During the twentieth century, most developed countries moved into Stage III of the health transition. In developing countries, the health transition has varied significantly among countries, with some still experiencing low life expectancy, an insufficient infrastructure for healthcare delivery and for water, hygiene, and sanitation. Meanwhile, the double burden of communicable and NCD is observed in many of these countries along with concurrent problems of undernutrition and overweight/obesity.

For a summary of the three stages, please see Table 3.5.1 and Figure 3.5.1.

Table 3.5.1 Stages of the health transition and associated activities

	Stage I The age of pestilence and famine	Stage II The age of receding pandemics	Stage III The age of chronic diseases
Health profile	• High, but fluctuating mortality rates due to epidemic, famines, and wars • High fertility rates • High rates of child mortality—with infectious disease the major cause of death • Among women of childbearing age, high risk of maternal mortality resulting from complications in pregnancy and labour • Life expectancy between 20–40 years	• Decreased prevalence of infectious diseases and malnutrition resulting in dramatically reduced mortality rates • Increased population growth rates due to high fertility rates with decreasing mortality • Life expectancy at birth increased to 35–50 years	• Low mortality and fertility rates resulting in reduced population growth • Reduced prevalence of infectious disease resulting in reduced mortality rates • An increasingly ageing society facing chronic degenerative diseases with relatively high morbidity • Significant changes in lifestyles • Life expectancy at birth increases to over 70 years
Health activities	• Absence of planned healthcare systems	• Healthcare and health technologies were developed, e.g. immunization programmes and the development of antibiotics for control of infectious diseases including acute bronchitis, influenza, and syphilis	• Social and national health insurance systems developed • Increased healthcare addressing needs of the elderly

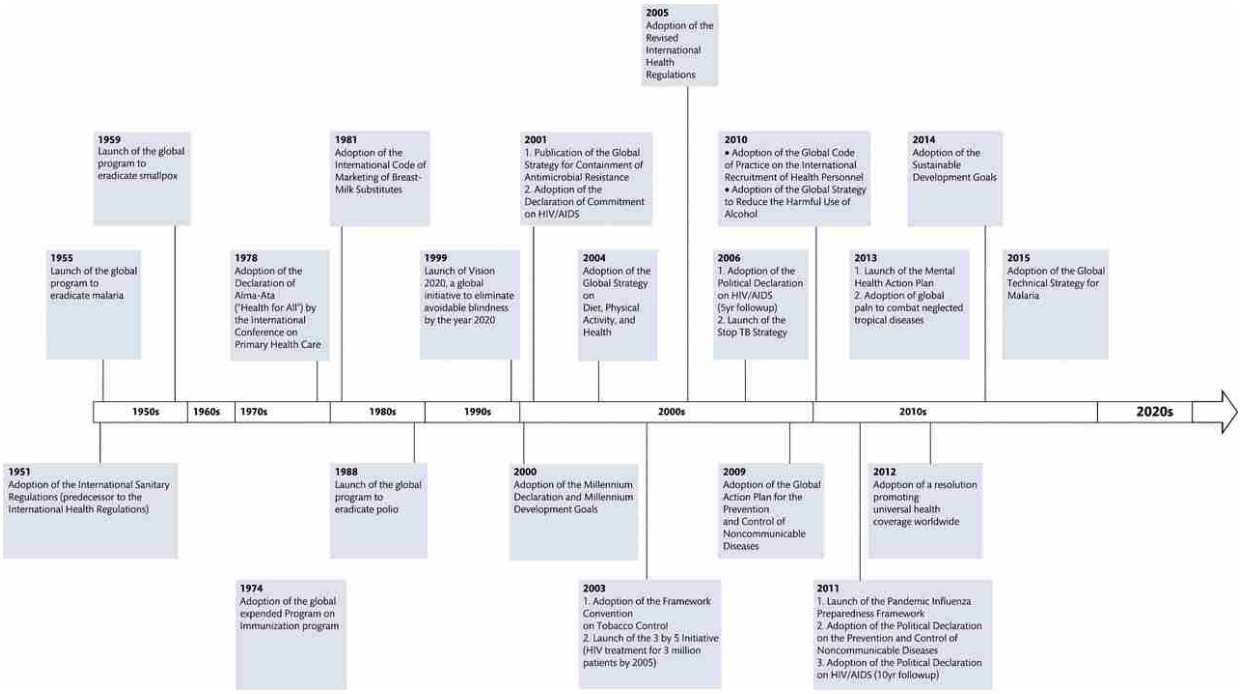

Fig. 3.5.1 Milestones of health policy.

Globalization and health policy

Globalization has been found to have direct and indirect impacts on public health (Welander et al. 2014). The development of global health policies also has been significantly affected by globalization and its impacts.

Globalization and the resulting surges in trade and migration have increased public health threats (infectious diseases, long-term illness, and environmental stress). Higher flows of goods and travel contribute to spread of diseases such as pandemic influenza, drug resistant tuberculosis and severe acute respiratory syndrome (SARS). The most recognizable example was the SARS epidemic in 2003. This epidemic spread most quickly during the three months when international travel peaked (Kovačić 2014). And, with more lower- and middle-income countries adopting the lifestyles common in industrialized countries, the prevalence of NCD has been steadily increasing.

On the plus side, production processes associated with globalization have sometimes triggered actions with positive effects on child health outcomes (Owen et al. 2007). During the nineteenth century, these included measures designed to reduce the health consequences of industrialization. Globalization also has brought with it an enhanced flow of information and

technology improving both health literacy and disease surveillance in developing countries, although the usage of such scientific findings is sometimes hindered by intellectual property rights, and despite the fact that the distribution of health services in most developing countries is highly skewed away from those in greatest need.

Global warming, likely increased by globalization, is one of the strong social determinants of health (Watts et al. 2015). The agricultural losses attributable to climate change have already had indirect health impacts in poorer countries which rely so heavily on their agricultural products. And a weakened agricultural sector inevitably has negative effects on the economy, reducing employment, increasing migration, and increasing food insecurity (Kovačić 2014; Watts et al. 2015).

In the 1980s and 90s, economic globalization had positive effects on the economies of some developing countries, particularly Costa Rica and Vietnam, with resulting increases in healthcare service delivery (Cornia Giovanni 2001; Díaz-bonilla 2002; Prabhat et al. 2002). China also has been a major beneficiary. By contrast, in many other developing countries, particularly in Africa, globalization has led to increases in income disparities coupled with and a sluggish, insecure and uneven pattern of growth and stagnation in health indicators has been observed with a general increase in mental illnesses, in alcohol and drug related health problems, and in stress-related deaths attributable to cardiovascular diseases and suicides (Cornia Giovanni 2001). Another frequent consequence of globalization has been higher numbers of insecure workplaces with poor safety regulation. And while global tariff reductions have had positive effects on food consumption, they also have had the effect of increasing tobacco consumption in some countries.

Current health challenges in developing countries

Developing countries are generally characterized by wide economic disparities which, in turn, are reflected in health status. These disparities, along with cultural and political factors have resulted in a far greater vulnerability to diseases among the poor in these countries (Orach 2009). Low-income households and individuals are rarely able to afford and access the quality healthcare received by the economically advantaged, and are far more likely to die from infectious disease and undernutrition. Such negative

health effects, in turn, have deleterious effects on productivity and national economic growth (Worldwash Institute 2018).

The spread of infectious diseases in these countries is, in part, an outcome of fragile health systems characterized by poor surveillance, low immunization rates, and problems of drug resistance. In some countries, new infectious diseases such as Middle East Respiratory Syndrome (MERS) and Bourbon virus have become prevalent; in others more common diseases have spread to other geographic areas or develop new clinical patterns resistant to existing treatment. As indicated, increased migration and changing social practices can contribute to the emergence or re-emergence of infectious diseases. Among the most serious, at present, are HIV/AIDS, SARS, H1N1 influenza and Chikungunya disease all of which take their toll both on individuals and on national economies (Heymann 2009; Dikid et al. 2013).

WHO estimates that more than 95% of HIV infections occur in developing countries with roughly 60% of them in sub-Saharan Africa. Over 7 million persons in Asia and the Pacific are infected with the virus. WHO data indicate that the primary mode of HIV transmission differs according to region (WHO 2017). Homosexual transmission is more common in Southeast Asia and in Central and South America than in Africa. Transmission from intravenous drug usage and transfusion of contaminated blood are also common in sub-Saharan Africa and South Asia. In developing countries as a whole, sex work, poor public health facilities, and poverty have been key factors in the spread of HIV infection (Morens and Fauci 2013).

HIV/AIDS is now the leading cause of death among women of reproductive age. UNAIDS has estimated that, in 2016, over 6,500 teenagers and young women between the ages of 15 and 24 were infected with HIV every week, the majority in sub-Saharan Africa (UNAIDS 2018). In some regions, women who have been subjected to violence are one and a half times more likely to become infected with HIV than women who have not. A UNAIDS project in Zimbabwe found that gender inequality, itself, is a major contributor to women's HIV vulnerability.

In addressing the HIV/AIDS problem in developing countries, governments and assistance organizations have, increasingly, been focusing both on prevention and control strategies with special attention to disease-specific intervention (particularly condom promotion and antiretroviral

therapy) and women's empowerment (focused both on education and employment). These efforts will be enhanced by overall economic growth and improved income distribution (Ruger 2004).

Another disease epidemic of recent decades has been SARS, a respiratory disease caused by the SARS coronavirus (SARS-CoV). In 2002–03, an epidemic originating in Guangdong Province of China spread globally, with over 8,000 known cases reported in 8 months from 33 countries on five continents (of which 21% were healthcare workers). The Asian Development Bank estimated that SARS resulted in the loss of US$20 billion in Gross Domestic Products among Asian countries in 2003 (Heymann 2009). The last known community case occurred in the USA in July 2003, but another localized SARS-related crossover from animals occurred in 2004. At the time of press in 2020, the SARS-CoV-2 pandemic is developing rapidly, with over 200,000 dead at the time of writing.

Another animal-related influenza was the re-emergence of the H1N1 pandemic in 2009 (the first outbreak took place in 1918). This pandemic, lasting from early 2009 to late 2010, was of a new strain resulting from a combination of a Eurasian pig flu virus with a previous reassortment of avian, swine and human flu viruses (Morens and Fauci 2013).

Some infectious diseases such as Dengue Fever, earlier considered to be lower level concerns, are now re-emerging with increased incidence, or spreading to new areas. This has resulted from combinations of drug resistance, the genetic evolution of agents of the diseases, inadequate public health measures, and the globalization issues discussed earlier. Drug resistance problems often result from over or under utilization of antibiotics. Some bacteria undergo genetic mutation from drug resistance, while others acquire the genes in question without a mutation. The same species of bacteria can sometimes receive the transfer of a resistance gene by bacterial genetic exchange mechanisms (NIH 2007). The contributing shortcomings in public health measures usually relate to low immunization coverage or to the absence of adequate international health regulations. These problems are exacerbated by population movement, conflict, and poor living standards (Heymann 2009). In the case of Dengue Fever, the spread of the infection in India has been attributed primarily to rapid population growth, poor sanitation, and migration. In Malaysia, nearly 60,000 cases of Dengue Fever and 165 deaths were reported in 2015 (Singh et al. 2017).

Among diseases of concern in Southeast Asia, is chloroquine-resistant *Plasmodium falciparum* malaria which began spreading in 1973. Although combination therapy with two antimalarial drugs is being used currently, ongoing surveillance for the evolution of antimalarial drug resistance of the protozoa is required. Primary prevention strategies include removal of risk factors through vector eradication, immunizations, and provision of uncontaminated drinking water, while, secondary prevention strategies include surveillance, and early therapeutic interventions. Underlying both sets of strategies is the need for infrastructure development to assure proper distribution of such care to all segments of communities (Singh et al. 2017).

Overall, the control of emerging and re-emerging infectious diseases requires fully functioning immunization efforts (accompanied by efforts to address cultural and trust-related resistance to such immunization), and strong surveillance systems supported by continuing region-specific research efforts and ongoing advocacy efforts aimed at policymakers in these countries. Control of these diseases also requires increased coordination among public health officials, clinicians and research scientists (Sarma 2017).

As indicated earlier, developing countries presently are in a stage of epidemiologic transition from common communicable disease-based mortality to one of increasing incidence of NCDs. WHO estimates that 71% of all deaths result from NCDs, with 15 million persons between the ages of 30 and 60 dying from these diseases. Over 85% of these ‘premature’ deaths occur in low and middle-income countries. While urbanization and industrialization have been boosting life expectancy in these countries, they also increase exposure to NCD risk factors. The World Economic Forum has estimated that the cumulative cost of NCDs will reach US$47 trillion or 5% of global GDP by the year 2030 (WHO 2018).

As part of their responses, national and international health policies are seeking to reduce alcohol and tobacco use through health education and with taxes and pictorial warnings on products. Such taxes have also been placed on sugary soft drinks in some countries to reduce overweight and obesity problems associated both with cardiovascular diseases and diabetes mellitus (Yamada et al. 2013; Baldwin 2015).

Maternal and child health

In February 2015, WHO published ‘Strategies towards ending preventable maternal mortality (EPMM)’ (EPMM Strategies), a direction-setting report outlining global targets and strategies for reducing maternal mortality under the Sustainable Development Goals (SDGs). The result of extensive consultations with stakeholders around the globe, the targets and strategies in the EPMM Strategies report are grounded in a human rights approach to maternal and newborn health and a focus on eliminating significant inequities that lead to disparities in access, quality and outcomes of healthcare within and among countries (Maternal Health Task Force).

As the agenda of the SDGs emerges, healthy societies where women, adolescent girls, newborns, and children thrive, and pregnancy and childbirth are safe everywhere, should be at the heart of its ambition. Ending preventable maternal and newborn deaths and stillbirths is possible within a generation and requires focused attention on high impact interventions and strategies to improve access and quality of care. Effective care around the time of childbirth is most critical for survival and health, but comprehensive strategies and high-impact interventions should span the continuum of care including before pregnancy. Since 2014, Every Newborn: an action plan to end preventable deaths (ENAP) came into being endorsed by 194 member states, at the 67th World Health Assembly. The plan identifies eight specific milestones that guide immediate actions needed by 2020 to best impact the ambitions of the SDGs and the Global Strategy for Women’s, Children’s, and Adolescents Health by their close in 2030. ENAP is a road map of strategic actions that harness evidence-based solutions to end preventable newborn mortality and stillbirths, and contribute to reducing maternal mortality and morbidity.

At the International Confederation of Midwives Triennial Congress in Toronto, a joint WHO and UNICEF publication—Reaching the Every Newborn National Milestones by 2020: Country Progress, Plans and Moving Forward—was released. The report details the country leadership and actions taken towards meeting the milestones throughout 2016. Progress was informed by the participating countries’ use of the Every Newborn Tracking Tool, which captures the processes of country ownership and action. The tool was adopted by 33 new countries between 2015 and 2016 (a 150% increase) and, as a result, the report provides a rich and internationally informed picture of progress made in addressing maternal and newborn health outcomes. Newborn health plays an increasingly important role in the

SDG period; the day of birth and the first 28 days of life are the most vulnerable time for a child's survival and health. Despite three-quarters of all newborn deaths resulting from preventable and treatable conditions, within the bracket of under-five deaths, newborn deaths declined at the slowest rate during the MDGs period (1990–2015), and now account for 45% of under-five deaths globally (up from 40% in 1990). The detailed strategic guidance, specific targets, interventions, and milestones from the ENAP and EPMM global action plans provide guidance for countries to use in their formulation of national health plans and funding priorities (Chou et al. 2015).

In many studies across the world especially in developing countries, differential analyses were conducted in order to better understand under-five mortality levels and patterns. Several variables were considered as differentials of under-five mortality rates. The most important variable was women's parity: the higher the number of children already born, the lower the probability of survival of the child. The 2013 Human Development Index (HDI) varies from 0.337 (Niger) to 0.944 (Norway). The value for East Asia and the Pacific is 0.707 (UNDP 2014). It is unlikely that mortality in developing countries with high mortality, and in particular under-five mortality, can be significantly reduced unless socioeconomic development experiences a substantial and sustained advance.

Under-five mortality rates are a leading indicator of the level of child health and overall development in countries. Worldwide, child deaths are falling, but not quickly enough. The global under-five mortality rate has declined by a little more than half, dropping from 91 to 43 deaths per 1,000 live births between 1990 and 2015. However, the current rate of progress was well short of the Millennium Development Goal (MDG) target of a two-thirds reduction by 2015. Under-five mortality remains the focus of the post-2015 MDG agenda, particularly in the newly adopted SDGs (Chou et al. 2015). It is important to remember that infant and under-five mortality estimates frequently differ between censuses and surveys as surveys usually use full birth histories which tend to underestimate infant and under-five mortality, while censuses use indirect methods which tend to slightly overestimate infant and under-five mortality.

Substantial progress was made in achieving the MDGs. Maternal mortality fell by almost 44% worldwide, from 385 deaths to 216 deaths per 100,000 live births over the period 1990 to 2015 (WHO 2015). This translates into an average annual rate of reduction of 2.6 percent. Although

this was a substantial decline, it was less than half of the 5.5 percent rate needed to achieve the three-quarters reduction in maternal mortality targeted for 2015 in MDG 5. In general, the ignominy of poverty has not ended at all. In 2016, members of the United Nations agreed on 17 SDGs to be achieved by 2030. This new set of goals aims to complete the agenda of the MDGs so that no country is left behind. Health is the third goal of the SDGs; one of its targets is to reduce the maternal mortality ratio to less than 70 per 100,000 live births by 2030 (WHO 2016).

Nutrition

An essential ingredient in the improvement of maternal child health is the improved nutritional status of these individuals.

Attention to maternal and child undernutrition—stunting, underweight and wasting, and deficiencies of essential micronutrients—increasingly focuses on the crucial period from conception to the child's second birthday, the 1,000 days during which the nutritional status of mothers and children have lasting effects on the life of the child.

The Lancet Maternal and Child Nutrition Series, 2008 and 2013 (Bhutta et al. 2008; Black et al. 2008; Ruel 2013; Black et al. 2013; Bhutta 2013; Victora et al. 2013) underlines these lifetime effects of nutritional conditions during this critical period, plus the adolescent period for girls, and reviews the evidence supporting interventions seeking to address the undernutrition problem.

The series also focuses on the so-called 'double burden of malnutrition'—these undernutrition problems coupled with problems of overweight and obesity, occurring in the same geographic areas, and with the latter sometimes a consequence of the former.

Increasingly, it is understood that, undernutrition problems, rather than being encompassed within the confines of public health, are multisectoral in their causality and, in turn, require multisectoral interventions. Where combinations of multisectoral interventions are put in place in vulnerable areas of developing countries, the effects on nutritional status have been found to be synergistic and often highly impressive. Figure 3.5.2, often referred to as the UNICEF Conceptual Framework, summarizes these multisectoral relationships

(https://www.unicef.org/nutrition/training/2.5/4.html, accessed September 2018).

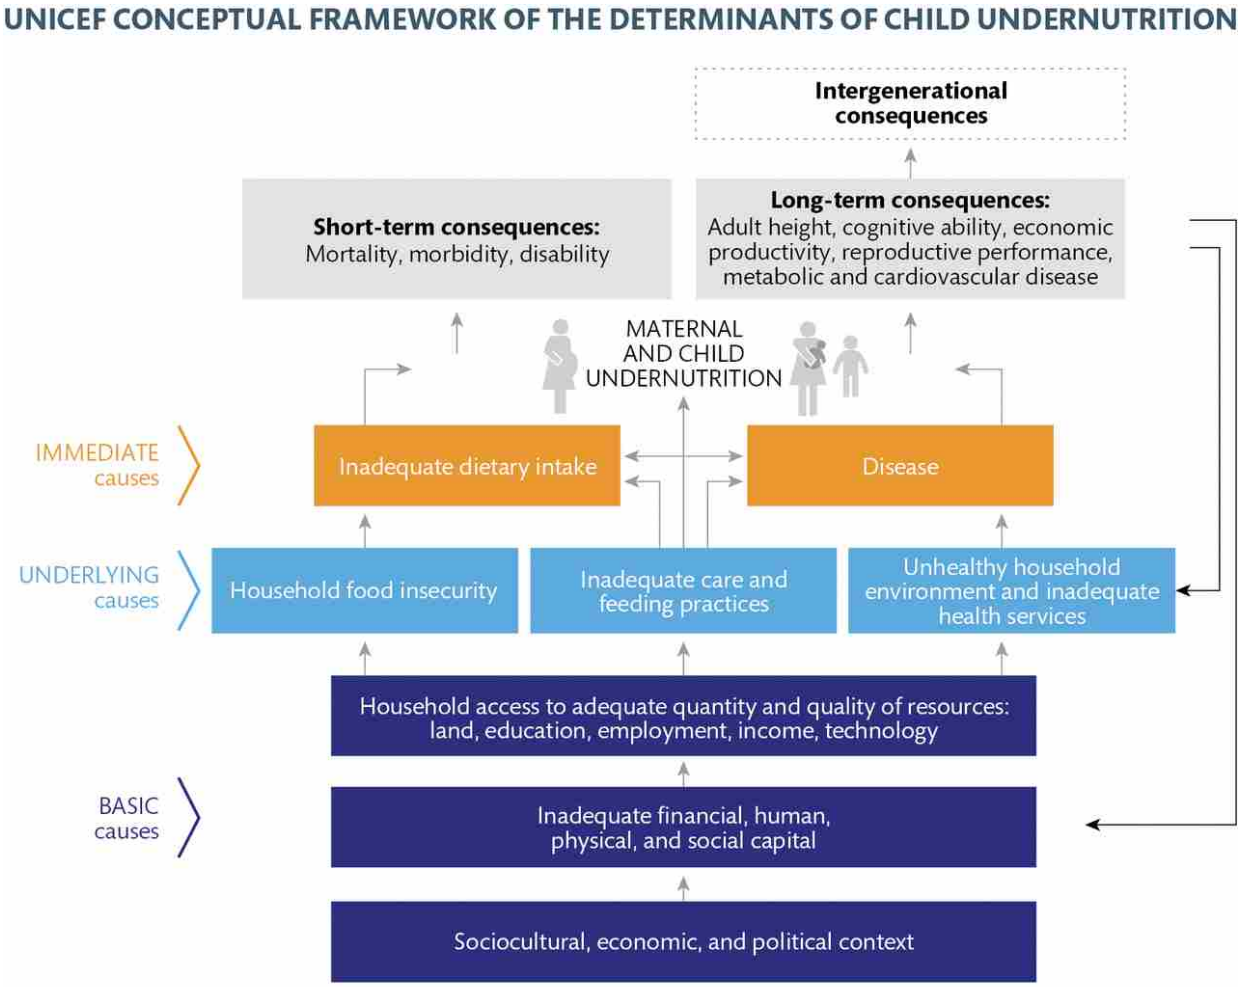

Fig. 3.5.2 Conceptual framework for the causes of malnutrition in society.
Reprinted from United Nations Children's Fund. UNICEF's approach to scaling up nutrition for mothers and their children. Discussion paper. Programme Division, UNICEF, New York, June 2015.

As indicated in the diagram, malnutrition is the result of some combination of inadequate dietary intake and infectious disease. These, in turn, are the result of a series of vitally important 'underlying causes'—which, depending on their relative importance in a given geographic area, require effective interventions. Accordingly, nutrition policies and strategies

often include project activities addressing food insecurity and poverty, behavioural change communications, health service delivery and water, sanitation, and hygiene (WASH) interventions, plus maternal and child feeding and micronutrient provision which address the ‘immediate causes’.

Interventions addressing undernutrition that fall outside of the health sector are generally referred to as *nutrition sensitive*, addressing, primarily, the determinants of undernutrition (Pinstrup-Anderson 2013). Examples of these are:

> *In the agricultural sector*—homestead gardens, small livestock, and small pond fish farming.
>
> *In the education sector*—inclusion of essential nutrition information in primary and secondary school curricula, and, more generally, generating increases in female enrolment and attendance at both levels.
>
> *In the social protection sector*—the coupling of social protection benefits with counselling that facilitates the translation of income supplements into improved nutrition and health status.
>
> *In the WASH sector*—assurance that these services are provided to those households at highest risk, and that the physical infrastructure provided is accompanied by adequate counselling on its use.
>
> In the health sector, nutrition-related interventions are often described as *nutrition specific*, addressing more directly the effects of undernutrition with a particular focus on prevention. These interventions include child feeding, behavioural change communications with special attention to optimal breastfeeding and complementary feeding practices, micronutrient supplementation and fortification, and the treatment of severe acute malnutrition.

Such nutrition-specific interventions in the health sector are particularly important given existing problems. Despite improvements in some countries, breastfeeding practices continue to be highly problematic and contribute significantly to high child mortality rates. Deficiencies of vitamin A, iron, iodine, and zinc adversely affect maternal and child health, while addressing these problems through supplementation and fortification have been found to be among the most cost-effective interventions functioning in developing countries.

Overall, over 165 million children in these countries suffer from stunted growth. The highest prevalence of stunting is found in eastern and western Africa and in South Asia. The largest number of children affected by stunting, over 70 million live in South Asia. The numbers of stunted children in Africa has actually been increasing in recent years (Black 2013). When micronutrient deficiencies are added in, undernutrition, resulting both in losses in cognition and reduced schooling has been found to reduce the

economic growth of a developing nation by at least 8% through productivity losses (Horton 2013).

There has been a significant response to these problems from governments, international and bilateral assistance agencies, and non-governmental organizations. These interventions, however, are unlikely to achieve the target of the World Health Assembly calling for a 40% reduction in stunting in children under age 5 between 2010 and 2025 (Black 2013).

Actors in health policy

Governments in developing countries play a primary role in the formulation of health policy formation and its implementation, often with the support of development partners. These partners include United Nations (UN) agencies, other international and bilateral donors, and international and domestic non-governmental organizations. International and national donors provide financial as well as technical expertise, often with an eye on international targets such as the SDGs set for the year 2030 (Koduah et al. 2015).

National governance and the orientation of key national political leaders inevitably have considerable influence on both the direction of health policies and their implementation (Shiffman and Smith 2007; Erasmus and Gilson 2008; Gilson et al. 2014; Koduah et al. 2015). At the same time, the role of officials and institutions at subnational levels, the extent of community involvement, and the capacity and commitment of front-line workers can be critical in this regard (Erasmus et al. 2017).

Multiple studies have highlighted the gaps and challenges in health policy implementation in developing countries (Belaid and Ridde 2012; Lehmann and Gilson 2013; Gilson et al. 2014). These shortcomings often relate to financial shortfalls or to the inadequate authority or commitment of implementing actors (Belaid and Ridde 2012). Limited responsibility and discretionary power at subnational levels have proven to be a particular liability (Lehmann and Gilson 2013; Gilson et al. 2014). More successful health policy implementation has often come on the heels of health sector reform including some combination of structural changes, e.g. decentralization, and changes in the model of healthcare delivery system (Atkinson et al. 2005).

Increasing attention also is being given to the role of social media in health policy. Where there are limitations on media freedom and, in turn, on

government transparency, or on the activities of civil society advocacy organizations there have usually been consequences (Ha et al. 2010; Green et al. 2011). By contrast, social media have played key roles in the success of behavioural change efforts relating to the consumption of alcohol and tobacco products and to traffic accidents (Grilli et al. 2002; Elder et al. 2004; Bala et al. 2013). Effective health policies generally include the role of social media in disseminating key elements of these policies and in providing the public with essential health information (Roland 2017).

Policy agenda setting is usually determined by combinations of health sector data (ideally disaggregated by geographic area), by the availability of funding, and by the orientation of policymakers themselves (Koduah et al. 2015). As indicated, donor agencies often have a key role in both policy formation and in its implementation (Grépin et al. 2017). The nature and scope of donor influence at different levels of policymaking have been well documented in Pakistan and Cambodia (Khan et al. 2018). Primary influences often include the utilization of financial resources and mechanisms to assure adequate monitoring and evaluation of policies and programmes (Hafner and Shiffman 2013; Khan et al. 2018).

Two other important influences on health policy development are the international agenda (e.g. SDGs), and the availability and quality of scientific evidence (Wallace et al. 2012).

Reviews in some African countries and in Myanmar have recommended an upgrading of evidence-based decision-making and policy development, and have underlined the vital importance of increased receptivity to such evidence, and of universities in the necessary capacity development (Lavis et al. 2005; Orton et al. 2011; Young et al. 2016; Ellen et al. 2018). To fill gaps in essential knowledge transfer, such training is necessary both for policymakers and research organizations, and improved communication between the two should be encouraged (Whitehead et al. 2004).

Political and economic impacts on health systems

Government health systems are significantly affected by the country's economy, and by its political structure and orientation. Where political instability exists, political systems are weak (e.g. overly centralized, bureaucratized decision-making, weak regulations), economic growth is

sporadic, or welfare systems are dysfunctional, health consequences are inevitable (Guha-Sapir and D'Aoust 2010).

In some countries with strong political commitment to reduce hunger, poverty, or inequality, the health status of citizens has improved markedly even without highlighted attention to health and nutrition. This has been seen during particular periods of recent history in China and Cuba, and during the early years of the Lula presidency in Brazil (Field and Levinson 1975). In Vietnam, health sector management until the mid-1980s was state–socialist or universalist. Health expenditure emanated both from the central and subnational governments and from other local resources. All citizens could enjoy preventive and curative healthcare free of charge as citizens' rights. As a result, child mortality rates dropped markedly. Unfortunately, in some regions of the country with more limited resources, health improvement was less dramatic and was often characterized by inequality in service delivery (London 2008).

Commercialization in the healthcare sector began in the mid-1980s. Often resulting from macroeconomic reform, such commercialization often led to a lower quality of healthcare delivery particularly in public hospitals where, despite an outward appearance of free services, the informal fee charges levied—emanating from the new profit orientation of these hospitals, often reduced hospital utilization by the poor. Similarly, financial decentralization in the social sector as a whole often resulted in inadequate budgetary allocation for actual health services at subnational levels, with most of the funding going for high level medical staff salaries, and more sophisticated equipment rarely available to those most in need (Forsberg 2011). The associated poor management and weak regulatory systems have usually led to reduced immunization rates and to the increased prevalence of particular infectious diseases.

In South Africa, racial discrimination was the primary cause of poor health services for the African population along with inequality in most services during the Apartheid period. The Bantustan regions set aside for large segments of the African population had their own healthcare systems which were invariably inadequate and resulted in high mortality rates (Maillacheruvu and McDuff 2014).

In 1994, with the election of Nelson Mandela and the end of Apartheid, a new National Health Plan was developed with comprehensive primary health services (Coovadia et al. 2009). Many health sector challenges

persisted, however. With inefficiencies in the health system, the percentage of Gross Domestic Product devoted to health was much higher than in most developed countries but without the quality of service delivery desired, and the expansion of health infrastructure resulted in an overly heavy work load for the often underpaid healthcare professionals—many of whom left the government for better jobs elsewhere. Meanwhile, continued poverty and health illiteracy among large segments of the population resulted in low immunization rates and high use of tobacco and alcohol. Over time, new economic policies emerged with a focus both on economic growth and redistribution, and results have improved accordingly (Mayosi and Benatar 2014).

With these new policies in South Africa, improved benefits for health staff reduced migration to the private sector (George 2013), and intensified community mobilization significantly increased awareness of communicable diseases, particularly HIV/AIDS and tuberculosis (TB). The country's Strategic Plan addressing HIV/AIDS 2007–2011 served as a model for many other countries (South Africa Department of Health 2007). At the same time, a new council of healthcare professionals became the regulatory body for new drug approval (Coovadia et al. 2009).

In sum, even countries with similar geographical conditions are likely to have marked differences in their health outcomes depending on the political and economic systems functioning and their quality (Chongsuvivatwong et al. 2011) In general, socio-democratic political systems with redistributive policies result in improved coverage of health systems and better health outcomes (Borrell 2007).

Challenges in implementing global and national health policies

Governance: responsibility and accountability

Public health policies in developing countries need to be compatible both with regional and global policies to increase cohesiveness, integration, and support. Where this is done, national policies will better assure that health priorities in local settings are addressed, and that international support can support health sector priorities. With the creation of MDG and now SDG goals, more attention is being given in these countries to policies and programmes which are results- and outcome-oriented. There remains, however, a tendency in many countries to be satisfied with the achievement

of input and activity targets (more easily achieved and less threatening to health system management likely to be concerned about the extent to which these activities actually will achieve outcome targets—- and the repercussions should these outcome targets not be achieved). There also is a tendency for health systems to address only disease symptoms and not their underlying causes.

Even where outcome targets are pursued and underlying determinants are identified, a country's ability to address these adequately is often limited by financial capacity.

Using the analogy of building a sound physical structure, a national health system needs to ensure a concrete foundation with (a) a clear understanding of its population's socio-cultural norms and its health problems—both symptoms and causes (disaggregated by geographic area), and of existing population disparities and inequalities, and (b) a functioning system of governance and accountability.

Accountability has to exist both in national and subnational governance, and applies both to financial disbursements and to health service delivery staffing and infrastructure. These, in turn, require skilled management.

Sound strategy development, actions plans, and programmes plus effective review processes might constitute the first layer of building blocks above the foundation. These can be problematic when they are formulated by a limited inner circle of officials and do not take into account the needs of local governance and communities, the latter, as indicated, often diverse in their socio-cultural norms and values. Even where efforts are made to involve communities in decision-making and to elicit their responsibility, those representing the communities are often only persons from upper income groups and (where relevant) from more advantaged religious groups, races, or castes.

The second layer of building blocks (above the foundation) would be the programme administrators, managers and service providers/front-line workers, with these persons fully cognizant of the building structures below them, clear about their own responsibilities (and, where relevant, their own accountability), competent to perform their tasks, and able to avail of the necessary resources to accomplish them.

The cement, if you will, holding these building blocks together and firmly attached to the foundation, consists of such values as honesty, vision, and the ability to keep results and outcomes in sight, fairness, mutual respect,

adherence to commitments, motivation, and sound judgement, the ability to instil confidence in others, and, perhaps binding *these* together, a sense of ownership of the undertaking as a whole. Exemplifying such cementing qualities might be segments of the health sector professionals in Brazil in recent years, believing so firmly in their country's healthcare pursuits that they regularly eschewed more lucrative offers from the private sector (Levinson and Balarajan 2013).

Health financing and the utilization of existing resources

The maximum utilization of existing resources through leveraging and aligning these interventions among stakeholders are necessary steps in health system modernization. These often can be accomplished by eliminating wasteful expenditures, reducing the cost of service provision, and encouraging new and more efficient means of providing care. Modernized healthcare also requires effective information technology (IT), which provides a base upon which to build managerial, staffing, and financial suprastructures. At the same time, cost-effectiveness studies comparing treatment and prevention modalities offer providers with valuable information to use in the selection of these modalities.

Health information

Health information system (HIS), which is an integral part of the health system strengthening needs a strong institutional regulatory framework. It is also an entry point into the health sector reform through provision of information and knowledge on the quantity as well as quality of health services. It is of paramount importance to have the reliable, relevant, and real-time information in order to make proper decision for improving the quality of services through proper and effective allocation of available resources.

Fragmentation of HIS is hampered further as donor funding sometimes targets specific areas and creates new information systems which are not integrated with the existing HIS (Braa Jørn et al. 2007). The role of the HIS in the health system is not just routine collection of health services data and reporting to higher levels of the healthcare system, but to be used by the health staff at various level and apply and facilitate evidence-based decision-making at all levels, most importantly at the point of collection but it is not

usually the case in real life situation. Moreover, health policies and plans should be based on such information, which also needs to be ensured to be aligned with the needs at the operational level. Many developing countries are still facing with the issues of data privacy versus data sharing as both are equally important and supportive to each other in realizing its function effectively. Proper regulation of the creation and use of healthcare information is imperative to everyone in the system.

It is crucial to strengthen health information including human resource for long-term cost-effectiveness in spite of having potential resistance to change and cost issues (Mpofu et al. 2014). Improved health worker capacity to monitor and evaluate programmes would improve data quality, management, and reporting, which further increased use of health data for disease surveillance and planning purposes. Quality data within the health sector itself is crucial for monitoring and evaluation (M&E) of health programme performance and for developing appropriate policies, plans, and strategies to ensure quality health services. It usually covers the dimension, comprised of data accuracy, reliability, completeness, timeliness, precision, and integrity (USAID 2007). Many developing countries experience challenges related to producing quality health data (Chaulagai et al. 2005). The contributing factors include weak linkages between M&E systems and data generation points and inadequate harmonization of multiple data collection and reporting systems (UNAIDS 2010). Additional challenges include poorly coordinated M&E systems characterized by duplication of data collection and underutilization of nationally-defined tools [12–15]. A frequently documented challenge related to producing quality health data in low and middle-income countries is the shortage of trained human resources (UNAIDS 2010). In addition, improved data quality better informed evidence-based planning at the all level. One approach that has been effectively used to address skilled health workforce shortages is task shifting (WHO 2008). In Botswana case, the district M&E officers took on M&E responsibilities that were previously conducted by nurses and other health workers as secondary activities to core programme and clinical responsibilities. This allowed such health workers to concentrate on delivering quality clinical services and focusing on implementation of quality, priority health programmes (Mpofu et al. 2014).

Several other studies also indicated that data quality improved by addressing human resource capacity issues, mainly through training of health

workers on the importance of public health information and regular feedback (Mphatswe et al. 2012). In Malawi and South Africa, it was found that data quality improved through provision of supportive supervision (Mate et al. 2009) and institutional research (Harries et al. 2011). Other initiatives, such as the transition from paper-based to electronic records, have also been shown to improve data quality (Ekouevi et al. 2011).

Infrastructure, technology, medical supplies, and logistics

Healthcare infrastructure must be adequate to ensure a reduced burden of diseases and an improvement in the health status of the population. A solid broad-based health infrastructure is composed of necessary physical structures accessible to the entire population served; other support facilities including laboratories, medical record systems, and transport; and a competent health workforce supported by systematic and effective resource allocation practices, supervision, and supportive monitoring. An effective healthcare infrastructure needs to be both human-centred and client-responsive. The proper location and management of health infrastructure components are essential to the health system's effectiveness in order to achieve the desired 'universal health coverage' and to meet basic health needs, primary healthcare centres should be within the reach of the entire community and fully cognizant of prevailing disease patterns. These primary, secondary, and tertiary healthcare centres, in turn, require the necessary facilities and equipment, competent and efficient staff, and the ability to deliver an essential health services package at affordable costs. These centres also should be characterized by a welcoming environment for both clients and service providers.

Proper formative research and area-specific baseline information on disease prevalence, collected through necessary surveys and research, should be in place prior to the formulation of actual health plans in order to determine the optimal location of each type of health centre, the anticipated workload, and the transportation that will be necessary. Often the establishment of fewer more efficient tertiary centres at strategic locations, with transportation available to assure access by more remote population groups, can provide greater benefit than establishing a larger number of tertiary centres with insufficient infrastructure and human resources. In the building of hospitals and other health facilities, a premium must be placed on proper design facilitating cost-effective, quality-assured service delivery,

and should include durable, built-in water and sanitation facilities which are adequately equipped.

The global trend towards high-end medical technologies presents a different type of challenge for developing countries, which, on the one hand, would wish to improve the quality of treatment by using these modern technologies—and save more lives in the process, but recognize also the exorbitant costs associated with much of this technology. Where resources are limited, and they usually are, choices often have to be made between acquiring such equipment—likely to benefit a relatively small portion of the population, and using available resources to upgrade the quality and availability of health services and preventive public health utilized by larger portions of the population. High-end medical technology also needs a cadre of sophisticated medical practitioners requiring high salaries, and well-equipped maintenance staff to keep the equipment functioning properly.

Some middle-income countries have found a workable balance in working with these choices. A prime example is Turkey, which has managed to expand high-quality diagnostic and curative services efficiently and effectively but without spending on them a disproportionate percentage of the country's health budget. This has been done, in part, by successfully enlisting the involvement of the private sector including pharmaceutical companies, as well as biomedical engineering societies and philanthropic organizations. Turkey also has put in place a reasonably effective referral system—including timely transportation arrangements—to increase the likelihood that those most in need of this more sophisticated technology will be able to benefit from it. See Case Study 3.5.1.

Case Study 3.5.1 Turkey's Health Reform

It shows an evidence of how a poor health system with health indicators below par changed into an improved system with population satisfaction for the health services they received. The fruitful outcomes within a decade were attributable to the decisive political action and effective reform, resulting from wisdom and forward thinking vision of health minister in 2002. Today, it has improved its health outcomes, achieving health-related Millennium Development Goals well before the 2015 deadline. The number of women dying from pregnancy-related causes more than halved since 1990 to about 20 per 100,000 live births in 2013. The number of infants dying before their first birthday dropped from 55.7 in 1990 to 16.5 per 1,000 live births in 2012.

Strong economic growth and political stability were also found contributed a lot to the strategic directions and its implementation in health reform. A tactful confidence building and support by doing 'easy first and difficult later' reform interventions was very thoughtful and noteworthy.

Major success reasons: Country-led strategic directions and realistic goals, embedded in a strategic management framework with effective implementation and M&E system.

Emergency Action Plan of the 58th Government, which under the heading Health for All was adopted shortly after the elections on 3 November 2002, contains 11 dimensions of reform and on the basis of the Emergency Health Action Plan, the HTP was prepared in early 2003 under eight themes. It had been transformed from working as provider of health services to steward of the health sector. Turkey's Health Transformation Programme met health-related MDGs quite ahead of the 2015 deadline. The lessons learned from Turkey centre on the importance of the sequencing of health reforms and their rapid implementation, and the benefits of primary healthcare reforms. The 'patient-centredness' of the Turkish system with a strong emphasis on health as a right was the cornerstone of reform.

Policy lessons

- Effective sequencing in health reform steps by ensuring a good start and winning people's hearts
- Rapid and timely interventions with right pace for future policy shift, for example dual practice of physicians
- Expanding public health expenditure and giving a space for non-contributory insurance scheme for the poor
- Ending fragmentation and duplication in public sector service delivery and introduction of family medicine programme
- Unification of various health insurance schemes and health financing reforms along with the changes in health service delivery

(http://www.worldbank.org/en/news/feature/2015/02/17/lessons-from-turkey-how-bahrain-is-looking-to-improve-its-healthcare)
(http://www.euro.who.int/__data/assets/pdf_file/0017/272321/Strategic-Planning-for-Health_Turkey.pdf)

An effective health workforce requires adequately detailed job descriptions, and then training to assure that these positions can be professionally met. Pre-service as well as in-service training needs to be both job-based and results-oriented. At the same time, supportive supervision and M&E systems are always necessary. As in the case of equipment support discussed previously, the private sector may, at times be in a position to support or augment a health workforce, although effective regulations and systems of accountability must be in place to assure that such a private sector role not being solely profit-oriented.

Retention of public health staff is often as important as recruitment and training. Cases exist in numerous countries of health professionals who are trained for public service and then, utilizing such training, seek better paying jobs in the private sector. Accordingly motivation through recognition and incentives is often a vital pre-requisite for sustaining an effective workforce.

These should be systematically included in protocols, guidelines, and standard operating procedures (SOPs).

The allocation of a country's health budget reveals much about a government's orientation, priorities, and level of commitment to its population as a whole. Where budgets are disproportionately weighted towards high-end urban hospitals and health services and with poor access to quality services by rural and lower income population groups, the overall health status of the country is likely to suffer. Responsible allocation should be based largely on the burden of diseases in the country, and on the relative urgency of preventing and combating each disease category. This, in turn, requires proper disease surveillance and antibiograms, effective treatment guidelines, and the use of generic drugs wherever possible. Prevention itself deserves high priority in a country's health budget, and involves health education, effective food and drug regulations, and attention to safe water, hygiene, and sanitation plus interministerial collaboration to assure, for example, adequate efforts to reduce road traffic accidents.

The existence of affordable health insurance systems can, in many country contexts, assure that adequate medical care can be provided for population groups across the income spectrum.

Service delivery—overcoming geographical factors and conflict

In most developing countries, the majority of the population still live in rural areas, even with rapid urban migration. Rural areas have higher death rates from chronic obstructive pulmonary disease, suicide, and unintentional injury compared to highly urbanized counties (Eberhardt 2001). As indicated, it is essential that this population have access to affordable quality both through health centres and some combination of health extension personnel and community health workers. Included in this health delivery should be pertinent behavioural change counselling, preventive health screening, and the opportunity to avail of low-cost health insurance. The active engagement of the population in these processes and some level of social cohesiveness also have been identified as important ingredients in health sector success stories and is a key element of the Alma Ata Declaration.

One of the primary causes of development failure and, in turn poor health status is conflict. Paul Collier notes that nearly 75% of people in the 'bottom billion' countries are engaged in a civil war or have recently been through

one. (Collier indicates that the primary factors that make a country prone to civil war are low-income, slow economic growth, and dependence upon primary commodity exports.) Increases in disease prevalence resulting from such conflict are likely to continue well after the fighting has ceased (Collier 2007). Accordingly, health plans in such areas need to include the capacity for emergency responses followed by sustained health delivery. At the same time, it is clear that no health policy is capable of adequately responding to a sustained environment of conflict such as that found in Libya (Nathan 2005). Overall, responses to armed violence and its prevention require intense efforts involving criminal justice, public health, anthropology, journalism, human rights, and education (Lemard 2004; Kaldor 2007; Arya 2008).

The direct consequences of armed violence pose multifaceted challenges for the health system (Valenti et al. 2007). The economic and human costs significantly burden resource-limited services. This correlates with a reduced capacity for quality health service provision in the post-conflict environment (Kopel 1995). The indirect effects of armed violence include the disruption of livelihoods through population displacement leading to pervasive insecurity and adverse health consequences. Moreover, such factors as psychological trauma, inadequacy of essential services, and a resurgence in vaccine-preventable disease adversely affect security, health, and development (OECD 2009; Krause et al. 2011). Globally, armed violence control is increasingly recognized as a public health asset, especially in the post-conflict environment (Gilligan 2000; Krug et al. 2002).

The health workforce

Workforce development

A well-built health workforce is essential to overcome the complex threats of rapidly spreading infectious diseases, emerging and re-emerging disease and the increasing trend of NCDs in a developing country—these NCDs spreading as a result of globalization and interdependence among countries, changing lifestyles, and the improper use of chemicals and medicinal products. The unfinished agenda of the MDGs regarding infectious diseases, malnutrition, and maternal complications persists in a diversity of settings. These are further jeopardized by the emergence of chronic vascular disease, diabetes, cancers, and lower respiratory conditions, which now often constitute the most common causes of death. Significantly, there also are

sharp increases in accidents and injuries, and a growing recognition of mental illness and its consequences (Adjuik et al. 2006; Tollman et al. 2008).

Globally, countries are facing a Human Resources for Health (HRH) crisis. However, those likely to suffer most are the underserved poor, rural, and marginalized individuals and groups in the rural areas of developing countries. The development of quality HRH takes time and requires careful needs-based planning, access to skills-based knowledge, and effective training.

Health workforces often can be divided into three basic categories: (a) community-based health workers (CHWs); (b) mid-level workers (MLWs); and (c) health workers with particular expertise on an aspect of health delivery. CHWs are involved in providing preventive medical services, monitoring the community's health, identifying patients at particular risk, and sometimes providing basic curative services. These CHWs are referred to by a variety of names: health auxiliaries, health volunteers, health promoters, family welfare educators, village health workers, and community lay health aides. These are often volunteers with limited training in commodity and information dissemination and disease prevention efforts with the associated behavioural change counselling (Tollman 2008).

In many low resource countries, MLWs are the backbone of their health service. Studies on the contribution of mid-level providers indicate that they often play a pivotal role in improving access to care for underserved populations, a role also seen in some higher income countries (Keni 2006; Staton et al. 2007). Indeed the significantly increased access to HIV treatment in most African countries was achieved through the use of MLWs —and in some instances, by staff with even less formal training (Médicins Sans Frontières 2007).

These MLWs are certificated individuals who have been trained to provide primary healthcare services at the community level, to diagnose and treat common health problems, to manage emergencies, to refer appropriately, and to transfer the seriously ill or injured for further care. These workers go by a range of titles depending on the country in which they work. In Myanmar, health assistants, lady health visitor, and midwives provide preventive services and the management of minor ailments; lady health workers in Pakistan provide maternal and child health services; técnicos de cirugía in Mozambique provide surgical care; clinical officers in East African countries provide diagnostic and treatment services at the

primary care level and in hospitals. In Nepal, health assistants staff health posts while auxiliary health workers are responsible for subhealth posts. In the United States, physician assistants provide a range of specific services (Lehmann 2008; McAuliffe et al. 2009).

The training of these MLWs is likely to vary considerably. Those who enter this work with pre-existing medical training, often nurses, are likely to require only 'top-up' training which is likely to be relatively brief in duration. Those without such a background receive training that usually ranges from 2 to 4 years including some that is field-based with supervision (Lehmann et al. 2008).

The third category, health workers with particular expertise in particular aspects of health delivery, represents an essential ingredient in the management of specific diseases, such as tuberculosis and malaria, for highly specific tasks such as the use of DOTS (Directly Observed Therapy, Short-course) in tuberculosis management, and in management of chronic diseases.

Building the human resource base for health delivery requires, in addition to physicians and nurses, these categories of health workers in order to provide the necessary services and to respond to changing health conditions in a country. Policies are therefore necessary to address the dynamics of the health labour market and the development and management of a skilled health workforce.

The challenges faced in optimizing these HRH are numerous and include carefully synchronizing a country's health workforce with its primary health needs and the inherent geographic variations in these needs (Dussault and Franceschini 2006).

With such training, health staff is often able to assume higher level responsibilities. In Rwanda, sets of tasks in HIV management have been transferred from physicians to nurses trained in HIV management. Subsequent analysis found that improvements in CD4 count, correct prescriptions, patient monitoring, and overall survival rates were similar between these nurses and the physicians they replaced in this work (AIDSMap 2010). In Malawi, clinical officers carry out nearly 95% of major obstetric operations in government hospitals with no significant differences in postoperative outcome, well-being, stillbirths, or neonatal mortality, compared with such operations carried out by medical officers. Evaluations

of the performance of MLWs in Mozambique showed no significant difference in outcome when compared to that of medical specialists.

Finally, there is often a critical shortage, particularly in developing countries of professionals trained in medical and nursing schools, of health managers and researchers trained in the schools of public health and of MLWs, lay community health workers, midwives, and other healthcare providers. (These shortages are also affected by those trained professionals who emigrate to higher income countries or seek employment in better paying private sector jobs.) Addressing these shortages often requires the attention and explicit involvement of the political leadership in these countries (Speybroeck et al. 2006).

Way forward and strategies to improve health policy and status of health in developing countries (recommendations)

This section recommends strategies to improve health policy and the overall status of health in developing countries. These recommendations are listed as follows and will be explored in turn.

Risk pooling to minimize catastrophic out of pocket expenditure
Forging and strengthening public-private partnerships
Evidence-based decision-making, strengthening of public providers in reporting and the introduction of updated technology
Decentralization and triage of workload, implementing proper referral system, empowering community healthcare and capacity building
Training, capacity building, and investment in infrastructure
Reducing disparities and inequity in minorities and other vulnerable population groups
Achieving Universal Health Coverage and the SDGs

Risk pooling, minimizing catastrophic out of programme experience (OOPE)

Risk pooling aims to achieve equitable access to health services with financial protection. It allows for redistribution of prepaid resources to individuals with the greatest health needs. The concept is that money flows from richer to poorer, and from healthier to sicker. When a poor or socially vulnerable person becomes ill or injured, the entire household can become

trapped in a downward spiral of lost income and high healthcare costs. Poor people are more vulnerable to this downward spiral as they are more prone to diseases and have more limited access to healthcare and social insurance. These catastrophic out of pocket payments arise under the conditions outlined in Figure 3.5.3.

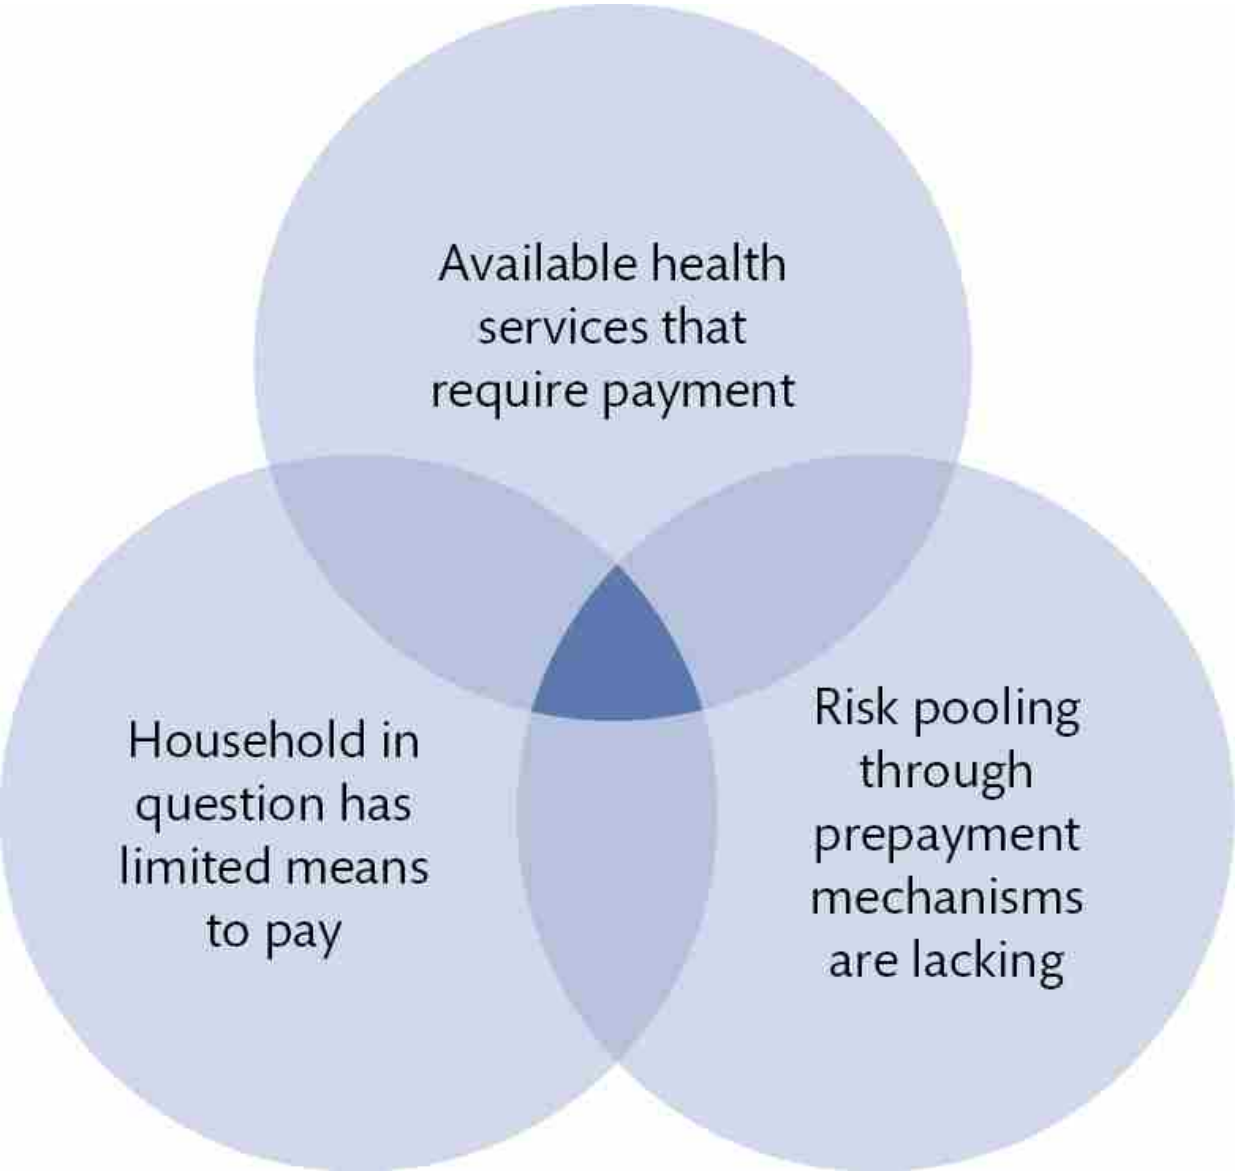

Fig. 3.5.3 Risk pooling.

As a consequence of inability to pay, households may refrain from using services. This will adversely impact their health, and this morbidity will adversely impact their earning potential. Reduced earnings have a knock on effect throughout the household. Not only the ill person is affected; their family and future generations can be affected too. High expenditure can result in reduced food and clothing purchases, and reduced investment in education, with associated sequelae.

Risk pooling addresses this point. Pooling of funds occurs through various prepayment mechanisms, which come in many forms. For instance there is tax-based financing of healthcare by governments, compulsory insurance contributions, external sources, and social health insurance. These mechanisms are common within developed nations, for instance the use of the Bismarck model in Europe. The Bismarck model uses an insurance system and is usually financed jointly by employers and employees through payroll deduction. Bismarck-type health insurance plans do not make a profit and must include all citizens (Wallace 2015). A larger and more diverse risk pool is more favourable. To create diversity compulsory participation in a health coverage scheme is required; if participation was to be voluntary there would be less likelihood of healthier individuals contributing, which ultimately would limit cross subsidy from healthy to sick and would undermine the financial stability of the system (OECD 2003).

When risk pooling, care needs to be taken to avoid fragmentation which can result in system inefficiency. Fragmentation is noted to take multiple forms, for instance local government health agencies, externally funded vertical programmes and overlapping and uncoordinated projects between different funding agencies such as Ministry of Health and health insurance funds.

Ultimately, health systems requiring lower out-of-pocket payments for healthcare offer better protection to the poor against catastrophic spending. Prepayment entails predictable expenditure for a given set of services. This allows opportunity to budget for healthcare and share risk with those more able to pay (e.g. as a ‘Sin Tax’; see Case Study 3.5.2). There is a reduced need for sudden acquisition of funds, and the payments required are reduced.

It is important to note that a prepayment model will not eliminate catastrophic out of pocket payments, as other factors; for instance health

services offered and copayments; need to be accounted for. Additionally, catastrophic expenditures do not automatically disappear with rising income.

Case Study 3.5.2 Philippines Sin Tax

In 1995, the Government of the Philippines set up the National Health Insurance Programme 'PhilHealth'. All Filipinos are automatically enrolled in and therefore entitled to benefits of the programme. There are formal and informal groups, and the formal are obliged to pay a premium, which essentially cross subsidizes other members. All senior citizens are mandatorily covered.

PhilHealth is mandated with improving access to quality care and reducing OOPE. To achieve this, it introduced a 'Sin Tax' in 2012. The basic premise is that taxes on alcohol and tobacco are earmarked for expenditure, mostly on healthcare:

- 85% of revenues are allocated for health, of which:
- 80% are for achieving UHC
- 20% for medical assistance and improvement of health facilities

Within its first year, Sin Tax raised more than 1.2billion USD, allowing enrolment of an additional 14 million families—totalling 45 million Filipinos—into PhilHealth.

What can be learned from PhilHealth?

