prevention and treatment of substance abuse, including narcotic drug abuse and harmful use of alcohol' (UN 2015).

Almost all countries have alcohol excise taxes and fewer than half use other price strategies, such as banning below-cost selling or volume discounts. Most countries have a combination of policy measures including taxes, limits on retail and wholesale distribution, advertising restrictions, age limits for consumption and legal limits for blood alcohol concentrations when driving (WHO 2018d).

The WHO launched a new initiative in 2018 to address the lack of progress in reducing the health harms associated with alcohol consumption.

The initiative provides governments with a technical package of five strategies: (1) strengthening restrictions on alcohol availability; (2) advancing and enforcing drink-driving countermeasures; (3) facilitating access to screening, brief interventions, and treatment; (4) enforcing bans or imposing comprehensive restrictions on alcohol advertising, sponsorship, and promotion; and (5) raising prices on alcohol through excise taxes and pricing policies.

Innovation, data, and statistics

When the Millennium Development Goal reporting period ended in 2015, 80% of the world's poor people were living in rural areas, 55% of whom had access to safe water for drinking, compared to 85% of the urban population. While considerable progress had been made, the richest and poorest people did not benefit equally. For example, between 2000 and 2015, skilled birth attendance rose from 80 to 89% in the richest quintile, but only from 33% to 43% in the poorest. Women continued to be more likely to live in poverty and to remain at a disadvantage in the labour market, earning 24% less than men globally. Equity is central to the sustainable development agenda. The world has learnt that national averages can hide gross disparities (Gurria 2011).

Part of the reason for these persistent inequities is that population level statistics have traditionally suffered from incomplete coverage; certain ethnic groups are systematically excluded, institutional populations are not included in household surveys, administrative data only reflect those who can access the services and school-based surveys can only count the children who are able to attend school in the first place (Carrera et al. 2012).

Disaggregated data are needed to track progress for the most vulnerable people, and it costs more to collect and analyse these data, to resolve issues of sample sizes, confidentiality, and transparency, particularly when indicators require multidimensional disaggregation, for example—'child labour in poorest quintile in urban areas'. The challenge is meeting the demand for high-quality, timely, disaggregated data across a very broad agenda. The UN General Assembly was clear: 'Sustainable Development Goal indicators should be disaggregated, where relevant, by income, sex,

age, race, ethnicity, migratory status, disability and geographic location, or other characteristics, in accordance with the Fundamental Principles of Official Statistics' (United Nations 2014).

The WHO welcomes this emphasis, as health systems do not naturally evolve to ensure a fair distribution of services. Decisions aimed at increasing a country's economic growth do not automatically protect the poor or promote their health. International trade agreements do not, by themselves, guarantee food security, job security, health security, or access to affordable medicines. All these outcomes require deliberate policy decisions that place equity at the forefront (Blas and Sivasankara Kurup 2010; Hoegh-Guldberg et al. 2015; FAO 2016) and the ability to measure impact across the diverse groups that constitute a national population.

To quantify its contribution to improvements in health outcomes, the WHO has developed an impact framework with three levels of measurements: health-adjusted life expectancy, an index for each goal and programmatic targets.

The WHO impact framework specifies the baseline data and the indicators by which performance should be measured. Thus, for the first time, all components of WHO's work—from guidelines and technical support, humanitarian response, policy dialogue, and health campaigns—will be measured in terms of the health impact delivered in countries and not merely by whether programmes delivered their planned outputs. This shift from output to impact responds to the demands made by governments and other donors for more transparency and accountability for public funds (OECD 2005, 2008, 2011).

Incentivizing innovation

Innovation can improve any aspect of policies, systems, products and technologies, services and delivery methods that affect people's health and well-being. The WHO is working

towards a more innovative culture in global health that promotes digital technologies for health. In 2018, the organization established an innovation hub with the Programme for Appropriate Technologies in Health (PATH). In partnership, WHO and PATH have developed vaccine vial monitors that show when the cold chain has been breached, vaccines for malaria and Japanese encephalitis, classification and guidelines for digital health

interventions, and the Global Digital Health Atlas, a technology registry platform designed to strengthen impact and facilitate scale of emerging health innovations.