PhilHealth is an example of a sustainable financing mechanism for healthcare, providing an alternative to out of pocket payments. Research suggests that even at low levels of public spending, countries can make significant steps towards UHC. Revenue raising needs to be coupled with the pooling of funds and the purchasing of health services; it is the combination of reforms which drive improvements in health system performance (Jowett et al. 2016).

The Programme has confirmed the need both to understand history and local environment, and to use a clear technical framework when analysing and assessing key drivers and impediments towards achieving UHC. There will be a struggle to attain UHC without a basic sense of solidarity in the community.

Criticism

While the country's UHC agenda is commendable for its pro-poor approach, other PhilHealth members must be kept in mind and feel the benefits of PhilHealth to ensure political support and stability. In this regard PhilHealth and the accredited hospitals need further strengthening to increase patients' access to and utilization of quality health services and establish transparent and fair provider payment processes.

Additionally, facilities need to be technically and managerially competent and empowered to respond to PhilHealth in its role as a powerful purchaser. Facilities should be held accountable for the delivery and quality of care that they provide.

Private–public partnership and strengthening

It is widely accepted that private–public partnerships are essential in the journey towards Universal Health Coverage (UHC). Governments are encouraged to recognize that they cannot achieve UHC on their own (OECD 2003).

UHC requires a resilient health system, one that is strong and responsive. Engagement between public and private sectors to achieve these qualities can take multiple forms, for instance capacity development, innovations, outsourcing, and consulting-all with varying degrees of commitment and financial risk sharing. Engagement of the private sector should ideally maximize strategic areas such as those shown in Figure 3.5.4.

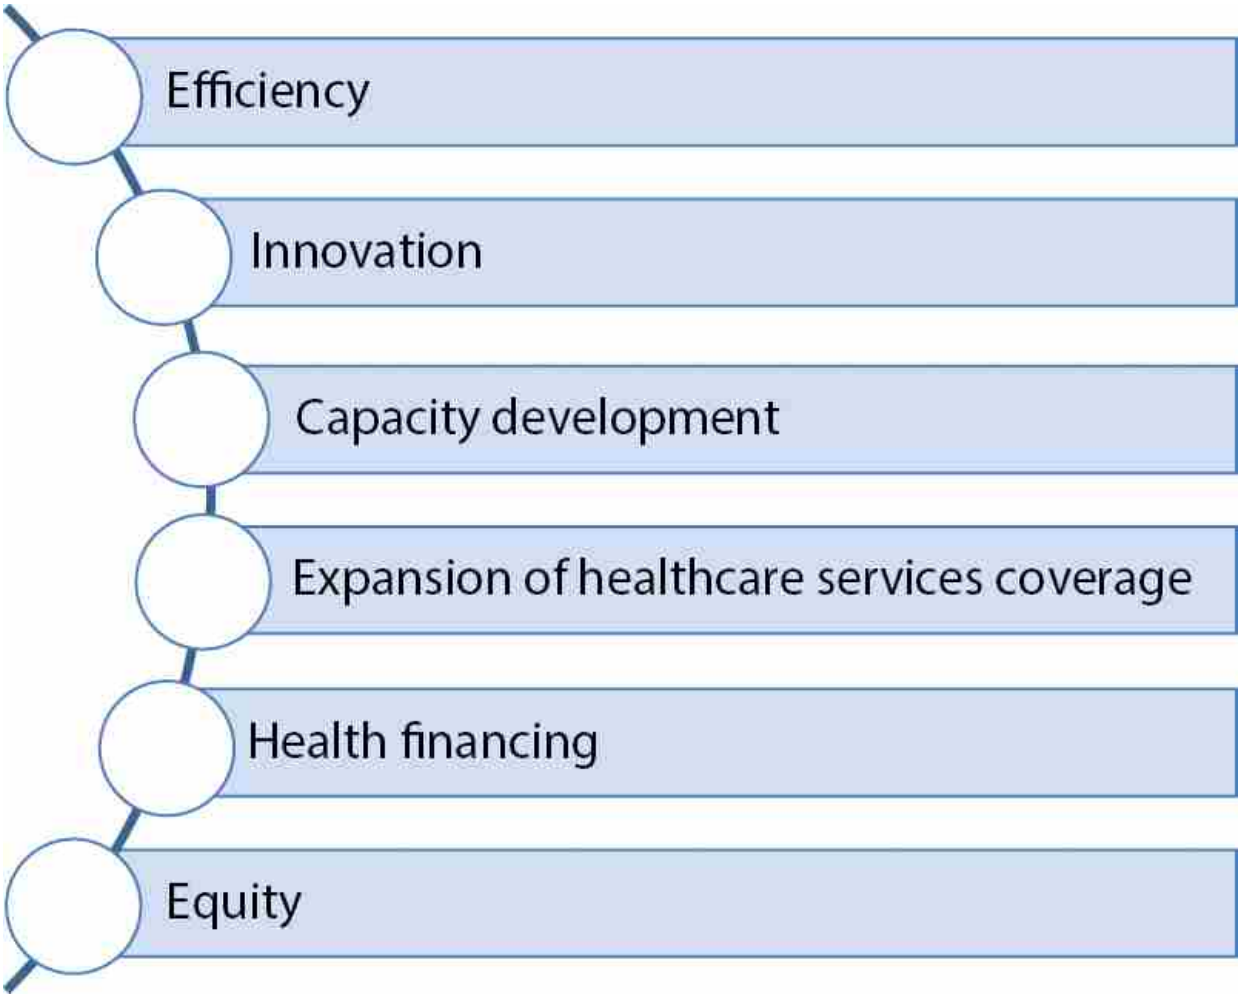

Fig. 3.5.4 Strategic areas to the engagement of the private sector.
Source: data from Ota, M.O.C., et al. (2018) 'Proceedings of the first African Health Forum: effective partnerships and intersectoral collaborations are critical for attainment of Universal Health Coverage in Africa'. *BMC Proceedings*, 12 (Suppl 7):8, 1–8.

Ultimately, governments can use the private sector to increase healthcare service provision. When embarking on these partnerships governments need to ensure that there are adequate regulatory frameworks, policies, and protocols in place to facilitate good communication across sectors. Poor communication may hinder engagement which subsequently risks poor understanding of government policies and procedures. In addition to communication, central to fostering enduring private–public partnerships is building trust between sectors. The potential benefits of collaboration are vast, and it would be a pity to lose out on such due to a failure by policymakers to ensure this trust. This could be facilitated by an organizational culture of openness and sharing.

The private sector has different needs to the public sector, which entails need for regulatory frameworks and accreditation systems to aid collaboration and foster partnerships. Literature suggests that development of protocols for communication across sectors could make coordination of projects smoother and more efficient (Suchman et al. 2018). To this effect, the private sector should be afforded regular opportunity to input into policy design, and both public and private entities should have standardized processes in place for when they collaborate. Shared goals, mutual understanding and structured ongoing communication that facilitates a strong working relationship when collaborating is crucial in making these endeavours a success (Baicker and Chandra 2017).

Considering achievement of the MDGs, a challenge was the limited focus on interventions that affect health however are not within the remit or oversight of the respective Ministry of Health, such as infrastructure. What should be learned from this in pursuit of UHC and the SDGs is the importance of partnerships and intersectoral collaboration (Garg 2018).

Of course private–public partnerships are not without challenges. Literature to date has highlighted a number of areas for improvement, notably:

Lack of information sharing
Weaknesses in management capacity
Funding insecurity
Mismatched organizational styles and differing priorities
Corruption (Suchman et al. 2018)

Evidence-based decision-making, strengthening of public providers in reporting, introduction of updated technology

Evidence-based policymaking has a fundamental role in improving the health status of countries. Evidence facilitates decision-making for the achievement of goals. Goals need to be clear, and it must be accepted that a rich body of evidence does not guarantee that these goals will be achieved. Often, the process of evidence-based policymaking will be uncertain (Baicker and Chandra 2017). As important as evidence is to sound policy choices, goals are determined based on values and priorities—a given body of evidence can be used to support very different policy positions.

The role of technology in healthcare improvement should not be underestimated. The literature highlights multiple applications:

Telemedicine
Training
Health education dissemination
Behaviour change promotion
Vaccination
Drug inventory and storage (Garg 2018)

Other applications of technology within developed nations are Electronic Patient Registries (EPR) and Clinical Decision Support Systems (CDSS). EPR benefits include greater accuracy, a higher proportion of correct information, time saved in locating information, more economical use of financial resources, greater ease, and speed of recovery of patient data. CDSS has been found to result in increased physician adherence to standardized treatment plans, cost reduction, easier standardization and regulation of requests for secondary and tertiary healthcare and examinations, thus reducing variability between services. From an administration point of view, it is possible to obtain greater adherence to public policies. Standardized programmes for earlier detection of diseases tend to have greater diagnostic value thereby contributing towards the promotion of equity, and the reduction of complications and costs related to more complex treatments (Tomasi et al. 2004).

Countries should adopt an open data sharing policy and develop a supportive legal framework to facilitate sharing and use of data in accordance with agreed standards for confidentiality and data sharing.

In general there is greater efficiency of management processes within the primary healthcare setting as a result of technology. Of course there is the issue of security and training to use systems. Ultimately, harnessing the opportunity that modern technology presents is key to improving the health status of countries.

Decentralization and triage of workload, implementing proper referral system, empowering community healthcare and capacity building

Health status and policy can be improved from the community level by empowering communities to take responsibility for their healthcare services.

According to the WHO,

> community empowerment is the process of enabling communities to increase control over their lives … It is the process by which they increase their assets and attributes and build capabilities to gain access, partners, networks, and/or a voice, in order to gain control … It assumes that people are their own assets and the role of the external agent is to catalyse, facilitate or accompany the community in acquiring power … Community empowerment implies community ownership and action that explicitly aims at social and political change … a process of re-negotiating power to gain more control … power is a central concept in community empowerment and health promotion invariably operates within the arena of a power struggle … seeks to build partnerships with other sectors in finding solutions.

The WHO concludes that empowerment can reduce health disparities (WHO 2018).

Globalization adds another dimension to the concept of community empowerment; the local and global settings are inextricably linked. Community empowerment recognizes and strategically acts upon this interlinkage and ensures that power is shared at both local and global levels.

Key to achieving community empowerment is communication. Approaches that encourage discussion and debate result in increased knowledge and awareness, and a higher degree of critical thinking. Critical thinking enables communities to understand the interplay of forces operating on their loves and helps them take their own decisions (WHO 2018).

Technology can help communities and individuals to develop opportunities, capacities and tools that benefit them and it can ensure that communities can mobilize targeted populations to obtain needed health resources by fostering awareness of a given problem (WHO 2018).

Policymakers must recognize and facilitate empowerment at a variety of levels. This can be done by involving community members and the underserved in the initiation and implementation of policy, as well as by relying on people who hold more traditional power. It is a responsibility of policymakers to achieve shared policymaking, to increase the sustainability of these advances towards improved health status and ultimately UHC (Thompson et al. 2016).

Training, capacity building, and investment in infrastructure

Central to improved health status and UHC is quality care. Quality matters as we are seeing a shift in disease burden to more complex conditions which require greater utilization of a health system and its services. These conditions are becoming an increasingly bigger influence on population

health, which makes addressing them an increasing priority. Countries require the appropriate infrastructure to meet quality standards, and governments are encouraged to establish a national quality guarantee for healthcare services. Literature states that poor quality care is now a bigger barrier to reducing mortality than insufficient access (Kruk et al. 2018).

For a health system to function and develop a quality service, there needs to be an adequate workforce. This can be achieved by increasing the number of training places for given professions, leveraging technology to provide required training, and ensuring respect for and good morale among staff. A concern however is brain drain. The workforce needs to be available, accessible, and have the capacity to deliver quality integrated care. Investment in primary healthcare is most needed and is recognized as the most cost-effective investment in improving equity in access to essential health services (Garg 2018).

Development agencies can play a significant role in increasing focus on human resource strategies—which are integrated into the health sector in wider civil service reforms—by:

Analysing the mix of personnel and skills
Reorienting training
Addressing pay and non-pay incentives
Improving job opportunities and conditions
Improving and expanding the use of information and communications technology in training and education programmes (OECD 2003)

Development agencies also have an interest in capacity building to enhance the effectiveness of their partnerships and to aid achievement of pro-poor health objectives.

Capacity building is necessary for multiple players within the healthcare arena. Taking research for example, it is crucial to align priorities and strategies of those investing in such, ensuring that programmes are coordinated and resources not wasted due to duplication. It is desirable to be able to detect and track research and innovations to facilitate progress. Health systems need to develop the capacity to measure and use data to learn. Additionally, countries should make it a priority to ensure sustainable financing mechanisms to optimize function. With investment in appropriate infrastructure and human resources, research priorities can be addressed (Ota et al. 2018).

Ultimately, capacity building should go beyond the health sector. It requires viewing pro-poor health approaches in a larger context of:

Political and economic restructuring
Fiscal policy
Administrative reform
Strengthening of participation and democratic systems (Ota et al. 2003)

Next there is investment in infrastructure. Looking at this from a health system perspective, the literature suggests various key facets of a high-quality health system. A commission by *The Lancet* concluded that high-quality health systems should be informed by four values—they are for people, equitable, resilient, and efficient (Kruk et al. 2018).

The WHO building blocks of a health system are shown in Figure 3.5.5.

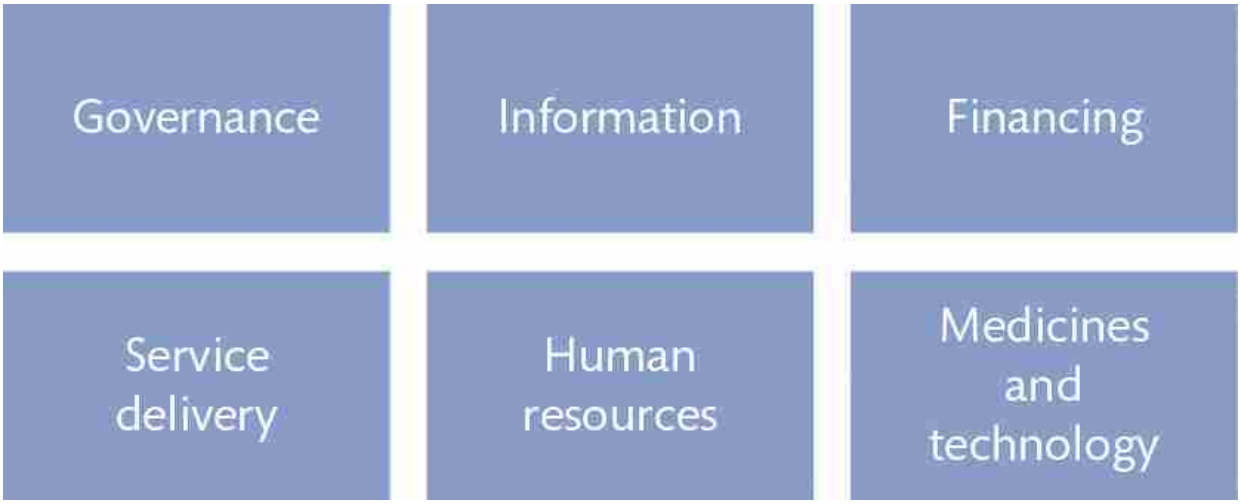

Fig. 3.5.5 System building blocks.
Source: data from World Health Organization (2010) Monitoring the building blocks of health systems: a handbook of indicators and their measurement strategies. Geneva, Switzerland: WHO.

It follows from this that strengthening these aspects will result in stronger health systems. Stronger health systems with strong infrastructure will help to provide quality care and UHC. By contrast, poor-quality health systems are posited to result in catastrophic expenditures and waste of resources.

The Lancet Global Health Commission 2018 endorses four universal actions to raise quality across health systems

Health system leaders need to govern for quality by adopting a shared vision of quality care, a clear quality strategy, strong regulation, and continuous learning. Ministries of health cannot achieve this alone and need to partner with the private sector, civil society, and sectors outside of health such as education, infrastructure, communication, and transport.
Countries should redesign service delivery to maximize health outcomes rather than geographical access to services alone.
Countries should transform the health workforce by adopting competency based clinical education, introducing training in ethics and respectful care, and respecting all workers to deliver the best care possible.
Governments and civil society should ignite demand for quality in the population to empower people to hold systems accountable and actively seek high-quality care (Kruk et al. 2018).

These improvement efforts should ideally be adapted for local context and monitored, in a bid to achieve sustainable change (Kruk et al. 2018).

Ultimately, national governments need to invest in high-quality health systems for their own people and make such systems accountable to people through legislation, education about rights, regulation, transparency and greater public participation (Kruk et al. 2018) Countries need to innovate to determine how they can efficiently utilize the available limited resources to provide access to essential healthcare services while exploring domestic sources of revenue to finance UHC. In achieving such, limited complexity and fragmentation is desirable. See also Case Study 3.5.3.

CASE STUDY 3.5.3 Ayushman Bharat programme, India

India is a vast, diverse, and a highly populated country. Its problems are complex and unique to itself. It is a challenge to reach out to vast different regions across India as local beliefs, culture, and practices influence every region's outlook.

On 1 February 2018, the Indian Government announced two major initiatives in the health sector, as part of the Ayushman Bharat programme.

The initiatives intervene to address health holistically at the primary, secondary and tertiary levels, and incorporate both disease prevention and health promotion. They are expanded on as follows:

1. Health and Wellness Centres
    a. India's National Health Policy 2017 envisaged Health and Wellness Centres as the foundation of India's health system, bringing the system and its services closer to the homes of people. The centres are intended to provide medical care to the poor, providing comprehensive healthcare ranging from diagnostic services to free essential drugs—including the realms of NCDs and maternal and child health. The national budget has set aside funds for this project, in addition to contribution of the private sector through CSR (?) and philanthropic institutions. To disseminate their services optimally, the centres must be accessible and appealing, providing a sense of comfort and belonging to the people of the regions where they are located.
2. National Health Protection Scheme
    a. This is the world's largest government funded healthcare programme Launched on 15th August 2018 and providing cover to more than 10 crore poor and vulnerable families. Coverage is up to 5 lakh rupees per family per year for secondary and tertiary care hospitalization. Adequate funds have been set aside to facilitate smooth implementation of the scheme. Benefits of the scheme are available across the country and a beneficiary covered under the scheme will be allowed to take cashless benefits from any public or enrolled private hospital.
    b. In partnership with think tank NITI Aayog, a robust, modular, scalable, and interoperable IT platform has been made operational, entailing a paperless, cashless transaction.

In order to further enhance accessibility of quality medical education and healthcare, 24 new Government Medical Colleges and Hospitals will be set up, by upgrading existing district hospitals in the country. This would ensure there is at least 1 medical college for every 3 parliamentary constituencies and at least 1 government medical college in each state of the country.

The aim of the Ayushman Bharat programme is to build a New India by 2022 and ensure enhanced productivity, well-being, and avert wage loss and impoverishment. These schemes will also generate jobs, especially for women.

Reducing disparities and inequity in minorities, vulnerable population

Health policy can be utilized strategically to target vulnerable population groups in society. Those identified as vulnerable populations are indigenous populations, minority and socially excluded groups, refugees, or displaced persons, the mentally or physically disabled and people living with HIV AIDS. These groups are among the poorest of the poor in many societies and require special attention in policy action for poverty reduction (OECD 2003).

A pro-poor health approach is one that gives priority to promoting, protecting, and improving the health of the poor. It builds on health systems, health financing and key policy areas beyond the health sector promoting policy coherence global public goods (OECD 2003).

Benefits of investing in the health of the poor include:

Higher labour productivity
Higher rates of domestic and foreign investment
Improved human capital
Higher rates of national saving
Demographic change (OECD 2003)

In addition to their beneficial macroeconomic impact, health improvements have intergenerational spillover effects (OECD 2003).

Gender inequality is a major determinant of poverty and ill health. Poor women and girls are worse off in relation to assets and entitlements; within the household and in society. Socio-cultural beliefs regarding the roles of men and women contribute to this inequality. Women are also major producers of healthcare through their roles as household managers and carers. But their health, including reproductive health suffers from inadequate nutrition, heavy workloads, and neglect of basic healthcare, factors aggravated by exposure to sexual abuse and interpersonal violence. Action on gender inequalities is therefore an essential element of a pro-poor approach to health.

It must be noted that focusing solely on the poor may not achieve desired results. Common shortcomings include that benefits packages with only limited services and high copayments. This supports focus on elderly, disabled, and those with chronic health diseases.

Ways to UHC and SDGs

UHC is a target of the 2015 SDGs. As defined by the WHO:

> UHC means that all individuals and communities receive the health services they need without suffering financial hardship. It includes the full spectrum of essential, quality health services, from health promotion to prevention, treatment, rehabilitation and palliative care. (WHO 2017)

It is widely accepted that countries who make progress towards UHC will as a consequence make progress towards other SDGs.

The rationale behind seeking UHC is avoidance of people being pushed into poverty due to unexpected illness that requires them to use up savings or sell assets. This can have catastrophic consequences for the current generation and indeed future generations. UHC exists to protect people from

adverse financial consequences of utilizing health services. Good health allows children to learn and adults to earn, helps people escape from poverty, and provides the basis for long-term economic development (WHO 2017).

Components of UHC are shown in Figure 3.5.6.

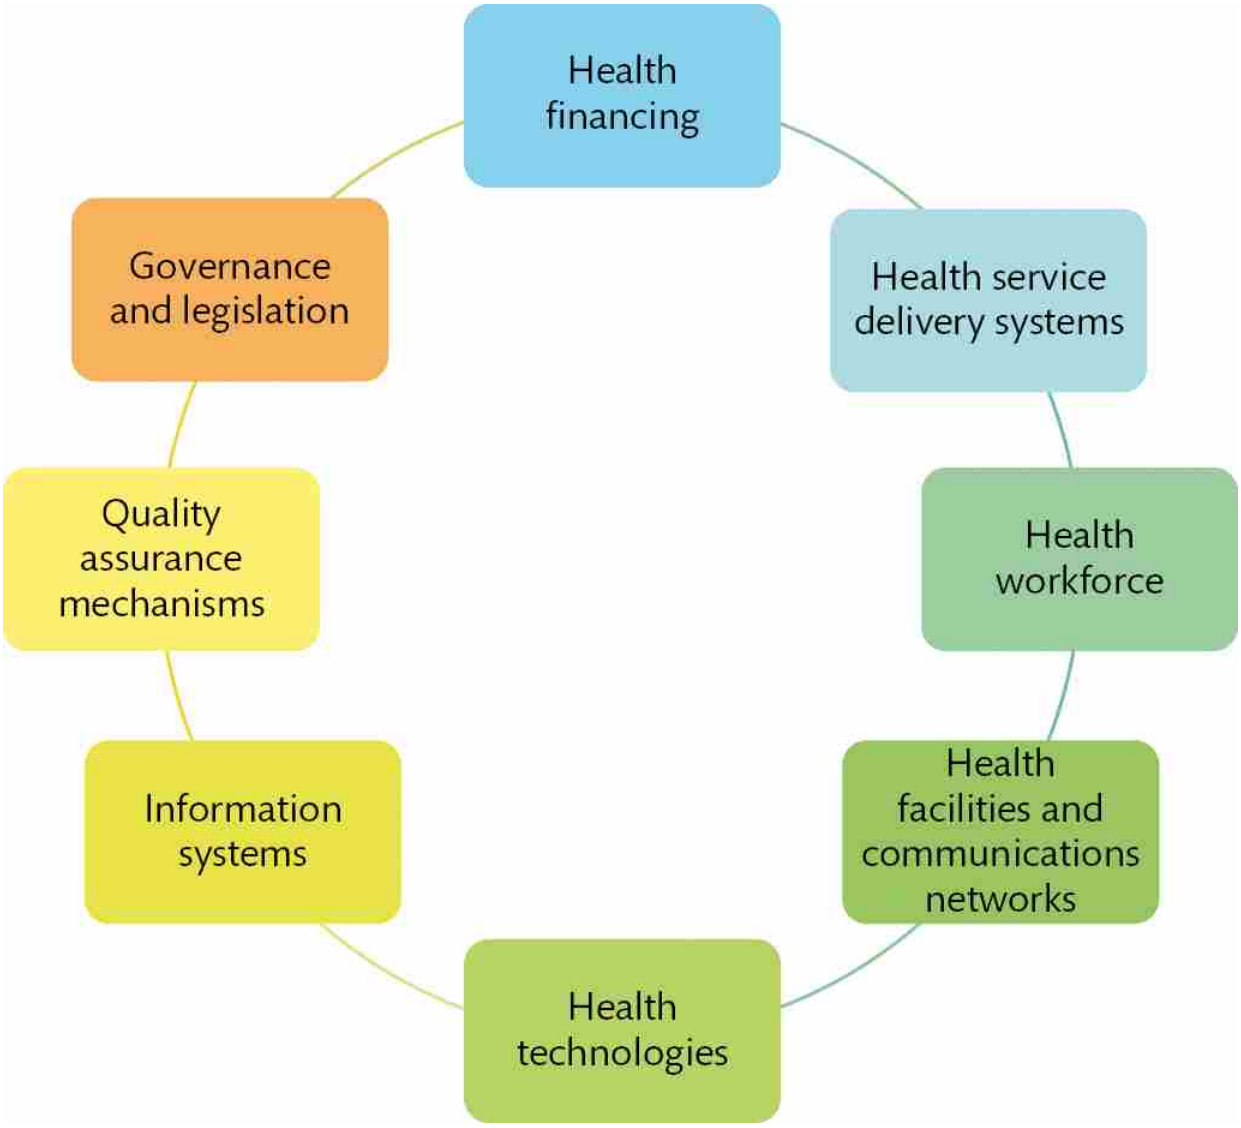

Fig. 3.5.6 Components of Universal Health Coverage.

Taking steps towards UHC means steps towards equity, development priorities, and social inclusion and cohesion. UHC requires quality care, a clear quality strategy, strong regulation, and continuous learning. Many

countries are already making progress towards UHC. All countries can take actions to accelerate the process or to maintain gains already made. Ways to UHC encompass what has already been explored in this chapter:

Strengthening health systems, ensuring robust financing and risk pooling. Limited complexity and fragmentation.
Workforce to improve health service coverage and health outcomes.
Good governance.
Sound systems of procurement.
Adequate supply of medicines—use of generics to ensure this.
Utilizing advances in health technologies.
Well-functioning HISs.
Addressing vulnerable groups.

(WHO 2017)

When developing healthcare services social and cultural norms need to be accounted for. Incorporating traditional medical services organized around the comprehensive needs and expectations of people and communities will empower communities to take a more active role in their health and health systems.

As developments in healthcare take place, it is essential that progress is measured. In the case of UHC this can be done by measuring:

Proportion of population that can access essential quality health services
Proportion of the population that spends a large amount of household income on health (WHO 2017)

Conclusion

An effective health system, especially in developing countries, needs strong health policy as a basic foundation. The chapter has highlighted the stages of health transition**,** which led to health activities and health policy development in both developed and developing countries.

Milestones of global health policy and global trends of health policy shifting were also described given its importance in changing global health trends from primary healthcare in the 1970s, global health initiatives in 1990s, the MDGs in 2000s, and then to current era of SDGs. How global

health policy and globalization impact and shape the health of people in developing countries were discussed through various health policies, health outcomes and achievements, and current health challenges and problems. The three case studies were chosen, namely Turkey's health system reform, the Philippines' Sin Tax, and the Ayushman Bharat programme, India, from which impressive information and inputs were received to be considered in formulation of health policies with a notion of country's adaptation wherever necessary.

Implementation of global policy as well as country's own health policy has challenges and pitfalls in various settings. It was explained within the context of health system building blocks and other related issues. Policy recommendations were made as way forward and strategies to improve health policy and status of health in developing countries in terms of; risk pooling, minimizing catastrophic OOPE; private–public partnership and strengthening; evidence-based decision-making, strengthening of public providers in reporting, introduction of updated technology; decentralization and triage of workload, implementing proper referral system, empowering community healthcare and capacity building; training, capacity building, and investment in infrastructure; reducing disparities and inequity in minorities, vulnerable population and ways to UHC and SDGs.

Policymaking for the effective, efficient, and equitable health systems in developing countries is more critical than ever to be realized through its optimal matrix of strategic plans and implementation modalities. New challenges are being addressed, including SDGs. We hope that this chapter will contribute the information for policymakers to be able to formulate not only knowledge-base, but also results-orient policy design.

Public health policy in developed countries

John Powles † *and Hebe Gouda*

> ... the best strategy to identify the social and political processes that drive change in public health policies is by cross-national comparison. (Nathanson 2009)

The nature and scope of public health policy

The scope and purpose of public health policy may be seen as implicit in widely used definitions of public health. Winslow's definition, as adapted by the Acheson Report in England, is: '*The science and art of preventing disease, prolonging life and promoting health through organised efforts of society*' (Secretary of State for Social Services 1988).

Public health policies might thus be thought of as the policies that guide these 'organized efforts' to protect and improve health. The scope of such policies depends a good deal, however, on what is considered to be entailed by 'organized efforts' and on how centrally 'organized efforts' are understood to be related to efforts that are more decentralized, more informal, less organized, perhaps even 'spontaneous'. The relative importance and legitimacy of centralized versus decentralized uses of knowledge in protecting and enhancing health is a common underlying theme in discussions of public health policy.

We need first to define our geopolitical scope by deciding which countries are currently classifiable as 'developed'. Many answers are clearly possible, but for the purposes of this chapter the boundary will be drawn as follows: the 33 members of the Organisation for Economic Co-operation and Development (OECD) not qualified as 'emerging' (OECD n.d.) plus 5 member states of the EU that are not included in the OECD list (indicated by (EU), plus Singapore. These 39 countries are grouped as follows: 21 in Western Europe (Austria, Belgium, Cyprus (EU)), Denmark, Finland,

France, Germany, Greece, Iceland, Ireland, Italy, Luxembourg, Malta (EU), Netherlands, Norway, Portugal, Spain, Sweden, Switzerland, United Kingdom (plus Israel); 11 in Eastern Europe (Bulgaria (EU), Croatia (EU), Czech Republic, Estonia, Hungary, Latvia, Lithuania, Poland, Romania (EU), Slovakia, Slovenia); 3 in Asian Developed (Japan, South Korea and Singapore); 3 in Other Developed (Canada, Australia, New Zealand). To reduce potential heterogeneity in the last group, and because of its geopolitical importance, we treat the United States (USA) separately.

As a topic, policy gains interest from the assumptions that it guides action and that deliberate actions to protect and enhance health are major determinants of actual health trends. A brief review of health trends sets the context for our consideration of health policy.

Context: survival trends since 1950

The unit of analysis for policy is typically the nation state. Estimates are available from the Global Burden of Disease project for trends in child mortality (risk of death before the fifth birthday) and premature adult mortality (risk for a 15-year-old of dying before 60, if age specific mortality rates were to remain unchanged) from 1950 to 2017.

Child survival

See Figure 3.6.1.

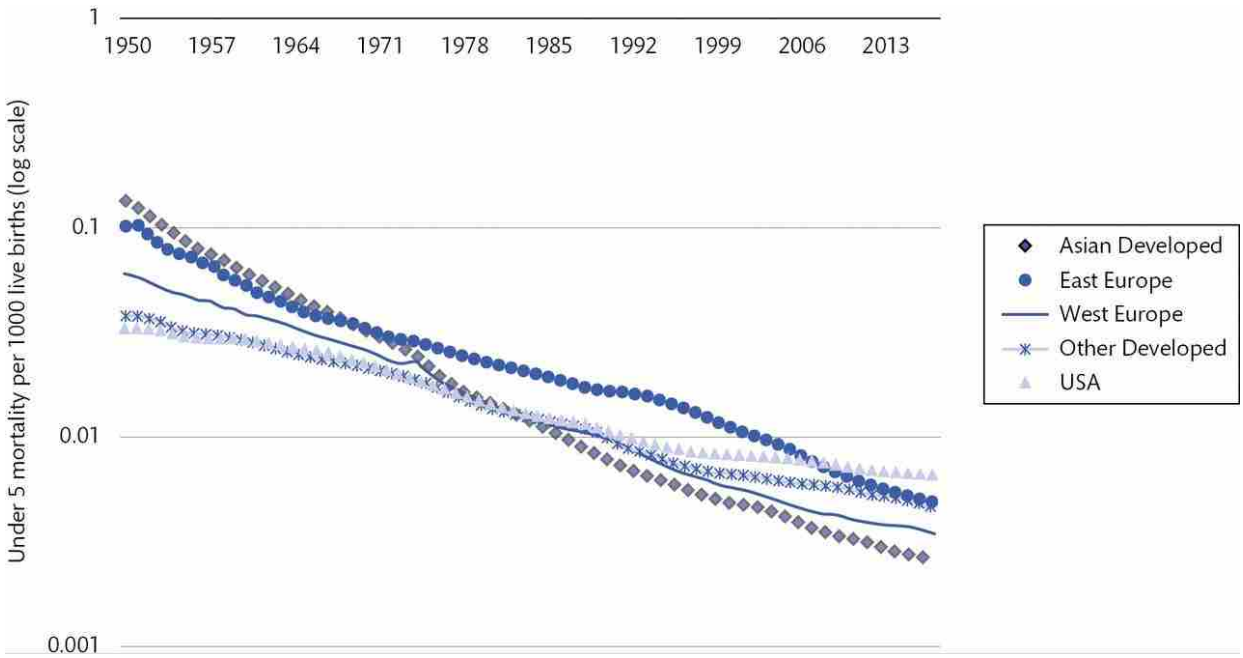

Fig. 3.6.1 Risk of death before the fifth birthday, unweighted means of four groups of countries with the USA shown separately, 1950–2017. For membership of country groups see Section 1.
Source: data from Global Burden of Disease Collaborative Network (2017). (Seattle, United States: Institute for Health Metrics and Evaluation (IHME)).

The most salient finding is the marked and widespread gains in child survival achieved since the mid-twentieth century, extending the even larger gains of the first half of the century. Risks of death before the fifth birthday have fallen, in proportional terms, by a remarkable average of around 95% since 1950—in absolute terms, from around 7.5% to around 0.04% (unweighted averages across included countries). These transformations suggest continuing pervasive improvements in the determinants of child health. Around the central trend there is also some interesting variation across country groups, brought out by the log scale used in Figure 3.6.1: most improved are the Asian Developed countries, moving from highest to lowest for group averages; least improved is the USA, moving from lower than any of the group averages in 1950 to higher than any in 2017. The East European group, which also started with high risks, improved rapidly to the mid-1960s and again from the mid-1990s, with a period of stagnation between.

Adult survival

See Figure 3.6.2.

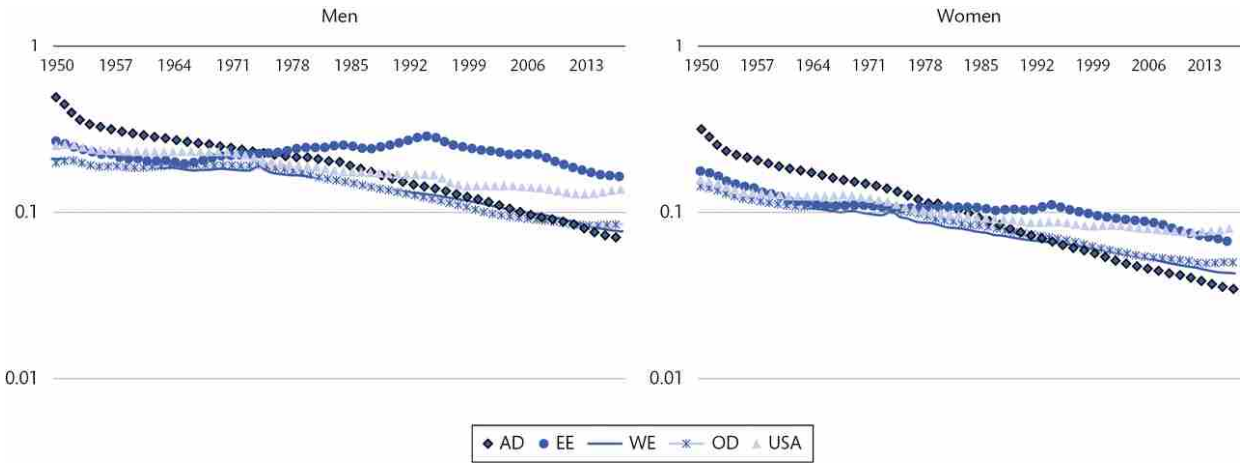

Fig. 3.6.2 Risks for 15-year-olds of dying before 60, unweighted means of four groups of countries with the USA shown separately, 1950–2017, semi-log scale; a. Men, b. Women
Source: data from Global Burden of Disease Collaborative Network (2017). (Seattle, United States: Institute for Health Metrics and Evaluation (IHME)).

Adult mortality estimates for the 39 countries in 1950, 1990, and 2017 are shown in Table 3.6.1.

Table 3.6.1 Risks for 15-year-olds of dying before 60, assuming mortality rates were to remain at levels for designated years, men, and women in 1950, 1990, and 2017. Countries ranked for each sex by estimates for 2017

Estimates for 1950 and 1990 for countries which became independent after 1990 have mostly been derived from vital statistics for populations living within the post-independence boundaries. In some cases they have been imputed using hierarchical Bayesian modelling with greater margins of uncertainty.

Source: data from Global Burden of Disease Collaborative Network (2017). (Seattle, United States: Institute for Health Metrics and Evaluation (IHME)).

The trends for premature mortality in Figure 3.6.2 and Table 3.6.1 reveal some striking divergences: From the mid-1960s mortality in the East European group rises substantially in men and stagnates in women before resuming declines from the mid-1990s. Also striking is the stagnation in adult mortality decline in the USA, apparent from the early 1980s. In relative

terms this is more notable for women: By 2017 only in Hungary, Latvia, Lithuania, and Bulgaria were rates of premature mortality in women higher than in the USA—which were about twice the median levels of all the other country groups apart from Eastern Europe.

Declines in risks of premature death in adults have been less profound and less uniform than the declines in child mortality. Overall risks roughly halved between 1950 and 2017 for both women and men. For men, proportional reductions were greatest in the Asian Developed group (almost 85%) compared with 36% for men in East Europe and 45% in men in the USA. In 2017 the risks for men ranged from around 8% in the Asian Developed, West European, and Other Developed groups to twice that in the USA and Eastern Europe.

Some qualitative similarities can be seen in the trends in child and adult survival: the USA and Eastern Europe each show lags relative to other groups—but with the lags occurring in different periods. In Eastern Europe, improvements were rapid until the mid-1960s after which they slowed (for children), stagnated for adult women and reversed (in some cases catastrophically) for adult men. From the mid-1990s these adverse trends in Eastern Europe changed course but with rates of improvement increasingly diverse for countries within the group.

These manifest changes in survival provide much food for thought. The part played by ‘policy’ is not self-evident and nor are the roles played by governments at different levels nor by officials, experts, and citizens considered as individuals, nor as collectivities such as state and professional organizations, corporations, social movements, and households.

Institutions, knowledge, and policies

Institutions

Because national (and subnational) boundaries separate populations with distinctive health trends, such trends can be assumed to reflect not just the characteristics of the individuals constituting such aggregates but also the differing national and subnational institutional contexts in which the individuals live. Here we understand institutions to be not just formally constituted organizations, such as those of states, but also the less formal and more fundamental rule-based structures which pattern social life (Searle

2005, 2010). Such institutional structures may have their own, typically longer term, patterns of evolution, in many cases beneath the surface of overt developments in the political realm (Williamson 2000; Thelen 2004).

Constance Nathanson has produced a monumental, systematic study comparing responses in the USA, Canada, Britain, and France, to two public health challenges in the early 20th century—infant mortality and tuberculosis—and two late in the century—cigarette smoking and HIV infection in injecting drug users. Her study brings out the diversity, complexity, and richness of societal responses to risks to health (Nathanson 2009). In spite of the widespread assumption that the agency of the state has been central to public health responses, she finds no simple relationship between the strength of state institutions (presumptively high in France, low in the USA) and the nature and strength of societal responses to risks to health. Her work helps to clarify the relationship between state and non-state 'actors', bringing out the often limited contribution of the former, at least during the earliest, creative phases when the societal responses to health hazards are just beginning to take shape.

> . . . in only one of the eight contemporary country-case combinations (AIDS drugs in Canada) did leadership in recognizing and addressing a serious public health issue come from local public health officers or departments. (p. 254)

At a national (as distinct from subnational) level she does find one striking example of rapid and successful state-initiated action in the face of a public health crisis—the British government's response to the threat of HIV/AIDS in injection drug users (p. 181). Although the contributions of state actors may be limited in the earliest phases they are typically engaged dynamically with civil organizations as soon as the policy process begins to evolve. State agencies usually lead in programme implementation.

Nathanson invokes three broad determinants of public health action: 'states, collective actions, and constructions of risk' and sees her task as understanding 'how structure, opportunity, and human agency interact to create, or inhibit, the possibility of change' (p. 203). Writing as a 'social constructivist', narrating public health 'stories', she makes little attempt to assess effects on objective health trends and pays little attention to the advance of objective knowledge about the causes of disease and injury. She concentrates instead on 'constructions of risk' which follow their own timetables, somewhat independent of advances in objective knowledge. In relation to the earlier influence of the germ theory of disease, she notes

> French public health was reenergized in the late nineteenth century, due in large part to the extraordinary impact of Pasteur on French medicine and science . . . Nevertheless, apart from the campaign against infant mortality, which had relatively little to do with Pasteur, the consequences on the ground were minimal. (p. 35)

While her approach serves well to bring out the importance of human agency and the ways in which social mobilization has taken place in response to public health challenges, her relative neglect of the escalating output and diffusion of new knowledge and her sketchy coverage of the links between actions and outcomes leaves her interpretation incomplete.

The growth of knowledge

The modern era has been characterized by an enormous increase in the production of new knowledge and this process has tended to accelerate through time. Global scientific output is estimated to be now doubling every 9 years (Bornmann and Mutz 2015). Medical research output has been highest in the USA and other English-speaking countries and in Scandinavia. This remains true when adjusted for population size. Research output in public health sciences follows a similar overall pattern but also with notably low outputs in Eastern and Southern Europe (Clarke et al. 2007).

Knowledge: ‘interventions’ plus less direct effects

The broad temporal coincidence between the increase of knowledge and the improvement of health suggests that the former is likely to be a fundamental cause of the latter. But the question of just how the advances in knowledge have actually contributed to gains in health remains unclear. One prominent idea is that the most important uses of knowledge are those embodied in ‘interventions’. The increasing use of idea of ‘interventions’ is linked to increasing reliance on randomized controlled trials to provide trustworthy evidence on ‘what works’. In each field of activity, summaries of the evidence identifying ‘effective interventions’ are marshalled for the benefit of ‘policymakers’.

The implication here is that the experimental arms of controlled trials provide a model for understanding how knowledge brings benefits in populations at large. But the ways in which knowledge about the causes of disease and injury is used in everyday life often differ from what happens in the experimental arm of a controlled trial. In a controlled preventive

experiment, agency—the capacity to decide ‘what is to be done’ and the execution of that decision—rests with the ‘intervenor’. The idea of ‘interventions’ thus carries with it the idea that agency lies with the ‘intervenors’, that is, with professionals and officials. In this framework, all that is needed is for ‘policymakers’ to take heed of what the experts are telling them about the scope for ‘effective interventions’ for the benefits of existing knowledge to be realized. This interpretation is inadequate.

Issues of agency are central to thinking about public health policy. They came the fore earlier in debates provoked by Thomas McKeown’s thesis on the causes of rapid mortality decline in England and Wales in the late nineteenth and early twentieth century. McKeown noted, in a series of publications, that there were no new effective interventions (‘medical measures’ in his terminology) that could explain the favourable shifts in mortality. The shifts must have been due to something else. His *deus ex machina* was improved nutrition. He justified his choice by invoking the logic of Sherlock Holmes: ‘*When you have eliminated the impossible, whatever remains, however improbable, must be the truth*’ (McKeown 1988, pp. 9–10, italics in original).

McKeown’s implicit, though fallible, logic was: if not ‘knowledge as embedded in interventions then not knowledge’. His choice of improved nutrition as the alternative explanation has been judged implausible by social, demographic, and economic historians. These critics have noted the lack of evidence for sudden changes in diet and emphasized instead the importance of changes in civic and state organizations facilitating sanitary reform (Szreter 1988), and in risk reducing changes in childrearing practices implemented by households. In the late nineteenth and early twentieth century households were key actors:

> The revolution was not just in the way physicians thought about disease, but in the growing awareness that households could control their destinies by their own actions and prevent disease by avoiding certain well-understood sources of infection. (Mokyr 2002, p. 206)

The nature of the relevant changes in childrearing practices during the period of rapid mortality decline has been documented further in Mokyr and Stein (1997, pp. 143–205), Cowan (1983), Tomes (1998), and Preston and Haines (1991).

The acceptance of new knowledge by households was not automatic, but depended on persuasion:

> Persuasion requires shared standards of evidence, chains of authority, networks of trust, and accepted rules of logic and evidence. Changes in the rules of discourse and communication, no less than the knowledge unearthed by science, are the background to the changes in health and longevity that are the mark of the 'modern' age. (Mokyr 2002, p. 180)

Put another way: it is not just the development of knowledge that is important but also the diffusion of knowledge and the associated evolution of institutions which increase receptivity to new knowledge and facilitate its use.

The economic historian Simon Kuznets saw the advance of knowledge as fundamental to modern economic development (Kuznets 1973); Mokyr (2002) and Deaton (2013) each see economic development and health improvement as the joint but distinct products of advancing knowledge, propelled in separate ways by advances in knowledge, and not always in synchrony with each other.

Two important conclusions, relevant to the understanding of more recent trends, thus emerge: (1) the advance of knowledge (understood broadly as 'useful knowledge', extending beyond the content of textbooks to knowledge useful in everyday life) has been fundamental to the improvement of health by both direct and indirect pathways; and (2) the persuasiveness of relevant knowledge has depended on institutional contexts evolving in ways that enhanced receptivity to new ideas.

Causes of health trends

Child health

Trends in child mortality have not exhibited the large swings and reverses seen in adult survival and are now in asymptotic approaches to very low levels. Measures to reduce risks to the health of children have generally faced little resistance and have been widely accepted and applied. A partial exception is the antivaccination movement's effects on immunization coverage with associated rises in measles incidence and deaths (Kmietowicz 2018).

Although absolute risks of death before the fifth birthday are now small, relative differences remain appreciable. Within Western Europe risks are almost twice as high in the United Kingdom as in Sweden. Most of this difference has been related to 'birth characteristics' such as prematurity and

birthweight (Zylbersztejn et al. 2018). These are more related to differences in the health of mothers than to professional services provided after birth. The 'biological standard of living' (Komlos 1993) of mothers is important and differences of this kind are likely to have origins that are embedded in the social structure.

Adult health

The large differences in long-term trends and recent levels of premature mortality in adults between different groups of countries shown in Figure 3.6.2 resist easy explanation. The Global Burden of Disease project produces estimates of the contributions of proximate causes (risk factors) but the role of more distal causes, such as policies, and the institutional supports for those policies, remains poorly understood.

We shall proceed by considering parts of this complex picture. The reduction of health losses from tobacco, traffic injuries and cardiovascular disease have accounted for a substantial part of the total health gains since the mid-twentieth century. They are relatively well documented, as are the collective measures that have sought to achieve these outcomes. Case studies of these may provide some insights into the links between advancing knowledge, institutional evolution, and health outcomes.

Tobacco

The first English language demonstrations of the quantitative relationships between smoking and lung cancer risk were reported in 1950 (Doll and Hill 1950; Wynder and Graham 1950). By 2012, all of the 39 developed countries except the USA and Switzerland had ratified an international treaty on tobacco control, committing themselves to a full repertoire of evidence based measures to reduce tobacco smoking (Conference of the Parties to the WHO FCTC 2003). Over a 60 year interval, the currently established repertoire of measures for tobacco control were invented, tested, and refined —ultimately gaining political support at the highest level.

The early 1950s to the 1970s was a period of gradual clarification at a scientific, professional, political, and public level of the nature and meaning of the health risks arising from tobacco use. The epistemology of professional medicine was still pre-quantitative. As reports from

epidemiological studies accumulated, high level policy debates continued to revolve around a largely illusory search for ‘proof of causation’ (Pollock 1999). Many physicians remained unconvinced of the hazards. In the USA a 1960 poll found that only one-third of physicians were convinced that smoking was a ‘major cause’ of lung cancer and 43% were still regular smokers (Proctor 2011). In the United Kingdom, physicians and public health professionals who appreciated the magnitude of the risks and who were in a position to do something about it struggled to find a way forward.

In the late 1950s, George Godber was Deputy Chief Medical Officer in Britain and was very keen to help reduce harm from cigarette smoking. But his superior, the Chief Medical Officer, did not want to take the matter forward with the Minister of Health who was known to be unenthusiastic about taking on the Chancellor of the Exchequer (Treasurer). The Treasury was keen to protect the 15 or so per cent of central government revenue provided by tobacco tax (Berridge 2007). Godber visited Charles Fletcher, a respiratory physician, at a London teaching hospital and invited him to his club for lunch so that they could discuss strategies. They decided on working through the Royal College of Physicians in order to by-pass the Chief Medical Officer. The College took up the matter energetically and decided to produce a report aimed at a large audience. In 1962, Smoking and Health appeared and quickly sold out (Pollock 1999), (Lock et al. 1998). The United States followed suit and in 1964 the Surgeon-General’s report on The Health Effects of Smoking appeared. The mass media covered these reports extensively and Pierce and colleagues have shown that smoking cessation rates in US middle-aged adults moved in synchrony with the news coverage (Pierce and Gilpin 2001). Coverage of the Surgeon-General’s report was not the beginning of mass media coverage of smoking and health in the USA—as early as 1946 a news magazine story ‘Cigarettes cause cancer?’, based on experimental work on the carcinogenicity of cigarette tar was ‘widely read’ (Proctor 2011). However, there is good reason to see the Surgeon-General’s report as a turning point in increasing public awareness in the USA of the hazards of smoking.

A major difficulty, in the 1950s, was that public health authorities were reluctant to tell adult men how they should behave. Reluctance of this kind had not previously inhibited anti-spitting campaigns to reduce risks of transmitting a communicable disease (tuberculosis). Nor had it inhibited strong and detailed directions to mothers, early in the twentieth century on

how they should care for their children (Lewis 1980). But advising adult men to abandon a widely accepted habit was seen as different. Crossing this frontier would ultimately change ‘the discourse of public health’ in Britain and legitimize government activity to promote health favouring lifestyles (Berridge 2007).

In Britain, early tobacco control activism was largely confined to professional and political elites who aimed to build constituencies ‘from above’ in support of action by parliament. This turned out to be a slow process. Kenneth Robinson who was health minister through the mid-1960s said that lack of public support had prevented him acting (Berridge 2007). In 1971 the Royal College of Physicians established a pressure group—Action on Smoking and Health—‘to make non-smoking the norm in society and to inform and educate the public about the death and disease caused by smoking’ (Action on Smoking and Health 2017). Most of the early office holders were activist physicians.

Major breakthroughs in mobilizing a broader base of public support came in the mid to late 1980s in Victoria, Australia. The 1987 Victorian Tobacco Act was the first to secure a tax hypothecated to health promotion—in this case to the Victorian Health Promotion Foundation (Vichealth). Vichealth then used this money (AUD 23m per year—about USD 7 per person per year) to buy out tobacco sponsorship of sporting and arts events and to fund health promotion programmes. The close passage of this Act was the outcome of careful planning, initially conducted in strict secrecy in order to catch the tobacco industry off-guard and prevent it deploying its enormous resources against the Act. Once the campaign was public, the large contributor base of the Anti-Cancer Council of Victoria was mobilized. Newspaper coverage was sympathetic—the main morning paper reported more correspondence on the topic than any other in the paper’s history (Borland et al. 2009). Over 150,000 letters of support were sent to state politicians and church leaders were engaged in the campaign. The idea of an hypothecated tax was taken to California and included in Proposition 99 which won voter approval in November 1988.

Nathanson notes the marked differences between countries in the groups who led the opposition to tobacco. In the USA ‘lay activists’ led the way. In California, an early victory was the passage in 1977 by the Berkeley City Council of an ‘indoor air ordinance’ instigated by the local branch of GASP (Group Against Smoke Pollution). (GASP had been launched nationally in

1970 by environmental activist Clara Gouin who attributed her father's death a year before to smoking.) From the 1970s local groups, many now constituted, in California, as Americans for Nonsmokers Rights, had achieved 117 local tobacco control ordinances by 1986 (Glanz and Balbach, p. 39). In the lead in to the Proposition 99 referendum, private polling commissioned by the Tobacco Institute reported as its 'bottom line' that '*people do not like smoking or smokers*' (V. Lance Tarrance and Associates (1987) cited in Glanz and Balbach, p. 42, italics in original). It was against this background that the 1988 vote was won, despite industry spending to defeat it being 13 times greater than the spending in support (Glanz and Balbach, p. 72).

The formal state-wide tobacco control programme mandated by Proposition 99 was funded by a 25c per pack levy on cigarettes, sufficient to pay for mass media campaigns and to fund activities developed and run by local groups. It did not fund professional and pharmacological assistance for smoking cessation. During the 1990s it was noted by programme evaluators that a substantial fraction of households were reporting that they had decided to make themselves 'smoke free' even though this had never been promoted by the formal programmes. This imitation by households of 'clean air ordinances' enacted for public venues provides a nice illustration of the complex decentralist—centralist dynamic at the heart of the California's response to the challenge of tobacco (Pierce et al. 2010).

From the 1990s the tobacco industry has suffered further losses of legitimacy and support in the developed world. In the USA, the 1998 Tobacco Master Settlement Agreement between 46 states and the largest cigarette manufacturers, resulted in the industry agreeing to restrict some marketing practices, to dissolve its three main front organizations and to pay the states $206 billion (sic) over 25 years to compensate for the extra state medical expenditures attributable to cigarette smoking. Interpretation of the potential effects on the Settlement on tobacco control have been mixed (Schroeder 2004) but the public release of previously secret industry documents during the discovery phase of the litigation has led to further damage to the industry. Proctor used these documents to show how the industry deliberately and secretly modified the composition of cigarettes to make the smoke more inhalable and the smoker more dependent (Proctor 2011).

In 2006 Philip Morris was convicted by a US federal court under legislation designed to counter organized crime (the Racketeer Influenced and Corrupt Organizations Act) for having: falsely denied that they market to youth, falsely denied that they manipulated cigarette design, falsely represented that light and low tar cigarettes deliver less nicotine and tar, falsely denied that ETS (second-hand smoke) causes disease and suppressed documents, information, and research (Proctor 2011). In November 2012 they were ordered to make public statements admitting that they had lied to the public (Associated Press 2012). Elsewhere, the closing off of marketing opportunities in high-income countries was taken one step further when, in December 2012, Australia enacted a law requiring that all cigarettes be sold in plain standardized packaging. As of mid-2018, seven more countries had followed suit: France, United Kingdom, Norway, Ireland, New Zealand, Hungary, and Slovenia.

The tobacco wars are not over yet. Despite declining deaths from smoking, tobacco was still ranked first for men and fifth for women among causes of lost healthy life in ‘high socio-demographic index’ countries in 2017 (GBD Compare 2018). Deaths from lung cancer provide a robust and comparable indicator of health losses from tobacco and those at younger ages reflect more recent trends in tobacco exposure. Table 3.6.2 gives years of life lost from lung cancer deaths in men and women under the age of 50. It shows that, for men, progress was almost universal between 1990 and 2016 with only Portugal and Cyprus showing increases. Reductions, both proportional and absolute, were biggest in the post-communist countries, with the Czech Republic and Hungary both showing very large reductions (from 659 to 143 and from 922 to 436 respectively). Trends for women are lagged relative to those for men with 21 out of 39 countries showing increased lung cancer mortality between 1990 and 2016. Meanwhile, the tobacco industry has moved its focus from developed countries to emerging markets in low and middle-income countries where prevalence rates are high and, in some cases, growing.

Table 3.6.2 Years of life lost to lung cancer from deaths at ages 15 to 49, men and women in 39 developed countries, 1990 and 2016: age-standardized rates per 100,000 person years with percentage changes from 1990 to 2016

The century long epidemics of cigarette smoking and its consequent disease burdens illustrate the time frame over which chronic disease determinants may rise and fall, making campaigns to reduce them into long

wars of attrition. Tobacco control also illustrates how the development of quantitative methods has supported appropriate policy responses. With increased acceptance of epidemiological reasoning and its transmission to political and wider publics (for example, Peto et al. 2013), quantitative assessments have become more central to policy deliberations, facilitating effective institutional responses, locally, nationally, and globally.

Traffic injuries

Deaths from traffic injury per unit of exposure (e.g. per 10,000 vehicles per year) have fallen up to 10-fold in many developed countries since the mid-twentieth century. Despite this outstanding success, traffic injuries still ranked sixth among causes of lost healthy life in males and fourteenth in females in 2017 (GBD Compare 2018). Because of the visibility of control measures and the short time lags between their implementation and their effects, traffic injury control provides a sensitive field in which to explore the relationship between policy adoption, programme implementation, and health effects.

First, it is appropriate to note that success has not flowed exclusively from centrally initiated policies, especially in the early decades of motorization. Smeed writing in the early 1970s showed that deaths from traffic crashes in relation to the number of registered vehicles had followed a general, and pronounced, downward trend as the number of motor vehicles increased in relation to population (Smeed's Law: Deaths/vehicle = 0.0003 $(\text{vehicles/population})^{-0.66}$) (Smeed 1972). However, over the past four or five decades organized policy responses have clearly made a bigger contribution. The Australian state of Victoria has been a pioneer in traffic injury control and its experience will be briefly reviewed here.

Consistent with Smeed's prediction, deaths per 10,000 vehicle years fell in Victoria as the number of vehicles increased in relation to population—from over 20 in the 1930s to about 9 in the early 1960s. During these early decades, Victoria generally had rates in excess of Smeed's prediction. The recurrent funerals resulting from avoidable deaths in young adults provoked a growing conviction that 'something needed to be done'. Early policy responses relied on exhortation—for example, encouraging motorists to sign a pledge to abstain from 'careless and discourteous behaviour' on the roads. This approach was not successful. A campaigning young police surgeon engaged journalists in the cause by taking them to the scenes of alcohol

related accidents on Friday and Saturday nights. At this time, the editor of ‘The Age’ a Melbourne daily newspaper threw the paper’s weight behind the campaign. A committee of the Royal Australasian College of Surgeons made a case before the parliamentary committee on road safety for more rigorous surveillance and for compulsion. In 1970, these submissions convinced the main political parties to support legislation, the first in the world, compelling Victorians to fit and wear seat belts. Compliance with the new law was high and road deaths fell. In 1976, the Victorian parliament was the first in the world to legislate for random breath alcohol testing, responding again to advice from professionals. Deaths declined over the following decade. In 1986 a Transport Accident Commission was established, with secure funding from the compulsory third party injury insurance levy on motorists being made payable to it. The Commission is required to pay no-fault compensation to those injured, giving it a financial incentive to reduce injuries. A specified proportion of its spending is required to be spent on programme evaluation—thus supporting the development of an independent accident research institution. In late 1989, after traffic deaths had begun to rise again, it launched one of the most intensive mass media campaigns ever run in Australia—combined with intensified police enforcement (Davison and Yelland 2004, ch 6). In 2009 police performed 1.24 million random breath tests in a total population of 5.4 million persons (Transport Accident Commission 2013). Since 1960 traffic fatality rates in Victoria have fallen to levels that are among the lowest of the developed world.

Local historians commented in 2004:

> Probably nowhere else in the world was the conduct of the individual motorist more closely monitored or more rigorously controlled. Yet, with only occasional grumblings, motorists overwhelmingly accepted these measures.
>
> (Davison and Yelland 2004, p. 166)

These strategies of education and enforcement were combined with those of engineering. In 1965, Ralph Nader denounced US cars as ‘unsafe at any speed’ (Nader 1965). In Australia, the national government negotiated against the resistance of the international automobile industry for ‘design rules’ to make cars safer—e.g. collapsible steering columns, shatter-proof windshield glass and the removal of dangerous protrusions from the passenger cabin (personal communication: Tony Ryan). For the US, Robertson has documented the continuing resistance of the motor industry to manufacturing safer cars (Robertson 2010).

Cardiovascular disease

Cardiovascular diseases, mainly ischaemic heart disease and stroke, remain the leading causes of lost life years in developed countries. The overall change from 1990 to 2016 in the level of lost life years from these diseases in our 39 countries is shown in Table 3.6.3. The median reduction was 58%. In both time periods Japan, France, Spain, and Switzerland occupy the top four ranks (i.e. have the lowest mortality). In 1990 the Eastern European countries were at the bottom of the ladder. Over the 26-year interval reductions are largest in South Korea (76%) and Israel (71%). The post-communist group shows increasing heterogeneity with Slovenia and the Czech Republic showing above average declines while, at the other end, Bulgaria and Lithuania only achieved half the average reduction. In 2016 rates of lost life years in Bulgaria were over three times those in Slovenia. The USA also performed poorly with a reduction of just 39%, falling in rank from thirteenth to twenty-eighth.

Table 3.6.3 Years of life lost to cardiovascular diseases, 39 developed countries, 1990 and 2016: age-standardized rates per 100,000 person years with percentage changes from 1990 to 2016

These trends prompt three policy-related questions:

What have been the main contributors to reductions in cardiovascular mortality over recent decades?
Why have the trends in the post-communist group been so diverse?
Why has the USA been less successful?

As with road traffic injuries and tobacco caused disease, endeavours to control circulatory diseases have been pursued in conjunction with determined attempts to better understand their causes. In the United States, President Harry Truman signed the National Heart Act in June, 1948. Between 1950 and 2018 the budget of what was to become the National Heart Lung and Blood Institute rose from US$10 million to US$3,380 million (NIH, n.d.). The deliberate rapid expansion of research into the causes of ischaemic heart disease contributed strongly to the modernization of the scientific base of public health, including the emergence of modern epidemiology and the concept of ‘risk factors’.

The causation of these diseases has turned out to be complex but much of the variation in cardiovascular risk, at individual and population levels, continues to be explicable by the three classic risk factors—blood pressure, blood cholesterol concentration, and cigarette smoking—whose quantitative relationship to risk is now well understood. Smoking epidemic in young adult males before 1980 in most of the developed countries. Less data is available on trends in blood pressure and blood cholesterol concentrations. Where documented, trends in both sexes in developed countries have tended to follow a broadly similar time course to those of cigarette smoking in males—that is, to have been generally favourable, especially since around 1990 (Danaei et al. 2013). The development of drugs that are effective in lowering blood pressure and blood cholesterol concentrations has enabled clinicians to also make an important contribution to the prevention of these diseases. More effective treatments for heart attacks and for precursor coronary artery disease also mean that the trends in mortality from heart attack reflect not only the extent of success in preventing disease onset but also in reducing the risk of death after onset.

In seeking to characterize societal responses to heart disease and stroke one might start with an hypothetical chain from the advance of scientific knowledge to increased professional and public knowledge, advocacy, and constituency building by activists at all levels, enactment of policy, programme implementation, changes in risk factors, and finally changes in disease incidence. However such sequences cannot be easily documented or

established in a convincing way. Early phases of development were often marked by the formation of physician-led voluntary organizations which sought to mobilize public support for research, prevention and treatment in many countries: The American Heart Association (founded 1924), the National Heart Foundation in Australia (founded 1959), and the British Heart Foundation (founded 1961). The European Heart Network now unites 29 member organizations from 24 European countries. In Australia the National Heart Foundation, with extensive public support, was rich enough to actually lead in establishing national risk factor surveys during the 1980s. In Finland the local government of North Karelia, a district with extremely high risks of premature death from vascular disease, petitioned the national government for support in reducing their disease burden. From this emerged the North Karelia project which spanned epidemiological investigation and mass mobilization to promote dietary change. Finland became an exemplar in the implementation, at community level, of science-based policies to reduce vascular risk (Puska 2005).

Few countries have long time series of data on public knowledge of risk factors or of risk factor levels. However, there are indications—not least in the salience of health claims in television advertising for foods—that public awareness of the determinants of cardiovascular risk has increased over time. By the mid-1990s a vast majority (96%) of men and women in England correctly identified at least three ways of achieving a healthier diet (Bridgwood et al. 1996, p. 62).

One assessment of associations between risk factor changes and declines in mortality from cardiovascular diseases plus diabetes in 26 ‘industrialized’ countries (including Chile, Argentina, and Brazil but no post-Communist country in Europe) found that ‘trends in body mass index (BMI), blood pressure, serum cholesterol, and smoking together may have alone accounted for nearly one-half of the decline in men and about 40% in women’ (Di Cesare et al. 2013, p. 847). However, many of the risk factor estimates in this study were imputed using hierarchical Bayesian imputation.

Capewell and colleagues have shown, in a series of studies, that favourable shifts in risk factors contributed much more than clinical measures (pharmacoprevention plus treatment) to the reductions in years of life lost from ischaemic heart disease in Scotland (1975–1994), USA (1980–2000), Ireland (1985–2000), and England and Wales (1981–2000) (Gouda et al. 2012).

To all of these activities intended to reduce disease risk must be added other background factors. As early as the 1960s, results from the study of 'Coronary Heart Disease in Seven Countries' confirmed that local food cultures varied markedly in their association with coronary risk—protective in the Mediterranean area and in Japan (once traditional high sodium intakes were abandoned) while being adverse, for example, in Northern Europe (Keys 1980). Favourable trajectories in mortality from circulatory diseases in countries such as France, Spain and Japan may owe a good deal to protective food cultures as well as deliberate efforts to reduce risk. While the effects of rising incomes on animal fat and cigarette consumption may have been adverse in the early decades of the twentieth century, once the associated risks were understood, rising incomes will have brought benefits, for example via the ability to support further scientific research the dissemination of findings and by the diversification of food supplies—reduced fat dairy products, margarines with low trans-fat content, year-round supplies of fresh fruit and vegetables, etc. Richer populations can also afford the relatively expensive strategy of controlling blood pressure and high cholesterol by long-term medication. These changing patterns of association between vascular risk factors and national income levels have recently been described (Danaei et al. 2013).

Large scale failures of public health policy

Eastern Europe 1965–1990: a pervasive failure of institutional adaptation

In the period up to the mid-1960s premature adult mortality fell at least as fast in Eastern as in Western Europe (Fig. 3.6.2). The Soviet model of health service organization (named after Semashko, the first commissar of health) dealt well with the main public health problems it was designed for—notably communicable diseases and maternal and child health (Field 1967). But when faced with the challenge of tackling non-communicable disease not only did things go badly wrong but these regimes appeared incapable of changing course in the face of manifest failure.

The communist-ruled countries with transplanted Soviet public health institutions, failed to build modern scientific foundations for responding to noncommunicable diseases: they did not invest in developing modern

epidemiology and they failed to make good use of international findings. The early years of the Soviet regime had been characterized by an enthusiasm for science but subsequent developments were not favourable to population based research in medicine. According to Terris, the policy of Semashko, of integrating prevention and treatment led, in practice, to the domination of Soviet medicine by clinicians rather than by public health experts (Terris 1988). Later, the legacies of the 'Lysenko affair'[1] weakened all biological sciences (Krementsov 1997) and the control of science through hierarchical systems of research institutes limited innovation. Soviet economic philosophy also saw the route to human betterment through the physical domination of nature, not by attending to biologically based needs. The physical sciences and engineering (related, in Soviet economic theory, to the 'productive sector') were valued and rewarded more than medicine (seen as part of the 'unproductive sector'). The idea that 'dietary affluence' could harm health was denounced as a capitalist ruse. These adverse internal characteristics were augmented by the isolation of the cold war years; at late as 1988, Terris observed that there were no Soviet members of the International Epidemiological Association. The transformative potential of the quantitative revolution in medicine and, in particular, of the randomized trial, was not realized (McKee 2007). Finally, there were problems of the supply of healthy foods: systems for counter-seasonal supplies of fresh fruit and vegetables were not developed (as in the west) and these foods tended to disappear from the shops in winter and spring. Such circumstances would not have provided a propitious background for programmes promoting dietary fruit and vegetable consumption.

In some of the 'laggard' post-communist countries, public awareness of risk factors has been notably low. When survey respondents in north-east Bulgaria were asked an open-ended question (in 2000 and 2003), why they thought stroke was so common in their region, high blood pressure and cigarette smoking accounted for less than 3% of all reasons offered (Dokova et al. 2005).

As shown in Figure 3.6.2, the East/West gap in Europe was mainly created by favourable changes in the West that were not matched in the East. This point has been somewhat obscured by the focus on 'things going wrong in the east', for example, the catastrophic effects of binge drinking in Russian men in the 1990s. But if we take for illustration, say, cardiovascular mortality in middle-aged women in Hungary and Spain (among whom binge

drinking and heavy smoking were not especially prevalent): all of the increased difference between Spanish and Hungarian mortality levels from the 1950s and the 1990s—from Hungarian levels being 1.5 times Spanish levels to being 4.5 times—was created by decreases in mortality in Spain that were unmatched in Hungary (personal calculations using data from the World Health Organization (WHO) mortality database (WHO n.d.)). What mainly needs to be explained is the absence of favourable changes in the East.

The surprising underperformance of the USA

The public health failure of the United States is extraordinary on many counts. It is contrary to expectations based on national income and schooling levels. It is occurring in the face of national strengths in medical and public health science. It is occurring in spite of prodigious levels of spending on clinical medicine. And, far from showing any early effects of corrective action, US mortality trajectories continue to deviate further from trends elsewhere in the developed world.

There is also surprising ethnic selectivity. Hispanics are largely spared, with midlife death rates 30–40% below those for non-Hispanic whites (Woolf et al. 2018)—despite median household wealth just one-tenth that of non-Hispanic whites (Taylor et al. 2011). Mortality among US blacks, though substantially higher than in whites has also been declining faster, with reducing black white differences. It is thus among non-Hispanic whites that trends deviate furthest from expectation. The USA has also experienced large increases in economic inequality, and while these are important in themselves (and dealt with elsewhere in this textbook, in Chapter 6.3), it is not clear that they can explain the unfavourable trends in average health levels (Panel on Understanding Cross-National Health Differences Among High-Income Countries 2013) (Lynch et al. 2004).

The relative failure of health improvement in the USA since the 1980s constitutes an enormous loss. Writing in 2002, the US economist Nordhaus asked his readers to consider the following choice (Nordhaus 2002):

> You must forgo either the health improvements over the last half-century or the non-health improvements. That is, you must choose either (a) 1948 health conditions and 1998 non-health living standards or (b) 1998 health conditions and 1948 non-health living standards. Which would you choose?

Respondents to his straw poll tended slightly to favour b), a result consistent with his more formal analyses:

> The major result that comes through using all techniques is that the value of improvements in life expectancy is about as large as the value of all other consumption goods and services put together.

Applied to the present, the implication is that the USA is losing the equivalent of a substantial fraction of its national income. It cannot be ‘great again’ without finding the means of closing the health gap with the generality of developed countries.

Although the US failure is generally pervasive across child and adult health and across major disease groups and injuries, it does appear that a higher prevalence of obesity and increased consumption of opioids, are making notable contributions (Jeffery et al. 2018; Preston et al. 2018). In this case, the puzzle is pushed one link further back in the causal chain: why are excess adiposity and the liberal prescription of opioids more prevalent in the USA than in Other Developed countries?

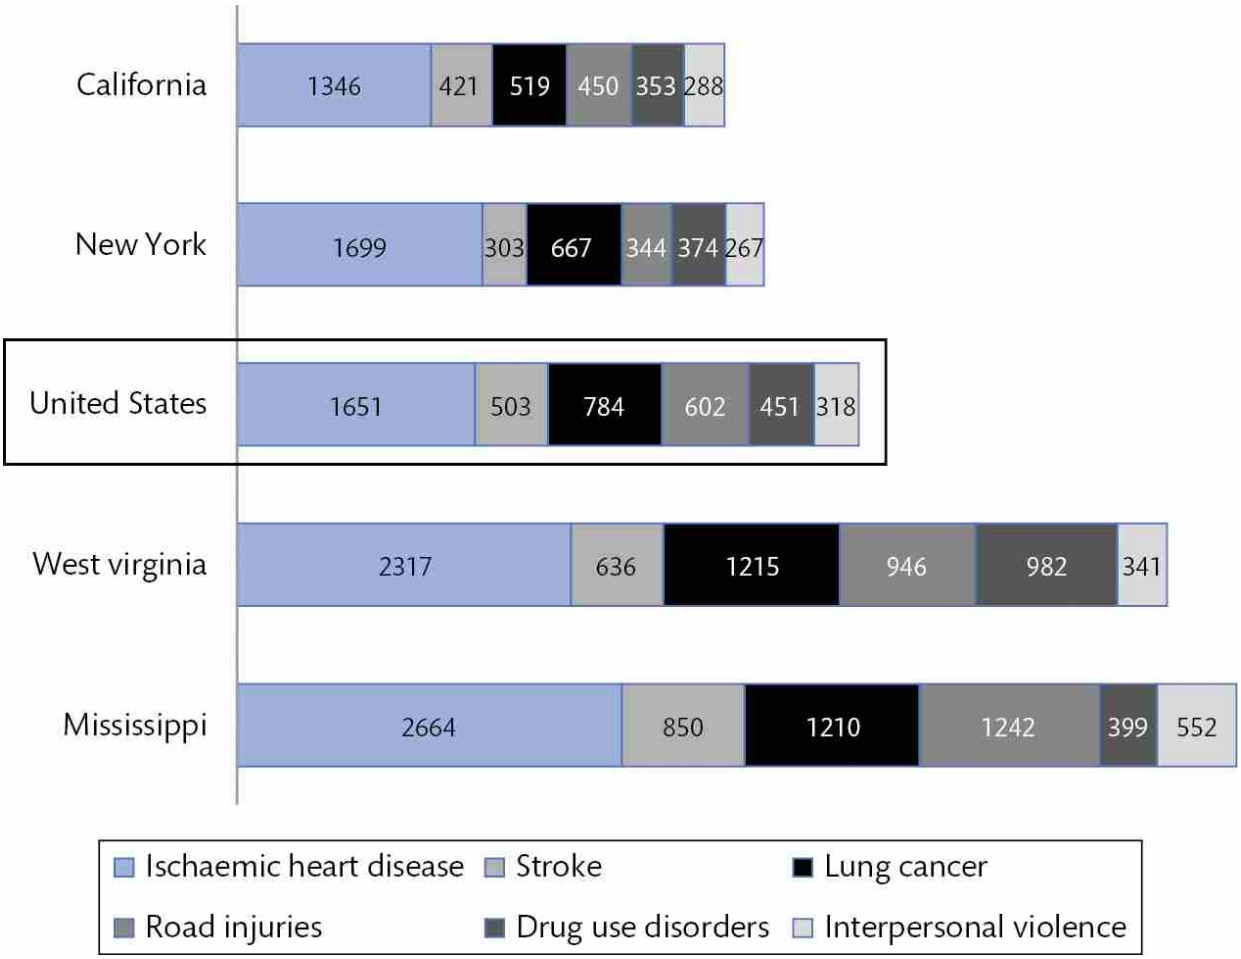

Fig. 3.6.3 Years of life lost in the US and four constituent states from six causes, age-standardized estimates for both sexes, 2016.

Source: data from U. S. Burden of Disease Collaborators (2018), 'The State of US Health, 1990–2016: Burden of Diseases, Injuries, and Risk Factors Among US States. *JAMA*, 319 (14), 1444–72.

So far we have been discussing the USA as though it were spatially homogeneous. In fact it is a very large country with marked internal heterogeneity in health experience across states and counties (see Fig. 3.6.3). Primary responsibility for public health programmes resides with the states (Institute of Medicine 2003, p. 102). The success of Californians in reducing health losses from tobacco have already been noted. This is now reflected in lung cancer mortality, at all ages, being one-third below the national rates (U.S. Burden of Disease Collaborators 2018, Fig. 6)—with even greater differences at the youngest ages. Between 1990 and 2016 California moved from twenty-fourth to second rank for life expectancy at birth. New York state, containing New York City, noted for its vigorous chronic disease prevention programmes (Ong et al. 2017), moved from thirty-ninth to fifth.

(The magnitude of these movements will have been exaggerated by the larger than average effects of the HIV epidemic in these two states in 1990.) By contrast, in 21 ‘downwardly mobile’ states, mortality at ages 20 to 55 actually increased over this period: In Kentucky, Oklahoma, New Mexico, West Virginia, and Wyoming, the increases in mortality exceeded 10%. Comparing lost life years by cause across the states of the USA in 2016 it is apparent that levels of the major causes tend to vary together. Thus rates in California and New York for 16 and 15, respectively, out of 20 causes considered in the GBD study are significantly below national rates. Similarly, states with above average rates of years of life lost tend to have high losses from most causes. The risk factors for premature mortality thus appear to vary together. Figure 3.6.3 illustrates the contribution of major preventable causes to differences in premature mortality between two low mortality states—California and New York—and two high mortality states—West Virginia and Mississippi.

In Eastern Europe there had been state-imposed embargoes on both knowledge and action to counter chronic disease risks; but in the USA relevant knowledge-based institutions are strong. The block in not on knowledge; it is on action. Characterizing institutional differences between countries is not straightforward, but some cross-national comparisons are suggestive.

Programmes to reduce traffic injury are relatively easy to identify and observe, as are their effects. The authors of the US National Academies report, *Shorter lives, poorer health* (Panel on Understanding Cross-National Health Differences Among High-Income Countries 2013) noted with some enthusiasm a study of traffic injury control in the USA and five comparison countries (Transportation Research Board [TRB] 2011): ‘ … the panel was struck by how closely the [Transport Research Board] committee’s overall findings parallel those documented in Part 1 of this report … ’ (p. 226). The TRB report noted how jurisdictions in the USA resist the application of measures proven effective elsewhere for reducing drink driving, increasing seatbelt and motorcycle helmet use, and controlling speed. It provides a detailed comparison of driving speed management in France, the United Kingdom, and Australia with the USA, using as subheadings ‘management and planning’, ‘technical implementation of countermeasures’, and ‘political and public support’. The USA came out poorly under all three heads. The TRB report concluded that ‘Most U.S. state and local transportation safety

agencies lack the institutional and technical capacities required to apply the management techniques observed in the benchmark countries' (p. 4).

Scientific evidence and expert opinion often carry less weight in political deliberations in the USA than in Western Europe. Nathanson contrasts the situation in Britain where '[c]redible scientific knowledge is monopolized and deployed by closely linked experts based within and outside the government—medical civil servants, the British Medical Association, the Royal Colleges, and government appointed advisory bodies' with the situation in the USA where experts 'enjoy no comparable authority' (p. 223).

One of the two dimensions on which the World Values Survey ranks countries from traditional/religious values at one end to secular-rational values at the other. Among developed countries, the USA is placed towards the traditional/religious end of this scale (World Values Survey 2017). Substantial proportions favour creation over evolution as an explanation of human origins (Swift 2017). Arguments based on orthodox interpretations of scientific evidence may face more competition than they would elsewhere. The much delayed uptake in the USA of syringe exchange programmes to help reduce HIV transmission in injecting drug users is often cited as an example of conservative morality blocking effective evidence based measures. It was not until December 2015 that a federal funding ban on these programmes was lifted. This happened after the prescription opioid epidemic led to new epidemics of injecting drug use and HIV transmissions in Republican Party constituencies that happened to be poor and rural, and not in Democrat voting cosmopolitan coastal cities (Showalter 2018).

Commercial interests are powerful and politically well-organized. Lobbying is a $4b 'industry' with one study identifying 37,000 (sic) lobbyists active at federal level in the decade to 2008 (Bertrand et al. 2014). The chronicles of California's tobacco wars provide insight into the challenges of operating in such an environment. The tobacco industry's carefully planned strategy for 'neutralizing' the participation of the California Medical Association to the Proposition 99 campaign in 1987–88 is very sobering (Glanz and Balbach 2000, pp. 46–9).

Responsibilities for public health programmes (like those already noted for traffic injury control) rest at state level. It is likely that the weaknesses noted in traffic injury control apply in other areas of disease and injury prevention at state level including: failure to marshall strong political and community support for preventive programmes; limited managerial capacity

and accountability for achieving programme goals; and lack of longer-term planning horizons. In 2003 an Institute of Medicine report on *The Future of the Public's Health in the 21st Century* concluded that 'the nation's entire governmental public health infrastructure—its human resources, information systems, and organizational capacity—must be revitalized and strengthened' (Institute of Medicine 2003, p. 169). Evidence that this is underway is awaited.

Emulation and globalization of public health strategies

In the previous section, 'Large scale failures of public health policy', we discussed the early, creative phases of societal responses to hazards such as tobacco and traffic injury. However, institutions evolve. For example, opportunities for discussion and comparison of early national experiences in tobacco control were created by the founding of world conferences: the first in New York in 1967, the second in London in 1971—a series that continues to the present with the seventeenth held in Capetown in 2018. The journal *Tobacco Control* was founded in 1992 and has since attained one of the highest impact factors among all public health journals. Knowledge of 'what works' in tobacco control has evolved in parallel with tobacco control activity.

Over time the number and range of civil, professional, and scientific organizations actively supportive of stronger measures to reduce tobacco consumption has grown as has support at the level of national governments and intergovernmental bodies. In the late 1990s these trends coalesced in negotiations which led to the unanimous adoption of the Framework Convention on Tobacco Control at the World Health Assembly of 2003 (Studlar 2006). This has been ratified by all but two of our included countries (USA and Switzerland).

The WHO website now presents a distillation of expert consensus on 'best practice' in tobacco control, summarized in the acronym MPOWER:

Monitor tobacco use and prevention policies

Protect people from tobacco use

Offer help to quit tobacco use

Warn about the dangers of tobacco

Enforce bans on tobacco advertising, promotion, and sponsorship

Raise taxes on tobacco.

The website includes 12 page profiles on each of over 190 countries, tracking their compliance with the MPOWER framework—conveniently and conspicuously summarized in a colour-coded bar (WHO n.d., Tobacco).

Global processes of emulation and policy convergence are not confined to tobacco. Also to be found on the WHO site are a 'Global Status Reports' on Alcohol and Health and on Road Safety (each with single page profiles for all countries) and 'More Active People for a Healthier World' (without country profiles).

Of our group of 39 developed countries, 28 are (currently) members of the European Union. From the late 1980s the European Commission began its engagement with public health by working on a directive to regulate tobacco advertising. This faltered due to member state resistance (especially from Germany) and adverse judicial rulings (Duina and Kurzer 2004). However such a directive was finally passed in 2002, and since then the EU has expanded its engagement in public health, extending from tobacco to alcohol, nutrition, and physical activity along with its previously established role in communicable disease control (European Commission n.d.). It is also active in promoting traffic safety—through the transport portfolio.

For the post-communist countries of Eastern Europe and for 'latecomers' such as the Asian Developed countries, the products of these supranational institutions provide practical guidance and models of 'best practice' for national emulation. They will be contributing, for example, to the recent above average declines in deaths from smoking in the younger cohorts in Eastern Europe—presaging further substantial declines in tobacco attributable mortality as these cohorts age.

The Asian Developed group—Japan, Singapore, and South Korea—have been late starters (with the partial exception of Japan) and rapid improvers for child and adult survival (Fig. 3.6.1 and Table 3.6.1). They have followed technology-intensive development strategies with high investments in schooling and in research. They have been moderate to good adopters of international best practices in tobacco control and traffic safety (based on

WHO score cards). They too can be assumed to be benefitting from supranational developments.

Recognizing that healthy populations are not the result of hospitals and health systems alone, other initiatives which address social determinants of health also have had increasing influence in developed countries. Health in All Policies (HiAP) was developed by the European Union and subsequently shaped by the Commission on the Social Determinants of Health and has been adopted across developed, and more recently, developing countries Kickbusch 2013). Furthermore, the Healthy Cities programme, which was launched over 30 years ago, was a WHO strategy designed to bring Health for All to the local level and recognized the importance of developing enabling environments for healthy lives (Tsouros 2015).

Reflections and prospects

In the period following the Second World War, the developed world faced a continuation of the challenges of communicable disease against which it had enjoyed substantial success earlier in the century and for which it now had new weapons (antibiotics and new vaccines). The momentum of post-war reconstruction provided a favourable political context. In the following decades continuing marked success in reducing deaths from communicable disease in children and adults has been universal.

But in this post-war period new challenges were to emerge for which existing knowledge and institutional forms were not adequate—conditions such as lung cancer, road traffic injuries, and ischaemic heart disease. Strategies that were ultimately to succeed included the building of new scientific bases for tacking non-communicable disease and injuries combined with what turned out to be cumulative piecemeal changes to social institutions related to health damaging behaviour patterns. Especially in their early phases, the actual form and content of the latter varied markedly between countries. Over time, as knowledge deepened and extended, and practical experiences in areas such as tobacco control, traffic injury reduction, and heart disease prevention were compared, it became possible to identify ‘best practice’ strategies and to codify these at an international level. Within countries, such institutions evolved over time, increasingly subject to scientific and public scrutiny. Since the mid-twentieth century risks of premature death have more than halved.

Where political regimes blocked these developments—as in the communist-ruled countries of Eastern Europe—the health of adults either failed to improve, or, especially in the case of men, deteriorated. With the end of communist party rule, these countries have, to varying extents, resumed improving adult mortality trajectories. Countries such as the Czech Republic and Slovenia have been rapid improvers and now have adult male mortality levels that lie within the range of other developed countries and that are only half of those of laggards such as Latvia and Lithuania.

The poor performance of the USA is noteworthy and puzzling. Adult mortality levels (at ages 15–60) are now around twice those of the best performing countries and the gap has continued to widen. Given the several background conditions favourable to the attainment of higher levels of health, suspicion falls on institutional obstacles to more effective action. There is now evidence that some other countries may be joining the US in experiencing slowdowns and reversals of previous mortality declines (Ho and Hendi 2018).

Respect for science, objectivity, and expertise have, in combination with a sense of human solidarity, provided the foundation for major health gains over the past several decades. They are currently under challenge from the upsurge of populism, so the prospects for successfully reversing recent adverse trends remain unclear.

4.1

Information systems in support of public health in high-income countries

Tjeerd-Pieter van Staa and Liam Smeeth

Introduction to information systems

Public health sciences have been described by a Wellcome Trust working group as follows: ‘effective public health actions are based on scientifically derived information about factors influencing health and disease and about effective interventions to change behaviour at the level of the individual, the family, the community or wider society’ (Public Health Sciences Working Group et al. 2004, p. 5). This field of science has made major contributions to the improvement of health such as the effects of sanitary reforms on infant mortality and, more recently, the reductions in cardiovascular disease incidence due to lipid lowering and blood pressure control. However, many challenges remain, such as how to tackle the increased prevalence of obesity and diabetes and how to relate the costs of interventions to their benefits (Public Health Sciences Working Group et al. 2004). This chapter will describe how information systems containing healthcare data can support public health research. We will first describe examples of public health information systems, followed by a description of various developments in these systems, including increased public health use of routinely collected electronic healthcare records (EHRs). More and more clinicians and healthcare professionals are using computers to store information: indeed the ‘meaningful use’ of electronic health records for patient care has recently been mandated in the United States (Blumenthal and Tavenner 2010). These data sources provide opportunities, among others, to test the effectiveness and impact of public health interventions. We discuss the role of randomization in public health research and conclude

this chapter by highlighting the importance of an impact assessment of public health interventions.

Sources of public health information

Vital statistics

Death certificates are routinely collected in many countries in order to report on specific causes of death including, for example, alcohol-related deaths, suicides, and drug-related deaths, deaths involving methicillin-resistant *Staphylococcus aureus* (MRSA) and *Clostridium difficile*, and estimates of excess winter mortality. Trends in, for example, all-age all-cause mortality, deaths from cancer, circulatory diseases, suicide and injury of undetermined intent, and accidents are reviewed periodically as are the association of mortality rates with socioeconomic deprivation. Live and stillbirth figures are also routinely collected in many countries. The birth counts may be stratified by occurrence within or outside marriage, multiple births, mother's area of residence and country of birth, place of confinement, and father's social class (examples are given at http://www.statistics.gov.uk).

Population surveys

Population surveys are frequently used information resources. One example is the US National Health Interview Survey, which targets annually an interview with 40,000 households. Questions include health status and health services utilization and activity limitations due to ill health. The Behavioural Risk Surveillance System is a telephone survey in the US involving 150,000 people. Data are collected on health risks and behaviours, exercise, and diet. The National Health and Nutrition Examination Survey examines diet, nutrition, health behaviours, and risk factors in 5,000 randomly selected persons.

A population census provides information about the characteristics of the population and facilitates understanding of the similarities and differences in populations locally, regionally, and nationally. The results are then used to allocate public money for services including healthcare services. They

are also used to identify areas with the greatest public health needs. As an example, national census data from the Strasbourg metropolitan area in eastern France were used to develop a small-area index of socioeconomic deprivation. It showed an association between increased rates of myocardial infarction and worse neighbourhood deprivation (Havard et al. 2008).

Disease surveillance

In many countries, there are systems for reporting and notification of cases of certain diseases to the public health authorities. Infectious diseases such as yellow fever and diphtheria are notifiable on diagnosis of a suspected case and should not wait for laboratory confirmation. All notifiable cases are then reviewed and appropriate action may be taken. Analyses of local and national trends are typically published on a regular basis. Despite legal requirements to report certain infectious diseases, reporting rates for these conditions are not always optimal. To address this, for example, a New York public health institute facilitated public health reporting by creating alerts within EHRs to remind clinicians at the point of care that a particular diagnosis is reportable and providing a link to the reporting form. Patient demographics are automatically populated in the form (Calman et al. 2012).

Administrative databases

There are many administrative databases that contain information recorded for the purposes of managing the healthcare system. Several of these systems can be used for public health research. The Hospital Episode Statistics is a data warehouse containing details of all admissions to National Health Service hospitals in England. It contains clinical information about diagnoses and operations on individual patients, demographic information such as age, gender, and ethnicity, administrative information such as time waited and date of admission, and geographical information on where the patient was treated and the area in which they lived. Main procedures (such as surgical operations) are also recorded. It contains admitted patient care data from 1989 onwards, with more than 12 million new records added each year, and outpatient attendance data from 2003 onwards, with more than 40 million new records added each year (Health and Social Care Information System n.d.).

Registries

A registry is an organized system that uses observational study methods to collect uniform data (clinical and other) to evaluate specified outcomes for a population defined by a particular disease, condition, or exposure. There are many different types of registries. An example of a product registry is the UK national registry of patients on biological therapy: patients starting such therapy are registered and followed, for example, for long-term safety issues. Healthcare service registries include patient-based individual clinical encounters, such as office visits or hospitalizations, and procedures. Examples include registries enrolling patients undergoing a procedure (e.g. carotid endarterectomy, appendectomy, or primary coronary intervention) or admitted to a hospital for a particular diagnosis (e.g. community-acquired pneumonia). These registries may be used to evaluate the processes and outcomes of care for quality measurement purposes. Disease registries use the state of a particular disease or condition as the inclusion criterion. These registries typically enrol the patient at the time of diagnosis at a routine healthcare service. Examples include cancer registries which are widely used for research (Edwards and Bell 2000).

Immunization registries have been created in order to assemble in one site a record of all immunizations and to provide reminder and recall notices when an immunization is due or late. Vaccination schedules are becoming complex due to the number of different vaccinations a child should receive. These may be further complicated by frequent changes of healthcare provider or insurance company. Immunization registries can provide a central repository of all the vaccinations given to children (Linkins 2001).

Electronic health record databases

EHRs are increasingly being used for research and public health purposes. There are currently over 300 EHR databases in 45 countries (http://www.ispor.org/intl_databases). This section describes a few examples of EHR databases that have been widely used for research. The Clinical Practice Research Datalink, previously known as the General Practice Research Database, collates the anonymized EHR information for over 5 million patients currently registered at participating general

practices. General Practitioners (GPs) play a key role in the UK healthcare system, as they are responsible for primary healthcare and specialist referrals. If a patient is treated in secondary care or by a specialist, the GP is informed about major clinical outcomes, and long-term treatments are frequently handed back to the GP. Almost all GPs in the UK use computers for maintaining health records, and communications between different health providers are increasingly sent electronically (Williams et al. 2012). The Dutch PHARMO Record Linkage System collects information on patient demographics, drug dispensing, hospital morbidity, clinical laboratory and pathology results, and GP information for more than 3 million community-dwelling inhabitants of 48 geographic areas in the Netherlands (Herings and Pedersen 2012). A recent development in the Netherlands is the Mondriaan project that has developed an IT and governance infrastructure for enrichment and linkage of EHR. Privacy enhancing technology such as linkage through a trusted third party (TTP) is applied and currently data from GPs (one million), community pharmacists (12 million), and various other EHR sources are retrieved for research purposes and as feedback information to healthcare providers (www.projectmondriaan.nl). In Denmark and Sweden, each national healthcare system provides universal coverage to all residents (5.5 million inhabitants in Denmark and 9.2 million inhabitants in Sweden). Healthcare coverage includes visits to GPs, specialists, hospital admissions, and outpatient visits; drug costs are either partially or completely covered. A centralized civil registration system has been in place in each country for many years, allowing for personal identification of each person in the entire population and for the possibility of linkage to all national registries containing civil registration numbers, for example, patient registry, cancer registry, prescription databases, and registry of causes of death (Furu et al. 2010). The Rochester Epidemiology Project medical records-linkage system captures healthcare information for the entire population of Olmsted County, Minnesota in the United States. It includes a dynamic cohort of over half a million patients who received healthcare for any reason. The data available electronically include demographic characteristics, medical diagnostic codes, surgical procedure codes, and death information (including causes of death). The system covers residents of all ages and both sexes, regardless of socioeconomic status, ethnicity, or insurance status (St Sauver et al. 2012).

Recent developments in information systems

The electronic information systems in the healthcare system are evolving and increasing (Table 4.1.1). Initial use of electronic healthcare data mostly consisted of aggregate analyses of administrative data such as hospital admission data. When clinicians started to use computers for record keeping, the first research databases collating anonymized EHRs were created. One of the first of these was the VAMP research database that started in 1987. This database eventually developed into the Clinical Practice Research Datalink. The richness and completeness of many EHR databases have been increasing over time as more information is being shared electronically between different parts of the healthcare system. Laboratory data provide an example in which test results are increasingly being communicated electronically and loaded automatically into the patient's EHR.

Table 4.1.1 Stages in the development of EHR databases

Time period (approximate)	Development of EHR databases
1980s onwards	Data collected for administrative purposes (such as hospital admission data and death certificates); mainly used for aggregate analyses
1990s onwards	Clinicians starting to use computers for record keeping (replacing paper records) and data collated into research database. These data initially mainly used for drug safety monitoring
2000s onwards	Monitoring of clinic encounters for symptoms that may represent infectious diseases and other conditions of public health concern
2000s onwards	Linkages between various EHR databases; mainly used to obtain complementary information or to validate outcomes
2010s onwards	Enrichment of routinely collected data by prospective data collection within EHR databases (e.g. collection of blood samples for genetic analyses or patient questionnaires)
2010s onwards	Development and implementation of triage tools to guide clinicians in hospital referral of patients with, e.g. influenza; electronic alerts for eligible patients or patients prescribed unsafe combinations of medications
2010s onwards	Introduction of randomization at the point of care using the EHR database to identify potentially eligible patients and for follow-up collection of major clinical outcomes (i.e. pragmatic and cluster trials); mainly used to evaluate the effects of medicines in routine clinical practice

An important development is the increased linkage between different healthcare databases. Typically, linkages are done by a TTP that collects from each data source the patient's identifiers (such as registration number in the healthcare system, patient's date of birth, gender, and postcode), and research numbers. The TTP then matches the records of the various databases retaining the linked records with the various research numbers without any patient identifiers. This approach allows the combination of different healthcare databases. Linkages between different EHR datasets are being done more frequently, benefiting both the quality and completeness of the EHR data. The UK Clinical Practice Research Datalink has been linked individually and anonymously to other healthcare datasets, including the national registry of hospital admissions, the national death certificates (with primary and secondary cause of death), and prospective disease registries,

such as the cancer and cardiovascular disease registries (Williams et al. 2012).

Comparisons of the information in linked EHR databases can highlight incomplete data records and inform efforts to improve data recording in the healthcare system. In a cohort study, primary care records were linked with those from cancer registries in the UK National Cancer Data Repository. Comparison of the two datasets showed a concordance rate of 83.3%, which varied by cancer type. Cancer registries recorded larger numbers of patients with lung, colorectal, and pancreatic cancers, whereas GPs recorded more haematological cancers and melanomas (Boggon et al. 2013).

Anonymized linkages between local air pollution data, records from primary care, hospital admissions, and death certificates have been used recently to evaluate the relationships between ambient outdoor air pollution and incident myocardial infarction, stroke, arrhythmia, and heart failure. While evidence was weak for relationships with myocardial infarction, stroke, or arrhythmia, consistent associations between pollutant concentrations and incident cases of heart failure were found (Atkinson et al. 2013).

An example of a public health resource that uses linked healthcare databases is the CALIBER programme. It is linking multiple data sources including the longitudinal primary care data from the Clinical Practice Research Datalink, the national disease registry of acute coronary syndrome, hospitalization, and procedure data from hospital admission records, cause-specific mortality from death certificates, and postcode-based social deprivation. Current cohort analyses involve a million people in initially healthy populations and disease registries (Denaxas et al. 2012). A recent study that used this resource was an analysis of the effect of influenza and influenza-like illnesses on triggering acute myocardial infarction (AMI). A self-controlled case series (i.e. only cases were evaluated) identified cases of myocardial infarction from the national registry of acute coronary syndromes and looked for associations with exposure to influenza from the consultation records of GPs. It found that influenza and other acute respiratory infections can act as a trigger for AMI (Warren-Gash et al. 2012).

The Massachusetts Department of Public Health in the United States has developed a system that loads EHRs every 24 hours from clinicians' proprietary software systems. These extracts are organized into separate

databases for patient demographics, vital signs, diagnosis codes, test orders and results, medication prescriptions, allergies, social histories, and provider contact details. These data provide clinically detailed surveillance data. Sensitive and specific disease-detection algorithms have been developed to overcome the limited accuracy of code diagnostic data by considering all available data. Diabetes surveillance is done using these algorithms and can provide information on, for example, the frequency of referrals for medical nutrition counselling stratified by race and locality. A comparison of this system and conventional reporting by clinicians showed a significant increase in the quantity and quality of case reports of notifiable conditions (Klompas et al. 2012).

The minimization of risk of preventable harm to patients is a priority for many healthcare organizations. In Scotland, a system has been implemented in routine primary care that provides a rapid audit method of screening electronic patient records to detect patient harm. The objective of this tool is to support clinical improvement efforts (De Wet and Bowie 2011).

The combination of routinely collected EHRs with prospectively collected data is an important development in improving the quality of information resources. A study in the Clinical Practice Research Datalink recruited about 8,000 persons aged 50–64 year for a survey about working life. Study participants completed questionnaires about their work and home circumstances and the EHRs will be used to analyse health outcomes over time. The inter-relationship between changes in employment (with reasons) and changes in health (e.g. major new illnesses, new treatments, mortality) will be examined. This study will contribute to the evidence base as to whether working beyond the traditional retirement age is feasible for those with major health problems associated with ageing and the effect of occupational and personal circumstances (e.g. savings, retirement intentions, domestic responsibilities, whether work is arduous or rewarding) (Palmer et al. 2015; D'Angelo et al. 2016).

Syndromic surveillance is the practice of monitoring clinic encounters for symptoms that may represent infectious diseases and other conditions of public health concern. There are several examples in which EHRs are used to conduct this surveillance. An example is QSurveillance which provides weekly information on the consultation rates of flu-like illness in general practices covering a total population of almost 22 million patients (QSurveillance n.d.). A comparable system has been developed in New

York State, United States, in which routinely collected EHRs from health centres are transferred daily to the research database. Respiratory illness, fever, diarrhoea, and vomiting are the key symptoms monitored, with analysis to determine when the incidence of these syndromes exceeds expected thresholds (Calman et al. 2012).

The EHRs can also be used to guide clinicians in hospital referral of patients with influenza-like illness during a pandemic. During pandemics of novel influenza and outbreaks of emerging infections, surge in healthcare demand can exceed capacity to provide normal standards of care. In such exceptional circumstances, triage tools may aid decisions in identifying people who are most likely to benefit from higher levels of care. A recent study (called FLU-CATs) developed a system for real-time capture of symptoms in patients presenting in primary care with influenza-like illness. GPs were prompted by a pop-up box to provide symptoms when a diagnosis of influenza-like illness was entered into the EHR. The collected data can then be used to refine and update the triage tools for predicting hospital admission and measure clinical outcomes such as hospital admission or death and GPs' clinical assessments and management decisions. Such a system is also potentially adaptive, since with ongoing data collection, triage tools can be regularly adapted to changes in virus, human behaviour, and models of healthcare provision in the community (Venkatesan et al. 2015).

Pandemic preparedness is a major public health activity in many countries, including the United Kingdom. The major objectives of the UK strategy are, in case of an influenza pandemic: to identify key clinical, epidemiological, and virological features of the new influenza virus; to count severe cases, and identify risk groups affected, to describe the evolving pandemic and its impact at the population level (e.g. by age-group) particularly in relation to hospitalizations and mortality; and to measure the uptake and safety of various pharmaceutical countermeasures. Several information systems would be used to collect the data to be used for this, including primary care consultations, records of calls to telephone help-lines and web-based advisory services relating to influenza-like illness, virological 'sentinel' surveillance schemes in primary care, laboratory analysis of a sample of cases to identify the genetic features of the virus, and analysis of death records (Department of Health 2011).

Future developments in information systems

There is an increasing need to perform studies across different EHR systems and across different countries mainly because of the need for a larger sample size. The healthcare systems in most countries consist of multiple healthcare providers who often use different systems to store data, either on paper or electronically. Furthermore, physicians often record data differently and inconsistently, both on paper and electronically. Various international initiatives have used different approaches to combine heterogeneous EHR databases. One approach focuses on IT aspects with the aim to develop EHR systems that are interoperable and allow seamless transfer of data (http://www.transformproject.eu/; http://www.ehr4cr.eu/). All the information in the various databases is mapped together with a detailed understanding of the content of each of the data elements and use of a single coding dictionary across the different databases. An alternative approach is to maintain the EHR data structure as collected by the participating health professionals but to develop a common protocol across the different databases. The operational definitions of how the data are classified will vary by individual EHR database but the research questions will be kept similar. This model is currently used by the Innovative Medicines Initiative PROTECT project (http://www.imi-protect.eu/). The third approach is used by the OMOP initiative in the United States: all EHR data from the different databases are integrated into a central research database according to a common data model (http://omop.fnih.org/). A distributed network model where basic analyses are run on federated datasets generating common input data and subsequent local aggregation and central pooling of results, constitutes the fourth approach to dealing with heterogeneous EHR databases. The EU-ADR project uses this approach. In one of their studies, data from eight European healthcare databases (administrative claims, medical records) were combined. This data set included over 1.9 million individuals (59,594,132 person-years follow-up) who used 2,289 different drugs. It found for a frequent event such as AMI, there were 531 drugs (23% of total) for which an association with relative risk ≥2, if present, can be investigated. For a rare event such as rhabdomyolysis, there are 19 drugs (1%) for which an association of same magnitude can be investigated. It concluded that even larger databases

would be required to detect signals for less frequent exposures and outcomes (Coloma et al. 2012).

A recent development is the use of EHRs to measure the quality of clinical care and provide financial incentives through 'pay-for-performance' programmes (Campbell et al. 2009). EHRs are used to evaluate clinician and system performance with the goal of making healthcare safer and more efficient. The adoption of computerized clinical records itself may be associated with improved care and outcomes (Cebul et al. 2011) although some doubts remain (Classen and Bates 2011). There are several different dimensions in which quality of healthcare can be measured. Examples of different quality measures include the number of patients with diabetes seeing an ophthalmologist, clinical outcomes in patients with hypertension, percentage of clinicians reviewing out-of-range laboratory results with a certain number of hours, and the percentage of patients receiving incorrect medications (Weiner et al. 2012). The quality and completeness of the EHRs are of course critical in achieving the goals of the 'pay-for-performance' programmes.

Internet postings, blogs, and social media postings may provide another source of information for the early detection of new infectious disease epidemics. A recent study analysed the queries to online search engines, which are used by millions of people around the world each day. It concluded that this approach accurately estimated the level of weekly influenza activity in each region of the United States, with a reporting lag of about 1 day. The use of search queries could detect influenza epidemics in areas with a large population of web search users (Ginsberg et al. 2009). This potential use of Internet searches was tested in a US study that compared Internet searches with rates of outpatient visits for influenza-like illness and of confirmed laboratory tests. It was found that Internet searches were highly correlated with rates of outpatient visits for influenza-like illness but less correlated with rates of laboratory-confirmed influenza (Ortiz et al. 2011). The main limitation of these analyses of unstructured Internet data is that it may be difficult to separate activities by concerned healthy people from those with the disease of interest. Healthcare seeking behaviour, physician testing practices, and Internet search behaviour can be influenced by high levels of media coverage (Ortiz et al. 2011).

The information on the Internet can also be evaluated for the monitoring of side effects of medicines. A study evaluated the text on Internet message

boards dedicated to drug abuse in order to compare different prescription opioids. Over 48,000 posts were analysed and the unstructured text was coded. It was found that the number of posts on these drug abuse message boards varied between the different opioids (Butler et al. 2007). While this approach is interesting, one cannot conclude that these differences in drug abuse messages were caused by the pharmacological differences between the opioids. Different levels of information provision by, for example, the clinicians or in the information sheet or prescribing to different patient populations could also lead to different levels of Internet activities.

Randomization in public health research

The present allocation of healthcare interventions is often inconsistent. Clinicians will be influenced in their prescribing behaviour, not only by clinical considerations, but also by other issues including drug preferences, exposure to marketing materials, and guidance from the local healthcare funders, which will vary considerably between practices and clinicians (Adamson et al. 2012). Clinicians will respond differently to uncertainties in the evidence base. The prescribing of antibiotics to patients with mild to moderate exacerbations of chronic obstructive pulmonary disease provides an example of this. A review of EHRs found major differences in the rate of antibiotics prescribing to these patients. Very few patients received an antibiotic in some clinics while antibiotics were routinely prescribed in other clinics. This variability in care (due to a lack of randomized trials conducted in these patient groups) produces a potentially unfair lottery for the receipt of healthcare interventions. Treating patients in this inconsistent manner generates no new evidence to improve clinical practice. On the other hand, randomization with structured data collection would provide the evidence to guide clinicians in selecting treatments. A possible model would be to offer randomization to all willing patients as part of routine clinical care in every situation where there is genuine uncertainty about which of two or more widely accepted treatments is best. The EHRs could be used to measure major clinical outcome and follow progress (van Staa et al. 2012). An analysis of the trial evidence for medicines used by millions of patients and with blockbuster sales showed that only one of the 24 top blockbusters in 2011 had a randomized trial including more than 10,000

participants and few of the blockbusters had evidence of beneficial effects on mortality (Ioannidis 2013). A mega-trial with mortality as an outcome could address concerns about side effects and also provide evidence of effectiveness of medicines in routine clinical practice.

EHR databases could offer an ideal platform to undertake large pragmatic trials, with randomization at the point of care and collection of follow-up data using the EHR (van Staa et al. 2012). Such an approach would allow the assessment of effectiveness of healthcare interventions in everyday clinical practice among representative populations. A recent study developed and evaluated the methods to implement simple pragmatic trials in primary care, identified the barriers and facilitators for clinicians and patients, as well as the experiences of trial participants. As part of this study, patients with high cardiovascular risk were randomized between simvastatin and atorvastatin (van Staa et al. 2012). Potentially eligible patients were identified in the EHRs using risk prediction tools. Outcome data such as continuation of statin treatment and occurrence of heart attacks were collected using the routinely collected data from primary care, linked data from hospital admissions, a prospective disease registry, and death certificates. This study concluded that EHR point-of-care trials are feasible, although the recruitment of clinicians is a major challenge owing to the complexity of trial approvals. These trials will provide substantial evidence on clinical effectiveness only if trial interventions and participating clinicians and patients are typical of usual clinical care and trials are simple to initiate and conduct (van Staa et al. 2014).

Discontinuation and non-compliance with medication over time can be an important outcome measurement in pragmatic trials. For example, if patients preferentially use e.g. atorvastatin for a longer period of time, this could mean a substantially lower number of patients suffering a heart attack. In most trials, study participants are regularly monitored and instructed how to take their medicines. But the rates of persistence are often considerably lower in routine clinical practice, as stringent monitoring procedures do not apply. Pragmatic trials that collect follow-up information unobtrusively (e.g. from EHR databases) would provide the answers that decision makers need: that is, will this intervention make a difference in routine clinical practice compared to alternative strategies (Tunis et al. 2003).

The TRANSFoRm project developed an approach to embed trial functionalities within the EHRs including the pre-population of electronic Case Report Forms directly from the EHRs and the potential to record trial-specific data at the point of care. In addition, it also implemented data standards which allowed users to query the EHRs without a detailed understanding of how data were originally recorded and stored in the EHRs and what coding system was used (i.e. interoperable data systems) (Ethier et al. 2017). The (TRANSFoRm) clinical trial tools were then used for automated identification, recruitment, and follow-up. A small feasibility study was conducted in three general practices in Poland. Participants were physicians and patients with gastro-oesophageal reflux disease. It found that physicians were satisfied with the usefulness of the system, as it enabled easier and faster identification, recruitment and follow-up of patients compared with existing methods (Mastellos et al. 2016).

Cluster trials randomly allocate entire areas or health service organizational units to intervention or control groups, with outcomes evaluated for individuals within each cluster. They facilitate pragmatic evaluation of the effectiveness of interventions delivered in routine practice settings. Public health interventions could be tested in cluster trials as one can, for example, implement the novel intervention in one set of randomly selected clinics and the old intervention in the remaining clinics. The effectiveness of screening programmes could also be tested in cluster trials, with half of the clinics conducting the screening and the other half not. An example of a study that used EHR data is a study that tested the effectiveness of providing clinicians with the guideline recommendations on antibiotic prescribing in respiratory illness. Electronic prompts are activated during a patient's consultation for upper respiratory illness. The EHRs are used to measure the outcomes of interest, which include the rate of antibiotic prescribing (Gulliford et al. 2011).

Phased access to new interventions has been proposed as a method to measure effectiveness and safety. Practices or regions would be randomized to early or late access and the EHR data would be used to measure the outcomes of interest. Because practices are randomly chosen for each new intervention, a practice will have access to some of the new interventions (Adamson et al. 2012).

Impact assessment of public health interventions

The measurement of outcomes of public health interventions in routine clinical practice should be considered a major public health activity. This impact assessment can inform the extent of uptake but also identify any issues with the implementation of the public health activity. However, this impact assessment is not consistently done. For example, measurements of outcomes are lacking in a major UK programme that targeted the use of statins in patients with high cardiovascular risk. Following a detailed review of evidence, the UK National Health Service introduced a population-wide vascular risk assessment programme. This consists of a systematic approach to assessing risk of vascular diseases for everyone between 40 and 74 years who is not yet diagnosed with cardiovascular disease or treated for risk factors. Statin treatment should be initiated if a patient has a high risk (20% or greater 10-year risk) of cardiovascular disease (National Health Service Health Check Programme 2008). However, a recent analysis of the EHRs found that many healthy patients were prescribed a statin despite having a below-threshold cardiovascular risk and that there was wide variation between practices in the extent of statin prescribing to patients at high risk.

Another example of the difference between intended use according to guidelines and actual use in clinical practice concerns the selective cyclooxygenase-2 inhibitors (coxibs). These drugs ranked, before September 2004, among the most commonly used medications in the world. They were developed to minimize the upper gastrointestinal side effects of conventional non-steroidal anti-inflammatory drugs. A large number of cost-effectiveness analyses were conducted in order to provide clinicians with guidance on which patient groups should be treated with coxibs. These analyses were based on mathematical models that took into account the higher prescription costs and lower incidence of gastrointestinal side effects of coxibs. The assumptions that were used in these models were obtained from the main coxibs randomized trials. However, an analysis of EHRs found that the vast majority of coxib users in routine clinical practice would not have been eligible for the main coxibs randomized trials, as they did not have osteoarthritis or rheumatoid arthritis and only used coxibs intermittently or short term. Thus, the many cost-effectiveness analyses that were conducted for coxibs lacked external validity and were of limited value in guiding clinicians on how to treat patients in routine clinical

practice. The authors of the EHR analyses concluded that the field of health technology assessments should move from evaluating cost-*efficacy* in ideal (hypothetical) populations with ideal interventions, to cost-*effectiveness* in real populations with pragmatic interventions (van Staa et al. 2009). The clinicians were not provided with any guidance on how to use coxibs in the vast majority of patients who could be treated with coxibs. Public health interventions should be developed with a focus on who could be targeted in routine clinical practice rather than on who had been included into randomized trials. It has been proposed that public health programmes should be preceded by a systematic review of the research evidence assessing the likely effects of these programmes followed by an impact evaluation after launch (Oxman et al. 2010).

Scientific challenges in research with electronic healthcare data

Data quality is of course very important for research that uses EHR data. There are several dimensions of data quality. The accuracy and validity of the information in EHR databases will depend on the level and specificity of the coding of medical data at the clinics. A clinic that mostly records data using unstructured free-text or using non-specific codes will provide data that are less useful for research. Data quality also depends on the completeness of information. A clinic that is not routinely informed about, for example, hospitalizations of their patients will not provide complete data, even if the clinic codes the medical data to highest standards. Reliability of information includes the level of changes in data collection over time. As an example of secular changes, the Quality and Outcomes Framework introduced in England in 2004 resulted in a substantive increase of the data included in this framework. Relevance of the collected data for the desired use is another component of data quality. An EHR database that is based on records from GPs may not contain all the data considered relevant by a specialist for making a diagnosis. Timeliness of information processing is also critical for data quality (Audit Commission 2007). Studies that use EHR data for public health research will need to consider these different aspects of data quality.

There are many different EHR systems and similar information may be recorded and stored differently, making it difficult to extract information in a standardized manner or to share information between different partners. Complex systems may need to be built in order to make computer systems interoperable and to exchange EHR data with public health agencies. An example of such a system is the US National Electronic Disease Surveillance System. This is a web-based infrastructure for public health surveillance data exchange between the Centers of Disease Control and the 50 US states. Forty-seven states had in 2010 fully operational general communicable disease electronic surveillance systems, of which 39 states had systems that were interoperable and 42 states had the capacity to receive electronic laboratory reports (Centers for Disease Control and Prevention 2011).

Ethical aspects of research with electronic healthcare data

Healthcare data contain sensitive information about individuals. Adequate protection of individuals' privacy and data security are very important requirements for researchers to adhere to. EHR databases typically remove patients' identifiers (such as name, address, and postcode) from the research database. In some databases, researchers will never be able to contact the clinician or patient; these data are considered fully anonymized. In other databases, researchers will not know the patients' identifiers but they are able to contact the clinician or patients through a gatekeeper; these data are considered pseudo-anonymized. In the Clinical Practice Research Datalink, the patient's clinician can be contacted (following approval by an ethics committee), who can then review the request and contact the patient, if appropriate.

There is considerable debate about whether (pseudo)anonymized healthcare data should be made available for research. In an opt-in system, data can only be made available to researchers dependent on their informed consent. In an opt-out system, patients can refuse to have their data used for research. In other systems, anonymized data are considered exempt from consent or dissent requirements and can be used for research as long as the data do not contain patient identifiers. The use of health data for research raises complex ethical questions of privacy. One interesting approach to

evaluating public acceptability of different approaches to challenging ethical questions like this is the use of citizens' juries. They are based on the premise that, given time, opportunity, support and resources, ordinary people can make decisions about complex matters. A project in the North of England explored what control informed citizens would seek over the use of EHRs for research after participating in a deliberative process using citizens' juries. They addressed the question of to what extent should patients control access to EHRs for research use? At the end of several days of deliberation, 33 out of 34 jurors voted in support of the secondary use of data for research, with 24 wanting individuals to be able to opt out, 6 favouring opt in, and 3 voting that all records should be available without any consent process. All jurors thought that public benefit was a key justification for access (Tully et al. 2018).

The critical question is whether the right of data privacy trumps all other rights and duties or whether there is a balance between different considerations. There is the right of patients to receive proper treatments and the duty of the healthcare to, for example, monitor treatments for effectiveness and safety, and be cost-effective. A healthcare system that generates and applies the best evidence for collaborative healthcare choices of each patient and provider has been defined as a learning healthcare system (McGinnis 2010). Such a system would continuously test interventions and collect data on the outcomes and then use the results to inform and improve clinical practice. Scientific research including public health requires high-quality data, and a learning healthcare system that aims to continuously improve cannot be achieved without such data. It has been proposed that data governance should be viewed as a matter of weighing up the value accruing to individuals, such as privacy and consent, against the value that the research may generate for the public (Rumbold et al. 2011).

The discussion about rights of data privacy and the research use of EHRs should not be restricted to abstract legal notions but also consider the likelihood of data privacy breaches and how these can be minimized. Staff training and standard procedures are essential, but the skills and attitudes of staff are also very important to ensure that data are treated with appropriate care. Regular audits of data security by external experts can also help to maintain a culture of continuous improvement (MacKenzie et al. 2011). With appropriate data security procedures, the risk of breaches of data privacy could be minimized. Also, the standards and quality of research are

important considerations in the balancing of rights of data privacy and the research use of EHRs. Registration of the study prior to the start of the analyses and external access to protocols after completion of the analyses have been advocated strongly for randomized trials (Chan et al. 2006). External access to protocols and the possibility for independent researchers to replicate the study findings could help to improve research standards. A public health system that uses EHRs for high-quality and transparent research and with minimal risk of privacy breaches is clearly ethically superior to a system that applies few standards.

Conclusion

Information systems are critical for public health activities with information being exchanged between public health agencies, clinicians/healthcare providers, individuals, and communities. The EHRs can provide information on diseases and healthcare activities and electronic alerts within the EHRs can be used to remind clinicians of necessary or required public health activities. The effectiveness of some public health interventions can be monitored and also tested using the EHRs. Better data on risks and benefits of healthcare interventions can also help to improve decision-making and informed consent by individuals (Calman et al. 2012). The increasing computerization of the healthcare system will offer many important opportunities to improve public health activities.