When an unmet health need is identified, an ideal product is defined, and a public–private partnership is formed to develop the product. These projects usually bring together expertise from academia, industry, and public health, with funding from philanthropic sources. Other examples include the Medicines for Malaria Venture, the International AIDS Vaccine Initiative, the Global Alliance for TB Drug Development, and the Drugs for Neglected Diseases Initiative.

The Meningitis Vaccine Project illustrates the benefits of designing a product based on the needs of low-income countries (Meningitis Vaccine Project n.d.; CDC 2012). Ministers of health asked the WHO for a vaccine that could prevent annual epidemics in the 26 countries that form Africa's meningitis belt, and defined its ideal characteristics, including the price they could afford to pay.

In less than a decade, the new vaccine was developed by a consortium of scientists, licensed with support from Canada's regulatory authority, and prequalified by the WHO. The technology for producing a conjugate vaccine was transferred from the United States of America and the Netherlands to the Serum Institute of India, which agreed to manufacture the vaccine at the target price of 50 cents per dose. The first campaigns using the new vaccine began in late 2011; more than 100 million doses had been administered by the end of 2012. Following these campaigns, some hyperendemic countries have recorded their lowest level of meningitis cases in more than a decade.

The economic benefits are expected to be significant. A single case of meningitis can cost a household the equivalent of 3–4 months of income. Mounting a reactive emergency response to epidemics can absorb more than 5% of a country's entire health budget. The project is ground-breaking in another sense. African countries usually wait years, if not decades, for new medical technologies to trickle into their health systems. In this case, Africa was first to receive the best technology that the world could offer.

Technological innovation is needed for other aspects of the medicines supply chain. For example, the problems caused by substandard, spurious, falsely labelled, falsified, and counterfeit medical products have been difficult to resolve by the traditional approach of strengthening national

drug regulatory authorities and quality-assurance laboratories (Cockburn et al. 2005). WHO estimates that only 20% of countries have well-developed systems for regulating medical products—of the remaining countries, around 50% implement drug regulation at varying levels of effectiveness, and the remaining 30% have either no drug regulation in place or a very limited capacity that barely functions. Online sales of medicines further complicate efforts to protect consumers from substandard or falsified medical products (WHO n.d. a).

Past efforts to address the problem of counterfeit and substandard medicines have been hampered by the confusion of public health issues with issues of intellectual property rights and copyright infringements, and high-profile trade incidents in which legitimate generic medicines were seized, in transit, as counterfeits. In many countries, the only legal instrument available to address the public health problems caused by counterfeit and substandard medicines is legislation related to intellectual property rights (Attaran et al. 2012).

The efficiency, effectiveness, quality, sustainability, safety, and/or affordability of products can always be improved. As shown by repeated shortages of insulin (discovered in 1923) and penicillin (in 1942), the fact that a medicine is long-established is not a guarantee of its availability.

Future directions

While much progress has been made in recent decades, global health is a field in need of continued innovation. For the world to sustain a human population of 11.2 billion, major changes are needed in the way that people live, eat, work, and receive healthcare. The SDGs have an ambitious scope and several contradictions that need to be resolved. The health sector faces major challenges from epidemiological and demographic transitions and the difficult task of leaving no-one behind in its provision of high-quality health services. The WHO will need to keep building on its history of success in infectious disease control when working across all sectors to maximize the health benefit of their policies.

Global health’s contribution to sustainable development can help to ensure equitable access to resources, a healthy interface with the natural environment, and negligible variation in life expectancies (FAO 2018c).

The WHO will continue to track changes in the determinants of health and the patterns of disease, identify effective interventions, and measure the degree to which, over time, its recommendations improve health and longevity.