4.2

Community diagnosis and health information systems in low- and middle-income countries

Zunyou Wu and Jennifer McGoogan

Introduction

Broad recognition of health as a basic human right began with the formation of the World Health Organization (WHO) in 1946 (see Box 4.2.1), as a specialized agency within the United Nations (UN) (WHO 1946). Twenty years later in 1966, the International Covenant on Economic, Social and Cultural Rights was ratified by the UN General Assembly (GA). Article 12 of the Covenant reinforces international commitment to protecting health as a natural human right, recognizing *'the right of everyone to the enjoyment of the highest attainable standard of physical and mental health'* (UN GA 1966). Since then, these agreements have been followed by other similar commitments; for example, the Declaration of Alma-Ata (1978), the Health For All goals (1981), the World Medical Association Declaration of Ottawa (1998), and the Abuja Declaration (2001).

Box 4.2.1 Constitution of the World Health Organization (WHO)

WHO founding principles (WHO 1946):

- Health is a state of complete physical, mental, and social well-being and not merely the absence of disease or infirmity.
- The enjoyment of the highest attainable standard of health is one of the fundamental rights of every human being without distinction of race, religion, political belief, economic or social condition.
- The health of all peoples is fundamental to the attainment of peace and security and is dependent on the fullest co-operation of individuals and states.
- The achievement of any State in the promotion and protection of health is of value to all.
- Unequal development in different countries in the promotion of health and control of diseases, especially communicable disease, is a common danger.
- Healthy development of the child is of basic importance; the ability to live harmoniously in a changing total environment is essential to such development.
- The extension to all peoples of the benefits of medical, psychological, and related knowledge is essential to the fullest attainment of health.
- Informed opinion and active co-operation on the part of the public are of the utmost importance in the improvement of the health of the people.
- Governments have a responsibility for the health of their peoples which can be fulfilled only by the provision of adequate health and social measures.

In 2000, the UN Millennium Declaration, with the support of 189 of its member states as well as 22 international organizations, launched the Millennium Development Goals (MDGs)—eight international development goals meant to be achieved by 2015 (UN GA 2000). MDG 4 (Reduce Child Mortality), MDG 5 (Improve Maternal Health), and MDG 6 (Combat HIV/AIDS, Malaria and Other Diseases) were meant to directly influence health. This helped to galvanize national and international health organizations by bringing awareness to these issues and pushing them to the forefront of political agendas worldwide. It also helped to provide renewed momentum, as considerable funds, earmarked for initiatives aimed at achieving the MDGs, became available through international aid organizations such as the United States President's Emergency Plan for AIDS Relief (PEPFAR), the President's Malaria Initiative (PMI), the GAVI Vaccine Alliance, The Bill & Melinda Gates Foundation, and The Global Fund to Fight AIDS, Tuberculosis and Malaria (The Global Fund).

The aspirations that the MDGs embodied were ambitious, but the tactical work that would be required to achieve them fit neatly into the usual purview of public health, which had already long been doing the work of elevating average health status and reducing burden of disease, combatting health inequity and inequality, ensuring provision of basic services, and improving health system efficiency, all at the community level. Thus, one of the near-immediate positive outcomes of the MDGs was the recognition of the human

race itself as a community and hence, ‘global health’ or ‘global public health’ as a concept (Marten 2019), a movement which had first begun in the mid-1990s with a refocusing of efforts at the WHO (Brown et al. 2006).

While overall, the MDGs were generally considered successful—development was accelerated, lives were saved, people were lifted out of poverty (UN 2015)—nearly every aspect of the MDGs were also heavily criticized (Fehling et al. 2013; Marten 2019). For example, the MDGs were written primarily by the United States, Europe, and Japan, with the heavy influence of large international aid organizations. Neither the citizens nor the governments of the developing nations the MDGs were meant to help were involved in their creation. Moreover, although the MDGs were written as global goals, assessments of performance against the goals were repeatedly applied at the individual country level. The mismatch between global-level goal setting and country-level performance measurement meant that many countries struggled and some were, arguably unfairly, labelled as ‘off-track’. Furthermore, the sense of futility felt in countries where the MDGs were not realistically feasible was harmful and, in some cases, counterproductive to growth and development of local public health infrastructure, governance, and accountability (Cohen et al. 2014; Easterly 2009; Easterly 2013; Fehling et al. 2013; Vandemoortle 2009).

This problem was further exacerbated by insufficiencies in data availability, quality, timeliness, and potential for aggregation and disaggregation, in statistical methodologies and capacity, and in national (and international) information systems. Although over the course of the MDG era (2000–2015), more and better data became available, coordination with statistical systems improved, and new statistical methodologies were developed, these issues were serious obstacles to progress in the MDG era (2000–2015) (UN 2015), and remain so today.

Not surprisingly, it was low- and middle-income countries (LMIC; see Box 4.2.2), in particular, that faced unreachable standards for success. These nations generally did not have the data collection infrastructure and information management systems to support measurement of current state, much less evaluation of achievement over time. For instance, some countries’ civil registration systems were inefficient and ineffective, leading to large gaps in vital statistics and related data. Consequently, governing bodies at local, subnational, and national levels relied on incomplete, outdated, and/or low-quality evidence for policy development and planning purposes. Thus, experience gained in monitoring progress toward the MDGs

underscored the power of effective use of data for setting appropriate targets, focusing efforts, successfully implementing interventions, assessing performance, and increasing accountability (UN 2015).

Fundamentally, this activity of describing the current state, setting goals for a future state, and measuring progress against those goals is the basis of community diagnosis. Careful and deliberate selection of health indicators, or metrics, is important to the planning, execution, and evaluation of any community diagnosis project. However, the effectiveness of health metrics selected and used relies heavily on the data available. Thus, robust information systems that can support timely collection, analysis, and distribution of high-quality data are central to any effective community diagnosis project. Recognition of the interconnectedness of community diagnosis, health metrics, and health information systems is important for supporting the iterative improvement of all three over time, especially in LMIC where sustained development is at its most challenging, yet the need for overall improvement in health status is greatest.

Community diagnosis

In contrast to clinical diagnosis, where health is assessed at an individual level through patient–physician interaction, community diagnosis is an assessment of health at a population level through community engagement in public health practice. As such, *community diagnosis* (sometimes also called a community health profile or health needs assessment) is defined by the WHO as *'a quantitative and qualitative description of the health of citizens and the factors which influence their health. It identifies problems, proposes areas for improvement and stimulates action'* (WHO 1995).

Community diagnosis projects can have one or more overarching goals, such as:

Description of a community's health status, health problems, and their determinants
Assessment of a community's health resources, services, and systems
Evaluation of community members' attitudes toward health and health services
Identification of priority issues and development of action plans for improvement
Definition of an epidemiologic baseline for measurement of change over time

A *community*, in the sense of community diagnosis, can be any cluster of people within the broader society who share at least one common characteristic; for example, geographic location, ethnicity, occupation, exposure to a specific environmental factor, or presence of a particular risk factor. However, it is not only the characteristics of the people (e.g. vital statistics, sociodemographics, religious and cultural beliefs, educational attainment) that define the community. Other factors—environment, safety, physical, and mental health and social services, economics, communication, transportation, and government—must also be included as the community is defined and as the current state of health in the community is described. Notably, any one individual may be a member of several different communities by this definition—citizen of Village A, but practitioner of Religion B, and worker in Factory C, etc. (Tindana et al. 2007).

The process of community diagnosis

Community diagnosis, whether performed in high-income settings or in LMIC, generally follows a fairly well-defined process that includes five main steps (see for example Box 4.2.3). However, the process is not only customizable, it is meant to be customized. Ideally, the base process of community diagnosis outlined here should be tailored to match the intent of the community diagnosis initiative, the resources and time available to execute it, and the unique attributes of the community itself. The process is meant to be pragmatic and its result is meant to be informative (i.e. improve understanding of the issue) and actionable (i.e. identify actions to be taken to improve the situation).

Box 4.2.3 Community diagnosis in a small village in Iran

Summary of methods used and results obtained in a community diagnosis effort in Qala-Sayed village, Kazeroun, Fars Province, Iran in 2013 (Basseej et al. 2015).

Step 1: Community assessment team created
Step 2: Primary and secondary data collected
Step 3 and 4: Data analysed and combined
Step 5: Community informed
Step 6. Health priorities selected
Step 7: Community assessment document created
Step 8: Action plan developed

A total of 649 households comprised of a mostly-rural population of 2,514, 25% of which were under the age of 11. For many years already, the village has had working water, electricity, gas, and telephone utilities. It had one 'health house', four schools, five mosques, one nursery school, four butchers, and 21 grocery stores.

Insufficient health knowledge was identified as the highest priority problem, followed by diabetes, oral health, addiction, and hypertension.

The plan of action focused on non-academic training designed to improve villagers' knowledge (regardless of educational attainment) of diabetes, with particular emphasis on healthy eating habits.

Step 1: Initiation. It is important that any community diagnosis effort is managed and coordinated by a dedicated team, committee, or working group. This team should be cross-functional in make-up, comprised of individuals from relevant government agencies, health bureaus, non-governmental organizations (NGOs), and representatives from the community. Once formed, this team should begin the process with refining the scope of the project. Taking into consideration the goals of the initiative, the financial budget and other resources available, and the time allotted to conduct the work, the team should have a detailed understanding of the work ahead, a plan for the methods of data collection and analysis to be used, and at least a high-level strategy for the ultimate output of the community diagnosis project (i.e. development and dissemination of the community diagnosis report). Development of a strategy for engagement of, and communication with, the community the project is intended to serve should be a critical element of the project's up-front planning. Another important component of this early planning stage is the selection of health indicators that ideally would be used, although this may be modified during the project based on data availability and analyses conducted. Furthermore, the team should anticipate obstacles and risks to the project and draft plans for overcoming barriers and mitigations for risks realized.

Step 2: Collection. Both primary (e.g. surveys, interviews, focus group discussions, mapping, observations) and secondary (e.g. records review) data collection methods are critical for gaining a thorough understanding of the community being studied. For the same reason, both quantitative and

qualitative data must be collected since neither provide a complete picture without the other (see for example Box 4.2.4).

Care must be taken to ensure representativeness of the data collected. For example, teams should be cautions of potentially causing over-representation of subgroups from which data are easier to obtain. This and other types of bias could lead to inaccurate findings and interpretations. Even more dangerous is the possibility that, as a result of these biases, inappropriate actions are taken, time and resources are wasted, opportunities for health intervention are lost, appropriate actions are delayed, and trust and belief in this process by the community is eroded. To help prevent these issues, it is crucial that different types of data be collected from multiple sources. While each source may be important individually, each will also have strengths and weaknesses. Taken together, however, data collected from a broad variety of sources are likely to be complimentary, more comprehensive, and less susceptible to bias.

Box 4.2.4 Malaria community diagnosis in Lomahasha, Swaziland

The importance of qualitative data is highlighted in a mixed-methods community diagnosis project aimed at better understanding social and behavioural factors influencing the success of malaria control measures in a rural area of Swaziland (Dlamini et al. 2017).

Individual interviews
Multiple researchers were strategically stationed around the village of Lomahasha on walkways and roadsides. They randomly stopped individuals passing by and interviewed them using a semi-structured questionnaire meant to collect both quantitative and qualitative information.

Focus group discussions
Focus group discussions were spontaneously convened by researchers who approached groups of people in Lomahasha already collected for some social reason (e.g. boy soccer players loitering in the street, women socializing near a water source, people waiting at bus stops).

Researcher observations
Six, one-day visits were made each year in 2004, 2006, and 2010 during which researchers drove around different parts of the Lomahasha community or stayed inside individual homesteads from early morning to late evening noting behaviours of individuals and social interactions among groups.

Several key findings important to future malaria control efforts were gleaned from qualitative data:

- Knowledge of malaria was relatively high, yet social norms and behaviours remained contradictory to control programme intentions—people stayed outside late into the evening, maintained pools of stagnant water, and sought care for symptoms late and in the wrong places.
- Severe poverty, drought, and the persistent presence of malaria in the community have desensitized people Lomahasha such that they regard malaria as a less serious problem and a normal part of life.

The study design most commonly employed for community diagnosis projects is cross-sectional. *Cross-sectional studies*, which consist of retrospectively evaluating a representative sample of a population at a single point in time, have the advantage of being relatively inexpensive and fast. They also facilitate the simultaneous investigation of multiple exposures and outcomes while providing the ability to control for confounding. Although these types of studies to not allow for assessment of temporality or causality (Thiese 2014), repeated cross-sectional measurement nevertheless facilitates observations of changes over time for the purpose of evaluating action plans executed or interventions implemented.

Step 3: Analysis. Raw data should be compiled, tabulated, and summarized using descriptive statistics. Statistical tests may be run and inferences made. Rates and ratios may be further analysed to assess correlates or determinants of health, injury, disease, etc. Historical trends in certain indicators may be accessible for comparison to current data, and projections may be made to help predict future changes in health indicators for planning purposes. Re-analysis (by the same methods) of selected health indicators after action plans are carried out or interventions are implemented is important for evaluating their effectiveness. Additionally, community data may be compared to that of other similar communities (i.e. Village A compared to Village B) and to larger geographical or administrative areas (i.e. village to county/district to province/state). Ultimately, the analyses selected by the team must relate to the objectives of the project, but again, caution must be exercised to ensure that bias is not introduced at this stage as well. Additionally, in selecting the analyses to be conducted, the team should be mindful of the need to communicate results of the project. The output of the analyses should be reasonably accessible and understandable to a broad range of audiences—government officials, public health and healthcare workers, and the general public.

Step 4: Diagnosis. Interpretations and conclusions drawn from the results of the analyses form the diagnosis of the community. This includes for

example, the current state of health, determinants of health, and health problems prioritized for intervention. This diagnosis must relate back to the initial intent of the community diagnosis project, and the diagnosis itself must be informative and actionable—suggestions for actions to be taken to improve health in the community should follow easily from the diagnosis. Furthermore, it must be specific and relevant to the community it is meant to serve.

Step 5: Dissemination. At its most basic, this step is the generation of a community diagnosis report, describing in detail the scope of the project, the methods used to collect and analyse data for the project, the results observed (i.e. the diagnosis), and the team's recommendations for further action. Emphasis should be placed on transparency. The report should be detailed, yet also include easily understood summaries of key points.

However, generation of the report itself is not enough. The report must be written in such a way that the information it contains is accessible not only to policymakers, public health authorities, or officials, other government agencies, and health workers, but also to the community members themselves. Ideally, a communication plan should be generated in parallel with the report. The results of the community diagnosis project should be shared with the general public in a variety of ways; for example, through presentations at meetings of local government committees, NGOs, and community-based organizations, through press-releases and news stories, and through community events such as health fairs or kick-off celebrations for new health interventions. Taking an active role in helping the community understand the project and how it will help improve health is important for building trust and belief in the process. Since the community diagnosis process is meant to be iterative, these kinds of activities may deliver the added benefit of improving participation in future community diagnosis projects.

Community engagement

Successfully conducting community diagnosis not only requires meticulous planning and execution, but also engagement and mobilization of the community to participate in the process.

Community diagnosis cannot be successfully performed or applied without involvement of community it serves. *Community engagement* (CE), the collaborative process of working with community members and groups

to address issues that impact their well-being, can take many forms. For instance, rates of participation by members of the community must be high in order for large-scale community-based studies or household surveys to be successful. Thus, involving community leaders, influencers, and champions in the planning process, communication plan, and launch, and ensuring that they are seen and heard by the community through all stages of the project can be important for encouraging participation from those who may be reluctant.

There are several important points during a community diagnosis initiative where focus should be placed on CE. A selection of these CE activities is listed here, but this list is meant to be neither exclusive nor comprehensive:

Creation of a project subteam whose mission is to lead CE
Identification of community leaders, influencers, and champions to be involved at each stage of the project
Review of plans to ensure the project is relevant to the community, culturally sensitive and pragmatic, not disruptive, designed to ensure fairness in community members' receipt of benefits from the project, and protective of vulnerable members
Identification of local community health workers who will participate in data collection
Development of a clear and consistent messaging strategy to ensure the community understands the project goals, processes, timelines, and expected outcomes and benefits
Sensitization of the community and the local media about the launch of the project
Execution of a high-profile launch, perhaps with a special community event where community leaders, influencers, and champions show their support for the effort
Provision of regular updates and feedback to the community during the project
Execution of a similarly high-profile project closure, with gratitude for community participation, transparent reporting on project outcomes, and details of action plans as well as funding and execution timelines for those plans

The benefit of collaboratively working with the community itself through truly authentic partnerships before, during, and after a community diagnosis

project cannot be overstated (see for example Box 4.2.5). It is not only palpable in the near-term on the current project, but also carries over in the longer term on future projects if community members feel their voices are heard, their contributions are valued, and their lives or the lives of those in their families or in their communities are bettered through this iterative and focused effort on improving health and well-being.

Box 4.2.5 Community engagement in rural Vietnam

A descriptive study of rural communes in Quang Tri Province in north central Vietnam underscores the value of community engagement (CE) in the community diagnosis process (Cho et al. 2018).

CE embedded in study methods

- **Study teams:** Study teams were comprised of nurse researchers, physicians, programme officers, programme evaluators, and local Vietnamese medical school faculty members.
- **Instruments review:** Local experts reviewed all questions included in all instruments used in the study for appropriateness relative to the local context.
- **RPA approach:** The study employed a rapid participatory appraisal (RPA) approach, which is a method for quickly collecting information about a set of problems and their causes that places strong emphasis on involvement of community members (Annett and Rifkin 1995).

Value of CE reflected in study findings

- **Multiple data sources:** Inclusion of multiple sources and types of data, made possible by CE, facilitated a better and more comprehensive understanding of community health needs.
- **Qualitative data:** Use of qualitative data, obtained through CE, helped compensate for relatively weak quantitative data (small data set from a small convenience sample).
- **Collaboration with local experts:** Many of the study communes were approached for the first time in this study and collaboration with local experts was essential for understanding the sociocultural context.
- **Community involvement:** Involvement of community members in the collection of information was critical to creating *'an acceptable and sustainable environment for successfully undertaking a new study'*.

Finally, CE is increasingly considered an ethical requirement of research involving human subjects, and thus, is no longer really considered optional (Tindana et al. 2007).

Community diagnosis in low- and middle-income countries

In LMIC, community diagnosis is particularly challenging for a wide variety of reasons. Primary data collection is fraught with difficulty in creating representative, non-biased samples and retaining participants in studies, as well as barriers to field work including low educational attainment and poor infrastructure. Secondary data collection efforts can be frustrating as the data required are often unavailable, incomplete, inaccurate, out-of-date, and difficult to obtain. These complications make for complex and labour-intensive data entry and analysis, which may reduce confidence in results obtained and interpretations made.

Challenges with primary data collection

It is nearly impossible to remove all bias when sampling a population. One significant source of bias is caused simply by community member participation in primary data collection efforts. Those who elect to participate are very likely to be more informed or more concerned about the issue being examined and addressed through the project and those who decline may, in fact, be the more vulnerable to the issue at hand. Obtaining high participation rates in LMIC is already challenging but obtaining any level of participation from those most in need of intervention is extremely difficult.

Dropout is an issue for projects that require repeated measurement or even just a seemingly-small time interval between study enrolment and primary data collection. Dropout can be caused by a wide range of issues, but in LMIC, predominant among these is the movement of people over time. Large proportions of populations in LMIC communities are either transient (i.e. characterized by frequent movement due to lack of stable housing and/or employment) or migrant (i.e. characterized by regular movement over large distances between family residence and employment).

Low education levels and literacy rates, more common in LMIC settings, mean the target population for a community diagnosis project is often ill-informed or unable to understand the importance of the health research project. This can render less expensive primary data collection techniques, such as self-administered questionnaires, impossible. Rather, home visits by study workers with high-level language skills and cultural knowledge may be required. This drives up the cost of the study, thereby driving down the feasible sample size, and increasing the risk of non-representative, biased sampling.

There are innumerable challenges with this kind of house-to-house field work in LMIC. Remote rural communities as well as poorer urban communities lacking or having poor-quality basic infrastructure that is susceptible to seasonal or severe weather effects mean transportation into and out of communities by field workers can be difficult, time-consuming, and sometimes dangerous. Lack of geospatial mapping, or simply street names and house numbers, creates obstacles for ensuring the homes of enrolled participants are correctly located. Field work that requires electricity (e.g. for visual observations or inspections), water (e.g. for hand washing before and after physical examinations), internet access (e.g. for record keeping), or other utilities can be problematic.

Finally, some of the world's LMIC most in need of improvements to community health are in the midst of ongoing violent conflict. Accessing these regions is unsafe for field workers seeking to gather primary data, and moreover, engaging with foreigners may be unsafe for community members as well. Additionally, interest among community members in participating in a community health needs assessment in regions of conflict is likely to be low, since primary among their concerns is not falling victim to the violence around them.

Challenges with secondary data collection

Challenges with secondary data collection in LMIC are numerous and persistent and can be frustrating for researchers attempting to conduct a community diagnosis or evaluate the effects of health policy changes or health interventions. Secondary data collection centres around review of records from a wide variety of sources—vital statistics from registries and censuses, surveillance systems, routine information systems, electronic medical records, disease registries, and other forms of information repositories. These records can be a rich source of quantitative information for community diagnosis initiatives and are frequently the focus of study in the public health field.

However, one of the most frequently cited challenges during the MDG era was the poor availability and reliability of data in LMIC—both for baseline assessment and for evaluation of progress toward MDG targets. What information systems did exist at that time suffered from, for instance, large gaps in record keeping, incomplete records, and poor-quality data entry (see for example Box 4.2.6 and Box 4.2.7). Many LMIC lacked birth and death

registries, health records repositories, or health statistics at any administrative level. Methods for gathering information in the absence of these secondary data sources were often unreliable and sometimes based on assumptions. Furthermore, these methods were variable within and between countries and over time, making individual country progress difficult to interpret and nearly impossible to compare. These issues, caused by widespread lack of robust, thoughtfully-designed, and secure information systems in LMIC, persists today, presenting major challenges to the mission of global public health and global sustainable development (Fehling et al. 2013).

Box 4.2.6 Timeliness of spotted fever surveillance reporting in Brazil

Study of spotted fever (SF) surveillance records in Brazil highlighting challenges with timely data availability (de Oliveira and Angerami 2018).

Background: In 2001, SF, an infectious tick-borne disease endemic to southeastern Brazil, became a compulsorily notifiable disease and in 2014 became an immediately-notifiable disease (within 24 hours of suspicion). Two systems have tracked SF reports in Brazil: the digital disease detection (DDD) system launched in 1997 and the national surveillance (SINAN) system launched in 2007.

Aim: To examine the timeliness of SF notification in the DDD and SINAN systems in southeastern Brazil.

Method: Records from Brazil's DDD and SINAN systems were matched and dates compared.

Findings: Only 62 records contained sufficient information to be matched and included in the study. More than 90% of these cases were reported to SINAN a median of 20.5 days earlier than DDD. Both systems' records contained different information and the data that could be extracted from each system were valuable and complementary.

Interpretation: The authors noted several critical limitations of these surveillance systems. For instance, although reporting to SINAN was faster due to immediate mandatory reporting of suspicion, reports were not available until diagnoses were confirmed generally 30 days later. Furthermore, SINAN did not contain location information, forcing reliance on the DDD system for identification of new transmission areas, clusters, and outbreaks. Delayed access to fragmented information prevents rapid and informed responses to health needs.

Box 4.2.7 Continuity of cancer registry reporting in Kosovo

Study of cancer registry records in Kosovo highlighting challenges with data quality and quantity (Berisha et al. 2018).

Background: Although malignant disease is a leading cause of death worldwide and an important contributor to morbidity and disability, public health efforts continue to be hindered in LMIC like

Kosovo by lack of non-communicable disease registry data, which prevents informed allocation of limited resources.

Aim: To investigate the incidence, prevalence, and types of malignancies reported in Kosovo.

Method: Records from the Kosova Cancer Registry (KCR), which was reinstated in 2011 after an extended gap in reporting, were reviewed. Data were collected and tabulated and incidence and prevalence calculated.

Findings: Incidence was 93.4 (per 100,000) in 2012, 83.3 in 2013, and 167.9 in 2014, while prevalence was 135.8 (per 100,000) in 2012, 101.6 in 2013, and 186.5 in 2014. Most common among men were malignancies of the skin and respiratory and intrathoracic organs, and among women were malignancies of the breast and reproductive tract.

Interpretation: Although the authors concluded that cancer incidence and prevalence are increasing in Kosovo, and that investments must be made in prevention, screening, diagnostics, and therapeutics, they also emphasized several critical limitations of their study. They stated that they were *'not satisfied with the quantity and quality of the reporting'* and highlighted the importance of better quality data for better public health planning and the critical need for political commitment to support and expand coverage of existing reporting efforts, such as the KCR.

Challenges with data management and analysis

Aforementioned issues with the data and data collection methods all have ramifications for the management of datasets as well as statistical analyses, which can be difficult to overcome. For example, collection of handwritten data on paper forms—common in LMIC where use of laptops or tablets is often precluded by financial constraints and suboptimal internet access—creates the momentous task of keeping track of all the paper generated by the study, accurately deciphering and entering all the data, and then quality-checking the data entry. In terms of analysis, for instance, standard practice to address issues of representativeness or bias in sampling is to attempt to control for confounding. However, in LMIC, confounding may be caused by a multitude of factors, many of which researchers, due to their own unconscious biases and lack of knowledge, may be unaware. This can easily result in confounding by unmeasured factors having a substantial effect on results and interpretation. As another example, in the case of high dropout-rate, teams will often add 'replacements'. However, these replacement participants, often added late in the study, may have different characteristics and perhaps different exposures, which can be difficult to handle in the analysis phase.

The future of community diagnosis in low- and middle-income countries

Without question, properly executing community diagnosis in LMIC is difficult work. However, despite all of the barriers and challenges,

performing a community diagnosis initiative is still a worthwhile endeavour, and having a little data or lesser-quality data is nevertheless better than having zero data. After all, the work of global public health is both a science and an art, meant to achieve a noble purpose—to prevent disease, prolong life, and promote health. In LMIC, where health needs are greatest and resources are most constrained, effectively executing the methodical process of community diagnosis can be especially impactful.

The Sustainable Development Goals

The Sustainable Development Goals (SDGs), the successor to the MDGs, were launched by the UN GA in 2016 and were comprised of 17 goals and 169 associated targets (see Box 4.2.8) (UN GA 2015). In contrast to the MDGs, where three of the eight goals were focused on improving community health, the SDGs contained only one goal directly related to health—Goal 3: Ensure healthy lives and promote well-being for all at all ages—which contained 13 targets.

Box 4.2.8 The United Nations Sustainable Development Goals (SDGs)

Launched in 2016, the 17 SDGs to be achieved by 2030 contained one goal directly related to health (Goal 3), which itself had 13 targets (UN GA 2016) (see Fig. 4.2.1.)

Fig. 4.2.1 Targets.
Reprinted from United Nations (2017) 'The United Nations Sustainable Development Goals', https://unstats.un.org/sdgs/report/2017/overview/

Goal 3: Ensure healthy lives and promote well-being for all at all ages

3.1	By 2030, reduce the global maternal mortality ratio to less than 70 per 100,000 live births
3.2	By 2030, end preventable deaths of newborns and children under 5 years of age, with all countries aiming to reduce neonatal mortality to at least as low as 12 per 1,000 live births and under-5 mortality to at least as low as 25 per 1,000 live births
3.3	By 2030, end the epidemics of AIDS, tuberculosis, malaria, and neglected tropical diseases and combat hepatitis, water-borne diseases, and other communicable diseases
3.4	By 2030, reduce by one-third premature mortality from non-communicable diseases through prevention and treatment and promote mental health and well-being
3.5	Strengthen the prevention and treatment of substance abuse, including narcotic drug abuse and harmful use of alcohol
3.6	By 2020, halve the number of global deaths and injuries from road traffic accidents
3.7	By 2030, ensure universal access to sexual and reproductive healthcare services, including for family planning, information and education, and the integration of reproductive health into national strategies and programmes
3.8	Achieve universal health coverage, including financial risk protection, access to quality essential healthcare services and access to safe, effective, high-quality, and affordable essential medicines and vaccines for all
3.9	By 2030, substantially reduce the number of deaths and illnesses from hazardous chemicals and air, water and soil pollution and contamination
3.a	Strengthen the implementation of the World Health Organization Framework Convention on Tobacco Control in all countries, as appropriate
3.b	Support the research and development of vaccines and medicines for the communicable and non-communicable diseases that primarily affect developing countries, provide access to affordable essential medicines and vaccines
3.c	Substantially increase health financing and the recruitment, development, training, and retention of the health workforce in developing countries, especially in least developed countries and small island developing states
3.d	Strengthen the capacity of all countries, in particular developing countries, for early warning, risk reduction, and management of national and global health risks

A great many of the aforementioned criticisms of the MDGs have been attributed to the way in which they were developed—largely by the United States, Europe, and Japan together with the World Bank, the International Monetary Fund, and the Organization for Economic Cooperation and Development without consultation from, and some would say, even without consideration of, LMIC. Regardless of whether one subscribes to this view or not, the complaints by many of LMIC not being represented in the MDG development process and then being the recipient of its dictated priorities, targets, measures, and deadlines (Cohen et al. 2014; Easterly 2009; Fehling et al. 2013; Vandemoortle 2009), combined with the emerging notion of ‘global public health’ as well as other factors, drove a very different approach to the development of the SDGs leading up to the 2015 MDG deadline (Coonrod 2014; Marten 2019).

In many ways, the process used to develop the SDGs strongly resembled community diagnosis effort on a global scale. Cross-functional working groups were formed, the scope of the project was refined, and a plan for community engagement was developed (i.e. initiation step). Massive amounts of information were collected (i.e., collection step), compiled, and tabulated (i.e. analysis step). Interpretations were made, priorities were set, and metrics were selected (i.e. diagnosis step), and finally, the SDGs were communicated (i.e. dissemination step).

Engagement of the global community in preparation for the development of the SDGs began in 2012. It was an extraordinarily large effort—widely considered the most inclusive and consultive participatory processes the world has ever seen. Led by a 30-member Open Working Group of the UN GA, government officials from more than 100 countries were engaged in face-to-face discussions, recommendations of more than 5,000 civil society organizations were reviewed, executives from more than 250 companies were consulted, and feedback from more than a million individual citizens was collected via the UN's online Survey for a Better World, which asked people to select six issues that matter most to them (UN 2013).

The SDGs were the output of this massive, global-scale community diagnosis initiative. Without question, the new goals address a much broader range of issues, and the targets beneath the health and well-being goal are much more comprehensive (see Box 4.2.8) (UN GA 2015). However, it remains to be seen how successful the health and well-being SDG will be at driving forward a unified global public health agenda and improving health and well-being for all peoples of the world (UN 2017; Marten 2019).

The 'data revolution'

The crucial importance of information sources and data to global sustainable development was recognized in the MDG era, and the UN High-Level Panel, tasked with developing recommendations on the post-2015 development agenda, called for a 'data revolution'. The panel identified the need for substantial investment to build capacity worldwide in data collection and statistical analysis methods and tools to ensure that monitoring and evaluation at all stages is strengthened to support decision-making, guide prioritization, and ensure accountability (UN 2013). This theme extended into the 2015 UN GA resolution detailing the SDGs and its critical nature is

underscored by its inclusion as targets under SDG 17 (UN GA 2015) (see Box 4.2.9).

The need to 'harness the power of data for sustainable development' features prominently in the UN SDGs Report 2017 (UN 2017):

> To fully implement and monitor progress on the SDGs, decision makers need data and statistics that are accurate, timely, sufficiently disaggregated, relevant, accessible and easy to use. Data availability and quality have steadily improved over the years. However, statistical capacity still needs strengthening and data literacy must be enhanced at all levels of decision-making. This will require coordinated efforts on the part of data producers and users from multiple data systems. It will also demand innovative ways to produce and apply data and statistics in addressing the multifaceted challenges of sustainable development.

The report goes on to emphasize the importance of building capacity via innovative approaches, creating synergies across different data environments, ensuring data improve clarity and do not mask disparities, improving data presentation and literacy, and implementing best practices and standards related to data management.

Box 4.2.9 SDG targets for data, monitoring, and accountability

SDG Goal 17: Strengthen the means of implementation and revitalize the Global Partnership for Sustainable Development contains two targets important to the improvement of data, monitoring, and accountability (UN GA 2015).

17.18: By 2020, enhance capacity-building support to developing countries, including for least developed countries and small island developing states, to increase significantly the availability of high-quality, timely, and reliable data disaggregated by income, gender, age, race, ethnicity, migratory status, disability, geographic location, and other characteristics relevant in national contexts.

17.19: By 2030, build on existing initiatives to develop measurements of progress on sustainable development that complement gross domestic product, and support statistical capacity-building in developing countries

Sources of information

There are many sources of information and data that are employed to conduct community diagnoses and to evaluate changes in community health over time. Each individual source has its own advantages and disadvantages, yet in combination with other sources (that have different advantages and disadvantages), the complementary larger data set becomes more powerful.

Several of the most common sources of health information used in LMIC are detailed here.

Census

Generally conducted every 10 years and typically at the national level, a *census* systematically collects data on the population number and sociodemographic profile of citizens. A major advantage of census data is its provision of a population count and age profile that may be disaggregated by a range of geographical, social, economic, and demographic variables, which can contribute significantly to health planning (see for example Box 4.2.10).

Box 4.2.10 Census data identifies an ageing population in Jamaica

Jamaica's census data has provided concrete evidence of significant and meaningful population ageing, 2001 compared to 2011 (Eldemire-Shearer et al. 2014), and projected to 2021 (PopulationPyramid.net).

Since ageing is associated with increased disease burden, urgent action must be taken to ensure that health and social services are expanded to meet the demands not only of the current, but also the future, elderly population. To promote the health and well-being of Jamaica's ageing population, investments need to be made in combatting chronic disease and age discrimination, creating programmes that support healthy, active ageing, and expand services for diagnosing and treating acute and chronic mental and physical illness in the elderly population. See Figure 4.2.2.

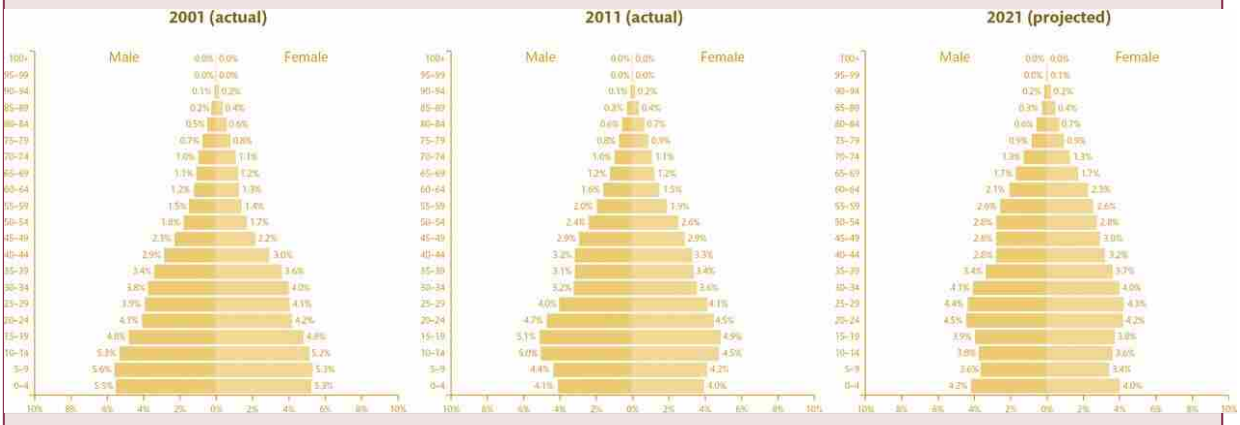

Fig. 4.2.2 Population pyramids.

Source: data from Eldemire-Shearer D, et al. (2014) 'Ageing of Jamaica's population—what are the implications for healthcare?' *West Indian Med J* 63(1): 3–8 and Statistical Institute of Jamaica (STATIN). Population and Housing Census 2011: General report. Volume 1. Kingston: STATIN; 2011.

However, while this form of data collection is somewhat successful in avoiding the pitfalls of sampling bias due to its focus on full participation by all citizens, bias still exists as many of those who fail to comply are perhaps the most vulnerable in society to health disparities. This is particularly true in LMIC. Furthermore, a census normally does not collect data that are directly related to the health of citizens and thus, cannot usually stand on its own for community health evaluation and monitoring.

Vital registry

Vital registration is the systematic recording of vital events including births, deaths, adoptions, marriages, and divorces. A country's vital registry (VR) can therefore provide important information on population dynamics (i.e. life expectancies, fertility rates, population growth rates) and health, via death records that can be used to evaluate morbidity and mortality, that a census cannot. Although VR is also intended to capture data from a nation's entire population, vital events are commonly under-reported in LMIC. According to a 2014 World Bank and WHO report, an estimated 85 million children under the age of five in Africa and 135 million in Asia and the Pacific were not registered. Likewise, an estimated 67% of deaths worldwide are not accounted for in VRs (WB and WHO 2014). Inadequacy of death reporting severely limits the use of VR alone to infer mortality rates from death records. Even deaths that are recorded sometimes have somewhat limited value since medical certification of deaths is often limited and thus, causes of death are not classified or miss-classified.

Verbal autopsy

VR death records can be augmented by *verbal autopsy* (VA), a process whereby a trained health worker interviews a person familiar with the deceased using a structured questionnaire for the purpose of gathering enough health information to determine a probable cause of death. However, VA has significant limitations beyond the obvious fact that it requires substantial time and resources. Although the WHO has developed VA standards as well as an instrument designed for routine use in cases were undocumented or poorly documented deaths require investigation (WHO 2016), considerable variability in VA procedures persist in many settings.

Furthermore, non-standard VA conducted by untrained or inexperienced individuals tends to be highly subjective, risking bias, or miss-classifications of causes of death.

Box 4.2.11 Household survey of essential obstetric and newborn care (ENOC) in Ecuador

A study of the impact of a 3-year intervention intended to improve ENOC availability, accessibility, demand, uptake, and quality in rural Cotopaxi province, Ecuador highlights the utility of household surveys, and the value of combining these data with data collected through other means (Broughton et al. 2016).

Method: Household survey

Women with a child under the age of 24 months were surveyed using a structured questionnaire meant to assess access to and uptake of postpartum and post-neonatal care, knowledge and practices, and patient-reported quality of care at study baseline (2010) and completion (2013). Women in geographic areas known (via census data) to have many households with children were selected by multistage sampling.

Method: Routine health information system

Clinical records at participating facilities were randomly sampled and extracted data were used to assess facility quality of care.

Method: Vital registry

Vital registry data were provided by the provincial government to support evaluation of neonatal mortality for the study.

Researchers found that receipt of postnatal visits and postpartum counselling on newborn care rose, health knowledge increased, quality of care improved, and newborn mortality declined.

Household surveys

Household surveys may be used to collect a broad range of data both as a means of regular surveillance and as a method for evaluating health interventions (see for example Box 4.2.11). *Household surveys* are a relatively common way of collecting demographic, social, wealth, and health data in LMIC as the size and complexity of the survey questionnaire and the size and complexity of the survey sample can be easily scaled up or down according to research needs and resource constraints.

Ideally, household surveys involve multistage or two-stage stratified sampling designs to facilitate generation of a sample that is representative on

a provincial or national level and to facilitate acquisition of data that may be aggregated and disaggregated by sampling stage/geographic area. However, single-stage cluster sampling plans may also be used if two-stage designs are not feasible, this may reduce costs and increase efficiencies in some cases.

To support the conduct of the household surveys, a standardized, structured questionnaire is developed and preferably pilot tested prior to use to ensure the data collected indeed answer the questions being asked in the study, to ensure the language used is easily understood, and to ensure the questions are culturally sensitive. However, although biomarker testing for clinical factors (e.g. anaemia, blood pressure, lead, vitamin A) and communicable diseases (e.g., diabetes malaria, measles, syphilis) has increasingly been included in household surveys in LMIC, information collected by household survey still relies heavily on self-reporting and is therefore subject to recall and social desirability biases.

Routine health information systems

The day-to-day collection of health information at public and private healthcare facilities and institutions is supported by *routine health information systems* (RHIS). A primary goal of RHIS is to provide reliable information that can be used to support health system improvement. As such, RHIS can be used to examine all manner of health indicators related to, for example, healthcare delivery, utilization, and policy implementation. Today, nearly all countries maintain these data repositories albeit in varying levels of completeness, complexity, and compliance. LMIC, especially, tend to have RHIS that operate on a suboptimal level, unable to provide complete and accurate information that is relevant and easily accessible in a timely fashion. Many types of interventions designed to strengthen RHIS have been evaluated, but evidence of effectiveness of these interventions in a range of settings has been mixed (Leon et al. 2015). Furthermore, even the most highly evolved RHIS still has limitations. For example, the creation of RHIS records and the augmentation of those records over time selects for those with more serious symptoms and those more likely to seek care. Many different types of RHIS exist (two examples described as follows), sometimes even within the same LMIC, often created for different purposes, and typically disconnected from each other, which causes fragmentation and reduced access to timely data.

Electronic medical records (EMR) are a system of digital patient records that replaces traditional, paper-based patient charts in clinical settings. This important source of information can shed light on all kinds of health indicators including facility-centric metrics (e.g. healthcare delivery, utilization, cost, and quality metrics) and patient-centric metrics (e.g. mortality, morbidity, and disability metrics). Having a facility-based or health system-based EMR system facilitates horizontal integration and greatly improves the speed with which health indicators can be evaluated. However, implementation of EMR systems in LMIC settings can be challenging and adopting practices for regular use of the data contained within the EMR system to evaluate and improve upon healthcare delivery is often slow and difficult due to constraints on human resource capacity.

Disease-specific information systems are generally developed, implemented, and maintained in response to a major emerging health issue. The structure and degree of complexity of these systems is highly variable as they are often constructed quickly with bare minimum functionality to meet the urgent needs of an acute situation, and then expanded over time.

One example of such a system is China's HIV/AIDS Comprehensive Response Information Management System (CRIMS). Early in China's HIV response, data collection was a highly-fragmented, paper-based, and labour-intensive exercise that was at once incomplete and duplicative—the many international aid organizations and donors who were funding much of China's initial efforts all required different reporting. Health workers, particularly at the local levels, were inundated with paperwork that did not directly serve their main mission, providing and expanding testing, treatment, and care services. This was exacerbated by fragmentation of information at the China Center for Disease Control (China CDC), the public health arm of the central government's Ministry of Health (now called the National Health and Family Planning Commission). The China CDC was maintaining eight different databases for sentinel surveillance, case reporting, treatment, prevention, methadone maintenance treatment (MMT), and other services and indicators. By 2005, the situation had become untenable. It was impossible to understand the epidemic and the effects of epidemic response efforts in a clear and holistic way.

Thus, in 2006, the National Center for AIDS/STD Control and Prevention (NCAIDS, a division of the China CDC) began developing an integrated, national HIV-specific information system, and in 2008, CRIMS was finally launched. CRIMS is a fully-secure, real-time, web-based system that

contains records for all individuals ever diagnosed with HIV in China and all individuals ever enrolled in MMT in China. It was built not only to optimize efficiency for health workers putting information into the system, but also to maximize performance for public health personnel and researchers extracting information out of the system.

The power of the new system in delivering value to health and public health workers and officials, researchers, and policymakers was felt nearly immediately. CRIMS has helped to generate an enormous body of evidence for the development and implementation of numerous important iterative improvements in HIV testing, treatment, care, and prevention programmes and has most certainly had an immeasurable positive impact on the trajectory of China's HIV epidemic (Mao et al. 2010) (see Box 4.2.12).

Box 4.2.12 The human immunodeficiency virus (HIV) care continuum in China

In 2014, the Joint United Nations Programme on HIV/AIDS (UNAIDS) set ambitious targets for the global HIV response to be achieved by the year 2020. These so-called 90-90-90 targets are 90% of those with HIV infection know their status, 90% of those with a confirmed diagnosis on antiretroviral therapy (ART), and 90% of those on ART virologically suppressed (UNAIDS 2014; UNAIDS 2017).

China was a partner in the development of these targets and is supportive of transparent and objective measurement of performance against the targets. In China, this would not be possible without the national HIV/AIDS Comprehensive Response Information Management System (CRIMS) (Ma et al. 2018).

Methods:
A nationwide, biennial cross-sectional study was conducted using CRIMS records from 2005 to 2015 (Ma et al. 2018), and 2017 (NCAIDS 2018). Individuals were categorized based on the definitions in the table. These definitions and the method by which proportions were calculated were consistent with the UNAIDS guidance on the evaluating progress toward the 90–90–90 targets (UNAIDS 2017).

Results:
Consistent improvement in the performance of China's HIV care continuum is shown in Figure 4.2.3. Bars represent the total number of people living with HIV and proportions are presented above the bars. As of the end of 2015, 68% of those estimated to be infected had been diagnosed, 67% of those diagnosed were on ART, and 65% of those on ART were virally suppressed (68–67–65) (Ma et al. 2018), and as of the end of 2017, performance against the targets had again improved to 79–80–91 (NCAIDS 2018).

Category	Number and proportion
Infected	Total number of individuals with HIV infection in China as estimated via a joint effort between UNAIDS, WHO, and China's Health and Family Planning Commission.
Diagnosed	Total number of individuals in CRIMS with diagnosed HIV infection who were still alive at the end of the year. Proportion diagnosed = number diagnosed/estimated number infected.
On ART	Total number of individuals in CRIMS who were receiving ART during the year and were still alive at the end of the year. Proportion on ART = number on ART/number diagnosed.
Suppressed	Total number of individuals in CRIMS who achieved viral suppression during the year and were still alive at the end of the year. Proportion suppressed = number suppressed/number on ART.

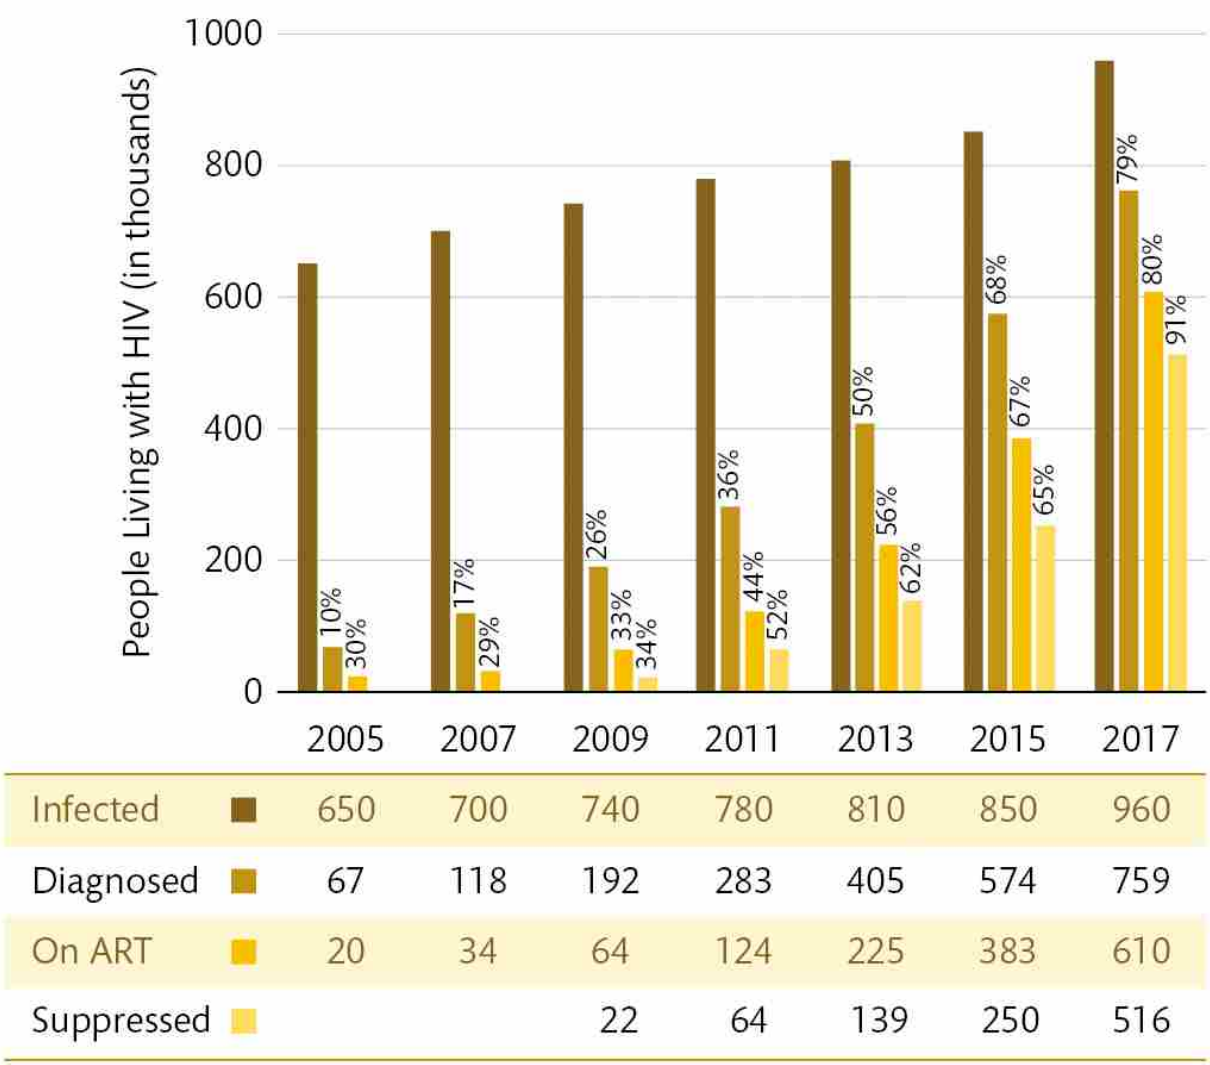

Fig. 4.2.3 Improvement in the performance of China's HIV care continuum.

Source: data from National Center for AIDS/STD Control and Prevention, China CDC. (2018) Annual progress of national HIV/HCV programs in 2017 and priorities and challenges in 2018. Presentation at the National Annual Provincial AIDS Directors Meeting. Ningbo, Zhejiang, China, 19 April 2018.

Key findings made possible by CRIMS

- The performance of China's HIV care continuum has consistently improved since 2005, and by the end of 2017, China had met 'The Third 90' target—90% of those on ART virally suppressed.
- However, China must urgently redouble its efforts in case finding and treatment initiation and retention, especially among those at greatest risk for attrition—adolescents, minorities, and injecting drug users.

HIV care policy implications

- Suboptimal care continuum performance observed from 2005 to 2013 spurred an interventional study and a cluster-randomized clinical trial (Wu et al. 2015, 2017), which provided ample, quality evidence for the individual (i.e. improved mortality rates) and community (i.e. improved viral suppression rates) benefit of streamlining and accelerating the care continuum.
- As a result, China began implementation of a new testing and treatment algorithm intended to drive faster diagnosis and treatment initiation, the effects of which are, at least in part, reflected in the performance of the care continuum in 2017.

Sentinel surveillance systems

When high-quality data on a disease or condition of interest are unavailable through passive channels (e.g. RHISs), other means of identifying health trends and disease outbreaks must be used. *Sentinel surveillance systems* can be a fairly economical method whereby a limited number of reporting units (e.g. hospitals) are carefully selected for their high likelihood of accurately identifying cases and their commitment to promptly report those cases. Sentinel surveillance data can provide estimates of symptom frequency, disease prevalence, incidence, and geographical distribution, and other key indicators, either among a broader population as a whole, or among subpopulations at particular risk.

Geographic information systems

Although spatial mapping of health problems is not new to public health, the development of new technologies and methods for rapidly manipulating enormous datasets has substantially increased our capacity for examining larger problems over larger geographic areas. *Geographic information systems* (GIS) are systems of computer hardware and software that are capable of combining high precision location information with health databases and analysis tools to visualize geographic distributions of health indicators such as morbidity, mortality, prevalence, and incidence related to a particular disease or condition of interest.

Other sources

There are many other sources of important information that can contribute to community diagnosis. These include lot quality assurance sampling, community key informants, risk factor surveillance mechanisms, morbidity

and mortality data, and health system data related to facilities and human resources, as well as service delivery, utilization, and cost.

Health metrics

Communities are diagnosed and changes in health status are measured over time using a wide range of objective health indicators or metrics. However, selecting the appropriate group of metrics is as important as properly measuring performance against them using quality data. Ideally, metrics for the assessment of community health should be (Bilheimer 2010):

Feasible—Performance against the indicator must be measurable. Good-quality, current data required to accurately assess performance against the metric must be available.
Valid—The indicator must be valid, meaning it must actually measure what it was designed to measure. Validation of the method of measurement should be prioritized.
Reliable—Measurement of performance against the metric must be robust enough to be unaffected by the individual doing the measuring. This reduces bias and facilitates comparison of repeated measurements.
Relevant—The indicator must be relevant. It should substantively contribute to improving understanding of the health issue being investigated.
Sensitive—The metric must be sensitive enough to allow detection of meaningful changes in performance against the metric.
Specific—The indicator must be specific enough to reflect changes only in the health issue being investigated.
Actionable—The metric should be actionable at some level—if not at the community level, then at the state/province or national level.
Accessible—The indicator should be accessible, meaning it should be quickly and easily understood by policymakers, health and public health workers, and community members.

Additionally, using metrics that have been used before and have recognized operational definitions can be advantageous. Finally, itis also important to consider the ability to aggregate or disaggregate selected metrics by geography, age group, sex, ethnicity, and perhaps other sociodemographic parameters.

Arguably, individual metrics that do not meet these criteria may be of questionable value. Thus, when considering selection of an indicator that lacks one or more of these characteristics, the benefit of using it should be weighed against the cost of measuring performance against it. However, it would be a rare situation where a single metric would provide sufficient information to adequately assess changes in the health of a community over time. Hence, groups of metrics should generally be selected—each individual metric providing meaningful information on its own and complementary information to other selected metrics, and together as a group of metrics providing a comprehensive assessment that is capable of meeting the needs of the project.

Community diagnosis projects have used a broad range of health metrics to investigate issues of interest (see Box 4.2.13). Since each individual community diagnosis project will have different research questions, each will spend considerable time carefully selecting the group of health metrics that best meet the aforementioned criteria alone, are complementary and comprehensive together, and meaningfully address the issues of interest (Bilheimer 2010).

Box 4.2.13 Health metrics

The following list of health metrics is intended to be neither exclusive nor comprehensive. Rather, it is meant to be a categorized selection of health indicators commonly used in community health projects.

Mortality metrics

- Case fatality rates
- Crude death rates
- Infant/child mortality rates
- Life expectancies
- Maternal mortality rates
- Mortality rates
- Proportionate mortality ratios
- Specific death rates

Morbidity metrics

- Admission/discharge rates
- Attendance rates
- Causes of death
- Disease incidence
- Disease prevalence
- Hospital stay duration rates
- Morbidity rates
- Notification rates

Disability metrics

- Disability-free life expectancy
- Disability rates
- Functional health status
- Lost work/school rates
- Restricted activity rates

Social/mental health metrics

- Accident/injury rates
- Alcohol dependence prevalence
- Mental illness incidence
- Mental illness prevalence
- Substance use prevalence
- Suicide/homicide rates
- Traffic accident rates

Nutritional metrics

- Anthropometrics measurements
- Clinical indicators of nutritional status (e.g. anaemia)
- Low birth weight rates
- Obesity rates

Healthcare delivery metrics

- Cost-effectiveness measures
- Hospital bed/population ratios
- Hospital facility/population ratios
- Physician/nurse ratios
- Physician/population ratios

Healthcare utilization metrics

- Antenatal care attendance rates
- Family planning uptake rates
- Hospital bed occupancy/ turnover rates
- Infant immunization rates
- Oral health attendance rates

Environmental metrics

- Clean water coverage rates
- Food safety indicators
- Pollution measures
- Safe sanitation coverage rates
- Tobacco use rates
- Vector density rates

Socioeconomic metrics

- Family sizes
- Homelessness rates
- Household income
- Housing condition measures
- Literacy rates
- Per capita GDP
- Population change rate
- Poverty rates
- Unemployment rates

Health policy metrics

- Healthcare expenditure per capita
- Proportion of GDP spent on healthcare
- Proportion of total health resources dedicated to primary care

Other metrics

- Basic needs indicators
- Quality of life indicators
- Risk factors for disease/injury

Since the effective use of health metrics to drive active, intentional efforts to improve community health is heavily dependent on the availability of good-quality, timely data, which is a serious challenge in most LMIC, many of the most helpful health metrics may be very difficult, if not impossible, to use in some settings. Thus, there must be some flexibility in the assessment of the value of particular health metrics. Above all, it is critical that a pragmatic and iterative approach to the selection of health metrics in LMIC settings is taken. This may first mean assessing what data are available that meet reasonable standards of completeness, quality, reliability, and timeliness, and using that data to measure what is possible to measure in the short term. Then, assessing what health indicators should be measured, and

developing the information system infrastructure to make it possible to measure what should be measured in the longer term. A few of the health metrics more commonly used LMIC are described in more detail here.

Mortality metrics

A broad range of mortality measures may be used to assess health in communities, all of which rely heavily on VRs, and where vital registration data are incomplete, on census data, household surveys, and health services records. However, since deaths commonly go unreported in LMIC, measures of mortality in these settings can generally be considered underestimates. *Mortality rates* may be calculated overall, or for a specific subgroup within the community (e.g. age group, ethnic group), as the numbers of deaths in a year per unit of population, usually per 1,000 or 10,000. This fairly simple metric is a valuable means of easily understanding health in the community as health must be improving if mortality is declining. Disaggregation of mortality measures by geography, demographic, and socioeconomic factors may offer clues as to how to help improve community health. However, there are many more specific methods of measuring mortality that are also commonly used and standardization of measurement aids comparison across communities and countries.

Maternal mortality ratio (MMR) is the number of maternal deaths per 100,000 live births in one year where a maternal death is defined as the death of a women due to pregnancy or childbirth, during pregnancy, or within 42 days after delivery. Since complications during pregnancy and childbirth are a leading cause of death and disability among women in LMIC, the MMR is an important indicator of women's health. MMR is the subject of the first of the 17 SDG health goal targets—reduce MMR to less than 70 per 100,000 live births by 2030.

Child mortality may be measured in a number of ways and is a good indicator of health among a community's most vulnerable members. Child mortality is usually measured based on specific age-based categories—probability of death within the first month of life (i.e. neonatal mortality), before the first birthday (i.e. infant mortality), before the fifth birthday (i.e. under-5 mortality), and between 5 and 14 years of age (i.e. mortality among children aged 5–14). Neonatal, infant, and under-5 mortality is generally expressed per 1,000 live births, while mortality among children 5–14 is usually per 1,000 children surviving to 12 months of age. Child mortality is

also emphasized in the health SDG as the second of 17 health targets—reduce neonatal mortality to less than 12 per 1,000 live births and under-5 mortality to less than 25 per 1,000 live births by 2030. Although many LMIC are still far from meeting these targets, measurement of child mortality is improving, which should help draw attention to the issue and facilitate development of meaningful interventions (see for example Box 4.2.14).

Box 4.2.14 Perinatal mortality in Kirakira, Solomon Islands

In a study conducted in the remote, provincial Kirakira Hospital, Solomon Islands, stillbirths, and early neonatal deaths in years 2014 to 2016 were examined to evaluate perinatal mortality rate (Jones et al. 2018).

Method: Birth registry and hospital records

A retrospective audit of birth registry and hospital records was conducted for 2014 to 2016. Perinatal deaths were classified as either stillbirths (i.e. infants that failed to breathe independently after birth) or early neonatal deaths (i.e. infants that breathed independently after birth and subsequently died).

Measure: Perinatal mortality rate

Perinatal mortality rate was calculated as the sum of stillbirths and early neonatal deaths divided by the total number of live births expressed per 1,000.

Result: Persistently very high

A mortality rate of 31 per 1,000 live births was observed, double the 12 per 1,000 SDG target rate, and unchanged over the past 6 years.

Although likely an underestimate since only an estimated 28% of deliveries in the province occurred in Kirakira Hospital, this study found that perinatal mortality was twice the figure officially reported previously for the Solomon Islands.

Morbidity metrics

Morbidity encompasses all conditions that are a departure from being healthy, or in a state of physiological and psychological well-being. There are many ways to measure morbidity in a community, many of which focus on data from RHISs. However, VR, VA, household surveys, and sentinel surveillance systems can also be important sources of data for evaluating morbidity metrics. Similar to mortality indicators, morbidity metrics are generally also easy to grasp as community health improves as morbidity

declines and disaggregation by a number of factors may yield clues as to how to help improve health in the community.

Prevalence, or the total number of people living with a particular disease, disability, or injury among a population at a given time (i.e. point prevalence) or within a given time interval (i.e. period prevalence), is a very common measure of morbidity in LMIC since it is fairly easy to measure or estimate. It is also accessible to a broad audience since it is simply expressed as a percentage of the entire population or per some unit of population. For example, in the Russian Federation, the prevalence of chronic hepatitis C Virus (HCV) infection was estimated to be 336 cases per 100,000 people in 2013 (Mukomolov et al. 2016), making it one of the top countries in the world for chronic HCV cases in the world. Prevalence measurement is one of the most straightforward means of evaluating the effect of interventions on burden of disease in a community (see for example Box 4.2.15).

Box 4.2.15 Mali trachoma prevalence

A study conducted the Kayes region of Mali underscores the value of using prevalence measures to evaluate the effects of interventions (Traoré et al. 2018).

Background: Trachoma, an eye disease caused by infection, is the leading cause of preventable blindness globally. Endemic in 41 countries, trachoma has been highly prevalent in Mali's southwestern Kayes region. In 2002, Mali implemented the WHO's comprehensive strategy to combat trachoma that focuses on surgery, antibiotics, cleanliness, and water/sanitation. Three rounds of mass drug administrations occurred prior to 2006, and since 2009, surgical, behavioural, and environmental interventions have been scaled up.

Aim: To evaluate the effectiveness of these interventions by measuring trachoma prevalence in Kayes, Mali in 2015.

Method: The 2015 population of the Kayes region was estimated, using census data, to be 2.5 million. A cross-sectional study using two-stage, cluster random sampling was performed in the four Kayes districts with the aid of village authorities to facilitate data collection via household survey with both questionnaire and medical examination components.

Result: A total of 11,620 people were examined. Prevalence of active trachoma among children aged 1–9 years declined below the 5% elimination threshold in all four districts and prevalence of trichiasis among adults >15 years decreased below the 0.1% elimination threshold in three districts.

Conclusion: Trachoma interventions implemented in Mali have successfully improved community health and Mali is nearing trachoma elimination.

Incidence is the occurrence of new cases of disease, injury, or disability in a population. Generally, it may be measured as either a proportion (i.e. the number of newly identified cases among a population) or a rate (i.e. the number of newly identified cases in a population during a measured quantity

of observed time). While prevalence measures the cumulative total number of cases regardless of the cases being new or old, incidence measures focus solely on new cases. Measurement of incidence tends to be considerably more difficult as it requires long-term observation of a cohort of people, which may be time and resource intensive.

Causes of death, commonly evaluated for a population as a whole, and for adults (age 15 and older) separately from children (age 14 and younger), may also be used as a good indicator of morbidity. VR is the standard source of information for evaluating causes of death. However, as these data are often incomplete in LMIC, they are supplemented with information obtained via VA and health services records. There are a number of ways to look at causes of death. For example, top causes may be ranked by crude death rates either overall or categorized into communicable diseases, non-communicable diseases, injury, and other causes (e.g. maternal, perinatal, nutritional).

Other metrics

There are a great many other indicators that can make important contributions to community health understanding (see Box 4.2.13), which cannot be covered in any depth here. However, careful consideration of metric selection, measurement, and communication is a critical task that must be prioritized early in any community diagnosis effort. Although the limitations in information sources and metrics measurement in LMIC must be recognized, it should not be merely accepted. It is imperative not only that health indicators are pragmatically selected (i.e. select from among metrics that are currently measurable), but also that health information sources are pragmatically developed to achieve the ability to measure health indicators that are important to the future improvement of health in the community they are meant to serve.

Looking forward

There are many good paths forward for community diagnosis and information systems in LMIC. However, to accelerate improvement in community health at any level beyond its current rate, new methods of solving problems and working together toward common goals must be both creative and realistic.

Private–public partnerships for health

Over the past roughly 20 years, some LMIC have engaged in what is now known as international private–public partnerships for health (PPPHs) (Kostyak et al. 2017). This is where a private, for-profit companies (e.g. pharmaceutical companies), typically based in other countries, enter into collaborative relationships with a public, non-profit entities (e.g. national governments) for the purpose of investigating and addressing larger, more expensive public health problems and providing humanitarian aid. These PPPHs can range from the simple, short-term, one-way arrangements (e.g. the pharmaceutical industry has spent billions of US dollars on cash and product donations to LMIC) to the complex, long-term, true partnerships where experience, expertise, and resources are pooled to achieve common health goals that would be out of reach by either party working independently, maximizing benefit to communities while minimizing risk to stakeholders.

The biggest benefits of PPPHs are the acceleration of innovation and research and development and the expansion of access to affordable health interventions. However, many challenges remain. Geopolitical instability and insecurity make private enterprises reluctant to invest in some countries, gains achieved through PPPHs may be unsustainable beyond the funded period, accountability and oversight is often lacking, and ethical questions abound. Profit-driven private companies may not be motivated purely by altruism, may not measure performance or success by unbiased means, and may not ensure conflicts of interest are properly investigated and adjudicated. Creation of guidelines or regulations governing PPPHs and mechanisms to audit compliance, may mean that LMIC entering into these partnerships can better ensure their people reap the full benefit of these relationships (Kostyak et al. 2017).

Multisectoral collaboration

The interconnectedness and indivisibility of the 17 SDGs was recognized by the UN and heavy emphasis has been placed on cross-sector collaboration and partnerships (UN GA 2015). Like many of the SDGs, ensuring healthy lives and promoting well-being for all at all ages (Goal 3) is unachievable by the healthcare sector alone. However, the healthcare sector has traditionally

operated in a very siloed fashion, separated from, for example, the financial sector, the public security sector, the education sector, and others.

All sectors have important, complimentary contributions to make toward achievement of health SDG targets, as well as health goals at regional, national, subnational, and community levels. The untapped potential of multisector collaboration could be a huge difference-maker, particularly for LMIC where this kind of cooperation has perhaps been less common. However, in order to attain full benefit of this kind of coordinated effort, strong leadership is required. Leadership capacity in LMIC must therefore be expanded and not only distributed across sectors, but connected across sectors, to ensure collaboration naturally yields solutions that are inclusive and implementation plans that are practical. Furthermore, it is critical that champions for health 'causes', or targets, are cultivated within the different sectors and they a have clear vision of how each of their pieces of the tactical and strategic work contribute to the larger common goal (Rasanathan et al. 2017).

New technologies

Promising new technologies have the potential to help the field of public health to make more than just incremental steps forward in LMIC. We are only just starting to embark on development of mHealth technologies, and the power of 'big data' is only beginning to be understood and applied. Together with new portable and point-of-care health technologies for clinical diagnosis and evaluation, the possibilities for rapidly collecting enormous data sets from the field and then applying newly emerging data analytics techniques mean global public health is on the precipice of making huge leaps forward.

Conclusion

As an international community, we must renew and redouble our focus on a human-rights based approach to improvement of global public health. One way to do this is through enhancement of community diagnosis in LMIC by helping in the further development of information systems that support the measurement of performance against important and actionable health metrics. Greater sharing across borders of experience and expertise, tools

and protocols, and lessons learned from both failures and successes can accelerate development of robust information systems in these settings. The resulting larger quantities of higher-quality data, properly analysed by reliable and validated methods, can yield invaluable information upon which health and public health authorities, funding agencies, international aid organizations, and policymakers can better base critical decisions related to allocation of limited resources, programme development, and implementation, and application of emergency services. This evidence-based, targeted approach will maximize improvements in health in individual LMIC, which will naturally drive the betterment global public health.

New communication technologies, social media, and public health

Patrick S. Sullivan, Aaron J. Siegler, and Lisa Hightow-Weidman

Introduction

Communication technologies have evolved at a breathtaking pace, and the resulting opportunities to disseminate information and to engage in interpersonal communication have critical implications for public health. These conduits for dissemination of public health content—whether prevention messages, public health advisories or alerts, or clinical or public health guidelines—offer opportunities to reach the right people with the right information more quickly than ever. Considering the public health framework for capitalizing on new communication technologies requires us to consider the technologies themselves, the kinds of content that can be shared, the audiences for such information, and theories of behavioural and systems change. This discussion must also acknowledge that the technology platforms, data speeds, and predominant communications software are heterogenous around the world. In this chapter, we articulate the major dimensions and considerations of the use of new communication technologies for public health, and reflect on important differences in different global public health settings.

Global versus developed country trends in the United States

Two-thirds of the global population are now mobile subscribers with smartphones, accounting for over half of the total connections globally (GSMA Intelligence 2017). According to the International Telecommunication Union, in 2015 there were more than 7 billion mobile

telephone subscriptions across the world, over 70% of which were in low-or middle-income countries (International Telecommunications Union 2015; International Telecommunications Union 2017). However, even though smartphone adoption is near saturated in many developed countries, approximately half the world is not yet online. India and sub-Saharan Africa account for 42% of the world's unconnected, with more than 60% of their respective populations not yet on the internet.

Trends in the United States follow a similar pattern, with the digital divide still seen related to income and geographic locations. Roughly three in ten adults with household incomes below $30,000 a year (29%) don't own a smartphone. More than four in ten with low incomes don't have home broadband services (44%) or a traditional computer (46%) (Pew Research Center 2019). By comparison, each of these technologies is nearly ubiquitous among adults in households earning $100,000 or more a year. Rural Americans also remain less likely than non-rural adults to have home broadband, smartphones, and other devices (Pew Research Center 2019).

eHealth has been a priority for the World Health Organization (WHO) since 2005, when the World Health Assembly resolution WHA58.28 was adopted: 'eHealth is the cost-effective and secure use of information communication technologies (ICT) in support of health and health-related fields, including healthcare services, health surveillance, health literature, and health education, knowledge and research'. The WHO Global Observatory for eHealth (GOe) 2015 survey of Member States documented the surge in adoption of eHealth in countries. All 194 WHO Member States were surveyed, of which 125 responded. Slightly more than half of the countries (n = 73; 58%) reported having an eHealth strategy in place (WHO 2016). Of those countries with an eHealth strategy, 69 (94%) reported that they had special funding allocated for the implementation of their strategy

Phone technology, data speed, data replacing cellular, cost structures

Although fixed-telephone subscriptions continue to decline with a penetration rate of 12.4% in 2018, the number of mobile cellular telephone subscriptions is greater than the global population. In 2018, there were more fixed-broadband connections (1.1 billion) than fixed-telephone connections

(942 million). The number of active mobile broadband subscriptions have increased from 268 million in 2007 to 5.3 billion in 2018. Mobile broadband is more affordable than fixed-broadband services in most developing countries. However, mobile broadband prices represent more than 5% of gross national income (GNI) per capita in most least developed countries (LDCs) and are therefore unaffordable for most of the population. Nearly the entire world population (96%) now lives within reach of a mobile cellular network, and most of the global population (90%) can access the internet through a 3G or higher speed network. Declining cost of smartphones and data plans globally is likely to continue and allow for increased access.

Since the inception of mobile phone service, there has been an ongoing trend towards increasing data speed. Data speeds have increased three orders of magnitude since the introduction of 2G service in 1991; the maximum speed of 5G networks (10 Gbps) are nearly 200,000 times faster than the 2G speeds of three decades earlier. These trends are important, because some public health applications of technology (e.g. streaming videos, transmitting high resolution images, video-based counselling, or situational assessments) require faster data speeds. As is the case for coverage of smartphone technologies, access to higher data speeds has substantial variability along dimensions of urbanicity versus rurality, and between low-/middle-income countries and high-income countries.

Multiple social networking channels, time on social network, generational changes

Social media platforms are ubiquitous globally, with substantial differences in use based on geography and demographics (race, age, gender). Within the United States, those ages 18 to 24 are substantially more likely than those ages 25 to 29 to say they use Snapchat (73% vs. 47%) and Instagram (75% vs. 57%). Roughly three-quarters of Facebook users (74%) visit the site daily, including about half who do so several times a day. Roughly eight in ten Snapchat users ages 18 to 29 (77%) say they use the app every day, including 68% who say they do so multiple times day. Similarly, 76% of Instagram users in this age group visit the site daily, with 60% reporting that they do so several times per day.

Popular social media and messaging platforms like Facebook and WhatsApp have drawn attention for their potential role in spreading

misinformation, facilitating political manipulation, and increasing violence and hate crimes. However, social media may also have a positive impact on the lives of youth. Most teens aged 13–17 (81%) say social media makes them feel more connected to what's going on in their friends' lives, while around two-thirds say these platforms make them feel as if they have people who will support them through tough times.

Need to anticipate technologies that work for youth

According to a 2017 report by ICT, in developed countries, 94% of young people aged 15–24 use the internet, compared with 67% of young people in developing countries and only 30% in LDCs. The proportion of young people aged 15–24 using the internet (71%) is significantly higher than the proportion of the total population using the internet (48%).

Types of social media

Social media channels constitute a dynamic set of applications that are designed to facilitate the circulation and promotion of information through social connections. Because the specific apps delivering these channels evolve over time, we here describe types of channels and their features, and cite current-day examples of these communication types. They vary largely based on the format of information sharing and length of messages, and on the means of sharing through social networks. Subsequently, we will discuss public health applications of these types of communication channels and provide examples of such applications.

Interaction of technology and public health

Technology-based public health services may interact with members of communities, healthcare providers, and policymakers in multiple ways.

Providing information: Websites, including mobile optimized websites, and apps provide static information on a wide range of topics. For example, public health agencies may provide information and guidelines on topics ranging from vaccine recommendations,[1] local and regional HIV prevention and care plans,[2] and Malaria control.[3] Twitter is used by many public agencies to distribute public health alerts (see Fig. 4.3.1a). Formats include

text about health programmes or conditions, infographics (which illustrate data through simple illustrations; see Fig. 4.3.1b).

Providing counselling or navigation: Chat functions and service locators are used by public health providers to distribute information, make referrals for appropriate services, and provide recommendations for service providers nearest to users. For example, PleasePrEPME: Connect is an online programme to promote appropriate use of pre-exposure prophylaxis (PrEP) that offers chat-based navigation for PrEP to US residents.[4] Services include health systems navigation, identifying appropriate providers, and HIV information.

Behavioural change interventions: The concept of providing behaviour change interventions through eHealth or mHealth channels is appealing for many reasons, including the opportunity to reach people in need of behaviour change services who do not live near public health centres, and the opportunity to provide such services at minimal marginal cost through computer-delivered interventions (Sullivan et al. 2013). In general, excitement about the promise of such interventions has been more consistent than rigorous evidence of the interventions themselves (Evers 2006). In fields as diverse as smoking cessation (Augustson et al. 2016; Ponciano-Rodríguez et al. 2018), diabetes prevention (Joiner et al. 2017), medication adherence (Linn et al. 2011), and engagement in health research (Khosropour et al. 2013), results on the efficacy of eHealth interventions have been mixed. However, newer generations of eHealth interventions feature increasingly interactive technologies (Muessig et al. 2015), and recent reports suggest efficacy of theory-based interventions that include multiple sessions, rich media, and interactive components (Mustanski et al. 2018). Meta-analyses suggest that certain types of interventions may be especially well suited to certain health behaviours (e.g. text messaging for smoking cessation and physical activity (Head et al. 2013)).

Identifying service locations: Other service leverage the geolocation features of computers and smartphones to provide tailored recommendations of service locations near to technology users. For example, an online service, PrEPLocator.org, provides tailored referrals to PrEP providers and driving directions to nearest providers (Siegler et al. 2017). Other locator apps or websites include referrals to blood pressure check points (HealthMapNYC.org; see Figure 4.3.1c), and syringe exchange services

(www.nasen.org). AIDSVu.org provides locators for HIV testing, PrEP providers, and HIV treatment (Valdiserri and Sullivan 2018).

Commodity ordering: As people increasingly use technology to order goods and services, public health programmes also have opportunities to use communication technologies to deliver commodities to promote health and prevent new health problems. For example, programmes to deliver home-testing kits for sexually transmitted infections have been highly acceptable. A randomized study of online ordering and mail distribution of STI test kits in London showed a doubling of the rate of STI testing and in the rate of STI diagnoses (Wilson et al. 2017). Similar mailout STI kits have been shown to have high acceptability and completion rate of specimen return among men who have sex with men (MSM) (Mustanski et al. 2017; Siegler et al. 2019a) and women (Gaydos et al. 2006) in the United States.

Data collection/outbreak identification: New communication technologies provide opportunities to collect information for public health action, both through active engagement of users of social media, through data mining of public social media content, and through use of social media content to tailor health interventions. Accessing people to participate in health studies, including surveys, offers opportunities to collect data episodically on geographically diverse populations. For example, the American Men's Internet Survey has collected data on over 10,000 internet-recruited MSM

annually since 2012, and publishes reports on trends in risk and preventive behaviours (Sanchez et al. 2015; Sanchez et al. 2018). The systematic analysis of public postings or search strings can also serve as a crowd-sourced surveillance system. Searches for influenza-related topics have been reported to correlate closely with traditional influenza surveillance systems (Cook et al. 2011), but cannot currently replace other traditional surveillance systems (Olson et al. 2013). Twitter-based systems for detecting outbreaks at large public gatherings (Yom-Tov et al. 2014) and a Twitter-based system for pharmacovigilance have also been evaluated (Freifeld et al. 2014).

Data visualization and access to services: The visualization of data—whether the data arise from social media, new media, or other sources—represents a powerful opportunity to depict the relationship between public health needs and current or future resources. For example, electronic mapping of surveillance data on HIV concentration relative to existing HIV testing facilities has informed the development and implementation of targeted community-based HIV testing programmes (Valdiserri and Sullivan 2018). In a different public health application, geolocation data on the whereabouts of users of a sex-seeking mobile phone app were plotted to identify areas of a city in which sexual health promotion programmes should be targeted (Delaney et al. 2014). In Slovenia, data visualization methods were used to depict the accessibility and availability of public healthcare resources (Lavrač et al. 2007); in the United States, data on public and private PrEP providers were used to illustrate ‘service deserts’, in which residents did not have meaningful geographic access to PrEP services (Weiss et al. 2018).

Drawbacks and public health concerns

Despite the substantial opportunities for public health presented by new communications media, there are also important drawbacks, and it is important to weigh the opportunities and concerns about new media. For example, the anonymous and continual opportunities to comment to and about others has given risk to an epidemic of cyberbullying: by 2008, nearly one in eight teens reported cyberbullying others, and nearly a quarter of teens in the Netherlands reported being cyberbullied (DeHue et al. 2008); being a victim of cyberbullying is reported more often by young women than by young men (Brochado et al. 2017). Internet addiction is also a public

health concern (Young 1998), and has been hypothesized to be associated with depression and obesity (Young 1998; Flisher 2010). WHO has organized a series of meetings on the public health implications of addictive behaviours; gaming addiction has been listed as a mental health condition by the WHO in the ICD-11 revision in 2018 (Reed et al. 2019).

Some mobile apps might also increase behaviours that undermine public health priorities. For example, the rise of dating apps for gay and bisexual men has occurred concurrently with rises in HIV infections (Chapin-Bardales et al. 2018), condomless sex (Hess et al. 2017), and diagnoses of sexually transmitted infections (Abara et al. 2016) among these men. Finally, there are privacy concerns associated with using new communication technologies to facilitate delivery of public health information and services. The transmission of health-related information must be conducted in compliance with recognized standards of security and encryption to avoid disclosure of health-related information. Further, providers of public health services through electronic modes of communication should establish and adhere to policies to limit disclosure of users' health information and secondary or collateral uses of data. For reporting of programme results with geolocating data, suppression schemes should be adopted to prevent indirect identification of users of new media health resources (Sullivan 2020).

Theory relevant to social media

The Diffusion of Innovations theory explores patterns and rates of new technology adoption. The theory posits, and has demonstrated empirical support for, five key attributes of new technologies that enhance their adoption. The *relative advantage of the innovation*, including economic, convenience, or satisfaction, influences it rate of uptake. The *compatibility of a new technology with social values or prior experiences*, and the *perceived complexity* of using it, also influence adoption. Interventions that can be easily tried (*trialability*) and whose impact can be observed (*observability*) are also more likely to have rapid uptake. These intervention traits do not exist in a vacuum, but instead are based upon each individual's values, and therefore are subject to change over time as societal norms and customs shift. For instance, the relative advantage of a social media intervention is likely to shift over time because social media platforms and their usage norms shift. New technology-based interventions to provide

health information may not be competing with calls to a clinician's office, but instead with 'google it up' strategies (Sundstrom 2016). Unlike many intervention theories, Diffusion of Innovations also describes characteristics of those adopting an innovation in order to facilitate targeting of programmes in the most relevant way. Innovators and early adopters (those most likely to first partake of a new technology or opportunity) are characterized by high ability and motivation to adopt. Stable traits of innovators have not been consistently identified, and therefore staging of individuals should be applied to a specific domain of the area of interest, where motivation and ability can be more granularly assessed and targeted (Greenhalgh et al. 2008).

Engagement in the research field, public health engaging with technologies

Public health adoption of interventions and programmes based on new communication technologies calls for engagement between the developers of technologies and public health programmes. Often, the new technologies that will shape public health opportunities are developed by commercial interests. Engagement between technology developers and public health officials is critical. For example, Building Healthy Online Communities[5] is a partnership between the developers of mobile apps for sex seeking and public health constituencies. App owners and developers receive feedback from public health about how to support the health of their users, and researchers gain access to best practices for advertising and targeting app users for public health interventions.

Increasingly, questions emerge about the best ways to implement public health interventions, and this field of inquiry is especially focused on how to implement eHealth interventions—an emerging area for which there are not a large number of historical examples of implementation. The implementation science field of inquiry ideally starts in the stage of design of eHealth interventions, with researchers discussing possible implementation approaches if the intervention proves successful. After efficacy trials or demonstrations of programmes, a second phase of study of implementation practices may occur. For example, after randomized trial evidence that an online intervention reduced rates of new sexually transmitted infections in young gay men (Mustanski et al. 2018), researchers

developed a research-focused protocol to ask about the best ways to implement the intervention in authentic public health settings.[6] The study will compare costs and participant engagement in two delivery models: one model in which the intervention is delivered by a local community-based organization, and a second model in which a single national provider delivers the intervention. These studies also provide further evidence about the performance of interventions in 'real world' public health settings.

Future trends in social media and public health

Current trends suggest that the future will be characterized by decreasing costs of mobile devices, increasing smartphone ownership rates, increasing data speeds, and increasing sophistication of platforms to disseminate content through social media. In one sense, this suggests an opportunity to democratize public health resources using social media as coverage and data speed increase. Simultaneously, computing platforms and artificial intelligence systems will offer new opportunities to analyse large quantities of data and use automated systems to identify emerging public health issues, predict where public health resources might be needed, and provide a broader contextual understanding of health behaviours (Neill 2012).

Another exciting trend is the growth of wearable technologies that can record certain biometric data (e.g. body temperature, heart rate), location, and movement (Patel et al. 2015). These devices offer several avenues to the improvement and evaluation of public health programmes. First, the devices document levels of physical activity, objective measures of which are key to understanding the risks of populations and the impacts of interventions to increase activity. Second, the devices may directly detect certain health conditions (e.g. potential atrial fibrillation), which can both promote early medical intervention and serve as a data source for planning health resources. Third, these devices provide data on the location of individuals. Such data are valuable in considering the locations in which certain health risks might occur, and the related deployment of health interventions. Preliminary studies suggest that people are willing to wear devices and share data to improve the health services offered to them (Duncan 2013). However, these new data streams should prompt careful consideration of how to protect the privacy and medical data of people who wear devices and share data for public health purposes.

Implementation of new communication and social media-based interventions

There are important questions about how public health programmes or interventions based on new communication technologies or social media would be implemented. Current public health delivery systems vary by country and operate in diverse structures, with varying levels of centralized or disseminated public health authority. Regardless, implementation of technology-based programmes or public health systems will require a workforce with specialized skills and facility with both technologies used for social media and public health intervention. The Combined Framework for Implementation Research (CFIR) suggests that we should consider how new technologies will impact public health delivery systems by considering multiple levels of implementation impacts (Damschroder et al. 2009). For example, public health programmes or interventions should be developed in consideration of relative advantage to current solutions, adaptability to diverse public health settings, and cost. Similarly, patient needs and resources and external policies (for example, on data security and data sharing) must be considered. A trained workforce with skills and comfort with requisite technology tools will be required, and champions within all levels of public health systems will be needed to overcome barriers to implementation.

Literacy and preference

There are multiple aspects of literacy and preference that should be considered as technology- and social media-based public health tools are developed and implemented. For example, full benefit from a mobile app to improve behaviours to reduce obesity will be realized only if users possess the technology literacy, health literacy, and linguistic literacy to be able to interact with the app and translate its information and suggestions to appropriate health actions. In turn, these aspects of literacy vary across elements of geography, age, race/ethnicity, and social determinants of health. Not coincidentally, some communities with highest needs for health interventions are also communities that are impacted by poor health literacy, low access to health facilities, poverty, and lack of meaning access to

technologies (e.g. sufficient bandwidth for multimedia tools, monetary resources to pay for data plans). There may be similar 'mismatches' of need and willingness to adopt eHealth tools for older people, who are at increased risk for many chronic health conditions and who, as a group, have lower eHealth literacy (Chesser et al. 2016). There might also be cultural and normative values favouring in-person modes of receiving health advice or services. For example, African American and Latinx patients in a Health Maintenance organization expressed concerns about using electronic modes of communication for health services, citing the lack of technical support for using eHealth tools and concerns about losing personal relationships with providers (Ansari et al. 2010). Such preferences for in-person public health services should both be qualitatively understood in the process of designing new eHealth tools, and should be respected by ensuring that comparable health services are available in traditional settings for those with such preferences.

Opportunities for the use of technology in the conduct of public health studies

Technology offers new opportunities to make the conduct of clinical trials and implementation research more efficient and to allow the collection of rich, granular, and time-, or location-informed data. For example the use of mobile devices is ideally suited to the collection of data as ecological momentary assessments, which aim to assess phenomena as they occur in the environments in which they occur (Stone and Shiffman 1994). Geofencing technology allows for the triggering of messaging or short surveys when the research participant is near a location of interest (for example, triggering data collection when a research subject is near a location of a health service or a risk environment) (Biello et al. 2019). By offering the opportunity to complete short data collections on mobile devices, recall bias can be minimized: for example, an app-based assessment approach to collecting data on condom usage and failure allowed collection of granular data on rates of condom breakage in a study of a new condom type (Siegler et al. 2019b). Other unique opportunities to improve the conduct of trials and granularity of data include incorporating data on activity spaces of participants (Duncan et al. 2014) and the use of paradata—data on the

patterns of technology uses—to enhance understanding of the mediators of effect in evaluating app-based interventions (Bauermeister et al. 2017).

Conclusion

It is tempting to cast the emergence of new communication technologies and social media as unprecedented disruptors of public health strategies. Although it is true that the speed with which these tools and communication channels have emerged is remarkable, public health and medicine have transitioned through many disruptive phases of medical practice and technology. At their core, new communication technologies and social media are new approaches to disseminating information, collecting information, and engaging in dialogue with the people that public health seeks to serve. They will change public health in ways that are incremental and the process of realizing their potential will evince many benefits of using these approaches in public health, and likely also some unintended outcomes.

It is critical to monitor and anticipate that, as with many new technologies, there exists a real possibility that the introduction of new technologies might initially exacerbate health inequities in access to services or in outcomes, because of iniquities in the component elements of access—access to suitable hardware, access to adequate data speed, and access to resources to pay for data access. These inequities must be anticipated and mitigated or avoided. Yet, these technologies also offer special potential to increase the availability of health services to populations who might have less access for reasons of lack of proximity to health facilities or lack of resources to commute within cities.

The growth of new communications media and social media are remarkable challenges and opportunities for public health. Getting the most out of these opportunities will require a willingness for technology developers and public health agencies to work together to leverage emerging capacities. Evaluation of public health new programmes and a commitment to systematically studying implementation methods will yield data to inform rational decisions about how, where, and when technology-based public health programmes and interventions will do the most good.

Epidemiology

The foundation of public health

Roger Detels

Introduction to epidemiology

Epidemiology is the basic science of public health, because it is the science that describes the relationship of health and/or disease with other health-related factors such as human pathogens in human populations. Furthermore, epidemiology has been used to generate much of the information required by public health professionals to develop, implement, and evaluate effective intervention programmes for the prevention of disease and promotion of health, such as the eradication of smallpox, the anticipated eradication of polio and guinea worm disease, and the prevention of heart disease and cancer. Unlike pathology, which constitutes a basic area of knowledge, and cardiology, which is the study of a specific organ, epidemiology is a philosophy and methodology that can be applied to learning about and resolving a very broad range of health problems. It is not enough to know what the various study designs and statistical methodologies are. The ‘art’ of epidemiology is knowing when and how to apply the various epidemiological strategies creatively to answer specific health questions.

The uses and limitations of the various epidemiological study designs are presented in this chapter to illustrate and underscore the fact that the successful application of epidemiology requires more than a knowledge of study designs and epidemiological methods. These designs and methods must be applied appropriately, creatively, and innovatively if they are to yield the desired information. The field of epidemiology has been expanding dramatically over the last three decades, as epidemiologists have demonstrated new uses and variations of traditional study designs and

methods (Pearce 2012). We can anticipate that the scope of epidemiology will expand even more in the future as increasing numbers of creative epidemiologists develop innovative new strategies and techniques.

The chapters in this section present detailed discussions of the principles and methods of epidemiology. In this introductory chapter, I will attempt to define epidemiology, to present ways in which epidemiology is used in the advancement of public health, and finally, to discuss the range of applications of epidemiological methodologies.

What is epidemiology?

There are many definitions of epidemiology, but every epidemiologist will know exactly what it is that he or she does. Defining epidemiology is difficult primarily because it does not represent a body of knowledge, as does, for example, anatomy, nor does it target a specific organ system, as does cardiology. Epidemiology is a scientific strategy/method for studying a health problem that can be applied to a wide range of problems, from transmission of an infectious disease agent to the design of a new strategy for healthcare delivery. Furthermore, this methodology is continually changing as it is adapted to a greater range of health problems and more techniques are borrowed and adapted from other disciplines such as mathematics and statistics.

Maxcy, one of the pioneer epidemiologists of the past century, offered the following definition:

> Epidemiology is that field of medical science which is concerned with the relationship of various factors and conditions which determine the frequencies and distributions of an infectious process, a disease, or a physiologic state in a human community. (Lilienfeld 1978, p. 88)

The word itself comes from the Greek *epi*, *demos*, and *logos*; literally translated, it means the study (*logos*) of what is upon (*epi*) the people (*demos*). John Last, in the *Dictionary of Epidemiology* (Last 2001), has defined epidemiology as follows:

> The study of the distribution and determinants of health-related states or events in specified populations, and the application of this study to the control of health problems.

Last's definition underscores that epidemiologists are concerned not only with disease but also with 'health-related events', and that ultimately epidemiology is committed to control of disease. All epidemiologists, however, will agree that epidemiology concerns itself with populations rather than individuals, thereby separating it from the rest of medicine and constituting the basic science of public health. Following from this, therefore, is the need to describe health and disease in terms of frequencies and distributions in the population. The epidemiologist relates these frequencies and distributions of specific health parameters to the frequencies of other factors to which populations are exposed in order to identify those that may be causes of ill health or promoters of good health. Inherent in the philosophy of epidemiology is the idea that ill health is not randomly distributed in populations, and that elucidating the reasons for this non-random distribution will provide clues regarding the risk factors for disease and the biological mechanisms that result in loss of health.

Because epidemiology usually focuses on health in *human* populations, it is rarely able to provide experimental proof in the sense of Koch's postulates, as can often be done in the laboratory sciences. Epidemiology more often provides an accumulation of increasingly convincing indirect evidence of a relationship between health or disease and other factors. This process, referred to as causal inference (see Chapter 5.14), includes considering an observed relationship in terms of its strength, consistency, specificity, temporality, biological gradient, plausibility, coherence, and experimental evidence (Hill 1965).

Although they will differ on the exact definitions of epidemiology, most epidemiologists will agree that they try to characterize the relationships among the *agent*, the *environment*, and the *host* (usually human). The epidemiologist considers health to represent a balance among these three forces, as shown in Figure 5.1.1.

Changes in any one of these three factors may result in loss of health. For example, the host may be compromised as a result of treatment with steroids, making him or her more susceptible to agents that do not ordinarily cause disease. On the other hand, a breakdown in the water supply system may result in an increased exposure of people to agents such as cryptosporidium, as happened in 1993 in Milwaukee, Wisconsin (MacKenzie et al. 1994).

Finally, some agents may become more or less virulent over time—often because of the promiscuous use of antibiotics—thereby disturbing the

dynamic balance among agent, host, and environment. Two examples are the cases of acute necrotizing fasciitis caused by group A streptococcus (Communicable Disease Surveillance Centre 1994) and the development of multidrug-resistant tuberculosis (Chapman and Henderson 1994).

The epidemiologist uses another triad to study the relationship of agent, host, and environment: *time–place–person*. Using various epidemiological techniques, described in subsequent chapters, the epidemiologist describes disease or disease factors occurring in the population in terms of the characteristics of time (e.g. trends, outbreaks, etc.), place (the geographic area in which the disease is occurring), and person (the characteristics of the affected individuals; e.g. age, gender, etc.) to elucidate the causative agent, the natural history of the disease, and the environmental factors that increase the likelihood of the host acquiring the disease. With this information, the epidemiologist is able to suggest ways to intervene in the disease process to prevent either disease or death.

Epidemiology has been described as the ‘art of the possible’. Because epidemiologists work with human populations, they are rarely able to manipulate events or the environment as can the laboratory scientist. They must, therefore, exploit situations as they exist naturally to advance knowledge. They must be both pragmatic and realistic; they must realize both the capabilities and limitations of the discipline. Morris has said that the ‘epidemiologic method is the only way to ask some questions … one way of asking others and no way at all to ask many’ (Morris 1975, p. 96). The art of epidemiology is to know both when epidemiology is the method of choice and when it is not, and how to use it to answer the question.

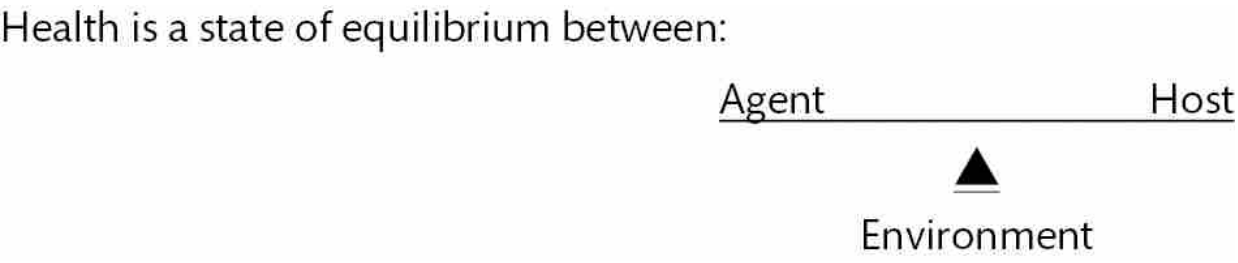

Fig. 5.1.1 The dynamic relationship between agent, host, and environment in epidemiology.

Applying the epidemiological method to resolve a health question successfully can be compared to constructing a memorable Chinese banquet. It is not enough to have the best ingredients and to know the various Chinese cooking methods. The truly great chefs must be able to select the appropriate ingredients and cooking methods to bring out the flavours of each dish, and further, must know how to construct the correct sequence of dishes to excite the palate without overwhelming it. They create a memorable banquet by adding their creative genius to the raw ingredients and the established cooking methods. Similarly, it is not enough for the epidemiologist to know the various strategies and methods of epidemiology; the innovative epidemiologist must be able to apply them creatively to obtain the information needed to understand the natural history of the disease. It is not enough to know what a cohort study is; the epidemiologist must know when the cohort design is the appropriate design for the question at hand, and then must apply that design appropriately and creatively. These skills make epidemiology more than a methodology. It is this opportunity for creativity and innovation that provides excitement for the practitioner and makes the successful practice of epidemiology an art.

For example, Imagawa et al. (1989) identified probable transient HIV-1 infection in men, implying clearance of the virus by the immune system of the men, by focusing their viral isolation studies on the relatively few HIV-1-antibody-negative homosexual men who had the highest numbers of sexual partners; a simple cohort study of antibody-negative individuals would have required a cohort of thousands of men rather than the 133 high-risk men studied. the effects of passive smoking were demonstrated by cohort studies of non-smoking family members of smokers and in nursing students by comparing the reported symptoms in room-mates of smokers and non-smokers who kept diaries of their symptoms: the room-mates of the smokers had a 1.8 greater risk of episodes of phlegm than room-mates of non-smokers (Colley et al. 1974; Tager et al. 1979; Schwartz and Zeger 1990). Tashkin et al. (1984) demonstrated that children of smokers had lower levels of lung function than children of non-smokers. All of these investigators used traditional study designs, but demonstrated their creativity by applying that design to those specific populations which were most likely to reveal a relationship if it existed.

Epidemiological studies rarely provide ‘proof’ of a causal relationship. Thus, there is continuing debate among epidemiologists about what

constitutes adequate criteria for inferring a causal relationship from epidemiological studies (Rothman 1988). Hill (1965) suggested the following minimum criteria for establishing a causal relationship between exposure and consequence/outcome: strength of association (statistical probability and risk ratio), consistency of findings across multiple studies, specificity of the relationship, temporality (outcome follows causation not heuristic), biological gradient (a dose–response relationship), plausibility, coherence (consistency with prior knowledge), experimental evidence, and analogy (relationship hypothesized is similar to that in known relationships). Susser has added to these criteria the ability of the observed relationship to correctly predict other relationships (Rothman 1988). Rothman and Greenland define a cause as 'an event, condition or characteristic that preceded the disease onset and that, if the event, condition or characteristic has been different in a specified way, the disease would not have occurred at all or would not have occurred until sometime later' (Rothman and Greenland 1998, p. 8). The sufficient component cause model defined a sufficient cause as 'a complete causal mechanism' that inevitably produces disease (Rothman and Greenland 1998, p. 8). A minimal set of factors results in an outcome, that is, each factor in a sufficient cause is a component cause and most 'causes' that are the 'causes of interest' in studies are component causes of a sufficient cause. For example, HIV infection can only occur following exposure to the HIV virus (sufficient cause). The exposure to the virus occurs through component causes (unprotected heterosexual intercourse, intravenous drug use). Therefore, a sufficient cause is a minimal set of factors that will cause the outcome. The debate goes on, but the principle is the same: epidemiological studies seldom provide 'proof' of a causal relationship in the sense of Koch's postulates, but may be used to reveal a possible relationship and build a convincing case that this relationship is causal. However, the presence of a relationship does not imply a causal relationship. The 'art' of causal inference assists in distinguishing causal from non-causal relationships (Aschengrau and Seage 2008).

More recently there is increased recognition that disease is not a product of individual circumstances at a given point of time, but rather a product of circumstances over a life course, possibly beginning *in utero* and continuing during a life course (Galea et al. 2010). This includes the complex interactions over time that result in a dynamic up- or down-regulation of

different factors that closely approximates the temporal nature of causality (Galea et al. 2010).

Uses of epidemiology in support of public health

Epidemiology is the basic science of public health because it is the health science that describes health and disease associations in *populations* rather than in individuals, information essential for the formulation of effective public health initiatives to prevent disease and promote health in the community. I have taken the liberty of updating the 'Functions of Epidemiology', first expounded by Morris (1957) and Holland et al. (2007). They are as follows:

Describe the spectrum of the disease: disease represents the end point of a process of alteration of the host's biological systems. Although many disease agents are limited in the range of alterations they can initiate, others, such as measles, can cause a variety of disease end points. For example, the majority of infections with rubeola (measles) virus result in the classical febrile, blotchy-rash disease, but the rubeola virus can also cause generalized haemorrhagic rash and acute encephalitis. Years after initial infection, rubeola can also cause subacute sclerosing panencephalitis (SSPE), a fatal disease of the central nervous system.

Various types of epidemiological studies have been used to elucidate the spectrum of disease resulting from many agents and conditions; for example, cohort studies have been used to document the role of high blood pressure as a major cause of stroke, myocardial infarct, and chronic kidney disease. For rare diseases such as SSPE and multiple sclerosis, case–control studies have been useful to identify the role of the rubeola virus (Detels et al. 1973; Alter 1976). Knowing the spectrum of disease that can result from specific infections and conditions allows the public health professional to design more effective intervention strategies; for example, education, screening, and treatment programmes to reduce the prevalence of high blood pressure will also reduce the incidence of myocardial infarct, stroke, and chronic kidney disease (Hypertension Detection and Follow-up Program Cooperative Group 1979).

Describe the natural history of disease: epidemiological studies can be used to describe the natural history of disease, to elucidate the specific alterations in the biological system in the host, and to improve diagnostic accuracy. For example, cohort studies of individuals who were infected with HIV, the 'AIDS virus', revealed that a drop in the level of T lymphocytes having the CD4 marker was associated with being infected with HIV (Polk et al. 1987), and that a further decline in CD4 cells was associated with developing clinical symptoms and AIDS (Detels et al. 1987). This observation stimulated immunologists to focus their research on the interaction of the immune system and HIV. From a clinical perspective, clinicians can target HIV-antibody-positive individuals who have declining CD4 cells for viral suppressive antiretroviral treatment.

Epidemiology can also be used to describe the impact of treatment on the natural history of disease. For example, a cohort study design was used to demonstrate the public health effectiveness of combined highly active

antiretroviral therapy on reducing the incidence of AIDS and extending survival of those who already had the disease (Detels et al. 1998). Thus, describing the natural history of AIDS among both treated and untreated individuals has assisted researchers to focus their studies and clinicians to use the treatment modalities available more effectively (Phair et al. 1992). The field of 'clinical epidemiology' applies research on the natural history of disease to improving the diagnostic accuracy of physicians in their clinical practice (Sackett et al. 1991).

Community diagnosis: epidemiological surveys are often used to establish the morbidity and mortality from specific diseases, allowing efficient use of limited public health funds for control of those diseases having the greatest negative impact on the health of the community. For example, an epidemiological survey in one area of China identified the epidemic of HIV due to unsafe plasma donations in villages (Wu and Detels 1995; Wu et al. 2001; Ji et al. 2006). The use of disability-adjusted life years (DALYs) has allowed quantification of the importance of non-lethal conditions on the public's health (Murray 1994).

Describe the clinical picture of a disease: epidemiological strategies can identify who is likely to get a disease such as capillariasis, the characteristic symptoms and signs, the extent of the epidemic, the risk factors, and the causative agent, and can help to determine the effectiveness of treatment and control efforts (Detels et al. 1969b).

Identify factors that increase or decrease the risk of acquiring disease: having specific characteristics increases the probability that individuals will or will not develop disease. These 'risk factors' may be social (smoking, drinking), genetic (ethnicity), dietary (saturated fats, vitamin deficiencies), and so on. Knowing these risk factors can often provide public health professionals with the necessary tools to design effective programmes to intervene before disease occurs. For example, descriptive, cross-sectional, case–control, cohort, and intervention studies have all shown that smoking is the biggest single risk factor for ill health, because it is a major risk factor for cardiovascular disease, chronic respiratory disease, and many cancers (e.g. of the lung, nasopharynx, and bladder). Thus, smoking is the leading cause of disability and death in developed countries, if not the world. Health education campaigns and other strategies to stop or reduce smoking, based on these epidemiological studies, are now a major public health activity in most countries of the world.

Identify precursors of disease and syndromes: high blood pressure, a treatable condition, has been identified through case–control and cohort studies as a precursor to heart disease, stroke, and kidney disease (Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure 1997).

Test the efficacy of intervention strategies: a primary objective of public health is to prevent disease through intervention in the disease process. But a vaccine or other intervention programme must be proven effective and safe before it is used in the community. Double-blind placebo-controlled trials are a necessary step in developing an effective intervention programme, whether that programme is administration of a new vaccine, a behavioural intervention strategy to stop smoking, or a community intervention study to lower heart disease. Although it may be argued that injection of a saline placebo is no longer considered ethical, a proven vaccine, such as polio, can often be used as a placebo for a trial of a new vaccine for a different disease, as was used for trials of rubella vaccines in Taiwan (Detels et al. 1969a). Widespread use of an intervention not subjected to epidemiological studies of efficacy may result in implementation of an ineffective intervention programme at great public expense, and may actually result in greater morbidity and mortality because of an increased reliance on the favoured but unproven intervention and a reduced use of other strategies that are thought to be less effective but which are actually more effective.

Although an intervention such as a vaccine may have been demonstrated to have efficacy in double-blind trials, it may fail to provide protection when used in the community. Double-blind trials may demonstrate the ‘biological efficacy’ of the vaccine; but if the vaccine is not acceptable to the majority of the public, they will refuse to be vaccinated, and the ‘public health effectiveness’ of the vaccine will be very low. For example, the early typhoid vaccine provided some protection against small infecting inocula, but the frequency of unpleasant side effects with the whole-cell vaccines and the need for multiple injections in the past influenced many people against being vaccinated (Chin 2000).

Another problem of inferring public health efficacy from small vaccine trials is that volunteers for these trials may not be representative of the general public, which needs to be protected against a specific disease. Thus, broad-based intervention trials also need to be carried out, to demonstrate the

acceptability and public health effectiveness of a vaccine or other intervention to the entire population in need of protection.

As there are adverse effects associated with any vaccine, ongoing evaluations of the cost–benefit relationship of specific vaccines are important. By comparing the incidence of smallpox with the incidence of adverse effects from the smallpox vaccine, Lane et al. (1969) demonstrated that more disease resulted from routine use of the vaccine in the United States than by transmission from imported cases.

There are several epidemiological strategies that can be used for ongoing evaluation of intervention programmes. Serial cross-sectional studies can be used to determine if there has been a change in the prevalence of disease or of indicators of health status over time. The cohort design can be used to compare incidence of disease in comparable populations receiving and not receiving the prevention programme. The case–control design can be used to determine if there are differences in the proportion of cases and non-cases who received the intervention programme.

Investigate epidemics of unknown aetiology: epidemiological strategies were used to establish the extent, cause, modes of transmission, and risk factors for Ebola haemorrhagic fever, which first occurred in the Congo in 1976 (Feldmann et al. 1996; King 2013), and capillariasis in the Philippines in the mid-1960s (Detels et al. 1969b).

Evaluate public health programmes: departments of health are engaged in a variety of activities to promote the health of the community, ranging from surveillance and vaccination programmes to clinics for the treatment of specific diseases. Ongoing evaluation of such programmes is necessary to ensure that they continue to be cost-effective. Periodic review of routinely collected health statistics can provide information about the effectiveness of many programmes. For programmes for which relevant statistics are not routinely available, cohort studies and serial cross-sectional studies of the incidence and changing prevalence of the targeted disease in the populations which are the intended recipients of these programmes can measure whether the programmes have had an impact and are cost-effective. For example, most countries have established sexually transmitted infections (STI) clinics, but studies in Thailand (Prempree et al. 2007) and Beijing (Zhao et al. 2007) have demonstrated that the majority of the patients with STIs do not attend the government STI clinics.

Elucidate mechanisms of disease transmission: understanding the mechanisms of disease transmission can suggest ways in which public health professionals can protect the public by stopping transmission of the disease agent. Epidemiological studies of the various arboviral encephalitides have incriminated certain species of mosquitoes as the vectors of disease and specific animals as the reservoirs for the viruses. For example, public health efforts in California to prevent western equine encephalitis have concentrated on control of the mosquito vector and vaccination of horses, which are a reservoir of the virus. Although an effective vaccine for smallpox had been available for almost 200 years, eradication of the disease was not achieved until the recognition that the low infectivity of varicella virus and the relatively long incubation for development of smallpox could be used to develop a strategy of surveillance for cases, with identification and immediate vaccination of all susceptible contacts (containment). Using this containment strategy based on epidemiological principles, smallpox was eradicated through a worldwide effort in less than 10 years (Fenner et al. 1988).

Elucidate the molecular and genetic determinants of disease progression: epidemiological strategies helped to elucidate the changes in the human immune response by CD4 and CD8 cells that accompany infection and disease progression by disease agents (Detels et al. 1983; Fahey et al. 1984; Ho et al. 1995), and genetic factors (such as CCR5 absence or heterozygosity) that prevent HIV infection and slow progression of HIV disease (Liu et al. 2004).

Implementation science: recently the scientific community and policymakers have recognized the slow rate at which scientific advances are translated into public health policies and medical and public health practice. Thus, there is growing support for identifying and testing strategies that will speed up the process of translating science into action and practice. Epidemiological methods will play an important role in identifying and testing these strategies.

From the examples given in the preceding list, it should be clear that epidemiology functions as the backbone or core of evidence-based public health practices, as well as a key strategy for evaluating the effectiveness of both clinical and public health interventions. As such it is a particularly pertinent instrument for evidence-based policy formulation as well as a tool

for building advocacy and resource justification for rational policies and programmes.

Applications of epidemiology

Specific epidemiological study designs are used to achieve specific public health goals. These goals range from identifying a suspected exposure–disease relationship to establishing that relationship, to designing an intervention to prevent it, and finally, to assessing the effectiveness of that intervention. The usual sequence of study designs in the identification and resolution of a disease problem is as follows:

Ecological studies
Cross-sectional (prevalence) surveys
Case–control studies
Cohort studies
Experimental studies
Adaptive trial design.

There are, however, many exceptions to the application of this sequence of study designs, depending on such factors as the prevalence and virulence of the agent and the nature of the human response to the agent.

The earliest suspicion that a relationship exists between a disease and a possible causative factor is frequently obtained by observing correlations between exposure and disease from existing data such as mortality statistics and surveys of personal or national characteristics. These can be correlations observed across geographical areas (ecological studies) or over time, or a combination of both. Many of the initial epidemiological investigations on chronic bronchitis used vital statistics data, particularly data on mortality. Case–control studies identified smoking as a possible causal factor for chronic bronchitis. Subsequent cohort studies confirmed the relationship. A decline in respiratory symptoms of chronic bronchitis and a concurrent but slower decline in lung function have been observed in individuals who cease smoking (Colley 1991). Using the information obtained from these studies, public health has implemented vigorous antismoking campaigns and has used epidemiology to assess their effectiveness.

Although this is the usual sequence in which the various epidemiological study designs are applied, there are exceptions to this sequence. Furthermore, all study designs are not appropriate to answer all health questions. The usual applications of each of the epidemiological study designs and their limitations are, therefore, presented briefly in this subsection and in greater depth in subsequent chapters.

Ecological studies

The use of existing statistics to correlate the prevalence or incidence of disease in groups or populations to the frequency or trends over time of suspected causal factors in specific localities has often provided the first clues that a particular factor may cause a specific disease. These epidemiological strategies, however, document only the co-occurrence of disease and other factors in a population; the risk factors and the disease may not be occurring in the same people within the population. These types of descriptive studies are inexpensive and relatively easy to perform, but the co-occurrence observed may be merely due to chance. For example, the incidence of both heart disease and lung cancer has increased concurrently with the increased use of automatic washing machines in the United States. Few people, however, would attribute the increase in these two diseases to the use of automatic washing machines. Thus, ecological studies must be interpreted with caution. Nonetheless, they often reveal important relationships and can provide a strong rationale for undertaking more expensive analytic studies (see Chapter 5.2).

Cross-sectional/prevalence surveys

Cross-sectional/prevalence surveys establish the frequency of disease and other factors in a community. Because they require the collection of data, however, they can be expensive. They are useful to estimate the number of people in a population who have disease and can also identify the difference in frequency of disease in different subpopulations. This descriptive information is particularly useful to health administrators who are responsible for developing appropriate and effective public health programmes.

Cross-sectional studies can also be used to document the co-occurrence of disease and suspected risk factors not only in the population but also in specific individuals within the population. The cross-sectional study design is useful to study chronic diseases such as multiple sclerosis, which has a reasonably high prevalence, but an incidence that is too low to make a cohort study feasible (Detels et al. 1978). On the other hand, they are not useful for studying diseases that have a very low prevalence, such as SSPE or variant Creutzfeldt–Jakob disease. Cross-sectional studies are subject to problems of respondent bias, recall bias, and undocumented confounders. Further, unless historical information is obtained from all the individuals surveyed, the time-relationship between the factor and the disease is not known. Also, prevalence surveys identify people who have survived to that time point with disease, and thus, under-represent people with a short course of disease.

The cross-sectional study design is used in two special types of studies: field studies and surveillance. Field studies are usually investigations of acute outbreaks, which require immediate identification of the causative factors if effective public health interventions are to be implemented in a timely fashion. Surveillance is the monitoring of disease- or health-related factors over time and uses serial cross-sectional surveys to observe trends in populations. Surveillance is important to identify diseases that are becoming an increasing public health problem, to assure that diseases already brought under control remain under control, and to evaluate the impact of public health intervention strategies (see Chapters 5.3, 5.4, and 5.17).

Case–control studies

The case–control study compares the prevalence of suspected causal factors between individuals with disease and controls who do not have the disease. If the prevalence of the factor is significantly different in cases than it is in controls, this factor may be associated with the disease. Although case–control studies can identify associations, they do not measure risk. An estimate of relative risk, however, can be derived by calculating the odds ratio. Case–control studies are often the analytic study design used initially to investigate a suspected association. Compared to cohort and experimental studies, they are usually relatively cheap and easy to perform. Cases can often be selected from hospital patients and controls either from hospitalized patients with other diseases or by using algorithms or formulas for selecting

community (neighbourhood) or other types of controls. Selection bias, however, is often a problem, especially when using either hospitalized cases or controls. The participants are seen only once, and no follow-up is necessary. Although time sequences can often be established retrospectively for factors elicited by interview, they usually cannot be for laboratory test results. For example, an elevation in factor B may either be causally related, or it may be a result of the disease process and not a cause. Furthermore, factors elicited from interview are subject to recall bias; for example, patients are often better motivated to recall events than controls because they are concerned about their disease.

The case–control study is particularly useful for exploring relationships noted in observational studies. A hypothesis, however, is necessary for case–control studies. Relationships will be observed only for those factors studied. Therefore, case–control studies are not useful for determining the spectrum of health outcomes resulting from specific exposures, because a definition of a case is required in order to do a case–control study. On the other hand, these studies are the method of choice for studying rare diseases, and are often indicated when a specific health question needs to be answered quickly (see Chapter 5.5).

Cohort studies

Cohort studies follow defined groups of people without disease to identify risk factors associated with disease occurrence. They have the advantage of establishing the temporal relationship between an exposure and a health outcome, and thus measure risk directly. Because the population studied is often defined on the basis of its known likelihood of exposure to suspected factors, cohort studies are particularly suitable for investigating health hazards associated with environmental or occupational exposures. Further, these studies will measure more than one outcome of a given exposure, and therefore, are useful for defining the spectrum of disease resulting from exposure to a given factor. Occasionally, a cohort study is done to elucidate the natural history of a disease when a group that has a high incidence of disease, but in which specific risk factors not previously known, can be identified. Although this cohort is not defined based on a known exposure, questions are asked, and biological specimens are collected from which exposure variables can be identified concurrently or in the future.

Unfortunately, cohort studies are both expensive and time consuming. Unless the investigator can define a cohort in which risk factors were measured at some time in the past and has the assurance that the cohort has been completely followed up for disease outcomes in the interim (historical cohort), this design can take years to decades to yield information about the risks of disease resulting from exposure to specific factors. Ensuring that participants remain in a cohort study for such long periods of time is both difficult and expensive. Further, the impact of those who drop out of follow-up must be taken into account in the analysis and interpretation of these studies. Finally, exposures may vary over time, complicating the analysis of their impact.

Because of the cost and complexity of cohort studies, they are usually done only after descriptive, cross-sectional, and/or case–control studies have suggested a causal relationship. The size of the cohort to be studied is dependent, in part, on the anticipated incidence of the disease resulting from the exposure. For diseases with a very low incidence, population-based cohort studies are usually not feasible, either in terms of the logistics or of the expense of following very large numbers of people, or both. Cohort studies establish the risk of disease associated with exposure to a factor, but do not 'prove' that the factor is causal; the observed factor may merely be very closely correlated with the real causative factor or may even be related to the participants' choice to be exposed.

A variant of the cohort study that has become popular is the 'nested case–control study' (Gange et al. 1997). Cases arising from a cohort study are compared with individuals followed in the cohort who have not developed disease using the usual case–control analytic strategies. The advantage of this type of study is that the exposure variables are collected before knowledge of the outcome, and therefore, are unlikely to be tainted by recall bias (see Chapter 5.6).

Experimental studies

Experimental studies differ from cohort studies because it is the investigator who makes the decision about who will be exposed to the factor based on the specific design factors to be employed (e.g. randomization, matching, etc.). Therefore, confounding factors such as choice that may have led to the subjects being exposed in the cohort studies are usually not a problem in

experimental studies. Because epidemiologists usually study human populations, there are few opportunities for an investigator to deliberately expose participants to a suspected factor. On the other hand, intervention studies of randomly assigned individuals (see Chapter 5.7) or communities (see Chapters 5.8–5.10) to receive or not receive an intervention programme that demonstrates a subsequent reduction in a specific health outcome in the intervention group do provide strong evidence, if not proof, of a causal relationship. Because of the serious implications of applying an intervention that may alter the biological status of an individual or the sociopolitical behaviour of a community, intervention studies should not be undertaken until the probability of a causal or risk relationship has been well established using the other types of study designs. A randomized clinical trial or vaccine trial is a typical example of an experimental study (see Chapters 5.7–5.10).

Meta-analysis

Because individual epidemiological studies rarely provide proof of causation and results of different studies can vary for a number of reasons, including small sample size, a recent trend has been to combine similar studies to increase the power of the analysis. This strategy for data synthesis is known as *meta-analysis*. It has been especially helpful in studying diseases with a low incidence or where similar studies have given conflicting results. But meta-analysis can yield opposite conclusions, especially if different sets of studies are used in the analysis. Meta-analysis investigates and identifies all available studies both quantitatively and qualitatively. The qualitative analysis excludes poor-quality studies that may be considered flawed by the investigators (Aschengrau and Seage 2008). Meta-analysis is prone to heterogeneity problems as different case definitions and different sources of controls cannot be adjusted for in the analysis (Rothman et al. 2008) (see Chapter 5.15).

Adaptive trial designs

Adaptive trial designs provide a way to address uncertainty about choices made during the planning of a study and allow for planned modifications after initiation of the study at pre-specified time points or end points as data

is accumulated within a study (Kairalla et al. 2012). This design provides flexibility and efficiency (smaller sample size) of study designs and increases the likelihood of a 'successful' trial that will yield the outcome of interest. However, improper adaptations can result in study bias. This type of study design can be applied in comparative effectiveness studies (Kairalla et al. 2012).

Methodological issues

Epidemiological studies, because they deal with humans, are subject to problems such as bias (deviation of results from truth), due to the strategies of recruiting participants or to differential recall among persons with and without disease, and confounding, due to factors which are associated with both the exposure variables and outcome variable under study. A cause may combine with another cause to produce an outcome (Susser et al. 2006). For example, a genetic abnormality can be modified by prenatal exposures, resulting in an adverse outcome (e.g. autism) or methylation of key genes. This process is called interaction or effect modification and attempts are made to capture these with statistical measures (Susser et al. 2006). In the last several decades, many new techniques have been developed to reduce the effect of these factors, which can influence the outcome of a study and, in some instances, can cause apparent relationships to be observed which are in fact false (see Chapters 5.12 and 5.13). Because epidemiologic studies rarely meet the criteria of Koch's postulates, care must be taken to infer causality from the results of a study. Recognizing this problem, the field of epidemiology has expanded to develop strategies, methodologies, and guidelines to improve the ability to make causal inferences from epidemiologic studies (Pearl 2016).

Summary

Epidemiology is the core science of public health because it defines health and disease in human populations, describes disease aetiology, and evaluates public health control efforts. It achieves these goals through a variety of strategies and methods. Epidemiology is a dynamic science that is

continually evolving new strategies and methods in support of public health goals.

Cross-sectional studies

Manolis Kogevinas and Leda Chatzi

Introduction to cross-sectional studies

Cross-sectional studies examine the relationship between diseases (or other health-related characteristics) and other variables of interest as they exist in a defined population at a particular point in time. They could be defined as studies taking a snapshot of a society. Synonyms used for cross-sectional studies include prevalence studies and disease frequency studies.

The principal characteristic of cross-sectional studies is that they provide information on the *prevalence* of disease, that is, they include prevalent cases. In cross-sectional studies, exposure and disease are measured at the same point in time but this characteristic is shared by other epidemiological designs, for example, case–control studies. In many cross-sectional studies information on past exposures is not collected but this should not be regarded as a characteristic defining these studies. The outcome measured in cross-sectional studies can be a continuous variable such as blood pressure or forced expiratory volume in 1 second (FEV_1), as compared to a dichotomous outcome measured in case–control studies and, in most occasions, in cohort studies.

As is frequently the case in epidemiology, studies may use mixed designs. For example, a cross-sectional study may measure a biomarker referring to current exposure (e.g. vitamin E), may request information for the past (e.g. use of health services the last year), may identify older and recent cases (e.g. subjects having had asthma in childhood or those having their first attack of asthma in the last few months), and may convert into a cohort study if subjects included in the cross-sectional studies are followed up. The statistical analysis of cross-sectional studies depends on their hybrid design and is frequently similar to that of a case–control study using logistic

regression and calculating (prevalence) odds ratios. Cross-sectional studies are extensively used to measure the prevalence of disease, exposures, or other health-related variables in a population. In these cases, the sample must be representative of the total population.

In this chapter we will first describe the uses of cross-sectional studies in epidemiological and public health research and then discuss methodological issues concerning the design, the main biases of these studies including response rates, and how to improve participation. We will finally discuss issues related to the statistical analysis of cross-sectional studies. Many of these issues are also relevant to other epidemiological designs.

Uses of cross-sectional studies

Cross-sectional studies have been used to evaluate the prevalence of diseases and of health-related variables and also to evaluate the aetiology of diseases. Large, multipurpose, national cross-sectional studies are conducted in several countries for administrative reasons and to provide background documentation on the health status of a population.

National multipurpose surveys

National (or regional) multipurpose surveys are carried out routinely or ad hoc in several countries. The purpose and themes of these surveys are multiple and they may cover different health problems in successive years. The Health Survey in England collects data from a representative sample of approximately 8,000 adults aged 16 and over and of 2,000 children in England (Department of Health 2012). Each year the survey consists of a series of core elements and also includes special topics. In 2012 the core survey covered general health, smoking, drinking, fruit and vegetable consumption, height, weight, blood pressure measurements, and collected blood and saliva samples. Special topics included were cardiovascular disease, hypertension, diabetes, social care, drinking, chronic pain, adult and child obesity, and information on well-being and dental health.

The National Health and Nutrition Examination Survey (NHANES) in the United States is the largest national multipurpose survey and is conducted on a routine basis (Centers for Disease Control and Prevention 2014). The NHANES is a programme of studies designed to assess the health and

nutritional status of the civilian, non-institutionalized population of the United States. The survey examines a nationally representative sample of about 5,000 persons each year and combines interviews and physical examinations.

Results of national health surveys can be used for several purposes, such as the evaluation of the prevalence of health-related behaviours or of symptoms, time trends in risk factors or health symptoms, the identification of causes of disease, and evaluation of health needs. Changes in health problems and risk factors in the population over time can be identified through repeated surveys. Repeated national multipurpose surveys may examine a sample of the same population, but not intentionally the same individuals. Thus, they are particularly useful for assessing changes in the same community, state, or nationally which may have undergone changes due to other factors, such as access to healthcare, population mixes and migration into and out of the community. This type of information may allow health planning through the identification of needs and effectiveness of existing policies and interventions. Time trends in obesity and in levels of toxic substances such as lead in blood are examples of the use of these types of surveys. The prevalence of overweight and obesity has increased in recent years in both children and adults in many countries. Time trends and the effect of socioeconomic status on childhood obesity in the United States were examined using data from two large, nationally representative health surveys and data systems: the 1976–2008 NHANES and the 2003 and 2007 National Survey of Children's Health (NSCH) (Singh and Kogan 2010). The prevalence of overweight and obese children increased significantly in relation to decreased levels of household education and income in both 2003 and 2007 (Fig. 5.2.1). The prevalence of obesity for children with parents having fewer than 12 years of education was 30% in 2007 compared to around 10% for children whose parents had a college degree. In addition the socioeconomic health disparities became wider in the period examined (Fig. 5.2.1).

The existence of a large national database has several advantages for the identification or confirmation of risk factors of a disease. Problems of cross-sectional studies that evaluate risk factors of diseases are discussed in the next section and particularly potential biases from the inclusion of prevalent cases and from frequent lack of information on past exposures. However, the evaluation of a national representative population sample, as is the case in

several multipurpose surveys, has the advantage of capturing a global image of the society including population groups that may be omitted in other types of design. An example provided here is of a study of cleaners based on NHANES. The importance of this study lies, among others, in the fact that domestic cleaners are a population group that is very hard to identify through the usual design strategies.

Information on the population distribution of health problems and risk factors, provide important clues to researchers on the causes of disease and also may confirm previous hypotheses in large population samples. Arif and colleagues used data from the Third National Health and Nutrition Examination Survey (NHANES III) 1988–1994, to evaluate associations between occupation and work-related asthma and work-related wheezing among US workers (Arif et al. 2003). They identified several occupations that were at risk of developing work-related asthma with domestic cleaners and equipment cleaners showing the highest risks. The population attributable risk for work-related asthma was 26%. The study confirmed a previous hypothesis on asthma in cleaners (Kogevinas et al. 1999), provided an evaluation of asthma risk in other occupations in the US population, and also gave an estimate of the burden of occupational asthma.

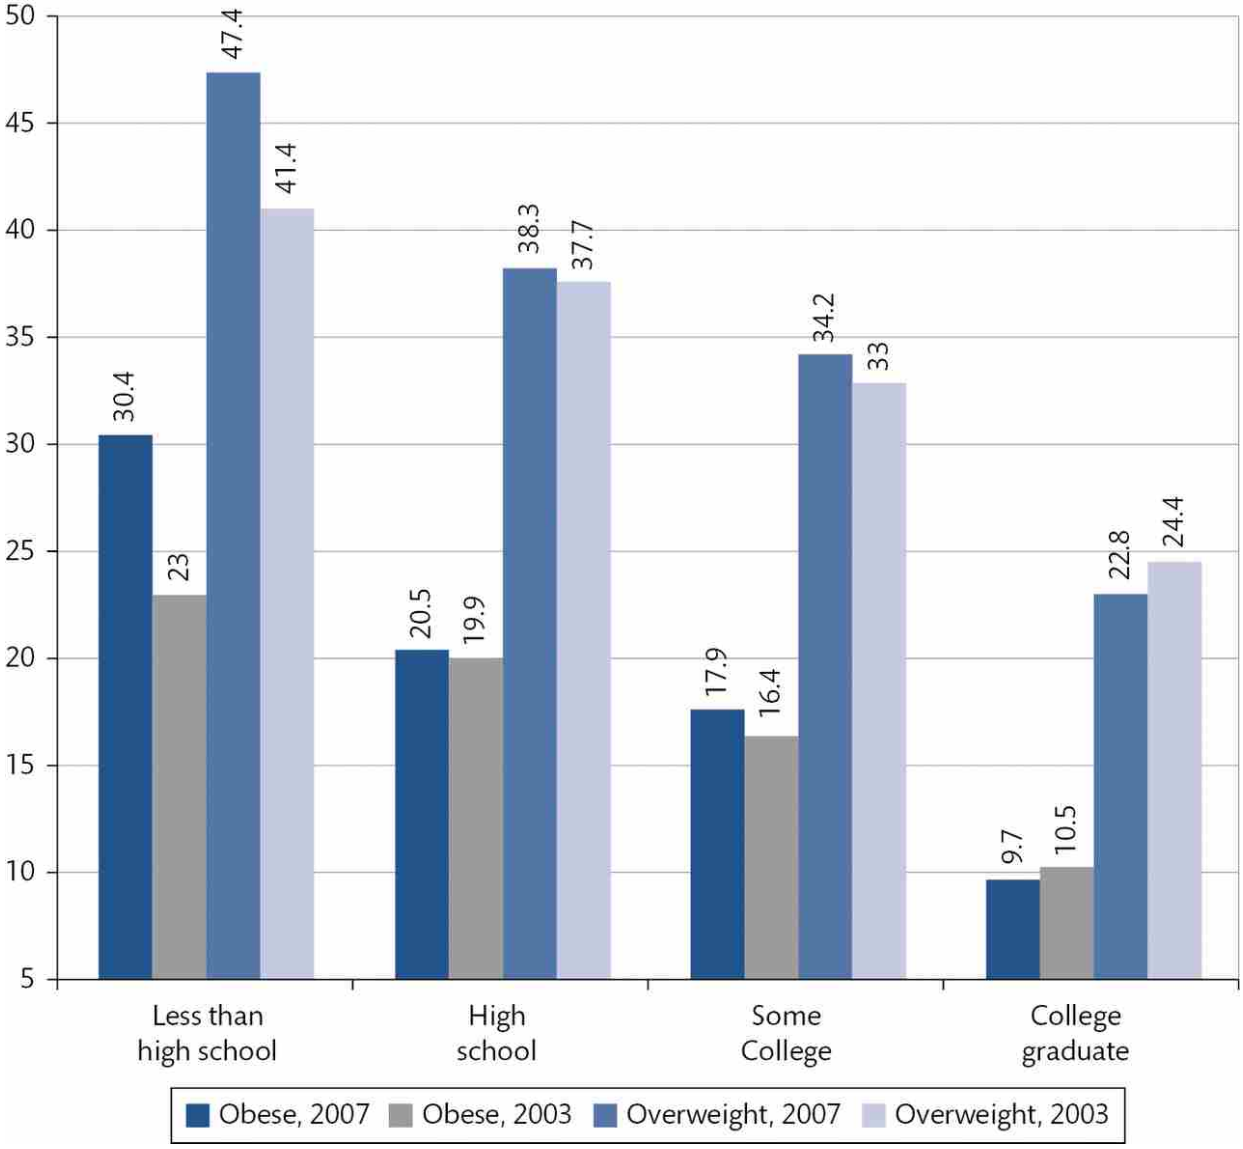

Fig. 5.2.1 Trends in the prevalence of overweight and obese children aged 10–17 years by parental education, United States, 2003–2007.

Reproduced from Singh, G.K. and Kogan, M.D., *Childhood Obesity in the United States, 1976–2008: Trends and Current Racial/Ethnic, Socioeconomic, and Geographic Disparities: A 75th Anniversary Publication*, Health Resources and Services Administration, Maternal and Child Health Bureau, Department of Health and Human Services, Rockville, Maryland, USA, 2010, available at: http://www.hrsa.gov/healthit/images/mchb_obesity_pub.pdf.

By identifying the healthcare needs of the population, government agencies and private sector organizations can establish policies and plan research, education, and health promotion programmes that will help improve present health status and prevent future health problems.

Studies examining the prevalence of disease

Cross-sectional studies are, by definition, the appropriate design to evaluate the prevalence of diseases. An evaluation of the prevalence of a disease may be performed for administrative purposes or for reasons related to the evaluation of aetiological factors. The main issues regarding the conduct of these studies include the representativeness of the sample, the size of the sample, and the measurement of outcomes and exposures. The International Study of Asthma and Allergies in Childhood (ISAAC) is among the largest cross-sectional studies ever done.

The ISAAC study was designed to allow comparisons of the prevalence of allergic disorders in childhood between populations in different countries and their trends over time (Asher et al. 1995). In the early 1990s although it was generally perceived that asthma prevalence was increasing there existed very limited population-based estimates. The study included simple 'core' instruments for measuring the prevalence of allergic disorders, suitable for different geographical locations and languages: (1) written questionnaires on the prevalence and severity of asthma, rhinitis, and eczema for self-completion in 13–14-year-olds, or for completion by parents of 6–7-year-olds; and (2) video questionnaires on the prevalence and severity of asthma for self-completion by 13–14-year-old children. In phase I, children aged 13–14 years were studied in 155 centres in 56 countries (n = 463,801) and children aged 6–7 years were studied in 91 centres in 38 countries (n = 257,800) (Anonymous 1998). Up to 20-fold variations in the prevalence of 'current wheeze' (in the last 12 months) were observed between centres worldwide (range 1.8–36.7%), with a sevenfold variation observed between the tenth and ninetieth percentiles (4.4%; 30.9%). The highest 12-month period prevalences were from centres in the United Kingdom, Australia, New Zealand, and the Republic of Ireland; the lowest prevalences were from centres in Eastern Europe, Albania, Greece, China, Taiwan, Uzbekistan, India, Indonesia, and Ethiopia.

Aetiological research

Cross-sectional studies are particularly valuable for the investigation of the aetiology of non-fatal diseases, degenerative diseases, diseases with no clear point of onset, for example, chronic bronchitis, and effects on physiological variables, as well as for low forced vital capacity (FVC) or elevated liver

enzyme levels. In diseases with no clear point of onset it is difficult to identify incident cases and conduct cohort or incident case–control studies. The prevalence of a disease will be highest if it occurs relatively frequently and if the disease persists in time. A disease could be described as persistent if it is not rapidly fatal and if it does not usually manifest as a transitory condition. Diseases such as asthma and osteoarthritis that have a relatively high prevalence have frequently been examined in cross-sectional studies.

The European Community Respiratory Health Survey (ECRHS) is in many aspects similar in design to ISAAC and was initially conducted as an international cross-sectional study enrolling young adults mainly from European centres to evaluate the prevalence and aetiology of asthma and related diseases (Burney et al. 1994). In an initial screening short questionnaire, the ECRHS included information from around 140,000 individuals from 22 countries. A subsample of the study incorporated extensive questionnaires and measurement of atopic markers, spirometry, and methacholine challenge. The key findings of the study are the large geographical differences in the prevalence of asthma, atopy, and bronchial responsiveness in adults, with high prevalence rates in English-speaking countries and low prevalence rates in the Mediterranean region and Eastern Europe. Analyses of risk factors have highlighted the importance of occupational exposure for asthma in adulthood (Kogevinas et al. 1999). The association between sensitization to individual allergens and bronchial responsiveness was strongest for indoor allergens (mite and cat). Analysis of treatment practices has confirmed that the treatment of asthma varies widely between countries and that asthma is often undertreated (Janson et al. 2001). Subjects were subsequently followed up in a prospective study which included subjects with and without asthma at the initial contact.

Design of cross-sectional studies

Main design issues in cross-sectional studies

The simplest form of a survey in a population is a one-time measurement of the prevalence of a disease (Checkoway et al. 2004). On some occasions, repeated surveys (panel studies) are conducted on the same or different individuals.

When evaluating the prevalence of a disease the sample studied should be representative of the base population from where subjects are recruited (internal validity). The random error of an estimate depends directly on the size of the study and standard techniques exist to calculate this error (e.g. free software such as Epi Info™ (Centers for Disease Control and Prevention (2013)). The measurement of outcomes may be particularly complicated since frequently prevalence studies are conducted for diseases that have a gradual onset and that are not fatal. In addition, problems may occur when comparisons of prevalence are done between countries that may have different systems for the identification of the disease or even different perceptions and oral descriptions of a disease. An example of this is the large prevalence studies conducted for the evaluation of the prevalence of children's asthma such as the ISAAC study (see earlier description). Wheezing is a key symptom defining asthma in childhood. However the perception of what is wheezing is not necessarily the same in different countries and, further, some languages do not have a single word to describe what in English is called 'wheezing'.

Generalizability is another aspect of representativeness and refers to whether the findings in one population can be extrapolated to other populations (external validity). Generalizability is less of a problem when examining risk factors of disease since biological mechanisms through which an agent may provoke disease tend to be similar between populations. Generalizability may be, however, more difficult to ensure when examining prevalence since this may vary considerably within and between populations and extrapolations from one population to another can be problematic.

Panel studies apply a hybrid design that combines cross-sectional and cohort study methods. They are series of cross-sectional studies performed over time on the same group of individuals (measuring, however, prevalence rather than incidence), or in different groups of a population in subsequent time periods. The objective is to evaluate change in health status in relation to changes in exposure. Small groups, or panels, of individuals are followed over short time intervals, and health outcomes, exposure, and potential confounders are ascertained for each subject on one or more occasions. This design is especially useful for the study of physiological variables (i.e. pulmonary function, blood pressure), for which changes over several years may indicate early stages of disease processes. It is also useful to evaluate time trends in the prevalence of a disease.

The third phase of the ISAAC study (ISAAC, phase III) could be regarded as one form of a panel study or serial cross-sectional study. ISAAC-III was a repetition of the phase I survey after 5–10 years to examine time trends in the prevalence of allergic disorders in the same ages in centres and countries that participated in ISAAC phase I. The findings from ISAAC phase III indicate that international differences in asthma symptom prevalence have reduced with decreases in prevalence in English-speaking countries and Western Europe and increases in prevalence in regions where prevalence was previously low. Although there was little change in the overall prevalence of current wheeze, the percentage of children reported to have had asthma increased significantly, possibly reflecting greater awareness of this condition and/or changes in diagnostic practice. The increases in asthma symptom prevalence in Africa, Latin America, and parts of Asia indicate that the global burden of asthma is continuing to rise, but the global prevalence differences are lessening (Pearce et al. 2007).

Panel studies may also evaluate the same individuals before and after an intervention or an exposure. These types of studies have been extensively used in occupational and environmental epidemiology to evaluate changes in symptoms or physiological parameters following an intervention in a workplace or in the general environment such as air pollution. An example is a study that examined the effects of short-term exposure to diesel traffic in 60 adults with asthma (McCreanor et al. 2007). Each participant walked for 2 hours along Oxford Street in London (United Kingdom) and, on a separate occasion, through Hyde Park, London. Physiological and immunological measurements were performed after each occasion. It was found that walking for 2 hours on Oxford Street induced consistent reductions of up to 6.1% in FEV_1 and up to 5.4% in FVC that were significantly larger than the reductions in FEV_1 and FVC after exposure in Hyde Park. Similar changes were also observed for markers of inflammation in the lungs.

Panel studies, particularly when examining the same individuals, could be regarded as prospective studies and frequently this distinction between study designs is blurred. The study in Oxford Street is a crossover study that includes aspects of a prospective experimental design and aspects of a cross-sectional study. The main difference between cross-sectional panel studies and prospective designs is that panel studies examine the prevalence of a disease or a physiological parameter rather than incidence.

Sampling and response rates

Cross-sectional studies aiming to identify the prevalence of a specific factor in a community should select a representative sample of that community. The same is, in principle, desirable in cohort and case–control studies but in these studies the main issue is internal validity rather than external validity (generalizability representativeness). In cohort studies the most important issue concerning subject selection and validity of results is completeness of follow-up. In case–control studies the crucial issue concerning selection of subjects is that cases and controls should be selected from the same study base; whether cases are representative of the general population is, by contrast, not crucial for the internal validity of a case–control study.

In a cross-sectional study, however, representative sampling is the only procedure that allows selection of subjects in a population that can be used as the basis of generalization. A sampling frame should be identified that allows the identification of any subject in a population that could be included in a sample. Different methods can then be applied to select the subjects. Sampling error estimation has been exhaustively addressed in statistics. This depends on the number of subjects included in a study and can be estimated. Non-sampling error refers to bias, and may be of considerably higher importance than sampling error. Enlarging the sample does not reduce non-sampling error. Non-response may be non-random and may, therefore, be related to factors of interest for a study such as education, ethnicity, or obesity.

Response rates and dealing with non-response

A response rate of 60% has been frequently accepted as an adequate response in population surveys. However, the issue of non-response is complex and the acceptance of a fixed percentage as an adequate and probably unbiased response rate is an oversimplification. To some extent, this seems similar to the arbitrary acceptance of $p < 0.05$ as the level for statistical significance (Timothy et al. 2012). There is a general perception, not only among epidemiologists, that it is becoming increasingly difficult in many industrialized countries to achieve high response rates in surveys (Hartge 2006). In an evaluation of 355 original epidemiological papers published in ten high-impact journals, it was found that average participation in epidemiological studies has fallen in the last 30 years and this has

particularly affected controls in population-based studies (Morton et al. 2006). At least some information regarding participation was provided in 59% of cross-sectional studies, 44% of case–control studies, and 32% of cohort studies. In 51 out of 86 cross-sectional studies that reported response rates, the mean participation was 74%, ranging from 28% to 100%. In recent years, response rates among population controls of around 50% are not uncommon. Participation in cross-sectional studies decreased by approximately 1% per year from 1970 to 2003 (Morton et al. 2006).

The use of telephones as a means for defining a sampling frame has been rapidly decreasing. The main assumption for the use of random digit dialling (RDD) was that there was one working residential phone number per household. This assumption is no longer valid due to rapid changes in telecommunication, particularly the use of mobile phones. The rapid increase in the use of mobile phones throughout the world has made nearly impossible the identification of a roster of phones identified to a specific area through which a sample could be derived. In addition, in several countries the use of telephone contacts for commercial reasons has resulted in a decrease of response rates to any such type of contact. Computer-assisted telephone interviews can be a valid and efficient means of collecting information among subjects who have been contacted and agreed to participate.

Studies collecting biological samples

In recent years an increasing proportion of epidemiological studies collect biological samples, following the advances in molecular and genetic techniques and their application in large-scale studies. A recent review of 355 studies identified very high participation rates (above 90%) in cohort and cross-sectional studies collecting biospecimens. However, only about a third of the studies reporting collection of biospecimens also reported response rates for the biological samples. A total of 134 of 355 (38%) articles reported the collection of biological specimens to measure exposure or disease and the proportion of cohort and case–control studies that collected biological specimens increased over time while that of cross-sectional studies remained fairly constant (Morton et al. 2006). Large cross-sectional studies, such as the NHANES, are regularly collecting biological

samples and the inclusion of the collection of biospecimens does not appear to influence the representativeness of the sample.

An increasing number of studies are collecting saliva or other biospecimens by mail. Several studies that have collected saliva samples by mail have obtained response rates that are not very different from those observed for paper-and-pencil questionnaires. In a study on 2,994 subjects at Geneva University, Switzerland, the response rate for subjects requested to provide a mail questionnaire and saliva was 52% while for those requested to complete only the mail questionnaire, it was 63%; using financial incentives increased the response rates by 6–11% (Etter et al. 2005). Sociodemographic factors may affect response rates in such a type of sampling. Self-collection of saliva was evaluated, concerning both response and quality of DNA retrieved in a random sample of 611 men (ages 53–87 years) in Sweden (Rylander-Rudqvist et al. 2006). The response rate was 80% and varied from 89% for those aged 67–71 years to 71% in those aged 77–87 years. Similar to other studies, the DNA extracted was of high quality and could be used as an alternative to blood DNA in molecular epidemiological studies. There is little empirical evidence in several cultures to evaluate general tendencies concerning participation when biospecimens are collected. Whether non-response may differentially affect the analysis of biomarkers is unknown. One study examined a series of genetic data (polymorphisms, haplotypes, and short tandem repeats) from 2,955 individuals of three studies and found no evidence of differential results by participation (Bhatti et al. 2005). A note of caution, however, has been made against assuming that willingness to participate should not vary with a particular polymorphism or other forms of genetic variation (Hartge 2006).

Source: data from Edwards, P. et al., Increasing response rates to postal questionnaires: systematic review, *British Medical Journal*, Volume 324, p. 1183.

Improving non-response

The difficulties in achieving high response rates and the potential biases resulting from self-selection makes indispensable the understanding of the reasons for non-response and the application of methods for limiting non-response. Numerous studies have evaluated factors affecting non-response in epidemiological and other types of studies. Most of the factors frequently identified such as age, sex, education, exposure status, method of recruitment, and type of questionnaire used may also be culture specific. This indicates that, in addition to some general guidelines, there is a need to verify main approaches to increase response in different sociocultural settings, and these may change in different time periods. Nevertheless, some general guidelines can be drawn up based on numerous observational and on randomized trials.

A comprehensive systematic review of available randomized trials from any relevant discipline (not restricted to medicine or epidemiology) evaluated factors that influence response to postal questionnaires (Edwards et al. 2002). Information from 292 randomized controlled trials that included 258,315 participants was reviewed. A total of 75 strategies that could influence response to postal questionnaires were reviewed. The review identified questionnaire length, use of monetary incentives particularly when not conditional on response, appearance of the package, layout of the questionnaire, type of follow-up, and registered delivery as the most influential factors in terms of participation rates. Figure 5.2.2 shows effect estimates for the most influential factors. Contacting participants before sending questionnaires increased response as did follow-up contact. Questionnaires designed to be of more interest to participants were more likely to be returned but questionnaires containing questions of a sensitive nature were less likely to be returned. Questionnaires originating from universities were more likely to be returned than were questionnaires from other sources, such as commercial organizations. Overall, response to postal questionnaires can be improved by following strategies shown to be effective in other research.

Adjusting for non-response

The most important measure to deal with potential biases from non-response is to minimize, as much as possible, the number of non-responders. As already discussed, this is done through selecting adequate ways of contact and through repeated contacts with subjects. Several approaches have been described to evaluate and adjust estimates of prevalence taking into account non-response.

An evaluation of basic characteristics of non-responders is important and may give clues concerning the representativeness of the sample. Such characteristics may be derived from information known for the target population from other surveys, for example, percentage of smokers. They can also be derived from a subsample of non-responders followed up intensively. Estimates of prevalence can then be weighed using the data of respondents but taking into account information on variables known for responders and non-responders such as age, sex, residence, etc.

A usual procedure in prevalence surveys is to perform repeated contacts of subjects to increase response rates. The final estimates are derived from the total number of responders. In an alternative procedure it can be assumed that responders at different mailings or contacts are not representative of the population. Under this assumption, the overall prevalence estimates are modelled using the prevalence of each mailing. A cumulative response at the time of each mailing can be calculated taking into account different covariates (e.g. age, sex) of the samples responding in each mailing, and estimates of the prevalence of non-responders are derived through extrapolation.

Such modelling was conducted analysing responses of 13,007 subjects in the three English centres of the ECRHS (Chinn et al. 1995). Modelling responses to take into account centre, age, and sex had only small effects on estimated prevalence. For example, in Norwich, out of 440 eligible individuals aged 20–24 years, 141 responded to the first mailing (32%), 58 to the second (cumulative response 45.2%), and 45 to the third mailing (cumulative response 55.5%). Prevalence of wheezing was modelled taking into account differences among responders and non-responders by age and sex and this gave an estimated prevalence of wheezing of 25.7%. This estimate was further examined through modelling. In a model that included a parameter for a linear trend in prevalence with each mailing by age and sex group, an overall prevalence of 23.9% was estimated. Overall in this study although several models gave statistically significant differences, in absolute terms the estimates of prevalence derived were rather similar. Such type of modelling is useful to explore the sensitivity of estimated prevalence to non-response bias. However, frequently changes due to such modelling are small and, in general, caution should be exerted when applying such models. In conclusion, the best way of adjusting for non-response is not having much of it.

Item non-response

Apart from the overall response rate the quality of the answers of participants deserves attention as well. The issue of item non-response has been little discussed and usually not reported. What is usually discussed and reported as ‘non-response’ refers to the non-contact with a selected person or the refusal of this person to participate (unit non-response). Failure of a

responder to answer an individual question or provide a sample (item non-response) should also be considered and can equally affect the representativeness of specific analyses in a study. In a study on bladder cancer in Spain, the overall response rate to the main questionnaire was 85%. However, the response to specific items was lower. For example, the questions on lifetime consumption of water and complete information on water quality in each of the residences of the subjects were available for 1,479 (59%) out of a total of 2,490 subjects (Villanueva et al. 2007). An evaluation of differences in sociodemographic characteristics of subjects included or excluded from the water analyses and also differences in the prevalence of known risk factors such as smoking indicated that on this occasion item non-response was not likely to bias results. Exclusion of subjects reduced, however, the statistical power of the study.

The inclusion of several variables in an analysis may result in a large amount of missing data due to item non-response. The pattern of missing data should be examined and, if possible, the causes of missing information determined. Multiple imputations methods are increasingly used to improve efficiency and minimize selection bias. It is frequently assumed that data are missing at random although this is not always easy to identify. Missing values are imputed and a set of complete data sets is generated that are further analysed individually to obtain a set of parameters and then combined into overall estimates (Rubin 1987). Several methods have been proposed to impute missing data and modern software has simplified the analysis of multiply imputed data (White et al. 2011; Cummings 2013).

Sampling methods

Different types of sampling may be applied in cross-sectional studies depending on the aims of the study, characteristics of the population studied, the available background information, and the means available in each study.

In a simple random sample, all subsets of the sampling frame are given an equal probability of being selected. What is used most frequently in large surveys is stratified sampling: this involves a first-stage selection of different categories of the population and subsequent selections at random within each stratum. The main reason for doing stratified sampling is efficiency, so as to secure adequate sampling of small population groups and avoid oversampling of larger groups. Several other probabilistic or non-

probabilistic types of sampling have been applied such as ‘cluster sampling’ in which the unit selected is a group of persons (e.g. a city block) rather than individuals, and ‘snowball sampling’ and ‘respondent-driven sampling’ where a first set of study subjects (‘seed participants’) is used to recruit more subjects into the sample. These latter types are convenience sampling methods that are applied when a complete identification of the primary sampling population is not possible or hard to find (Magnani et al. 2005). Respondent-driven sampling is a variation of snowball sampling that allows a better control of the selection of the population examined, mainly by collecting information from recruiters on the size of their social network and on also on persons approached but who did not participate. The availability of such information, however, does not secure the selection of a random sample from members of a network (Heimer 2005). In addition, respondent-driven sampling is believed to have higher external validity than other convenience sampling methods because it may extend better to all potential members of a network (Magnani et al. 2005). The same approach has been used for the identification of samples for interventions in hard-to-reach populations. For example, respondent-driven sampling was used in a cluster-randomized trial in India to assess the effectiveness of HIV counselling and testing among men who have sex with men (Solomon et al. 2013).

Snowball sampling was applied in a study on the prevalence of depression among female sex workers of eastern Nepal (Sagtani et al. 2013). Snowball sampling is especially useful when the objective is to reach populations that are inaccessible or hard to find. The participants were 210 female restaurant-based and street-based sex workers in five cities of eastern Nepal. In countries like Nepal where commercial sex is illegal, the criminalized status of their work means that commercial sex workers are prone to harassment and violence. Under such conditions, identifying a base population and sampling from this population is impossible. Sex workers were contacted through snowball sampling. The first few respondents were traced with the help of a non-governmental organization working on HIV prevention in the study area. Face-to-face interviews were conducted and additional respondents were nominated. The prevalence of depression among respondents was 82%. A major limitation of this type of sampling is that external validity of the study is questionable due to the unknown sampling frame.

Biased samples are samples where some members of the population are less likely to be included than others. (Note that some stratified samples are deliberately biased but the degree of bias can be estimated.) There are several classic examples of biased sampling. Among the most well-known is a large opinion poll in the US presidential election in 1936 that erroneously predicted that the incumbent president, Franklin Roosevelt, would lose by a large margin. This poll of approximately 2 million persons was based on people who were readers of a magazine, supplemented by records of registered automobile owners and telephone users. The error was produced because the sample overrepresented more affluent people who were less likely to vote for the Democratic candidate.

Examples of different sampling procedures are listed in the following paragraphs, namely sampling in a large multipurpose survey (NHANES) in the United States, a large international prevalence survey (ISAAC), together with a local survey of a difficult-to-identify population of drug addicts in Spain.

The NHANES survey in the United States applies a multistage (four stages) probability sampling to select participants representative of the civilian, non-institutionalized US population (Centers for Disease Control and Prevention 2014). In stage 1, primary sampling units (mostly single counties) are selected. In the second stage, these units are divided up into segments (generally city blocks) and sample segments are selected taking size into account. In stage 3, households within each segment are listed and a sample is randomly drawn. In the final stage, individuals are randomly chosen from a list of all persons residing in the selected households within designated age–sex–race strata. NHANES is designed to sample larger numbers of certain subgroups of particular public health interest including African Americans, adolescents, and others.

In ISAAC, a combination of non-random and random methods was used. The areas participating within each country were not selected at random but instead qualitative criteria and convenience sampling were used. Stratified random sampling was then used within a given geographical area to select the school children. All schools in each geographical area centre were listed and a random sample was selected. The sampling unit was the school and non-participating schools were replaced. All children on a selected school within the two specified age groups (6–7 and 13–14 years of age) were included.

Web-based research and the use of wireless technologies

Web-based research has been expanding in recent years. The Internet has been used in research and clinical settings to enhance contact with participants. Prevalence surveys have traditionally been based on self-administered paper questionnaires, face-to-face or telephone interviews. Internet surveys have been proposed as having advantages compared to traditional approaches, for example, face-to-face or telephone interviews, regarding turnaround time and expenses. Internet-based surveys similar to computer-assisted personal or telephone interviews have advantages concerning data management as compared to paper-and-pencil questionnaires.

The two main issues regarding the validity of use of Internet surveys are response rates and quality of the data collected. Several studies that focused on specific population groups with high indexes of Internet use have found comparable response rates between internet-based questionnaires and more traditional approaches (Pealer et al. 2001). However, many of these studies report response rates for populations recruited through the Internet rather than for population-based samples. These results are therefore difficult to generalize, although they indicate that in specific populations, internet-based surveys provide high-quality data.

Few studies exist that compare population-based data using both Internet and traditional type approaches. Results differ and depend crucially on the degree of education and computer literacy in different cultures, ages, and sociodemographic groups. Women referred for mammography at a Danish public hospital aged less than 67 years and without a history of breast cancer, were randomized to either receive a paper questionnaire, with a prepaid return envelope, or a guideline on how to fill in the internet-based version online (Kongsved et al. 2007). The response rate was 18% for the Internet group compared to 73% for the paper questionnaire. An interesting aspect of this study was that after sending a reminder and offering the possibility of using the alternative questionnaire form (i.e. a paper questionnaire in the Internet group), the response rate for the Internet group became comparable to that of the group assigned the paper questionnaire. In the Millennium cohort (Smith et al. 2007) of military personnel in the United States, a similar proportion of the approximately 70,000 responders chose to respond using the Internet. Web responders were more likely to be male, to be younger, have a higher education, work in technical occupations, to be

obese, and to smoke more cigarettes. They were less likely to be problem alcohol drinkers and to report occupational exposures. Several studies have evaluated quality of information from web-based studies and have found that it is similar to, if not better than, self-administered questionnaires. In the Danish mammography study mentioned earlier (Kongsved et al. 2007), the quality of the information was better in the Internet version with 98% having no missing data compared to 63% filling in a complete paper questionnaire. A study in Sweden (Bonn et al. 2013) compared web-based self-reports of bodyweight with weight measured at the study centre in a convenience sample of 149 individuals. As frequently happens with self-reported weight, overweight subjects (body mass index ≥25 kg/m^2) tended to underreport their weight and the overall mean difference between self-reported and measured weight was −1.2 kg. The Spearman correlation coefficient, however, between self-reported and measured weight was 0.98 ($p < 0.001$) indicating that self-reported weight and perhaps other anthropometric measures via the web can be a valid method of data collection.

The use of wireless technologies and devices is rapidly increasing and it is expected that smartphone technology has become a frequent way to access information in the World Wide Web. The ubiquity of mobile device ownership and the development applications allows new ways of contact and recording of health-related information in population studies. A study in Barcelona used smartphone technology to improve environmental exposure assessment applying novel sensor technologies integrated with mobile phones (de Nazelle et al. 2013). Geographic location and physical activity patterns were tracked through a smartphone application in 36 subjects and were then linked to space–time air pollution mapping for improved air pollution exposure assessment. This information provides an accurate account of mobility of the subjects during the day and of physical activity. Mobile technologies also allow individuals to record and communicate behaviour in real time from any location. A study on 50 trained subjects evaluated the feasibility of using Twitter to capture dietary behaviour and reasons for eating over three consecutive days (Hingle et al. 2013). A list of hashtags representing food groups, for example, #fruit, and reasons for eating, for example, #mood, were provided to participants who were encouraged to annotate hashtags with photos, text, and links. A total of 773 tweets including 2,862 hashtags were reported and eating behaviours were

visualized through ‘maps’ of hashtag co-occurrences suggesting time-varying diet and behaviour patterns.

On the basis of existing evidence it appears that internet-based surveys may provide high response rates in selected populations. In most general populations, however, internet-based surveys do not yet seem to provide adequate response rates and this may lead to selected sampling. Several studies indicate that Internet surveys may be efficiently combined with traditional techniques to save resources and perhaps provide more complete answers. Clearly, more research is needed in the future in population-based surveys to evaluate changes in response in internet-based research as more of the population becomes more technologically savvy. While sensor-based applications in environmental epidemiology have been widely used and have been shown to improve exposure assessment, there is a lack of empirical evidence in public health research concerning the use of popular software applications such as Twitter.

Bias in cross-sectional studies

Cross-sectional studies may suffer from the same potential biases as other epidemiological designs: misclassification, selection bias, and confounding. Issues of particular concern in cross-sectional studies are the potential biases from the mixing of incident and prevalent cases, the frequent lack of information on past exposures and consequently on the time sequence of events, and the lack of representativeness in studies evaluating the prevalence of disease or of other health-related variables. Because of these difficulties, it has been recommended that cross-sectional studies examining the risk factors of disease are appropriate for diseases that produce little disability, and are also appropriate to the presymptomatic phases of more serious disorders (Coggon et al. 1997).

Incidence–prevalence bias (known as Neyman bias; also discussed as length-bias) is a type of selection bias due to the mix of incident and prevalent cases in cross-sectional studies. Incidence– prevalence bias refers specifically to the selection of a case group that is not representative of cases in the community. Figure 5.2.3 (left graph) shows the hypothetical time of occurrence of disease and the duration of disease. A cross-sectional study would include a disproportionately high percentage of cases with long duration while those with more aggressive disease and hence short duration

would have a lower probability of being sampled. The latter is exemplified in Figure 5.2.3 (right graph). A bias would occur if survivors of a condition studied are atypical with respect to the exposure evaluated. If the exposure examined is not directly or indirectly related to survival, inclusion of prevalent cases would not bias any association. In addition, as noted by Hill et al. (2003), for diseases with extremely low case fatality (e.g. rheumatoid arthritis), studies based on prevalent cases are not subject to Neyman bias even if the risk factor under study produces increased mortality from other causes.

The association of smoking with Alzheimer's disease has been discussed as a potential effect of incidence–prevalence bias. Several cross-sectional studies have suggested that smoking exerts a protective effect on Alzheimer's disease. Evidence, however, from a few cohort studies is controversial. A cross-sectional study that included a prospective component suggested that part of the protective effect could be attributed to Neyman bias, specifically because smokers with dementia could have worse survival than smokers without dementia. The study was a population-based cohort of 668 people aged 75–101 years in Sweden (Wang et al. 1999). Smoking was negatively associated with prevalent Alzheimer's disease (adjusted odds ratio = 0.6, 95% confidence interval (CI) 0.4–1.1). Over 3-year follow-up (1989–1992), the hazard ratio of incident Alzheimer's disease due to smoking was 1.1 (95% CI 0.5–2.4). In addition, mortality at follow-up was greater among smokers in demented (hazard ratio = 3.4) than non-demented subjects (hazard ratio = 0.8). The authors concluded that smoking does not protect against Alzheimer's disease and that the cross-sectional association might be due to differential mortality.

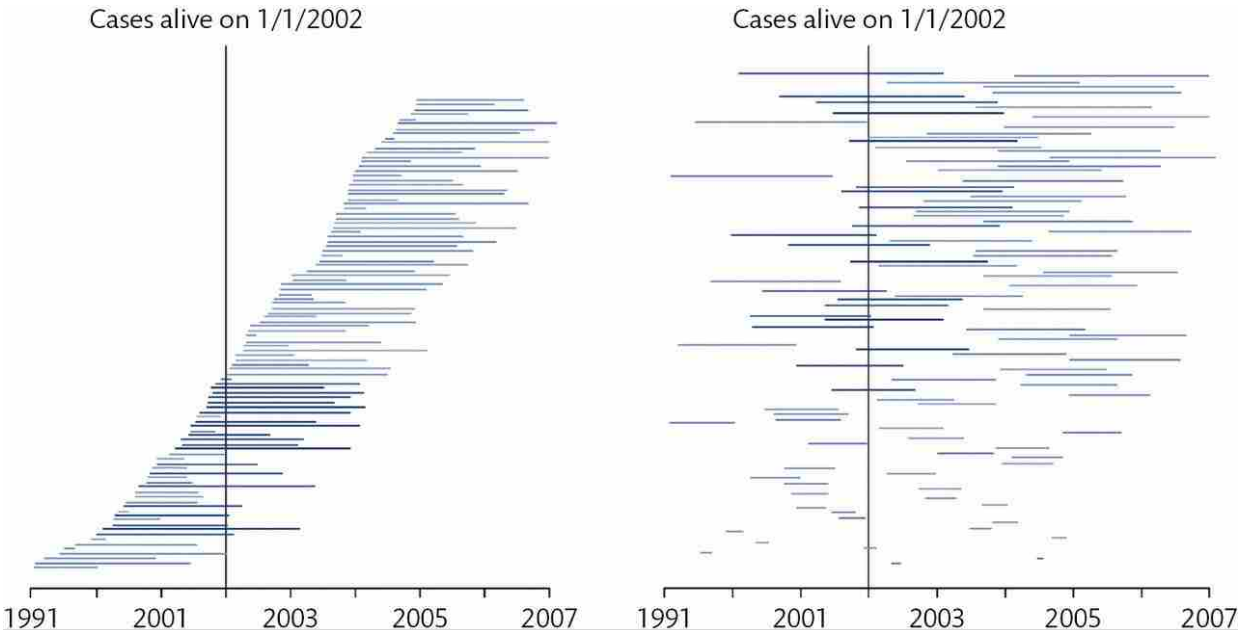

Fig. 5.2.3 Incidence–prevalence bias in cross-sectional studies. Note: the lines on this graph represent the duration of disease with the left end point representing the date that the disease was first diagnosed and the right end point representing the date that the patient died. In the left graph, subjects are ordered by time of initial diagnosis. A cross-sectional study in January 2002 selected those patients who were alive at that time (indicated with vertical line). Notice that patients diagnosed before 2002 with a short survival would have less probability of being selected compared to subjects diagnosed the same period but with a longer survival. In the graph on the right, patients with the shortest survival times appear at the bottom of the graph and the patients with the longest survival times appear at the top. Notice how rarely the patients with short survival times appear among the prevalent cases.
Reproduced from *StATS: Neyman bias* (December 15, 2004), available from http://www.pmean.com/04/NeymanBias.html, licensed under a Creative Commons Attribution 3.0 United States License.

When examining prevalent cases an additional problem may occur if diseased persons modify their exposure or if disease affects measures of exposure, for example, the presence of disease distorting biomarker levels. Treatment with insulin of diabetes mellitus type 1 is an example. Before insulin was available, patients had a very poor survival of less than 1 year. At that time, a cross-sectional study would simply not identify many diabetics. With insulin treatment, survival has spectacularly increased to more than 20 years. A cross-sectional study evaluating diabetes and use of insulin would therefore find an association, simply because diabetics take insulin while non-diabetics do not. This bias has also been described as a type of Neyman bias (incidence– prevalence bias) but in reality it is rather a case of reverse causation provoked by misclassification due to an erroneous evaluation of timing of exposure.

In recent years there has been an increase in the number of studies using data from large surveys such as the NHANES. Experimental data suggest that phthalates, a widespread contaminant, could produce metabolic derangements that may lead to obesity. The association between urinary phthalate metabolites and body mass was examined in a cross-sectional analysis of 2,884 children 6–19 years of age who participated in the 2003–2008 NHANES. Phthalates were measured at one time point and monoesters of phthalates typically have half-lives of around 24 hours. An association of phthalates with childhood obesity was identified among non-Hispanic black children while no significant associations were identified in any other ethnic groups. Making maximum use of a resource such as the NHANES is understandable and advisable given its cost and the population sampling and these findings should lead to additional research. However, making causal inferences from this type of cross-sectional data may be complex. Reverse causation may be a problem in cross-sectional analyses since both physiological aspects and behavioural pathways, for example, restricted mobility of subjects with disease, may influence measured exposures. The London bus drivers' study in the 1950s is a classic example of potential reverse causation.

The study by Jerry Morris on the incidence and prevalence of cardiovascular disease among London bus drivers and conductors (Morris and Dale 1955) is an example of selection bias in a cross-sectional study. Bus drivers in London were shown to have very different lipid profiles, blood pressure patterns, and eventually cardiovascular disease risk compared to bus conductors. Bus drivers were less physically active on the job than conductors, but could the difference in cardiovascular disease risk be ascribed to physical activity? One potential alternative explanation was that some characteristic of the persons such as obesity, could have led to self-selection in a job that was more (bus conductors) or less (bus drivers) active. The studies in London busmen were eventually the first to convincingly demonstrate the importance of physical activity for health.

The healthy worker effect may lead to an underestimation of an association in case–control studies that evaluate occupation and disease at a specific point in time (Checkoway et al. 2004). This happens because workers with health problems at work are more likely to change jobs than subjects without symptoms. In this case the selection is out of the job, contrary to what was a potential problem in busmen. Any cross-sectional

evaluation will, therefore, not capture cases that have occurred in the past and will over-represent healthy individuals who have stayed in the job. An example of this was observed in a cross-sectional study on occupational asthma in Spain (Kogevinas et al. 1996). Subjects were asked about their current occupation and about current respiratory symptoms. The prevalence odds ratios (PORs) for asthma in subjects employed in high-risk occupations was 1.4 with 95% CI of 0.6–3.3. Subjects were also asked whether they had suffered respiratory symptoms in the past and, if yes, what type of job were they doing. The POR for employment in a high-risk occupation at the time of respiratory problems was 2.8 (95% CI 1.5–5.2) indicating that, indeed, the cross-sectional analysis failed to identify health risks due to the selective migration of subjects with respiratory symptoms out of high-risk jobs.

This type of bias is less of a problem if current exposure is a reliable surrogate for past exposure and is not a problem for non-changeable characteristics, for example, race, gender, and genetic variability. Case–control or cross-sectional studies are currently the most widely applied designs evaluating the effects of genetic susceptibility, such as the effects of SNPs (single nucleotide polymorphisms), on disease risk.

Social desirability bias has long been recognized and falls within the wider category of misclassification (Armstrong et al. 1994). Requesting information on behaviours that are regarded as sensitive by respondents may lead to refusal to participate or may lead to a tendency to over-report behaviours regarded as socially desirable (or, what is the same, under-report what is regarded as socially undesirable). This has become particularly evident in recent years in large surveys that inquire into health-related behaviours such as sexual activity and drug use.

There is extensive research showing that self-administered questionnaires lead to more valid information on socially sensitive issues compared to face-to-face interviews (Schuman and Presser 1981; Armstrong et al. 1994). In recent years the use of computers in soliciting information has considerably expanded. In addition to CAPIs (computer-assisted personal interviews) the technique of audio-computer-assisted self-interviewing (ACASI) has been proposed as an efficient method to enhance validity when evaluating behaviours that could be perceived as socially undesirable (Turner et al. 1998). In ACASI (also quoted as audio-CASI), respondents hear the questions through headphones and enter their responses directly into a computer. An experimental comparison of sexual behaviours in adolescent

males using a paper-and-pencil self-administered questionnaire and ACASI identified an almost fourfold increase in the number of respondents reporting male–male sexual contact in the ACASI (5.5%) as compared to 1.5% in the paper-and-pencil questionnaire (Turner et al. 1998). Among the reported advantages of ACASI is that it reduces the literacy requirements of respondents compared to other forms of self-administered questionnaires (paper and pencil or computer assisted). ACASI has been tested in multiple settings and has generally been shown to provide higher estimates of prevalence of socially undesirable behaviours compared to face-to-face interviews (Ghanem et al. 2005). Results are less consistent when comparing ACASI with self-administered questionnaires (Morrison-Beedy et al. 2006). Different computer-assisted methods (audio or text) may have little impact on reported socially undesirable behaviours and the choice of one method over another should be based on an evaluation of wider considerations on the study settings.

Analysis of cross-sectional studies

Prevalence is the ratio/proportion of the number of cases of a disease in a population at a particular time, to the size of the population at that time:

$$\text{Prevalence} = \frac{\text{number of existing cases of disease}}{\text{total population at a point in time}}$$

Point prevalence is estimated at one point in time, while period prevalence denotes the number of cases in a time interval (e.g. 1 year).

For example, in a given state in June 2007, there were 14,000 women with a diagnosis of breast cancer. The total female population in June 2007 was 1,558,000 women. The prevalence of breast cancer in this population on this specific date is 14,000/1,558,000, which equals 0.009 (or 0.9%). This means that nearly 1% of the women in June 2007 had breast cancer, a figure that corresponds to the actual prevalence of this disease in several industrialized countries. This estimate does not show how many new cases of breast cancer occur each year or when the 14,000 women had their disease diagnosed. In these types of estimates it is usually assumed that none of the persons

diagnosed with a chronic disease is entirely cured, although such calculations could be incorporated into the estimation of prevalence.

Prevalence is, strictly speaking, a proportion although it is sometimes indicated, erroneously, as a rate. However, the term ‘prevalence rate’ should be regarded theoretically as an impossible concept (Elandt-Johnson 1975).

Prevalence reflects determinants of incidence as well as survival (duration of a disease). The prevalence of bladder cancer in the United States in January 2004 (377,523 persons alive with a history of bladder cancer) was higher than that of lung cancer (174,880 persons), even though the incidence of lung cancer (81.2 per 100,000) was clearly higher than that of bladder cancer (37.3/100,000). This is a reflection of the much better prognosis of bladder cancer (5-year relative survival rate of 79.5%) compared to 15% for lung cancer (National Cancer Institute n.d.).

In its most simple expression prevalence odds are equal to incidence rate times the duration of the disease:

$$\frac{\mathrm{P}}{1-\mathrm{P}} = 1 \times \mathrm{D},$$

where P is prevalence, I is incidence, and D is duration (survival). This, however, is only true under stable conditions, that is, unchanging rates and population structure that are unlikely in most occasions in true populations. If two populations are compared, say 1 indicating the exposed and 0 the non-exposed, then the POR can be calculated as:

$$\mathrm{POR} = \frac{P_1(1-P_1)I_1D_1}{P_0(1-P_0)I_0D_0}.$$

If the duration of the disease is expected to be equal in the exposed and unexposed, then the POR is equal to the incidence rate ratio (under steady conditions in the population). Under the same conditions, the ratio of prevalences (as compared to the ratio of prevalence odds) will only estimate the incidence rate ratio if the prevalence of the disease is low. In that occasion, 1 − P would be roughly equal to 1.

There has been some controversy whether cross-sectional studies should be calculating POR or prevalence ratios (Thompson et al. 1998; Pearce

2004). The choice of one or the other depends essentially on the purposes of the research, with the POR having advantages compared to the prevalence ratio if aetiological research is conducted. However, the prevalence ratio or probably the absolute difference in prevalences may be preferred if two populations are compared regarding the prevalence of disease.

Statistical analysis in cross-sectional studies is frequently limited to descriptive statistics through the use of standard statistical measures for proportions or a comparison of distributions (e.g. blood pressure) between an exposed and an unexposed group. Standard statistical tests comparing means of a distribution such as Student's *t*-test can be used. For the evaluation of multiple variables, standard techniques such as multiple linear regression can be used. For dichotomous outcomes, the POR is the most common effect measure estimated in cross-sectional studies comparing groups, using logistic regression or equivalent techniques. A wide range of other analytical regression techniques is readily available for the modelling of prevalence ratios (Thompson et al. 1998; Barros and Hirakata 2003). The selection of the effect measure, that is, POR versus the prevalence ratio as the preferred effect measure, should, therefore, not depend on the availability of statistical tools (Pearce 2004), but rather on the objectives of the research.

Summary

Cross-sectional studies are among the most frequently applied designs. The principal characteristic of cross-sectional studies is that they provide information on the prevalence of disease. In many cross-sectional studies information on past exposures is not collected but this should not be regarded as a characteristic defining these studies. On many occasions, cross-sectional studies tend to follow a hybrid design, an analysis incorporating aspects of cohort and of case–control studies. Repeated cross-sectional studies (panel studies) offer the possibility of assessing short-term and long-term physiological changes. Cross-sectional studies are extensively used to evaluate the prevalence of disease. Large cross-sectional studies are conducted in several countries to provide background information on health-related variables including health services use. In recent years these surveys have also incorporated the collection of biospecimens. In aetiological research, cross-sectional studies are suitable epidemiological means for studying non-fatal diseases and effects on physiological variables that do not

have a clear time of onset. However, the design of cross-sectional studies makes them less appropriate than other study designs for investigating causal associations. Among the major limitations of cross-sectional studies are the inclusion of prevalent rather than incident cases and the frequent lack of information on past exposures and on the time sequence of events. The representativeness of the sample is crucial when evaluating prevalence of a disease and several policies have been developed to increase participation in studies, reduce non-response, and improve the quality of the recorded information.

Principles of outbreak investigation

Sopon Iamsirithaworn, Panithee Thammawijaya, and Kumnuan Ungchusak

Introduction to principles of outbreak investigation

Knowledge of medicine and diseases has increased enormously over the last few decades. With the advance of knowledge, public health services in many countries can implement effective prevention programmes, and are able to protect people from many avoidable illnesses and death. However, people around the world still suffer and die from various known and unknown outbreaks of disease. Some outbreaks are old diseases that have re-emerged, some are newly identified or emerging, and some have been deliberately started. Outbreaks can occur anywhere, from a very remote area where no health facility exists to nosocomial outbreaks in a very sophisticated hospital where hundreds of health personnel are employed. Moreover, outbreaks may even spread across borders thereby threatening international health security. It is a challenge for governments and public health professionals of all countries to detect and control these outbreaks as early as possible. Outbreak investigations provide the opportunity to discover new aetiological agents, to understand factors that promote the spread of the diseases, and to identify the weaknesses of existing prevention and health programmes. For these reasons, all public health professionals should have the ability to detect, conduct, and play essential roles in supporting outbreak investigations.

This chapter provides a definition of an outbreak and describes the objectives of outbreak investigation, the methods for planning and conducting an investigation, and what needs to be done after the investigation has been completed. For simplicity, mainly examples of communicable disease investigations are discussed; however, the concepts and principles can also be applied to non-communicable diseases and injuries as well.

What is an outbreak?

The terms *outbreak* and *epidemic* can be used interchangeably. However, most people understand the term *outbreak*, which coveys a greater sense of urgency. Some epidemiologists prefer to use the term *epidemic* only in a situation that covers a very wide geographical area and involves large populations. For example, it is possible to use the term ‘outbreak of HIV’ to describe a sharply increasing human immunodeficiency virus (HIV) prevalence rate among commercial sex workers in a city where the normal rate was low in the previous year. However, the term *HIV epidemic* can be used when an abnormally high HIV prevalence is found among sex workers in many cities of the country.

In general, infectious diseases can be newly emerging but once the disease is able to sustain its transmission in the population of a geographical area we call it an endemic disease. Outbreak is used for a new emerging disease or situation when an endemic disease or health events occur at a greater frequency than normally expected within a specified population, time period, and place. There is often a misunderstanding that only communicable diseases can cause outbreaks. Non-communicable outbreaks such as mass sociogenic illnesses are sometimes reported as acute outbreaks of unexplained illness, especially in school settings (CDC 1990, 1996). Another example of an event that can be called an outbreak and needs investigation is mass casualty. Following a fire in a pub on New Year’s Eve 2009 in Thailand, an unprecedented number of 67 deaths and 153 hospitalizations resulted (Jongcherdchootrakul et al. 2011).

Because the criteria for judging an outbreak can be very subjective, it is useful to define ‘outbreak’ in more measurable terms. The criteria for judging that an outbreak has occurred can be one of the following:

The occurrence of a greater number of cases or events than normally occurs in the same place and during the same period as in past years. An example is detection of influenza outbreaks in the United States. The surveillance data from the 122 sentinel cities provides the seasonal baseline mortality attributed to influenza and pneumonia on a weekly basis, and an influenza outbreak is signalled by a rise of the mortality rates above the epidemic threshold. Another example is the community outbreak of HIV infection among injecting drug users in a rural county in Indiana, USA when 135 persons were tested positive for HIV during January-April 2015, whereas fewer than five cases of HIV infection had been reported annually in this county in previous years (Conrad et al. 2015).

A cluster of cases of the same disease occurs that can be linked to the same exposure. The term *cluster* means aggregations of relatively uncommon events or diseases in space and/or time in amounts that are believed or perceived to be greater than could be expected by chance (Porta 2008). For example, in Denmark during August 2007, the Danish clinical notification system identified many cases of *Shigella sonnei* among employees of two companies. The patients had eaten in their workplace canteen, which were served by the same catering company (Lewis et al. 2009).

A single case of disease that has never occurred before or might have a significant implication for public health policy and practice can be judged as an outbreak that merits investigation. The first documented case of avian flu (H5Nl) in the Hong Kong Special Administrative Region in a 3-year-old boy in May 1997 alerted the local authorities and scientists around the world to start a full-scale investigation (Lee et al. 1999).

How can an outbreak be detected?

Public health professionals need to maintain monitoring or surveillance of the disease situation in their local area or country, and also at the international level. It is possible to identify an outbreak by monitoring many sources of information, which will help to detect the abnormal occurrence of disease or symptom clusters. Some useful sources are listed as follows.

Health personnel

Doctors and nurses in hospitals have a good opportunity to observe an abnormal increase in the number of patients with a particular disease or syndrome. A cluster of food poisoning in a northern province of Thailand was reported to an epidemiologist during a business telephone conversation with his colleague. The epidemiologist started an investigation and identified the first confirmed outbreak of *Clostridium botulinum* food poisoning associated with home-canned bamboo shoots in the country (CDC 1999a). Without this personal contact, the outbreak would not have been investigated. Thus, public health authorities should maintain a cordial relationship with doctors and hospital staff, both in the governmental and private sectors. Conversely, doctors should report all suspected outbreaks to local public health authorities.

Laboratories

Every laboratory or network can serve as a source of support for an outbreak notification. However, it is important that the laboratory be qualified and capable of using state of the art methods. The avian flu outbreak in the Hong Kong Special Administrative Region was first discovered by the Influenza Surveillance Network, which reported an abnormal influenza type A (H5N1) (Lee et al. 1999). Without the necessary laboratory capacity, avian flu might have been overlooked and not have triggered a field investigation. A public health professional should communicate regularly with laboratory technicians and vice versa. Laboratory scientists can prevent further spread if they report abnormal findings to public health authorities regularly and without delay.

Official disease notification systems

Most countries have official systems for notification of cases and deaths of epidemic-prone diseases in hospitals. The systems are designed to detect outbreaks by comparing cases occurring in the current week or month with the average number of cases in the same area during the same period in past years.

For some diseases such as HIV/AIDS, a sentinel surveillance system was designed to monitor and detect abnormal trends in particular sentinel populations and sites. The first HIV sentinel serosurveillance in Thailand,

which started in June 1989, detected HIV prevalence of 44% among commercial sex workers in a popular northern tourist province. This finding was very alarming, and prompted a field investigation to confirm the high prevalence and to look for risk factors of HIV infection among sex workers (Siraprapasiri et al. 1991). The investigation confirmed the outbreak and revealed low levels of condom use, which led to a recommendation for promoting condom use in this high-risk population.

One of the most important functions that epidemiologists and public health professionals perform is regular analyses of reported disease data. Unfortunately, this task has been neglected, and the usefulness of disease reporting systems has been downgraded and often serves only as vital statistics reports. If this neglect of the reporting system can be overcome, the public health system will regain this powerful tool to detect and control outbreaks.

Newspapers and media

Public health professionals learn of outbreaks from the media more often than from the official surveillance system. Newspapers receive outbreak news directly from their reporters or people in the community, and are able to report them immediately. The Programme for Monitoring Emerging Diseases (ProMED), operated as an official programme of the International Society for Infectious Diseases was the prototype for a communication system that monitors emerging infectious diseases globally, which obtains much of its outbreak news from the domestic or international media reports, official reports, online summaries, local observers, and its subscribers. Although timeliness is the strength of the media, the validity of the information is often of concern, so media reports require verification.

Internet and social media

In addition to conventional newspaper and media, people increasingly use internet and social media (such as blogs, Facebook, Twitter, MySpace, etc.) as new ways to connect themselves with their families, friends, colleagues, and the world. Massive amounts of information on those internet blogs and social media are produced and shared extremely quickly, virtually real-time, and therefore create opportunities to epidemiologists and data scientists to

apply advanced data analytics or data mining techniques for detecting and tracking disease outbreaks or hidden health-related phenomena. However, sorting through this massive amount of data presents a real challenge. Although analytical techniques for utilizing internet and social media reports have not been widely utilized by public health organizations or government disease surveillance units, several studies have shown the potential of social media for outbreak detection (Corley et al. 2010; Charles-Smith et al. 2015).

Village leaders, health volunteers, and concerned citizens

In rural areas where there are no health facilities and communication is limited, village leaders or health volunteers can often help to recognize an abnormal increase in the numbers of some clinical diseases, such as diarrhoea, chickenpox, fever with rash, deaths from unknown aetiology both in humans and animals. For example, between 2004 and 2005 there was a nationwide outbreak of avian influenza (H5N1) in poultry. The Thai Ministry of Public Health asked the health volunteers to report any abnormal deaths of poultry in their village to local health officers and the animal health authorities. With these notifications from villagers and a policy to provide compensation to households that lost chickens through culling of the suspected infected flock, Thailand was able to control the highly pathogenic avian influenza outbreak in poultry that then resulted in only 25 human cases.

In many situations, public health officials received outbreak news from concerned citizens and key persons in community networks. Those include teachers, parents, religious leaders, safety officers of factories, etc. who observe a cluster of illnesses in their facilities. Good relationships and regular communications between surveillance officers and the community networks can be great portal to rapidly detect an outbreak in a community.

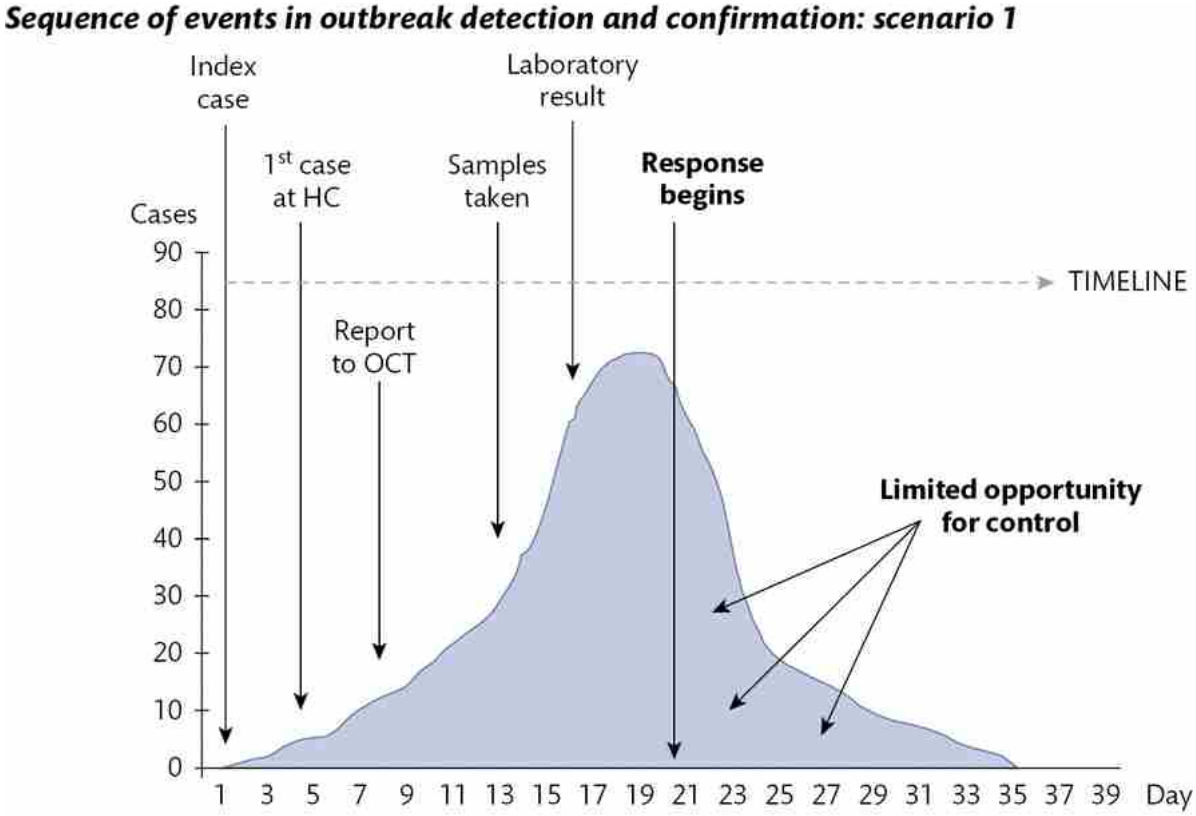
Purposes of outbreak investigation

An outbreak investigation can have many purposes, but the critical ones are as follows.

Controlling the current outbreak

This should be the primary ultimate goal. If the investigation can start early, the findings can guide implementation of appropriate control measures to stop further spread. The avian influenza (H5N1) outbreak investigation found a link between infection and illness in chickens and humans. The same virus was found in both. There were a total of 18 cases and six deaths before the Hong Kong Special Administrative Region decided to kill all of the 1.5 million chickens in the islands within 3 days to end the outbreak (Lee et al. 1999). There have been no human cases in Hong Kong since then. To achieve the goal of controlling the current outbreak, it is necessary to eliminate the delay in detecting the outbreak, to start an investigation as soon as possible, and to immediately implement appropriate preventive and control measures indicated by the investigation results. With early case detection and timely reporting to an outbreak control team, an opportunity of reducing a disease burden is potentially greater following the prompt response (Fig. 5.3.1).

Sequence of events in outbreak detection and confirmation: scenario 1



Sequence of events in outbreak detection and confirmation: scenario 2

Prevention of future outbreaks

Not all investigations start at the beginning or before the peak of the outbreak. The findings or lessons learned from the investigation may be too late to help fully control the current outbreak, but they can still contribute to prevention of future outbreaks. Through sound investigations, the weaknesses of the prevention programmes and/or necessary measures can be identified. If recommendations are taken seriously, the chance of recurrence of the same outbreak or other diseases that share common risk factors can be reduced. There was a thorough investigation of a reported case of a neurological syndrome after eating a common local dish of fish-porridge in Bangkok during October 2002. The investigation revealed that the meat was from puffer fish, which is widely used as a substitute because it is less expensive and easy to obtain from large markets. The result of the investigation was presented to the authorities of the Thai Food and Drug Administration. A new regulation to prohibit selling of puffer fish was enacted to minimize a risk of tetrodotoxin poisoning from puffer fish consumption in the country (Samitsuwan et al. 2005).

Research to provide knowledge of the disease

Information about new diseases and their natural history, clinical spectrum, incubation periods, etc. can often be best learned during an outbreak investigation. Outbreak investigation can help ascertain new information, for example, modes of transmission, population at risk, and so on, and so provide essential information which can significantly contribute to the medical/public health literature. The outbreak of encephalitis in Malaysia, which continued until the end of April 1999 and resulted in 257 cases and 100 deaths, prompted an international outbreak investigation, resulting in the discovery of a new virus, Nipah (CDC 1999b, 1999c). The mode of transmission was close contact with infected pigs through their blood and secretions.

Evaluation of the effectiveness of prevention programmes

Investigation of an outbreak of disease, which is the target of a public health programme, may reveal weaknesses in that programme. Investigation of an outbreak of vaccine-preventable diseases often identifies populations that have not received the vaccine. For example, investigation of a measles outbreak that occurred in 1993 in Espindola, a rural community in the Peruvian Andes, revealed that more than a quarter of the 553 residents were affected, and that more than 3% of those who contracted measles had died. One year before the outbreak, a national measles campaign targeting children younger than 15 years had been conducted. Although national data reported the coverage to be 78%, the investigation revealed that only 4% of the children in Espindola had actually been vaccinated (Sniadack et al. 1999).

Evaluation of the effectiveness of the existing surveillance system

An effective surveillance system should be able to detect a cluster of patients with the same diseases or syndromes. However, outbreaks of diseases under surveillance may emerge without the notice of health officers, especially when there is a shortage of surveillance staff or a change in the surveillance procedure. Some attributes of the surveillance system can be evaluated during an outbreak investigation, such as the timeliness, validity, sensitivity, appropriateness of case definitions, and use of the surveillance information for outbreak detection.

Training of health professionals

The Epidemic Intelligence Service of the US Centers for Disease Control and Prevention (CDC) and 69 field epidemiology training programmes around the world use real outbreaks as an opportunity for training health professionals, as well as to provide emergency services by investigating the causes and determinants of outbreaks. Recommendations and actions taken by these applied epidemiology programmes contributed to a limited scale of outbreaks and improved the health of the public.

Responding to public, political, and legal concerns

In many situations, an investigation must be conducted because the media has publicized the complaints of people to politicians, or even when there are widespread rumours. The main objective for this kind of investigation is to verify the outbreak and diagnosis. If it is groundless, the investigator can supply the media with new information that can end the rumours. Conversely, if it is a true outbreak, investigators must decide what steps need to be taken.

In general, for a real outbreak, many objectives can be achieved fully or at least partially. However, the ultimate goal is to control the current outbreak and to prevent future ones. It is unethical for investigators to compromise this ultimate goal with other goals such as training or non-essential research that does not directly contribute to control activities.

Components of an investigation team

In this chapter, the term *investigators* represents people who are directly involved in planning and conducting outbreak investigations from start to finish. In principle, local health professionals at the district or provincial level should assume the role of investigators and start work as soon as possible. For complicated or difficult field investigations, additional disciplines or international experts can provide assistance. It is best to form an investigation team with a team leader in charge of the operation. A good investigation team should include the following:

A field epidemiologist who is technically competent to conduct field investigations systematically. The field epidemiologist usually serves as one of the primary investigators, and should be involved in all the investigative steps.
Disease control specialists who are experienced in implementing basic disease control measures such as food and environmental sanitation, vector control, and vaccination. If available, an educator who can provide essential knowledge to villagers in clear terms is also very useful for disease control implementation.
Laboratory technicians who are able to provide basic and advanced laboratory support to the investigation team. They might not need to travel to the field and collect the specimens themselves, except when a special collection procedure is required.
Specialists in particular areas (e.g. veterinary medicine) would be very helpful for an outbreak investigation of zoonotic diseases. An entomologist is a key team member for an outbreak investigation of vector-borne diseases.
A social scientist with expertise in qualitative methods can help identify risk behaviours among affected populations and assess the acceptability of the recommended interventions.
Public health administrators who are good at providing logistic support, mobilizing resources, and providing administrative expertise for the team.
In certain situations, when the outbreak has caused panic or has gained the intense attention of the public, the investigation team should recruit or appoint a person to be in charge of public relations and press releases. This person should appropriately reassure and not unduly alarm the public.

In practice, all of these team members are not always available at the subdistrict or district level, due to limited human resources. Public health professionals and field epidemiologists need to have basic knowledge of all these relevant disciplines and be able to assume these tasks if needed. In the event of a technical problem or the need for consultation from the field, telecommunication equipment should be provided to field investigators.

Due to the sudden nature of a field investigation, it is best to establish in advance a list of people who will be on call and are ready to join an investigation team once an outbreak has occurred. Most countries including Thailand developed ‘Rapid Response Teams’ at their appropriate administrative unit for responding to local epidemics and/or public health emergencies. Public health officers of those teams received practical

epidemiology training, and subsequently became frontline armies tracking outbreaks in their local area.

Issues to be considered before implementing an investigation

The team leader should consider all of the following issues before initiating a field investigation.

Assessing the existence of the outbreak

No matter how outbreak news is obtained, an investigator should confirm the validity of the information. The best way is to have direct communication with the responsible local health authority or field staff. It is not unusual for the information to be groundless. Sometimes, the outbreak has in fact occurred, but the media incorrectly quoted the name of the location. The investigator should carefully check with all other possible local health authorities so as not to overlook the outbreak.

Gathering available basic information

If the local health authority or field staff confirm the existence of the outbreak, the investigator should ask for additional information related to the situation and control measures being implemented. It is not necessary to gather all of the following listed information before leaving for the field, but having it will help investigators to plan an effective investigation.

Information related to the disease situation

What are the main symptoms and signs of the patients?
By whom and how was the diagnosis made; for example, using only clinical or also laboratory evidence?
How many patients were seen and how many died?
What was the average age of the patients and were there any differences in gender distribution?
Where did the patients come from? Are they clustered or scattered?
When was the increased number first observed and what is the trend at the moment?

Information related to control and response activities

What has already been done in terms of the field investigation and implementation of control activities?
Are there any serious constraints that compromise the field investigation and/or implementing control measures?
Who are the key people responsible for the investigation and control activities?

Ensuring that clinical specimens and suspected materials are collected in a timely and appropriate manner

It is absolutely critical to contact the doctors who saw the cases and made the diagnosis to obtain relevant clinical specimens such as serum and blood for future laboratory tests. The items to which the cases were exposed, such as food and water, should be collected immediately before anything is unintentionally destroyed or untestable. The investigator should contact the local and reference laboratories so that the necessary supplies and equipment can be obtained immediately.

Obtaining permission and adequate support from local and national authorities

The investigation team should ask the permission of the local health authorities, which will create a sense of shared responsibility and partnership. Usually, local authorities are pleased to receive assistance. In a few situations, the local authority might be unhappy about having outsiders conduct the field investigation because of the sensitive nature of the problem. The investigator needs to convince local authorities that a thorough and sound investigation will incur more benefits than harm. The investigator should also request field support from the key authorities, such as field staff who will facilitate the fieldwork and provide transportation, medication, etc. In some situations, if the outbreak is possibly of international concern spelled out by the International Health Regulations (IHR) (Connolly 2005), the principal investigator should inform national health authorities so they are aware and can plan further necessary steps to report to the World Health

Organization (WHO) and deal with the media and international communities.

Planning the field operation

The investigator needs to have a short meeting with team members to summarize the situation, set up the objectives of the investigations, divide responsibility among team members, and check the readiness of laboratory and logistical support.

It is also important to plan the duration of the field investigation. The investigation team should stay in the field until all investigation processes such as data collection, analysis, interpretation, and the executive summary have been completed. Leaving the field without accomplishing all these objectives could delay the implementation of control measures. Most outbreak investigations should plan to obtain preliminary results and recommendations within a week of the start of the investigation to ensure that the findings will be timely enough for control of the current outbreak. Additional studies and subsequent investigations can be conducted later.

The investigation team should not spend too much time preparing a perfect plan, because of the urgency of the outbreak; rather, they should obtain what is most necessary and start the investigation as soon as possible.

Steps of outbreak investigation

An outbreak investigation is an observational study by nature, because the events have already occurred. Every outbreak investigation needs to start with a good descriptive study, followed by analytical studies whenever possible and necessary. Conclusions about the causes, sources, mechanisms, and determinants of the outbreak need to be drawn, based on sound epidemiological, clinical, laboratory, and environmental evidence.

A descriptive study can help to identify the risk population(s) and risk area(s) so that immediate interventions can be directed to those who need them the most. A good descriptive study can also generate hypotheses about how the outbreak has spread and what factors contributed to the abnormal occurrence of the disease. In theory, hypotheses derived from a descriptive study should be confirmed by further analytical study; in reality, this is not always possible, due to many constraints.

It is preferable to translate the methodology for outbreak investigation into steps of action. Gregg (1996) has divided the outbreak investigation process into ten steps; with a slight modification, this ten-step investigation process has been summarized in Box 5.3.1. Steps 1–4 use descriptive epidemiology to generate basic facts and hypotheses, steps 5–7 are processes to test the hypotheses and draw conclusions, and steps 8–10 emphasize the importance of communication of the results and follow-up of the recommendations.

Box 5.3.1 Ten steps to take in an outbreak investigation

1. Confirm the existence of the outbreak.
2. Verify the diagnosis and determine the aetiology of the disease.
3. Develop a case definition, start case finding, and collect information on cases.
4. Describe persons, places, and times, and generate hypotheses.
5. Test the hypotheses using an analytic study.
6. Carry out necessary environmental or other studies to supplement the epidemiological study.
7. Draw conclusions to explain the causes or the determinants of the outbreak, based on clinical, laboratory, epidemiological, and environmental studies.
8. Report and recommend appropriate control measures to concerned authorities at the local, national, and if appropriate, international levels.
9. Communicate risk to mobilize cooperation from other public health professionals and the general public.
10. Follow-up the recommendations to ensure implementation of control measures.

Source: data from Gregg, M.B. (ed.), Conducting a field investigation, p. 44–59, in *Field Epidemiology*, Oxford University Press, New York, USA, Copyright © Oxford University Press, Inc. 1996.

This outline does not imply a strict course of action. In real outbreak investigations, many steps may be undertaken concurrently, depending on the situation.

Step 1: confirm the existence of an outbreak

The main question is: ‘Is this a true outbreak?’ Applying the definition of an outbreak outlined in this chapter, the investigator should be able to establish or refute the existence of the outbreak. Investigators should review the number of cases with the local health officers or hospital staff and compare it with the number found during the same period recorded in past years.

For example, the outbreak of trichinosis in North Rhine-Westphalia, Germany, was confirmed because there were 52 cases in a 3-month period between November 1998 and January 1999, compared with no more than ten cases annually during the same time period in the past 10 years (CDC 1999d).

Step 2: verify the diagnosis and aetiology of the disease

If the number of cases fits the case criteria for the outbreak, the next related questions are:

What is the correct diagnosis and aetiology of the disease?
What can be done immediately to prevent new cases from occurring?

Knowing the exact diagnosis and aetiology of the disease will help to establish appropriate preventive measures immediately. This will protect susceptible people and allow the team to start educating villagers to avoid the risk factors. For example, many adults in a remote village were ill with fever, muscle and joint pain, rashes, etc. If the diagnosis and aetiology of the disease is unknown, the local public health officials will find it very difficult to educate the public or implement effective preventive programmes. Until the serology of some patients showed sharply rising immunoglobulin M (IgM) antibodies to dengue virus, control measures to destroy the larvae of the *Aedes* mosquito, the vector of dengue which breeds in water containers, may not be started.

In many situations, an unknown or unclear diagnosis can cause panic due to rumours. This was demonstrated by an outbreak of pneumonic plague in Surat, India in 1994, and of encephalitis in Malaysia in 1999, which resulted in severe panic among local people and foreign tourists. Thus, it is very important to obtain the exact diagnosis as rapidly as possible.

Investigators should have basic knowledge of the clinical diagnosis and how to confirm the aetiology of suspected disease by using well-established laboratory techniques. It is recommended that investigators visit and talk with some patients, review and visualize the signs and symptoms, and hold discussions with the attending doctors. The information from this step will help to develop a case definition to facilitate active case finding. The information on aetiology will also help to interpret the findings from the later descriptive study and establish a causal association.

The investigators should also visit the laboratory facilities and ask for either positive or negative results of the testing of specimens. It is not necessary for all cases to be laboratory confirmed, but at least some of the apparent clinical cases or deaths should be confirmed. Once there are laboratory-confirmed cases, the investigator will find it more reasonable to assume that other cases with the same clinical manifestations in the same period and location are the same disease.

It is unfortunate that specimens from patients are often thrown away when the primary results (either positive or negative) are obtained. The investigators should plan with the doctors and laboratory scientists to perform further investigations on the specific strain, and to establish drug sensitivities, genetic markers, etc. Many new laboratory technologies, such as serological testing, culture and isolation, and molecular techniques, are very powerful for diagnosing and tracking the connections between cases, even in different geographical areas. For example, outbreaks of *Shigella sonnei* infections in Denmark and Australia were detected during the same week in August 2007, and 215 laboratory-confirmed cases were reported in Denmark, with an additional 12 cases in Australia. Antibiotic resistance and pulsed field gel electrophoresis in isolates identified in those two outbreaks were indistinguishable. A hypothesis that the patients were exposed to the same implicated food item from the same original source was soon proven (Lewis et al. 2009).

Step 3: develop an appropriate case definition, start case finding, and collect information on cases

At this stage, the investigator needs to answer at least three questions:

Who should be counted as a case?
Are there more undetected cases in the hospitals and in the community?
What are the characteristics of cases?

To answer these three questions, the investigators must follow three steps.

Develop an appropriate case definition

It is important that the investigator develop a case definition, which will be applied consistently during the investigation. The definition should be

sensitive or adequate at the beginning, in order to capture actual cases. A good case definition for investigative purposes should be specific to time and location. The case definition should not include any specific suspected exposure that the investigator plans to verify. This would create selection bias when the investigator generates the hypothesis or tests the hypothesis in the subsequent steps. Using the information obtained from the previous steps, the investigator can divide the case definition into different levels.

For example, in September 2012, when two patients with a novel coronavirus from Saudi Arabia and Qatar were found, WHO requested member states to start surveillance of the disease by using the interim case definitions as shown in Box 5.3.2 (WHO 2012). Note, there was a further update in 2014 to reflect the MERS-CoV outbreak, and doubtless an interim for SARS-CoV-2 is forthcoming.

Box 5.3.2 2012 WHO interim case definitions for a novel coronavirus

1. Patients to be investigated (referred to as ‘patient under investigation’):
    - A person with an acute respiratory infection, which may include fever (≥38°C, 100.4°F) and cough; *and*
    - Suspicion of pulmonary parenchymal disease (e.g. pneumonia or acute respiratory distress syndrome (ARDS)), based on clinical or radiological evidence of consolidation; *and*
    - Travel to or residence in an area where infection with novel coronavirus has recently been reported or where transmission could have occurred (see updated area in WHO website); *and*
    - Not already explained by any other infection or aetiology, including all clinically indicated tests for community-acquired pneumonia according to local management guidelines.
2. Probable case
    - A person fitting the definition given in (1) of a ‘patient under investigation’ with clinical, radiological, or histopathological evidence of pulmonary parenchyma disease (e.g. pneumonia or ARDS) but no possibility of laboratory confirmation either because the patient or samples are not available or there is no testing available for other respiratory infections, *and*
    - Close contact with a laboratory-confirmed case, *and*
    - Not already explained by any other infection or aetiology, including all clinically indicated tests for community-acquired pneumonia according to local management guidelines.
3. Confirmed case
    - A person with laboratory confirmation of infection with the novel coronavirus.

Active case finding

In places where there is good surveillance, cases from all hospitals can be reported to the epidemiology unit at the district or provincial level. The investigator can apply the case definition and count the number of cases, and review data that are collected on the reporting form. If enough cases and basic information on cases have already been gathered, the investigator can start descriptive epidemiology. Conversely, if only a few cases have been seen at the health facility, the investigator should plan to search for more cases in the community. The investigator must start a process called *active case finding*. The objective of active case finding is to gather enough cases to analyse. At the same time, this case finding will give a better picture of the magnitude of the outbreak. The investigator must frequently visit many

hospitals in the outbreak area and review medical records themselves. Sometimes, they must search for cases in each village by interviewing house to house, which is the true nature of outbreak field investigations and the way people learn epidemiology. This active case finding in the community also provides two more benefits:

Control measures can be implemented if the aetiology of the disease is known and treatable. During an investigation of influenza A (H1N1) 2009 outbreak in a prison in August 2011, the investigator conducted active case finding and laboratory investigation to confirm an aetiology. A total of 421 case-patients with an attack rate of 19% were identified. A mobile clinic from the provincial hospital was deployed into the prison to provide early diagnosis and oseltamivir was given to 17% of cases to prevent complication. Meanwhile, multiple intensive control measures including promoting hand washing, mask use, and case isolation were implemented to reduce the transmission in the prison. (Karnjanapiboonwong et al. 2011)
Rapid environmental assessment can be started during the visit to the affected families or villages. From the direct interview with the cases, the investigator can develop hypotheses and implement necessary interventions immediately, such as sanitation improvement among food handlers and treatment of water to prevent a waterborne outbreak.

In situations in which the outbreak is not localized but widespread, the investigator might need to use the media to alert the public about the outbreak. People can then avoid suspected exposures and see a healthcare provider if they have developed symptoms compatible with the case definition.

Collecting information on cases

For each case, the investigator should collect at least four types of information:

Identifying information: name, hospital number, contact person, and address of contact. This additional information will help to avoid duplication of enumerated cases. The investigator can also maintain communication with these cases when more information is needed.
Demographic information: age, gender, occupation, religion, ethnicity, area of residence, place of employment, etc. This important information may help to determine the characteristics and distribution of cases.
Clinical information: symptoms and signs, date of onset, duration of illness, and results of diagnostic procedures. These data will help to confirm a true case, provide the pattern of clinical manifestations, and also the distribution of cases by time.
Suspected risk factors: investigators can ask for a history of exposure to factors before the disease developed. The timing of interest is usually one incubation period if the aetiology is known or suspected. Questions about contact with other patients who have similar clinical symptoms are also very helpful. If the diagnosis is not known, the investigator should collect this information in a qualitative manner.

The investigator should develop a questionnaire as a tool to collect the relevant information from the hospitals or during active case finding in the community. In practice, some of the information will not be available or not of good quality. The investigator should validate all data in doubt.

In addition to using a traditional paper-based questionnaire, development of information and communication technology allows epidemiologists to use mobile devices, such as smartphones or tablet computers, to collect data during outbreak investigation. The power of mobile technology will enable outbreak response teams to collect and transfer data rapidly and smoothly. For example, during the 2014–2016 epidemics of Ebola virus disease in West Africa, mobile devices and related applications were used to collect data when conducting contact follow-up and identifying new cases (Tom-Aba et al. 2015). Using the right technology in the right situations will therefore effectively facilitate outbreak situation awareness and prompt response.

Step 4: describe the outbreak in person, place, and time, and hypotheses formation

In this step, investigators need to answer the following questions:

What are the main clinical features?
What population(s) is at risk?
What are the risk factors?
What are the most likely explanations of how the outbreak began?

A simple approach is to analyse clinical information from each case and see the distribution of cases in terms of person, place, and time. The analysis should be done using rates rather than absolute numbers; the investigator needs to obtain the denominators from an available source or to estimate them. Using rates, the investigator can compare and determine the populations and areas of highest risk. With the advent of computers, many software programs are available to analyse these data. A popular one is EpiInfo™, which is public domain software from the US CDC that is designed specifically for field investigations. In the absence of a computer, investigators can still analyse data manually. Individual questionnaires can be compiled into a line listing, which includes important variables of all cases. With this line listing, simple counts can be made. In this way, investigators will gain knowledge about populations and areas of risk. Resource and control measures can then be directed to the risk populations and risk areas. Enumeration will also produce information for hypothesis formation to explain how and why the outbreak occurred.

Clinical manifestations of cases

Signs and symptoms of cases can be analysed in percentages and presented in a summary table. In an outbreak of unknown aetiology, clinical information will help to establish the diagnosis. For an outbreak in which the aetiology is already known, the investigators still need to compare the clinical information found in the investigation with previous knowledge. Any discrepancy between the investigation and previous knowledge such as the attack rate, mortality rate, severity, and so on should be carefully examined, because this might indicate that a new strain or different specific host response is occurring. The high mortality rate of approximately 40% in the Nipah encephalitis outbreak in Malaysia 1999 (CDC 1999c) indicated that this outbreak might not be due to the usual endemic encephalitis.

Populations at risk

Investigators should analyse the characteristics of cases by gender, age, occupation, ethnicity, and so on. Initially this can be carried out by examining the proportion of all cases, but the specific attack rate by age and gender will be more useful for comparisons and hypothesis formation. The rates will provide useful indicators of the possible aetiology of the outbreak. In the Ebola haemorrhagic fever outbreak in Zaire in 1976, all ages and both genders were affected, but females slightly predominated. Age- and gender-specific attack rates indicated that adult females had the highest attack rate. This finding suggested that parenteral injection with unsterilized syringes and needles given during antenatal care in the local hospital was the means of transmission (WHO 1978).

The outbreak of Nipah encephalitis in Malaysia in early 1999 was initially thought to be due to Japanese encephalitis alone. However, after careful analysis of the descriptive information, it was clear that the cases were mainly male, adult, involved in pig farming, and of Chinese ethnicity. This descriptive information did not fit the pattern for Japanese encephalitis, which mainly affects children of both genders, with no preference for a particular ethnicity. The investigator then began to suspect other organisms and to hypothesize that pig farming increased the risk of becoming ill.

Primary, index, and outlier cases

In infectious diseases, the first case on the epidemic curve is called the primary case. The primary case is important, because of the possibility that he/she brought the disease into the community either from the local area or from other locales. In investigations, sometimes the first case that draws the attention of the investigator is not the primary case. We call this the ‘index case’. Index cases may be detected at the hospital or during the active case finding. The investigator may find the primary case among those who were sick in the community but did not seek medical care. Cases that appear at the very beginning or at the end of the epidemic who are markedly different from the rest of cases should also be given careful attention. These cases are called *outlier cases*, and can provide important information about the source and the way in which the disease is spread. A tourist who happened to be only a short time in the village during the outbreak and got sick is an example of an outlier.

Typically, the very first and very last cases in the epidemic curve should be critically appraised. The first case may not be the true index case because of misdiagnosis, a case unrelated to the epidemic, etc. The late cases may be due to misdiagnosis, a case unrelated to the epidemic, or a secondary case that had a different exposure than the majority of the cases in the epidemic.

During the outbreak of severe acute respiratory syndrome (SARS) in February 2003, the index case was identified as a 65-year-old medical doctor from Guangdong, mainland China, who stayed on the ninth floor of a hotel in Hong Kong (Fig. 5.3.2). He had treated patients with atypical pneumonia prior to his departure, and he was symptomatic upon arrival in Hong Kong. He infected over a dozen guests and international visitors. During the outbreak investigation, the investigators tried to identify contacts of this index case to prevent further transmission. A history and information of this index case obtained by the investigation team traced these cases back to previous atypical pneumonia outbreaks or undiagnosed SARS since late 2002 (World Health Organization Regional Office for the Western Pacific 2006).

Location

Investigators can calculate attack rates of cases in different locations. These can be places of residence, places of employment, sites of exposure, etc. Locations with high attack rates often indicate the sources of infection or contamination. A spot map showing the locations of cases can give a very good idea of the source, as demonstrated by Snow in his classical investigation of a cholera outbreak in the Golden Square area of London between August and September 1854 (Frost 1936). In that investigation, Snow found most cases clustered around the Broad Street pump. From this information, Snow deduced that the Broad Street pump was probably the primary source of the outbreak.

If cases are scattered in many locations, investigators should explore the secular pattern of the cases over time, which will indicate whether the outbreak started in one area and spread to other areas, or whether people living in different places had a common exposure. The SARS outbreak is a good example of when cases are distributed worldwide originally from a single source of infection.

Time

The objective is to show the occurrence of cases over time and look for a pattern of occurrence. In general, there are two major types of outbreaks: a common source and a propagated source. The way to differentiate between these two patterns of outbreak is to draw an epidemic curve that shows the number of cases (on the *y*-axis) over time of onset (on the *x*-axis). The epidemic curve of each outbreak will suggest whether the mode of spread is by a common source or from person to person.

Common source outbreak

This kind of outbreak occurs when people are infected by exposure to the same source of infection. For example, a group of people contract viral hepatitis A because they ate the same contaminated food served during a wedding party. A common source outbreak can be divided into a point common source and a continuous common source:

A point common source outbreak occurs when there is a single source that exists for a very short time and all cases have common exposure to it at that particular time.
A continuous common source outbreak occurs when there is only one source that provides continuous or intermittent exposure over a longer period of time.

Epidemic curve of a point common source outbreak: the epidemic curve shows a sharp increase of many cases suddenly followed by a rapid decline, although not as rapid as at the beginning of the epidemic. Another criterion to judge a point common source is that the first and the last cases usually occur within one incubation period.

If the aetiology and the data of the incubation period of the disease are known, the investigators can then roughly estimate the probable time of the initial exposure. This can be done by identifying the peak of the epidemic from the curve and counting back on the *x*-axis the equivalent of the incubation period. The investigator can also use the first case and count back on the *x*-axis the duration of the minimum incubation period, which will also give a rough estimate of the time of exposure. In the opposite way, if the information on aetiologic agent and incubation period is unknown but the common exposure time is known, the mean incubation is the duration from exposure to the peak of the curve. The shortest incubation period is the duration from the time of exposure to the onset of the first case and the longest incubation period is the duration from the time of exposure to the onset of the last case.

If the aetiology of the disease is not known, but the epidemic curve fits well with a point common source outbreak, the investigator can estimate the average incubation period if he or she knows the times of common exposure.

Epidemic curve for a continuous common source outbreak: the epidemic curve shows an abrupt increase in the number of cases, but instead of having a peak and a decline within one incubation period, new cases persist for a longer time, with a plateau shape instead of a peak before decreasing. In the outbreak of food poisoning caused by *Shigella sonnei* infections linked to consumption of imported raw baby corn in Denmark and Australia in August 2007, the peak of the outbreak was observed 6 days after the onset date of the first case and gradually declined (Fig. 5.3.3). All of the cases developed symptoms within a 2-week period, and the outbreak subsided soon after a recall of the implicated batches of baby corn on 17 August 2007 (Lewis et al. 2009). However, if there are many peaks or irregular jagged curves, it suggests an intermittent common source.

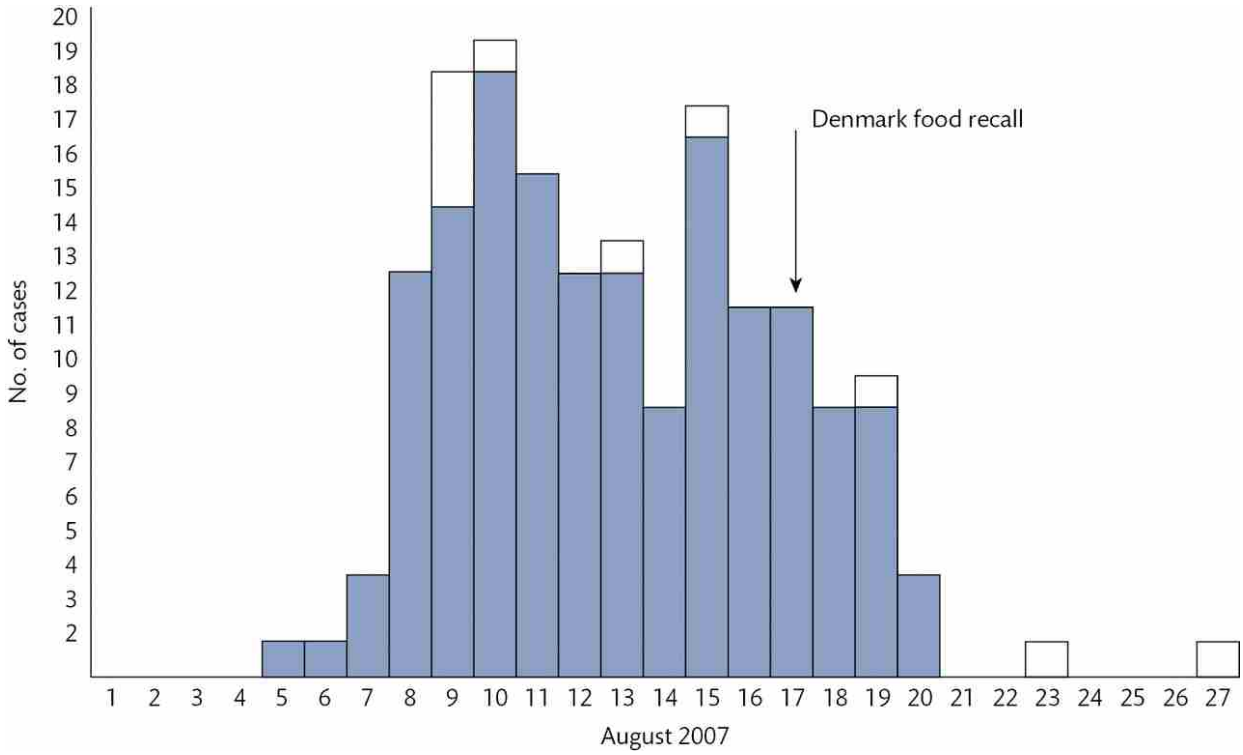

Fig. 5.3.3 Dates of illness onset for 163 cases in an outbreak of *Shigella sonnei* infections linked to consumption of imported raw baby corn in Denmark (■) and Australia (□) in August 2007.

From Lewis HC et al., Outbreaks of Shigella sonnei infections in Denmark and Australia linked to consumption of imported raw baby corn, *Epidemiology and Infection*, Volume 137, Special Issue 03, pp. 326–34, Copyright © 2009 Cambridge University Press, reproduced with permission, DOI: http://dx.doi.org/10.1017/S0950268808001829.

Propagated source outbreak

A propagated outbreak is caused by transmission from one person to another, and requires direct contact such as touching, biting, kissing, or sexual activity, or via vector such as in vector-borne disease outbreak.

Epidemic curve of propagated source outbreak: the epidemic curve shows a slow increase in the number of cases, with progressive peaks approximately one incubation period apart. The investigators might observe an abrupt decrease in new cases, because everyone has already been infected. The span from the first to the last case will also last longer than several incubation periods.

The outbreaks of SARS in Singapore demonstrated the propagated source of transmission beginning from a young female who returned home from Hong Kong. This patient had stayed on the same hotel floor as the index

case. She had initially infected many hospital staff before the disease spread for further generations (Kamps and Hoffmann 2003). The outbreak resulted in 238 cases and 33 deaths in a few months (Fig. 5.3.4).

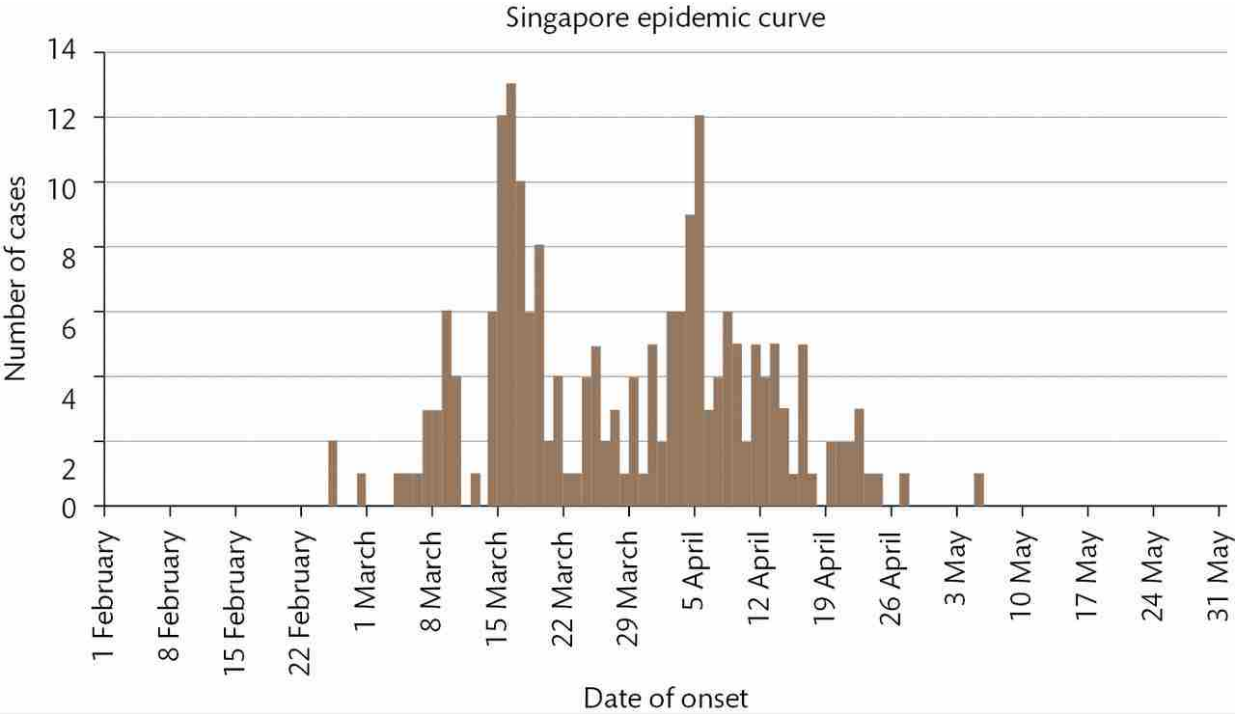

Fig. 5.3.4 SARS cases by date of onset—Singapore, 2003.

Step 5: testing the hypotheses by an analytic study

In an outbreak of infectious disease, the investigator needs to answer the following questions:

What is the aetiology of the disease?
What is the source of infection?
What is the pattern of spread?
What are the risk factors for an individual to get the disease?
What are the determinants of the outbreak or the factors which, when combined together, result in the outbreak?

The aetiology of the disease should be derived from the laboratory study. The pattern of spread can be identified by a careful descriptive study. Sometimes it is not as simple as expected, and a descriptive study does not give enough clues. The investigator must carefully re-examine the descriptive information, carry out more active case finding, and re-analyse the data. The investigator also needs to directly observe the location, lifestyle, and/or behaviour of the cases. These additional investigations usually help the investigator to generate some reasonable hypotheses.

A hypothesis needs to be tested by an analytical study design. The most common is a case–control study. The investigator needs to define the cases and measure the odds of suspected exposed factors found among cases in comparison to the odds of exposure found among appropriately selected controls. The case definition for the analytical study may be more specific than that used for a descriptive study in order to reduce misclassifying non-cases as cases. Conversely, the controls may also need to be tested to avoid classifying non-apparent cases as controls.

An example is the analytic study for identifying risk factors for haemolytic–uraemic syndrome in a large outbreak of Shiga toxin-producing *Escherichia coli* O104:H4 infections in Germany during May 2011 (Buchholz et al. 2011). A matched case–control study was carried out to obtain data from 26 case subjects with the haemolytic–uraemic syndrome and compared to data from 81 controls. The investigation revealed ingestion of raw sprouts as the vehicle of infection (matched odds ratio, 4.35; 95% confidence interval, 1.05–18.0). A month after, a similar food poisoning outbreak of the same organism was detected in France (King et al. 2012). The investigators conducted a retrospective cohort study and they found an increased risk of developing the disease among adults who attended the buffet at the Children's Community Center Event on June 8, 2011 (relative risk, 5.1; 95% confidence interval, 2.3–11.1) in multivariable analysis (Table 5.3.1).

Table 5.3.1 Multivariable Poisson regression with food-specific relative risks and 95% confidence intervals among adults who attended the buffet at the Children's Community Center Event, France, June 2011 (n = 64)

Food item	RR	95% CI	P-value
Sprouts (any of the 3 kinds)	4.2	1.7–10.0	0.001
Gazpacho (tomato-based cold soup)	2.4	0.9–6.4	0.08
Carrots	2.3	0.8–7.1	0.14
Water (bottled)	2.0	0.8–5.2	0.14
Dip sauce (mayonnaise)	1.7	0.8–3.3	0.15
Lettuce	1.4	0.6–3.6	0.43
Green peppers	0.4	0.1–1.3	0.15

CI, confidence interval; RR, relative risk.

[a] All but 1 of the covariables in the presented final multivariable model have *P* values that are non-significant at the 0.05 level. These variables were left in the final model to ensure a sufficient numeric stability of the model.

Reproduced from King LA et al., Outbreak of Shiga toxin-producing *Escherichia coli* O104:H4 associated with organic fenugreek sprouts, France, June 2011, *Clinical Infectious Diseases*, Volume 54, Issue 11, pp. 1588–94, Copyright © The Author 2012, published by Oxford University Press on behalf of the Infectious Diseases Society of America, by permission of Oxford University Press.

Step 6: environmental or other studies to supplement epidemiological findings

Although an analytical study might be able to confirm a hypothesis, the investigator still needs to find environmental or other evidence to support and explain the epidemiological evidence. In an outbreak of unknown illness in a rural village of Egypt, in which the cases developed severe abdominal pain, persistent vomiting, and generalized weakness, the investigator was able to detect abnormally high blood lead levels among the cases. The analytical study revealed an association between high lead levels in the blood and eating flour from a particular mill factory. The mill implicated in the outbreak was visited, and upon arrival at the mill, the investigators noted a lead smelting pot in the corner of the mill. Lead was used by the miller to attach the crosspiece to the grinding stone. Occasionally the lead would

break off and contaminate the flour. The miller reported using about 2 kg of lead per year. Analysis of grain from the mill showed no lead; however, lead was found in flour from the surface of the mill stone and in samples of flour after grinding was complete (Abdel-Nasser 1996).

Step 7: establishing the causes of the outbreak

Once the hypothesis has been tested and other necessary studies have been carried out, the investigators can draw their conclusions about the causes of the outbreak. This conclusion is very important, because action should follow. Many restaurants or factories have been closed because they were implicated as the source of the outbreak. Outbreak investigations are naturally faced with constraints of time and other uncontrolled conditions that do not favour perfect design and methodology. The findings potentially include both random and systematic errors. Before drawing any conclusions, it is important that the investigator carefully examines the weaknesses or limitations of the investigation. In principle, the investigator must identify the cause of the outbreak based on the agreement of the following four pieces of evidence.

Laboratory evidence

The aetiology of the disease is identified in the patients and in the suspected source of infection. If the investigator cannot identify the aetiology from the suspected source, it is still possible to use certain markers to support their conclusions. For example, although a *Vibrio cholerae* type O1 could not be cultured from the drinking water supply of the affected community, the observation of human faecal coliform bacteria in the water helped to indicate that human faeces had contaminated the water.

Clinical evidence

It is necessary to verify that the incubation period and clinical manifestations of cases are compatible with the aetiological agents reported from the laboratory. In the SARS outbreak, most patients developed respiratory symptoms within 7 days after an exposure, then having atypical pneumonia with rapid progression to respiratory failure, and a fraction of them also had

diarrhoea, which could be explained by the findings of SARS coronavirus both in the respiratory tract and stools of patients.

Environmental evidence

Careful investigation of the environment should reveal clues that the causative agent can pass from the source to the cases or the index case to subsequent cases. The investigation of early SARS cases revealed that the index case passed the virus to several people who stayed on the same floor and used the same elevator (CDC 2003).

For an outbreak of food poisoning, a cooking environment that is dirty or located close to the toilet is convincing evidence of food being contaminated by faeces. Crowding in bedrooms is very convincing evidence for a respiratory tract infection outbreak.

Epidemiological evidence

Epidemiological evidence found in the descriptive and analytical studies should clearly explain the following aspects:

Pattern of spread, as described by an epidemic curve.
Statistical strength of association between exposure and developing the disease.
Dose–response relationship, which demonstrates a higher strength of association when the exposure is increasing.
Exposure should precede an illness.

It is not uncommon to see some disagreement in the evidence from different sources. In this event, the investigator needs to verify the validity of each piece of evidence and discuss the data with people who have expertise in that particular area in order to obtain more information and draw a valid conclusion.

Step 8: on-site reporting to and recommendations for concerned authorities

The most important step leading to a timely response is to report the findings to the responsible individuals both at the local and national levels so that

they can take appropriate action. Keeping this in mind, the investigators need to complete two tasks before leaving the outbreak area:

Complete analysis and data interpretation: leaving the field without completing these tasks will reduce the sense of urgency necessary to finish the work. Data are easier to retrieve when staying in the field rather than instructing field people to send them to the investigation team later.
Present the main findings with recommendations: some findings may be very sensitive because they reflect the weaknesses or mistakes of health personnel or other authorities. The investigator needs to select the appropriate approach, either formal or informal, with those responsible. Leaving the field without providing the information that the team obtains from the investigation will be detrimental to other people who could be prevented from becoming ill if the information were known. In many urgent situations, the findings and recommendations might be regularly given to the people responsible during the outbreak investigation process instead of waiting until the end. The investigators also need to present or communicate the findings and recommendations to the national authorities as soon as possible. The recommendations for action should be based on the findings of the investigation. These might include the following aspects.

What can be done to control the outbreak?

With timely investigation, some interventions can be implemented to stop further spread. In the outbreak of measles in a rural community in Peru, measles vaccines were given to children aged between 6 months and 15 years who were not measles cases, regardless of their previous immunization status. Using knowledge about the complication of measles in previous studies, the investigators estimated that the action prevented 87 cases of diarrhoea and 46 cases of pneumonia, and averted five deaths (Sniadack et al. 1999). Outbreaks can be controlled even if the disease aetiology is not known at the moment, but the mode of transmission is known from the investigation. One good example is the early story of the HIV/AIDS epidemic when sexual transmission was identified as a major mode of transmission among sexually active, young gay men. Therefore, promotion of condom use and safe sex practice was immediately implemented to prevent the transmission.

How to prevent future outbreaks

In many instances, interventions cannot be implemented for the current outbreak, but the findings can be used to set up new practices or policies. These recommendations can help prevent future outbreaks. In Thailand, the recommendation was made to change practices of chicken farming and avoiding direct contact with sick poultry, which was recommended through the results of the investigation of human H5N1 cases. The Egyptian government, after reviewing the results of the investigation of lead contamination in flour mills, agreed to ban the use of lead in privately owned flour mills (Abdel-Nasser 1996).

How to improve the investigation

The investigator should review the performance of the investigation and identify the weaknesses of the methodology or the field operation so that improvements can be made. These might include a more appropriate case definition, a better investigative design, improved laboratory support, a different team composition, lower costs, a shorter time course, etc.

How to improve surveillance

The best time to evaluate the surveillance system is during an outbreak investigation. In most outbreaks, the investigator must review data from existing surveillance systems. With this direct involvement, the investigator will be able to evaluate the timeliness, completeness, validity of diagnosis, sensitivity of the system, and utilization of the surveillance information. The investigation of human cases of avian influenza (H5N1) in Thailand led to an improved definition of a human case in the areas experiencing an H5N1 virus outbreak in poultry.

Step 9: Communicating risk

In addition to on-site reporting, the investigator team should or be supported to do risk communication to educate and mobilize cooperation from the health professional community and the general public. Occasionally, there may be other communities that are also prone to a similar outbreak. The proper information will raise the awareness of public health and government authorities to assess their own situation and implement appropriate measures

to prevent the potential outbreaks. Key messages should promote specific actions that people can realistically take to protect their health. Risk communication is extremely critical and must be delivered in a timely manner with the purpose to build trust and engage community for minimizing consequences of the outbreak. To enhance risk communication capacity of the member states in emergency situation including outbreak setting, WHO has published guidelines for emergency risk communication policy and practice to improve performance of concerned authorities and health workers in the field (WHO 2017).

Dissemination of key messages should occur in a timely manner through weekly or monthly reports. With the advancement of information and communications technology including real-time access to large amount of data, ability to conduct sophisticated analytical techniques with high-performance personal computers, wireless and mobile technology, and availability of various functional applications packages, it is feasible and convenient to disseminate the information on disease situation using online and interactive graphical presentation. The way WHO developed online interactive maps, graphics, and reports to illustrate Ebola outbreak situation in West Africa during 2014–2016 (Fig. 5.3.5) is a wise example of using information technology to visualize epidemic situation in order to inform policy decision and raising situation awareness of the public (WHO 2017).

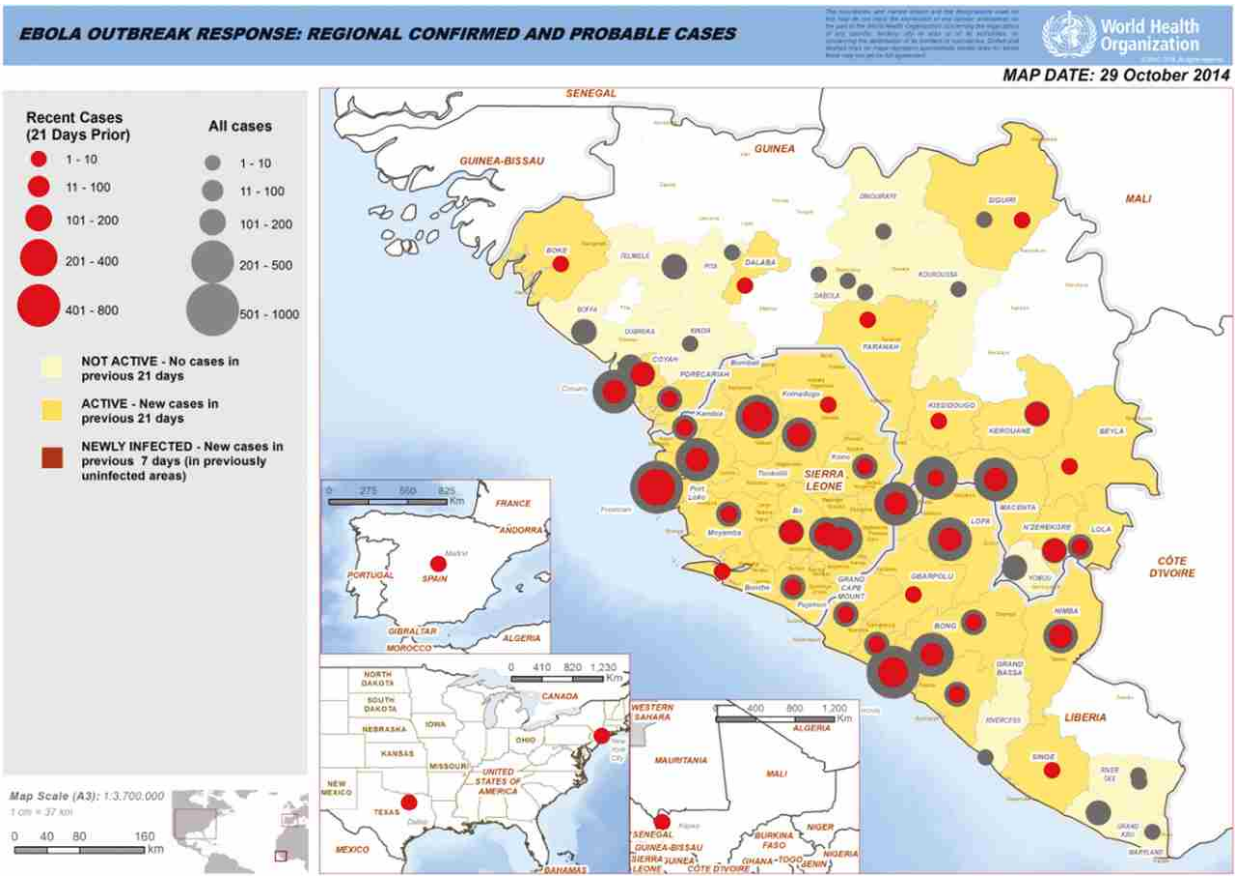

Fig. 5.3.5 Example of maps of Ebola outbreak situation in West Africa, 29 October 2014. Reproduced with permission from Word Health Organization (2014), http://www.who.int/csr/disease/ebola/photos/geographic-map-29-oct-2014.png?ua = 1, accessed on 30th Apr 2018).

Release of important findings through the mass media is also very useful for educating and communicating risk to the general public. Before releasing the investigation results through the media, the investigator must ensure that all the facts are delivered in a constructive manner and do not result in blame of any organization. The investigator should also report the investigation results in an international journal or bulletin such as the *Weekly Epidemiological Record* of the WHO, the *Morbidity and Mortality Weekly Report* of the US CDC, the *Eurosurveillance* of the European Centre for Disease Prevention and Control, or the epidemiological bulletin of own country. This practice is necessary to alert health professionals in other countries and keep them informed of the problem.

In recent years, sharing of information for outbreak detection and control through the internet and email has been increasingly practised for timely

responses. Telecommunications played an important role in the outbreaks of SARS when the disease was spread rapidly by air transportation to countries on the other side of the world. An example is a teleconference on the clinical features and management of SARS that was held by the WHO, which united 80 clinicians from 13 countries worldwide (World Health Organization Regional Office for the Western Pacific 2006).

Step 10: follow-up to ensure implementation of control measures

Finally, the investigator should follow-up the investigation by maintaining close communication with local health authorities. An absence of new cases for at least two incubation periods of the infectious disease under investigation could suggest that the outbreak is subsiding. A good investigator should follow-up on the recommendations. An outbreak investigation is a waste of time if sound recommendations have not been implemented. The investigator should learn the reasons why the recommendations were or were not implemented. If the recommendations were implemented, the investigator can also learn the impact by observing the trend of the disease.

Cooperation for international outbreak investigation and emergency response

The world today is especially prone to outbreaks because of frequent cross-border movement, civil war and migration, rapid transportation, international trading, tourism, etc. An outbreak in one country can spread to other countries very easily. For example, in the multicountry SARS outbreak, international travellers were at risk of disease spreading from a single infectious case in a hotel (CDC 2003). Ultimately, there were over 8,000 cases reported in 26 countries worldwide. The world's experience with the SARS outbreak led to the commitment of countries around the world to improve surveillance and international joint investigation of emerging infectious diseases through International Health Regulations (Connolly 2005), which were legally effective in 2007, requires all countries to improve capacities 'to prevent, protect against, control and provide a public

health response to the international spread of disease in ways that are commensurate with and restricted to public health risks, and which avoid unnecessary interference with international traffic and trade' (WHO 2017). Each country needs to prepare resources and implement strategies to develop, maintain, and monitor its own disease prevention and control capacities according to the IHR (Connolly 2005) in which outbreak investigation and response are among key components.

A massive outbreak of botulism in northern Thailand in March 2006 tested the international capacity to respond to a public health emergency. Botulism poisoning due to contaminated home-canned bamboo shoots caused illness in 209 villagers, of whom 134 persons were hospitalized and 42 required mechanical ventilation. A global search for botulinum antitoxin began, involving international agencies, embassies, national laboratories, airlines, and commercial organizations in seven countries. Sufficient antitoxin was obtained from four sources for treatment of 90 patients, with a delay in treatment of 5–9 days from time of exposure. Rapid local outbreak detection and an effective international response likely prevented mortality and additional morbidity (WHO 2007).

An outbreak anywhere in the world must therefore be treated as a threat to all countries. It is important for each country to build up its capacity for surveillance, outbreak preparedness, and investigation. In addition to the US CDC Epidemic Intelligence Services, over 100 countries have participated in training programmes that is ready to investigate all kinds of outbreaks. These applied epidemiology training programmes are known by different names, such as the Field Epidemiology Training Programme (FETP) or the Field Epidemiology and Laboratory Training Programme (FELTP), and The European Programme for Intervention Epidemiology Training (EPIET). The WHO has supported the establishment of the Global Outbreak Alert and Response Network, a technical collaboration of existing institutions and networks to pool human and technical resources for the rapid identification, confirmation, and response to outbreaks of international importance. It is a wise investment, and a commitment that is needed by the international community for information exchange and collaborative investigation of outbreaks in a timely manner. With continuous growth of emerging disease outbreaks across borders, joint international investigations to control those outbreaks at source continue are increasingly needed.

Conclusion

Outbreak investigation is an essential function of public health professionals who care for the well-being of the community. It is an opportunity to gain new knowledge of diseases and to discover the weaknesses of current public health practices and systems. A good public health professional must always be alert to the possibility of outbreaks. Normal surveillance systems or unofficial sources, such as the mass media, can be a good source for detection of an outbreak. Before starting field investigations, investigators should organize the team, review previous knowledge, prepare the technical and management aspects, and start the investigation as soon as possible. The investigation can be conducted by following the ten steps outlined in this chapter. The investigation usually starts by confirming the existence of the outbreak, verifying the diagnosis, gathering case information, obtaining laboratory support, descriptive epidemiology, formulating and testing the hypothesis when necessary, conducting environmental surveys to supplement epidemiological evidence, providing timely on-site reporting of the findings, with practical recommendations to local and national responsible authorities and communicating risk to health professional community and public. Competent outbreak investigators combine sound scientific knowledge and good management skills. Involvement of other professionals with specific skills and training may be indicated. Direct participation in conducting the investigation is needed to gain the necessary skills. A good investigator should be a field-oriented person with strong levels of perseverance, scepticism, and common sense. The investigator should not end his or her work with the report, but should follow-up on the recommendations and continue vigorous surveillance of the problem. In the future, increasing joint international investigations will be needed. Rich countries and resource-limited countries need to collaborate to detect and stop outbreaks before they get out of control. Through this cooperation, the world will be a safer place amidst the threat of old and emerging disease outbreaks.

5.4

Case–control studies

Noel S. Weiss

Introduction

In 1971, Herbst et al. (1971) * reported that mothers of seven of the eight teenage girls diagnosed with clear cell adenocarcinoma of the vagina in Boston during 1966–1969 claimed to have taken a synthetic hormone, diethylstilboestrol, while pregnant. None of the mothers of the 32 girls without vaginal adenocarcinoma, matched to the cases mothers with regard to hospital and date of birth, had taken diethylstilboestrol during their pregnancy. Within a year, a New York study of five girls with and eight girls without vaginal cancer obtained similar results (Greenwald et al. 1971). The introduction of prenatal diethylstilboestrol use into obstetric practice in the United States during the 1940s and 1950s followed by the appearance of this hitherto unseen form of cancer some 20 years later supported a causal connection between *in utero* exposure to diethylstilboestrol and vaginal adenocarcinoma. The means by which *in utero* diethylstilboestrol exposure might predispose to the occurrence of clear cell vaginal adenocarcinoma was unknown in 1971. (It is now believed that diethylstilboestrol acts by interfering with normal development of the female genital tract, resulting in the persistence into puberty of vaginal adenosis in which adenocarcinoma can arise.) Nonetheless, a causal inference was made at that time by the Food and Drug Administration, which specified pregnancy as a contraindication for diethylstilboestrol use.

The investigation by Herbst et al. was a case–control study: A comparison of prior exposures or characteristics of ill people (cases) with those of people at risk for the illness in the population from which the cases arose. Generally, the prior experience of people at risk is estimated from

observations of a sample of that population (controls). A difference in the frequency or levels of exposure between cases and control—that is, an association—may reflect a causal link.

A case–control, cohort, or any other form of non-randomized study has the potential to identify associations that are not causal, either because of chance, or because of the influence of some other factor associated with both the exposure and outcome. Even so, the evidence that is provided by well-performed case–control studies can carry great weight when evaluating the validity of a causal hypothesis. Indeed, a number of causal inferences have been based largely on the result of case–control studies. These include, in addition to the diethylstilboestrol–vaginal adenocarcinoma relationship, the connection between aspirin use in children and the development of Reye's syndrome, and the use of absorbent tampons and the incidence of toxic shock syndrome.

One of the criteria used to assess the validity of a causal hypothesis is the strength of the association between exposure and disease, usually as measured by the ratio of the incidence rate in exposed and non-exposed people. In most case–control studies, it is not possible to measure incidence rates in either of these groups. Nonetheless, from the frequency of exposure observed in cases and controls, it is usually possible to estimate closely the ratio of the incidence rates.

To understand how this can be done, consider a cohort study in which exposed and non-exposed people are followed for a certain period of time. Table 5.4.1a–c summarizes their experience with regard to a particular disease.

Table 5.4.1a Disease incidence in relation to exposure

	Diseased	Non-diseased	Total
Exposed	*a*	*b*	*a*+*b*
Non-exposed	*c*	*d*	*c*+*d*

The cumulative incidence of the disease in exposed and non-exposed people over a given period of follow-up is $a/(a + b)$ and $c/(c + d)$,

respectively. The relative risk (RR) is the ratio of these:

$$RR = \frac{a/(a+b)}{c/(c+d)}.$$

If the incidence of the disease is relatively low during the follow-up period in both exposed and non-exposed people, then *a* will be small relative to *b* and *c* will be small relative to *d*. Therefore,

$$RR = \frac{a/(a+b)}{c/(c+d)} \approx \frac{a/b}{c/d} = \frac{a/c}{b/d}.$$

Table 5.4.1b Disease incidence in 100,000 people

	Diseased	Non-diseased	Total
Exposed	100	9,900	10,000
Non-exposed	300	89,700	90,000

If a case–control study had been carried out in this population, in which 50% of the cases were included but only 1% of the non-cases, then the following results would have been obtained:

Table 5.4.1c Exposure status in a sample

Cases	Diseased	Non-diseased
Exposed	100 × 0.5 = 50	9 900 × 0.01 = 99
Non-exposed	300 × 0.5 = 150	89 700 × 0.01 = 897

In this expression, the numerator (*a/c*) is the odds of exposure in people who develop the disease and the denominator (*b/d*) is the odds exposure in

people who remain well. Therefore,

$$\text{Odds ratio (OR)} = \frac{a/c}{b/d}.$$

The numerator can be estimated from a sample of cases, and the denominator can be estimated from a sample of non-cases. Neither estimate is influenced by the proportion of cases among the subjects actually chosen for study.

In the following hypothetical example, assume that 100 of 10 000 people exposed to a particular substance or organism developed a disease, compared with 300 of 90 000 non-exposed people:

Therefore,

$$RR = \frac{100/10{,}000}{300/90{,}000} = 3.00$$

$$RR = \text{OR} = \frac{50/150}{99/897} = 3.02.$$

In many studies, controls are chosen as they were in this example; that is, from people who have not developed the disease by the end of the same time period during which other people (the cases) have become ill. In such studies, the less common the disease in both the exposed and non-exposed people during the period, the better the odds ratio will estimate the ratio of cumulative incidence. In the example, only 0.1% and 0.33% of exposed and non-exposed people, respectively, developed the illness: So, the relative cumulative incidence and odds ratio are nearly identical (3 vs. 3.02). However, it is also possible to choose controls from people free of disease only until the corresponding cases have been diagnosed; a person can appear in the study first as a control and later as a case. If this approach is used, the odds ratio will be a valid estimate of the ratio of incidence rates (i.e. cases divided by person–time at risk) irrespective of the disease frequency (Greenland and Thomas 1982; Pearce 1993).

* This chapter is excerpted from *Epidemiologic Methods* (2nd edition) by N.S. Weiss and T.D. Koepsell (2014).

Retrospective ascertainment of exposure status in cases and controls

Epidemiological studies seek to obtain information on exposures present during an aetiologically relevant period of time; that period varies across aetiological relationships. For example, although excess consumption of alcohol predisposes to both motor vehicle injuries and cirrhosis of the liver, it does so during considerably different time intervals before the occurrence of the injury or the onset of the illness, respectively.

Some case–control studies are nested within cohort studies in which specimens (e.g. blood or urine) have been obtained before diagnosis on all cohort members, but have not yet been analysed for the exposure(s) in question. When these analyses are carried out on cohort members who developed a particular illness and on controls selected from the cohort, the results obtained are not influenced by the events occurring after the diagnosis of the illness. (To avoid the possibility of occult illness in cases influencing levels of a suspected aetiological factor, many studies of this type exclude from the analyses specimens obtained in the period before diagnosis that might correspond to the preclinical stage of disease.) Also, among the large majority of case–control studies in which exposure status is not measured until the illness or injury has been diagnosed, some are concerned only with an exposure or characteristic that would have been the same at all times in a person's life. This is true for a genetically determined characteristic such as ABO blood type or the absence of glutathione transferase M_1 activity (an enzyme that metabolizes several potentially carcinogenic constituents of cigarette smoke). Clearly, these studies are no less valid for having had to measure exposure in retrospect.

However, most case–control studies are required to consider explicitly how best to assess in retrospect the subjects' exposure status during one or more possible aetiologically relevant time periods. Possible sources of exposure data include interviews or questionnaires, available records, and physical or laboratory measurements.

Interviews or questionnaires

For many exposures, a subject's memory is an excellent window to the past. A number of important aetiological relationships have been identified through interview-based case–control studies. Generally, study participants will report longer-term and more recent experiences with greater accuracy than shorter-term and more distant ones. Attention to the ways in which questions are asked (White et al. 2008), along with the use of visual aids when appropriate (e.g. pictures of medicines, or containers of household products, and calendars for important life events to enhance recall of the timing of other exposures), will maximize the accuracy of the information received. These efforts, along with the use of the same questions for cases and controls asked in the same way, will also minimize the potential for bias that could result from the subject's or interviewer's awareness of case or control status.

One advantage of exposure ascertainment via interview or questionnaire is that information can be sought for multiple points in the past. It is possible that a given exposure plays an aetiological role only if present at a certain age, for a certain duration, or at a certain time in the past. Because there is often little guidance before a study starts that suggests the most relevant age, length, or recency, key exposures are often elicited throughout much of the subject's lifetime. However, care must be taken not to include exposures that took place after the illness began. An instructive example is provided by (Victora et al. 1989) in a case–control study of infant death from diarrhoea as related to the type of feeding. These investigators asked mothers whether their child was or was not being breastfed immediately before the onset of the fatal illness (mothers of controls were queried about type of feeding prior to a comparable point in time). Mothers were also asked if subsequent to the onset of the illness there had been any changes in the type of feeding; following the development of diarrhoea, many children were switched to formula and cow's milk. Relative to infants who were solely breastfed, those who were supplemented with powdered or cow's milk prior to their illness had about four times the risk of diarrhoeal death. However, the authors showed that if one inappropriately considered the feeding method that was present during the illness, about a 13-fold increase in risk associated with supplementation would have been estimated.

Records

Case–control studies have exploited the presence of vital, registry, employment, medical, and pharmacy records, to name a few, as a means of obtaining information on exposures. However, because the information contained in the records is usually assembled for purposes other than epidemiological research, they may not provide precisely the information desired by the epidemiologist. For example, a death certificate or an occupational record may state an individual's job, but often not his or her actual exposure to the substance(s) of interest to the study. A pharmacy record will indicate a prescription having been filled, but not necessarily whether the patient took the medication on a given day, or took it at all. This sort of imprecision will impair a study's ability to discern a true association between an exposure and a disease—the greater the imprecision, the greater the impairment.

Nonetheless, some very strong associations have been identified through record-based case–control studies. For example, Daling et al. (1982) conducted a tumour-registry-based case–control study to test the hypothesis that homosexual men have a relatively high incidence of anal cancer. Although registry data do not specify a man's sexual preference, they do contain information regarding his marital status. The investigators found that three times more men with anal cancer than controls (men with colon or rectal cancer) had never been married. Being single is far from a perfect predictor of homosexuality, of course. Nonetheless, the presence of such a large case–control difference, given the very poor means of gauging the relevant exposure, was a stimulus to conduct interview-based studies that could elicit information regarding sexual history with greater precision. The latter studies showed an exceedingly strong association between anal cancer in men and a history of sexual intercourse with another man (Daling et al. 1987).

In case–control studies in which medical records are used to characterize exposure status, care must be taken to restrict the information obtained to that which precedes the case's diagnosis (and the presence of symptoms, if any, that led to the diagnosis). The records of controls must be truncated at similar points in time. Without this safeguard, it is possible that bias will arise because there are systematically more records available to review on cases than controls; the case's illness may have stimulated an enquiry by

medical personnel into his or her past, whereas no corresponding enquiry would necessarily have occurred for control subjects.

Physical and laboratory measurements

The recognized limitations of interviews and records in characterizing a variety of potentially relevant exposures have stimulated the conduct of epidemiological studies that use laboratory and other methods of measurement. A woman cannot tell an investigator the level of her reproductive hormones, the concentration of various micronutrients in her blood, or whether her cervix is infected with human papillomavirus, but laboratory tests can. Unfortunately, such tests tell us what these things are only at the time that the specimens have been obtained. For some exposures, there will be a high correlation between the measured level following case and control identification, and that which was present during the aetiologically relevant time period. For example, lead enters and does not leave the dentine of teeth. Therefore, in young school-age children, lead dentine levels are an indicator of cumulative lead exposure, a good portion of which could be relevant to the development of intellectual impairment and other adverse neurological outcomes. In contrast, one would not rely on serum levels of reproductive hormones of postmenopausal cases of breast cancer and controls to indicate what their premenopausal levels were, much less their hormonal status during their very early reproductive years (at which time the hormones may be exerting their greatest impact on future risk of breast cancer).

Case definition

Ideally, the cases in a case–control study would comprise all (or a representative sample of) members of a defined population who develop a given health outcome during a given period of time. For studies of disease aetiology, that outcome is the disease incidence. For studies that seek to determine the efficacy of early disease detection or treatment, the outcome generally is the occurrence of complications of the disease or mortality; such studies have been described in detail elsewhere (Selby 1994; Weiss 1994), and will not be covered any further here.

The population from which cases are to be drawn may be defined geographically or on the basis of other characteristics such as membership in a prepaid healthcare plan or an occupational group. The identification of all newly ill people in a defined population can be facilitated by the presence of a reporting system such as a cancer or malformation registry that seeks to accomplish this identification for other purposes. Occasionally, care for the condition being studied may be centralized, so that it will be necessary to review the records of only one or a few institutions to identify all cases in the population in which those institutions are located. However, in many instances, it is not feasible to identify all cases that occur in a given population; therefore, case–control studies are often based on cases identified from hospital records, or from the records of selected providers from whom patients had sought healthcare. The study by Herbst et al. (1971) on vaginal adenocarcinoma was of this type. Whether or not the cases are derived from a defined population, it is necessary that they be drawn in an unselected manner with regard to exposure status; for example, by including in the study all otherwise eligible cases diagnosed or receiving care during a defined time period.

Although the goal of a case–control study of aetiology is to enrol incident cases, under some circumstances it may be necessary to enrol prevalent cases at a particular point in time, irrespective of when each one's illness had begun. For some conditions, the date of occurrence may simply not be known; for example, in the absence of very close sero-monitoring, one generally cannot determine when a person acquired an HIV infection. Furthermore, for uncommon diseases of long duration, an incidence series may yield too few cases for meaningful analysis. The disadvantages of using prevalent cases in a case–control study relate in part to the added problems of accurate exposure ascertainment. For prevalent conditions whose date of diagnosis is known, pre-illness exposure information on study subjects must be obtained for more distant points in the past, on average, than would be necessary for an incident series. For prevalent conditions whose date of occurrence is unknown (e.g. HIV infection), there will be uncertainty as to the best point in time before which one should elicit exposure information. Also, by studying people remaining alive with a given condition, one is simultaneously studying not only aetiological factors but also those that influence survival from the condition.

Ideally, the criteria used to identify and select individual cases for study should be objective with high sensitivity and specificity for the disease. Specificity is of particular concern, because the inadvertent inclusion of people without disease into the case group will generally obscure any true association with the exposure. With this in mind, in the case–control study of Reye's syndrome and antecedent analgesic use conducted by the Centers for Disease Control (Hurwitz et al. 1985), only cases with a substantial degree of neurological impairment (stage 2 or higher) were included. The use of this criterion minimized the chances that children with a disease other than Reye's syndrome, which generally would have a lesser degree of severity, would be included in the case group. It also was intended to serve as protection against selective misclassification of Reye's syndrome based on knowledge of exposure status, because the hypothesis of the association of aspirin with Reye's syndrome was well-known by the time the study took place. Conceivably, the knowledge that the child had consumed aspirin could have led some doctors to diagnose Reye's syndrome in cases with an atypical illness.

Control definition

Occasionally, the proportion of ill people who have had a specific exposure is so high, unequivocally more than would be expected in the population from which they were derived, that the presence of an association (although not its magnitude) can be surmised from a case series alone (Cummings and Weiss 1998). For example, when it was learned that all cases of a form of pneumonia that was epidemic in Spain in 1981 had ingested adulterated rapeseed oil, a causal inference was drawn, leading to efforts to eliminate further use of this oil. This action was taken before any formal comparison of cases with controls was made (Tabuenca 1981).

However, in the vast majority of instances, an explicit control group is needed to estimate the frequency and degree of exposure that would have taken place among cases in the absence of an exposure–disease association. An ideal control group would be one that comprises individuals:

Selected from a population whose distribution of exposure is that of the population from which the cases arose;
Who are identical to the cases with respect to their distribution of all characteristics (a) that influence the likelihood and/or degree of exposure, and (b) that, independent of their relation to the exposure, are also related to the occurrence of the illness under study or to its recognition;
In whom the presence of the exposure can be measured accurately and in a manner that is identical to that used for the cases.

If these criteria are not met in a particular study, then selection bias, confounding, or information bias, respectively, will be present.

Minimizing selection bias

If the cases identified in the study are all or a sample of those that occurred in a defined population, one can seek to achieve comparability by choosing as controls people sampled from that same population. For geographically defined populations, a number of different sampling methods have been used, including random digit dialling (RDD) of telephone numbers, area sampling, neighbourhood sampling, voters' lists, population registers, motor vehicle licences, and birth certificates, among others. When cases are members of a prepaid healthcare plan who develop an illness or injury, a sample of people who were members of the health plan when the illness or injury occurred can serve as controls. When cases are ill or injured members of an employed population, controls can be selected from this same population.

Enumeration of the defined population from which the cases arose may require an innovative approach. For example, Smith et al. (2001) identified recreational boating fatalities in Maryland and North Carolina among persons 18 years and above during 1990–1998, seeking to determine the presence and magnitude of an association with alcohol consumption. Of 221 fatal cases on whom blood alcohol levels were measured, 55% tested positive. To provide a basis for comparison, the investigators devised a plan to randomly sample recreational boats on the waterways of the two states, and then to obtain a breath sample for alcohol testing from the boat operator and a random sample of any passengers aboard (n = 3,943). Only 17% of

these persons chosen as controls had a positive result, and the disparity between cases and controls grew with increasing alcohol levels.

If cases have not been selected from a definable population at risk for the disease, but from people treated for a particular illness at one or a few hospitals or clinics, then selection bias may be introduced if controls are not chosen from people who, had they developed the illness under study, would have received care at these hospitals or clinics, and if people who do and do not receive care from these sources differ with regard to the frequency or level of exposure. Therefore, when cases are chosen from a narrow range of healthcare providers, controls are often chosen from other ill people treated by these providers. Such ill controls may also be used if, irrespective of the source of the cases, there is no feasible way to sample from the population at large, or if sampling from the general population would result in a substantial level of non-response or information bias. For these reasons, in some studies of fatal illness, exposures in people with a given cause of death are compared with exposures in a sample of people who died from other causes.

However, the choice of ill or deceased controls can itself give rise to selection bias if the illnesses (causes of death) represented in the control group are in some way associated with the exposure of interest. For example, ill or recently deceased people tend to have been smokers of cigarettes more often than other people (McLaughlin et al. 1985), because smoking is associated with a variety of causes of illness and death. Because smoking histories of ill people overstate the use of cigarettes in the population from which the cases arose (even if that population cannot be defined), the odds ratio associated with smoking based on the choice of ill people as controls will be spuriously low.

To minimize selection bias related to having chosen ill or deceased controls, an attempt can be made to omit potential controls with conditions known to be related (positively or negatively) to the exposure. For example, in the analysis of a hospital-based case–control study of bladder cancer and earlier use of artificial sweeteners, the investigators excluded from their control group people who were admitted to hospital for obesity-related diseases (Silverman et al. 1983). They showed that without this restriction, the control group would have a spuriously high proportion of users of artificial sweeteners relative to the population from which their cases had actually come. This approach will succeed to the extent that one judges

correctly which conditions are truly exposure-related, and how accurately the presence of those conditions can be determined. For many exposures, this may pose little problem, and judicious exclusion will yield a control group capable of providing an unbiased result. For others, such as cigarette smoking or alcohol consumption, it has been shown that admitting diagnoses or statements of cause of death are incapable of identifying all people with illnesses related to these exposures (McLaughlin et al. 1985).

Some case–control studies simply compare exposure status among subgroups of patients with the same outcome. For example, Laumon et al. (2005) obtained blood samples of 10,748 drivers involved in fatal road accidents in France during 2001–2003, and had these analysed for a metabolite of cannabis. The investigators contrasted the proportion testing positive between drivers judged to have been at fault for the crash (‘cases’) and drivers judged not to have been at fault (‘controls’). The results of such a study will be valid when it is possible to identify those drivers who were at fault. To the extent that this is not possible, the misclassification that ensues will tend to make the size of the observed association smaller than the true one.

Occasionally, controls are chosen from individuals who are tested for the presence of the disease under study and are found not to have it. For example, in a study of the effectiveness of influenza vaccines, nasal and oropharyngeal swab specimens were obtained in persons with an acute respiratory illness. Vaccination histories were compared between persons who tested positive for the presence of influenza virus and those who tested negative (Jackson et al. 2017). As another example, the prior use of oral contraceptives was compared between women diagnosed with venous thromboembolism and women seen at the same institution for suspected venous thromboembolism who were diagnosed as not having this condition (Bloemenkamp et al. 1999). It may be relatively inexpensive to select controls from people who receive the same diagnostic evaluation as do cases, and it is also possible to achieve case–control comparability with regard to the choice of a healthcare provider (and the correlates of that choice). This approach can have an impact on the study’s validity if the frequency or degree of exposure differs between otherwise comparable members of a population who do and do not receive the test. It will increase the validity if the disease being investigated is generally asymptomatic, and so would not be detected in the absence of testing. Thus, the relation of the

use of oral contraceptives with the incidence of *in situ* cancer of the cervix is best studied in women who have undergone cervical screening, by comparing oral contraceptive use between cases of *in situ* cancer and women with a negative screen. This is because:

In most societies, women who use oral contraceptives are screened more commonly than women who do not.
In situ cancers are asymptomatic and will not be identified in the absence of cervical screening.

Therefore, if controls are chosen from women in general, who may or may not have received cervical screening, an apparent excess of oral contraceptive users would be present among cases of *in situ* cancer even if no true association were present.

However, the choice of test-negative controls can detract from a study's validity if the large majority of the people who develop the disease would soon be diagnosed whether or not the test was administered. There was a controversy in the late 1970s regarding the suitability, in case–control studies, of postmenopausal oestrogen use and endometrial cancer, of a control group restricted to women with no evidence of cancer on endometrial biopsy. Among women without endometrial cancer, oestrogen use differs greatly between those who have and have not undergone biopsy, because oestrogen use predisposes to uterine bleeding of non-malignant causes, which often leads to endometrial biopsy. Those investigators who believed that there was a great prevalence of occult endometrial cancer in the population suggested that the optimal control group ought to be women undergoing endometrial biopsy and found not to have cancer (Horwitz and Feinstein 1978). However, the majority of the investigators believed that no such large pool of prevalent, occult disease existed, and that choosing biopsy-negative controls would lead to a spuriously high estimate of oestrogen use in the population at risk, and thus, a spuriously low odds ratio (Shapiro et al. 1985).

No matter how controls are defined in a case–control study, selection bias may be introduced to the extent that exposure information is not obtained on all who have been selected to participate. The magnitude of this bias will increase in relation to the frequency of missing data and the degree to which exposure frequencies or levels differ between study subjects on whom

exposure status is and is not known. The problem of incomplete ascertainment of exposure on study subjects is particularly common in interview- or questionnaire-based case–control studies. Strategies for minimizing the degree of non-response in case–control studies are discussed in detail elsewhere (White et al. 2008).

Minimizing confounding

Characteristics of confounding variables in case–control studies

Confounding occurs when the estimate of the relationship between an exposure and a disease is distorted by the influence of another factor. In any study design, confounding will occur to the extent that the other factor is associated with both the exposure (although not as a result of the exposure) and the disease or its recognition. In case–control studies alone, a factor may confound even if it is not associated with an altered risk of disease, if the proportions of cases and controls vary across levels or categories of the factor. For example, in a collaborative study of ovarian cancer and use of oral contraceptives (Weiss et al. 1981), an attempt was made to identify and interview all incident cases over several years in two American populations. In one of the populations (western Washington State), several controls per case were interviewed, whereas the control-to-case ratio in the other (Utah) was 1:1. Because oral contraceptive use was more common among women in Washington than in Utah, failure to take into account the state of residence in the analysis (e.g. by adjustment) would have led to a spuriously high estimate of the frequency of oral contraceptive use by controls relative to that by the cases.

Means of controlling for confounding

One straightforward way of preventing confounding is to restrict cases and controls to a single category or level of the potentially confounding variable. For example, in their study on physical activity and primary cardiac arrest, Siscovick et al. (1982) excluded people with conditions, such as clinically recognized heart disease, that could both predispose to cardiac arrest and might be expected to alter level of activity. A second way is to obtain information on exposures or characteristics that may differ between cases and controls, and then make statistical adjustments for those that are

also found to be related to the exposure or characteristic under investigation (Rothman et al. 2008).

Finally, it is possible to match one or more controls to each case's category or level of a potentially confounding factor. It is appropriate to match if:

The variable is expected to be strongly related to both the exposure and disease. Thus, in a case–control study of breast cancer and use of hair dye, it would make sense to match on gender (if the study has not already been restricted to women) because use of dye is more common among women than men in most cultures. Although confounding by gender could be prevented even without matching by adjustment in the analysis, the statistical precision of the unmatched study would be substantially reduced relative to that of a case–control study having a more similar proportion of female cases and controls.

Information on possible matching variables can be obtained inexpensively. There are some means of control selection in which information regarding some confounders can be obtained at no cost. For example, from voters' lists or prepaid health plan membership records, it would generally be possible to choose directly one or more controls who were identical to a given case's age. Conversely, if a population sampling scheme such as RDD were being employed, the age of the respondent would not be known in advance of approaching him or her. Rather than omitting already contacted controls who did not match a particular case's age, the matching can be done much more broadly; additional control for finer categories of age can be accomplished in the data analysis.

Information on exposure status cannot be obtained inexpensively. The higher the cost of exposure ascertainment, the greater the incentive to limit the number of control subjects to the number of cases. Case–control differences regarding confounding factors particularly will reduce the statistical power of a study that does not have a surplus of controls. Enriching the group of controls selected with people more similar to the cases with regard to confounding factors (i.e. matching) can prevent this loss of statistical power.

In case–control studies of genetic characteristics as possible aetiological factors, some investigators have used a matched design in which a specific

type of relative (e.g. parent, sibling, or cousin) is chosen as a control for each case (Yang and Khoury 1997; Witte et al. 1999). This approach has the advantage of minimizing potential confounding by other genetic characteristics with which the one of interest is associated. However, it has the disadvantage of excluding a possibly large fraction of cases for whom there is no relative available of the type needed to provide a sample for genetic analysis.

It should be remembered that matching alone is not sufficient to eliminate a variable's confounding influence; failure to consider a matching variable in the analysis of the study can lead to a biased result (Rothman et al., 2008). Analyses of studies that have matched controls to cases on a given characteristic can adjust for that characteristic as if no matching had taken place. Alternatively, these analyses can explicitly consider cases and controls as matched sets. In the instance of matched case–control pairs and a dichotomous exposure variable, the following table could be constructed. See Table 5.4.2.

Table 5.4.2 Matched case-control study

Cases	Controls	
	Exposed	Non-exposed
Exposed	*a*	*b*
Non-exposed	*c*	*d*

Only the *b* pairs in which the case was exposed but not the matched control, and the *c* pairs in which the reverse was true, would enter the analysis. The odds ratio would be calculated as *b/c*. When there is more than one control per case, the matched odds ratio can be calculated as well (Breslow and Day 1980).

Minimizing information bias

For case–control studies in which information on exposure status is sought via an interview or questionnaire, the chief safeguards against information

bias entail asking questions about events that are salient to the respondent, that are framed in an unambiguous way, and that are presented identically to both cases and controls. Employment of these safeguards, however, will not prevent differential accuracy of reporting between cases and controls in all circumstances. Some past exposures or events will simply be more salient to people with an illness, who might have dwelled on possible reasons for its occurrence, than to people without that illness. Other exposures may be viewed as socially undesirable, and there may be a difference between cases and healthy controls in their willingness to admit to them. If the anticipated difference in the quality of information between cases and otherwise appropriate controls is too great, a control group that is less than ideal in other respects may be selected instead so as to minimize the potential for information bias. For example, some studies of prenatal risk factors for a particular congenital malformation that utilize maternal interviews as the source of exposure data have selected as controls infants with other malformations (Lieff et al. 1999). This control group will provide a more valid result than a control group that consists of infants in general if mothers of malformed and mothers of normal infants report prenatal exposures to a different degree even in the absence of an association, and the exposure in question is not associated with the occurrence of the malformations present in control infants.

Similar reasoning led Daling et al. (1987), when conducting their case–control study on anal cancer and a history of anal intercourse, to eschew the geographic population from which their cases had arisen as a sampling frame for controls. They feared that interviews that sought information about prior anal intercourse might be more complete among men with cancer than men in the population at large. Thus, they chose as controls men with a cancer of a different site (colon), which they believed was unlikely to have been aetiologically related to prior anal intercourse.

When the exposure under consideration is sufficiently imprecise or is open to subjective interpretation, there may not be any control group that will provide information comparable to that provided by cases. An instructive example comes from a case–control study on Down's syndrome (Stott 1958), conducted shortly before the chromosomal basis for the aetiology of this condition had been learned. The study sought to determine whether emotional 'shocks' during pregnancy might be a risk factor. The author interviewed mothers of children with Down's syndrome with regard

to the occurrence of a ‘situation or event [that would be] stress- or shock-producing if this would have been its expected effect on an emotionally stable woman’. Identical interviews were administered to mothers of normal children, and also to mothers of children with mental retardation who did not have Down’s syndrome. Even though it is not possible that an emotional shock in pregnancy could play any aetiological role in a condition already determined at conception, a far higher proportion of mothers of cases of Down’s syndrome reported an emotional shock than did mothers of normal controls (RR estimated from the data, 17.0). The use of other children with mental retardation as controls only partially reduced the spuriously high RR, to a value of 4.3.

When conducting an interview-based study of a rapidly fatal disease, or a disease that impairs a person’s ability to provide valid interview data, it is necessary to obtain information from at least some surrogate respondents; typically, these respondents are close relatives of the cases. In general, for purposes of comparability, similar information ought to be obtained from surrogates of controls, even though the control would be expected to provide more accurate data. Results of case–control studies based on exposure information provided by surrogate respondents need to be interpreted with particular caution. Although by no means present in every instance (Nelson et al. 1990, Campbell et al. 2007), there can be a large difference in the validity of the responses given by case and control surrogates. For example, Greenberg et al. (1985) investigated the basis for an apparent strong association between cancer mortality and ‘nuclear’ work among employees of a naval shipyard, which had been found during a comparison of work histories provided by surrogates of men who died from cancer and of those who died of other conditions. They observed that, regarding work in the nuclear part of the industry, surrogates of the cases generally provided information similar to that contained in employment records of the shipyard; in contrast, the surrogates of controls substantially misclassified the nature of their relatives’ jobs as not involving radiation. Using the data provided by employment records, which included individual radiation dosimetry, little or no association was found between cancer mortality and radiation exposure received at the shipyard (Rinsky et al. 1981).

What was undoubtedly a spuriously negative association was found in a case–control study of lung cancer and passive cigarette smoking that used,

for one analysis, information obtained from surrogate respondents (Janerich et al. 1985). In this analysis, the RR of lung cancer among non-smokers associated with a spouse's having smoked—0.33 (i.e. a 67% reduction in risk)—would seem almost certainly due to a spurious minimization or the denial of smoking by spouses of cases, who may have feared their habit caused their spouse to develop lung cancer.

In most interview-based case–control studies, information is not sought from cases until days to months have elapsed following the diagnosis of their condition. These persons are queried regarding exposures that occurred during what is presumed to be the aetiologically relevant period prior to diagnosis. For controls, for whom there is no 'diagnosis' date, what is the appropriate timeframe in which to focus the questions that are asked of them? If exposures that occurred sometime in the past, or that occurred over an extended period, are most likely to be relevant, controls are generally asked about events during the same calendar time as the cases. However, when studying exposures that could act acutely to lead to illness, having the case recall events immediately prior to illness and the control do the same for the corresponding time in the past may lead to bias: Only the cases will have the onset of their illness to help in recalling events that took place shortly prior to that time. This difference could lead to relatively more complete ascertainment of exposure among cases.

In response to this concern, some case–control studies investigating potentially rapidly acting exposures query controls about the time period prior to the date of interview instead of the date of their case's diagnosis (or, in an unmatched study, the date of a typical case's diagnosis). So, in a study of risk factors for meningococcal disease in adolescents (Tully et al. 2006), cases were asked about events during the two weeks prior to diagnosis (which occurred, on average, 53 days before the interview) and controls about events during the 2 weeks just prior to the interview itself. The investigators felt that the plausibility of case–control comparability on recall of exposures involved in transmission (e.g. 'intimate kissing with multiple partners') would be greater using this approach than one in which the controls were asked about a 2-week period ending 53 days prior to the interview. However, although a sound approach when trying to estimate the short-term influence of many exposures, this strategy can backfire if recall of an exposure diminishes over time to the same degree in cases and controls. For example, in the study of meningococcal disease, a far smaller

proportion of cases than controls reported attending religious observances during their respective two-week intervals (adjusted odds ratio = 0.1, 95% confidence interval = 0.02–0.6). Almost certainly, this difference had more to do with relatively poorer recall of churchgoing among cases (who had to think back some 2 months) than to a genuine salutary effect of church attendance on the incidence of meningococcal disease.

Incomparable assessment of exposure status between cases and controls is not confined to interview- or questionnaire-based studies. Most laboratory-based studies seek to prevent this by testing samples blind to case and control status. If feasible, it is desirable to also carry out this blinding for studies in which exposure is to be determined from medical or other records. However, there are instances in which the nature of the information available in records has already been influenced by whether the subject is a case or a control. For example, it was found that among 100 infertile women who underwent laparoscopy (Strathy et al. 1982), 21 had endometriosis. Only 2% of the 200 women who underwent laparoscopy for another indication, tubal ligation, were noted in the procedural records as having endometriosis. However, the interpretation of this association is unclear, because the identification and/or recording of endometriosis in cases and controls (women undergoing tubal ligation) may well have been incomparable—only in the infertile women was the laparoscopy expressly done as a diagnostic tool to investigate the possible presence of conditions such as endometriosis.

Estimating attributable risk from results of case–control studies

Occasionally, a case–control study identifies a large odds ratio relating an exposure to a disease, and for this and other reasons, a causal influence of the exposure may be suspected. The decision to seek to limit or eliminate that exposure requires weighing its negative and positive consequences. This weighing must be done in absolute, rather than in relative terms, because the same relative increase (or decrease) in risk is of far greater consequence for common than for rare outcomes. The absolute increase in the risk of disease believed to be due to a dichotomous exposure, sometimes referred to as the ‘attributable risk’ (AR), can be estimated directly from

data gathered in cohort studies or randomized trials as the difference between the incidence among exposed (I_e) and non-exposed people (I_n). The formula $I_e - I_n$ can be rewritten as RR(I_n) − I_n, or as I_n(RR − 1). Because the RR can be estimated from the results of a case–control study by means of the odds ratio, the only additional piece of information needed to estimate the attributable risk is an estimate of I_n. For the population in which the study has been conducted, I_n can be estimated if:

The overall incidence (I) of the disease in that population is known or can be approximated.
The frequency of exposure (P_e) in the controls selected for study reasonably reflects that of the population that gave rise to the cases.

Given (1) and (2),

$$\begin{aligned} I &= I_e(P_e) + I_n(1 - P_e) \\ &= I_n \mathrm{RR}(P_e) + I_n(1 - P_e) \\ &= I_n\left(P_e[\mathrm{RR} - 1] + 1\right) \end{aligned}$$

So,

$$In = \frac{I}{P_e(\mathrm{RR} - 1) + 1}$$

Therefore,

$$\mathrm{AR} = \frac{I(\mathrm{RR} - 1)}{P_e + (\mathrm{RR} - 1)} = \frac{I}{P_e + 1/(\mathrm{RR} - 1)}.$$

For example, consider a disease with an incidence rate of 10 per 100,000 per year in a population in which 5% of people have been exposed during a relevant period of time. Table 5.4.3 summarizes data from a case–control study conducted in that population:

Table 5.4.3 Data from a case-control study

Exposed	Cases (%)	Controls (%)	OR
Yes	15	5	3.35
No	85	95	1

The attributable risk that corresponds to the estimated 3.35-fold increase in risk is

$$10 = 0.05 + 1/(3.35 - 1)\ 21.0 \text{ per } 100{,}000 \text{ per year}$$

From the results of case–control studies that suggest a causal relation, it is also possible to estimate the percentage of exposed people with the disease who developed it because of their exposure, rather than through one or more causal pathways not involving the exposure. This measure, often termed the 'attributable risk per cent' (AR%) among exposed people, is defined as

$$\frac{I_e - I_u}{I_e} \times 100.$$

It can be described in terms of the RR alone:

$$\text{AR\%} = \frac{I_e}{I_e} - \frac{I_u}{I_e} = 1 - \frac{1}{\text{RR}} = \frac{\text{RR} - 1}{\text{RR}} \times 100.$$

Therefore, the results of a case–control study that provide a valid estimate of the RR (via the odds ratio) can provide the attributable risk per cent as well, with no additional assumptions or sources of data. It is also possible to estimate the percentage of a disease's occurrence in the population as a whole that resulted from the actions of given exposure. This measure, the 'population attributable risk per cent' (PAR%) or 'aetiological fraction', is simply the attributable risk per cent multiplied by the proportion of cases in that population who were exposed (P_e):

$$\text{PAR\%} = \text{AR\%} \times P_e$$

In the present example,

$$AR\% = \frac{3.35 - 1}{3.35} = 70.1\%$$

and

$$PAR\% = 70.1\% \ (0.15) = 10.5\%$$

The role of case–control studies in understanding disease aetiology

Randomized trials will not be able to answer all questions regarding the reasons for disease occurrence. Many potential disease-causing or disease-preventing exposures cannot be manipulated, either at all—for example, most genetic characteristics—or in any practical way for purposes of a study. For many exposure–disease relationships, either the disease is too uncommon or the induction period is too long to conduct a randomized trial that is not unfeasibly large in size or long in duration. Finally, it generally will not be possible to conduct separate randomized trials to measure the impact of all potential types, amounts, and durations of a class of exposure.

Also, it is not possible to rely solely on cohort studies for answers. Just as with randomized trials, the disease outcome being studied may be too rare to allow a cohort approach to be useful. This explains why the aetiologies of vaginal adenocarcinoma and Reye's syndrome, for example, have been evaluated exclusively by case–control studies—these diseases are simply too uncommon for most cohort studies to generate any cases, even in 'exposed' individuals. Prospective cohort studies are also of limited use when the induction period for the exposure–disease relationship is either very short or very long. If the induction period is very short and the exposure status of an individual varies over time, a cohort study would need to assess exposure status repeatedly among cohort members. For this reason, studies of alcohol consumption and the occurrence of injuries typically are case–control in nature (Holcomb 1938). Similarly, unless information on exposure status can be ascertained retrospectively, it would

not be feasible to initiate a cohort study of a suspected aetiologic relation that requires a very long time (perhaps several decades) to manifest itself.

Although case–control studies may be of particular value in the evaluation of the aetiology of uncommon disease, they may have difficulty in obtaining statistically precise results if the frequency of the exposure in the population under study is either extremely common or extremely uncommon (Crombie 1981). Thus, only an association as strong as the one between cigarette smoking and lung cancer could have emerged reliably from case–control studies of several hundred British men conducted in the late 1940s (Doll and Hill 1950), given that well over 90% of that population were cigarette smokers. For very uncommon exposures—for example, occupational exposure to a specific substance suspected of posing a risk to health, or an infrequently prescribed drug—barring a strong observed association based on a large number of subjects, even the best-designed case–control study will usually offer no more than a suggestion of the presence or absence of a relation with regard to the occurrence of a given illness.

Conclusion

Case–control studies compare ill or injured persons (cases) with those at risk of the illness or injury (controls) in terms of prior exposures or characteristics.

From most case–control studies of a given condition it is possible to obtain an estimate of the RR associated with an exposure by dividing the odds of exposure in cases by the odds of exposure in controls (odds ratio).

The validity of the results of a case–control study can be compromised by differences between cases and controls with regard to exposures or characteristics that are also correlated with the likelihood or degree of the exposure in question.

In most case–control studies, ascertainment of exposure status is undertaken after the cases have sustained their illness or injury. These studies will produce an unbiased estimate of an exposure–disease association to the extent that exposure status prior to disease onset can be ascertained with a high degree of sensitivity and specificity.

In a setting in which (a) randomization of potential study participants is unethical or infeasible and (b) the outcome under study is an uncommon one, data from case–control studies may be the best available by which to judge a potential cause–effect relationship between the exposure and outcome.

Cohort studies

Alvaro Muñoz and F. Javier Nieto

Introduction to cohort studies

Cohort studies constitute one of the basic types of designs in epidemiological research. The key element of cohort studies is temporality (i.e. exposure preceding an outcome). Specifically, a cohort (i.e. group of individuals) is enrolled at the beginning of the study (baseline) to examine how characteristics (exposures) predict the occurrence of a discrete event (typically a disease onset) or changes in markers of health/disease status. In the former case, the cohort is typically formed by individuals who are free from the outcome of interest and have sufficiently heterogeneous profiles of putative risk factors (whose simplest form is as exposed or unexposed). In the latter case, the central aim is to characterize the heterogeneity of the change or trajectory of markers of disease progression according to constellations of putative risk factors.

The identification of exposures and risk factors for disease provides a basis for prevention. There are numerous examples of cohort-based exposure–disease associations that have resulted in beneficial prevention strategies: for instance, to prevent lung cancer, cigarette smoking should be avoided; to prevent infection with human immunodeficiency virus (HIV), high-risk sexual practices and injection with unsterile needles should be avoided; and to prevent heart disease, adequate lipid profiles should be achieved (by diet, exercise, and/or lipid-lowering medications). Needless to say, there are instances in which the design of prevention strategies faces the complexity of multifactorial aetiology and of exposures that cluster so that exposures have to be taken into account jointly. When an exposure is not a *sufficient* cause but a *component* of a more complex constellation of causal factors (Rothman et al. 2007; Szklo and Nieto 2018), acting only on that exposure may not result in successful prevention strategies; for example, based on data from cohort studies, high levels of beta carotene markers (purportedly resulting from appropriate diets) had been associated with protection against cancer (Willett et al. 1984), but supplementation with beta carotene only has not resulted in a lower incidence of cancer in clinical trials (Alpha-

Tocopherol, Beta Carotene Cancer Prevention Study Group 1994; Virtamo et al. 2003).

Types of cohort studies

The observational cohort design shares with the experimental design or controlled clinical trial the temporal relationship between exposure and disease. The clinical trial design is a special type of cohort study in which the study subjects are randomly assigned to the different experimental (exposure) groups. Given the inherent limitation of observational designs to control for potential confounding variables unidentified by the investigator, the difference between these study designs lies on the validity of the conclusions on causal inferences. The role of randomization in clinical trials is to make the two groups comparable so that the effect of a therapy can be determined. But randomized controlled trials are not ethical or feasible when exploring the effects of potentially harmful exposures; moreover, the generalizability of results in highly selected trial participants is often limited. This is the reason why observational cohort studies, with all their limitations and caveats, will always be an important study design in epidemiological research.

In some studies, the investigator collects the data *concurrently* with the study being conducted, and in others, the data are available before the study is designed and the study is conducted to obtain that data (i.e. the data for the study precedes its conduct or the study is *non-concurrent*). This type of design is called ‘retrospective study’ by some authors (Vandenbroucke 1991), a term that can cause confusion because it is also used for case–control studies.

The simplest cohort design is to obtain exposure data at baseline and follow-up individuals to only obtain data for when the event of interest occurs. A richer design includes regularly scheduled visits to update exposure data, including repeated physical exams and collection of biological samples, as appropriate. When the outcome of interest is not an event but is change in the profile of a biomarker over time (e.g. change in kidney function measured by filtration rate), cohort studies are often referred to as *longitudinal studies*.

Design issues in cohort studies

The nature of a cohort study provides the temporal structure necessary to associate a particular exposure with a subsequent event of interest. The time at which an exposure first occurs, placing individuals at risk for event development, is referred

to as the *origin* (e.g. birth in population-level life-course epidemiology, infection with a microorganism in infectious disease epidemiology). Ideally, a cohort study will have complete data of the time elapsed between the origin and the event of interest for as many participants as possible. However, in most studies, not all individuals are followed up from the origin: some will have been at risk for some time since the origin when enrolled into the cohort study. Those followed up from the origin are called the *incident* cohort and those entering the study after a certain duration from the origin are called the *prevalent* cohort. Implementation of the appropriate statistical methods to combine incident and prevalent cohorts may not only yield more efficient estimates but also provide the means for appropriately describing the timing of events beyond the study duration (Muñoz et al. 1997).

For some diseases, the origin is well defined and observable, such as employment into an occupation deemed to place workers at risk for health events. For others, the origin is well defined but difficult to observe, such as infection with a virus. Still others do not have a well-defined origin, as in the case of coronary heart disease in which the origin may be the time of initiation of atherosclerotic plaques in the inner layer of the coronary arteries, the time when a certain level of coronary artery stenosis is reached, or the time when an atherosclerotic plaque ruptures and acutely occludes an arterial branch leading to clinical manifestations (angina or myocardial infarction). Cohort studies with data on individuals from origin to the event of interest as well as with baseline information and updated information on predictors at regular intervals between the origin and event provide the most complete data to describe the natural history of a disease (Muñoz et al. 1992; Muñoz and Xu 1996; Muñoz et al. 1997).

Study population

The cohort can be the totality of a geographically and temporally defined population. For example, Hoffmans et al. (Hoffmans et al. 1988) constructed a non-concurrent study of mortality among Dutch males born in 1932. This cohort included the totality of the 84,349 Dutch males who were 18 years old in 1950, when they were examined for eligibility to military service; the investigators used the data collected at baseline (when the individuals were 18 years old) to describe the relationship between obesity at 18 years and subsequent cause-specific mortality (Hoffmans et al. 1989).

Instead of the totality of a population, it is more common to include only a fraction or a sample of a population defined temporally and geographically. For instance, as outlined in Table 5.5.1, the Framingham study was initiated at the beginning of the 1950s in Framingham, Massachusetts, United States, with the goal of studying the incidence of and risk factors for cardiovascular diseases

(Dawber 1980). From a list of residents aged 35–59 years (18,000 persons in total), 6,507 adults were randomly selected, among whom 4,469 agreed to participate in the initial examination. To compensate for the unexpectedly high rate of refusal, 734 volunteers were also added as members of the cohort. Of the resulting 5,203 participants in the baseline examination, 76 persons were excluded for having clinical manifestations of cardiovascular disease, leaving a total of 5,127 participants in the Framingham Heart Study cohort. The follow-up consisted of physical examinations every 2 years with comprehensive data collection on suspected risk factors.

In order to improve generalizability, subsequent cohort studies of cardiovascular disease conducted in the 1980s aimed at recruiting more diverse geographic, ethnic, and socioeconomic groups in the United States. Specifically, the CARDIA study (Friedman et al. 1988) recruited a total of 5,115 persons between 18 and 30 years of age in four states; the Atherosclerosis Risk in Communities (ARIC) study (ARIC Investigators 1989) cohort comprised 15,800 persons aged 45–64 years at the beginning of the study and residents of four states; and the CHS (Fried et al. 1991) followed up 2,955 participants 65 years or older in another four communities of the United States.

In addition to strict temporal and geographic criteria, a cohort can also be defined by a group of individuals sharing common characteristics, which facilitates the follow-up and the accuracy of the data to be collected. For example, the Multicenter AIDS Cohort Study (MACS) (Kaslow et al. 1987; Dudley et al. 1995) comprised homosexual men in four metropolitan areas of the United States with the overall aim of describing the natural history of HIV infection and AIDS (see Table 5.5.1).

From April 1984 to March 1985, a cohort of 4,954 men were recruited into the MACS in four metropolitan areas of the United States (Baltimore, Chicago, Los Angeles, and Pittsburgh). To increase minority enrolment, an additional 668 men, 69.3% of whom were non-Caucasian, were recruited in 1987–1991. To address issues of long-term effectiveness of therapies and their putative adverse effects, 1,397 men were additionally enrolled in 2001–2010. Therefore, the entire MACS cohort as of September 2012 consisted of 7,019 men with three primary inclusion criteria: men having sex with men, older than 18 years, and AIDS-free at enrolment. Of them, 2,905 (41%) were seroprevalent for HIV at entry into the study. All men were followed up every 6 months with repeat interviews, physical examinations, and collection of blood used to characterize the level of HIV-induced immunosuppression. Confirmation of AIDS diagnoses was made by obtaining physician and hospital summaries and by reviewing medical records and deaths were monitored by follow-up and through an ongoing search of death records.

When a specific registry with baseline data is available, it provides the opportunity to conduct a non-concurrent cohort study. For example, Nieto et al. (1992) used a registry of physical examinations carried out on schoolchildren between 1933 and 1945 in Hagerstown (Maryland, United States) to assemble a non-concurrent cohort of about 13,000 children in order to study the relationship between childhood obesity and adult mortality; the baseline information obtained between 1933 and 1945 was linked to the mortality experience of the cohort up to 1985. In other historical cohorts, the study population is defined from the beginning as a function of the exposure factors to be investigated. Thus, participants are selected explicitly according to the presence or absence of the characteristics considered to be possible risk factors, such as a cohort of Norwegian electricians. As summarized in Table 5.5.1, this historical cohort of 37,945 workers was defined from the registry of occupations of the working population in Norway according to the 1960 census (Tynes et al. 1992).

Table 5.5.1 Examples of cohort studies

	Framingham (Dawber 1980)	**MACS (Kaslow et al. 1987; Dudley et al. 1995)**	**Norwegian electricians (Tynes et al. 1992)**
Study aims	Incidence and risk factors for cardiovascular diseases and hypertension	Natural history of HIV infection and AIDS	Relationship between electromagnetic radiation and cancer incidence
Type of study	Concurrent	Concurrent	Non-concurrent
Date	1949– current	1984– current	1960–1991
Study Population	Adults resident in Framingham, Massachusetts, USA	Homosexual men in four metropolitan areas of the USA	Electricians in 1960 census in Norway
Simple size	5,127	7,019	37,945
Sex	Male and female	Male	Male
Age at baseline (years)	30–62	18–70	20–70
Active follow-up	Study visits every 2 years including physical exam, electrocardiogram, and laboratory exams	Study visits every 6 months with extensive interviews including behaviour and medical care, physical exam, laboratory exams, and collection of blood samples for national repository	–
Passive follow-up	• Clinical records (in case of hospitalization) • Death certificates	• Clinical records • Death certificates • National Death Index	• Cancer registries • Death certificates

With the increasing availability of electronic health records, new opportunities to use administrative healthcare databases as a basis for defining and conducting large-scale cohort studies are emerging (Phillips et al. 1999; Sterne et al. 2009; Manolio et al. 2012). These approaches can be particularly powerful when combined with a comprehensive system of national registries, such as those offered by countries like Denmark (Frank 2000). On the other hand, they may be limited by the relative scarcity of ‘negative’ controls (i.e. healthy subjects) and by an under-representation of people who do not have access to (or choose not to take

advantage of) healthcare services. In addition, the quality of the data collected for clinical purposes is variable, not usually subject to the rigours of standardization and quality typical in research settings, especially when studying phenomena that are not directly related to clinical care (e.g. upstream community determinants, psychosocial factors).

Finally, cohort studies can outlive themselves such as when the offspring of the cohort members are recruited with the purpose of conducting family and genetic studies. The Framingham Heart Study was again a pioneer in this methodology, when in the late 1970s the daughters and sons of the original cohort members (and their spouses) were recruited to constitute the Framingham Offspring Study (Kannel et al. 1979; Djoussé et al. 2002).

Baseline visit

The objective of the baseline visit in a concurrent cohort study is generally the classification of the study participants according to the exposure factor or factors under investigation, as well as according to potentially relevant covariates (confounders) and/or effect modifiers. For example, Furth et al. (2006, 2011) designed a cohort of children with chronic kidney disease to determine the risk factors for progression towards end-stage renal disease; for this, they recruited 586 children aged 1–16 years with an estimated glomerular filtration rate of between 30 and 90 mL/min/1.73 m^2, indicating a level of insufficiency in their kidney function that put them at risk of end-stage renal disease. Also important is the collection of information that facilitates the subsequent tracking of study participants during the follow-up including information on contacts.

In its simplest form, the baseline visit can take place over a single continuous time period until the desired sample size is reached. In many cases, however, more participants are recruited: (1) to replace those who have developed the event of interest or who have been lost to follow-up, (2) to include groups of individuals who were under-represented in the original recruitment, and/or (3) to respond to new scientific challenges due to the changing nature of the epidemiology of the disease of interest.

Follow-up

The follow-up can be active, by repeated contacts via successive visits to a health centre, mailed questionnaires, phone calls, or online contacts. Sometimes, the different forms of contacting participants are alternated. For example, in the follow-up of the ARIC study, participants were invited every 3 years to return to the clinic for a new physical examination and complementary assessments (ARIC

Investigators 1989); in addition, each participant was called every year and asked about illnesses and hospitalizations occurring in the interim period since the last clinic visit. This is in contrast to clinic-based cohort studies in which visits take place according to the health needs of the participants.

For certain diseases and events (e.g. death, cancer), external sources (i.e. national death index, registries) can be used to record events occurring among the individuals enrolled in the study. The type and automation of the record linkage system is determined in each case by the availability of data and the characteristics of each particular registry.

The quality of the information about the occurrence of events is fundamental for correct estimation of the incidence and its determinants. Therefore, in many cohort studies, a special effort is made to ensure that the information about disease occurrence or death is accurate. Generally, events recorded in interviews with study participants are verified by requesting documents such as the clinical records, not only to verify the occurrence of the event but also to improve the information regarding diagnosis (e.g. to obtain the histological type in a study of lung cancer; to distinguish between thrombotic and haemorrhagic episodes in a study of cerebrovascular events). A major challenge in cohort studies with cause-specific mortality as the event of interest is the determination of the cause of death, which may require confirmation by inspecting clinical records or by interviewing the physician who attended to the participant before his or her death.

Types and measures of exposures

The classification of study participants according to exposure factors is one of the most complex challenges in a cohort study. *Exposure factor* means any attribute of the subject or any external agent that can influence the subject's health (Armstrong et al. 2008).

Types of exposures

Exposure factors include host factors (such as age, sex, race, genetic factors, metabolic factors, and immune function) and environmental factors (such as viruses and bacteria, environmental pollutants, diet, alcohol, and/or tobacco consumption). Sometimes, an exposure factor represents a set of factors that are difficult to separate. For example, social class encompasses external environmental factors, related to individual behaviour, access to healthcare services, socioeconomic status, and others.

The exposures can be either fixed over time (e.g. race) or variable. The latter could be exposures that change directly with time (e.g. age and calendar) or change at their own pace with time (e.g. cigarettes smoked per day, biological marker levels, diet). When exposures not only change over time but do so heterogeneously (i.e. change differently over time in different individuals), they are referred to as *internal* (i.e. at the individual level) time-dependent exposures. In contrast, exposures that change over time but affect groups or populations who are subject to the exposure in a similar way are referred to as *external* (i.e. at the population level) time-dependent exposures (i.e. they change equally over time for different individuals comprising a given population) such as for example, calendar time, seasonal weather changes, levels of air pollution in a given region, supplements in the food, and introduction of newly approved medical therapies.

Follow-up visits provide the opportunity for collecting data to update internal time-dependent exposures. External time-dependent exposures may be obtained from external sources, but data obtained at the individual level can sometimes be used to define eras (i.e. calendar periods) when there are changes at the population level. For example, the MACS started in 1984 and has since been conducted concurrently with major advances in therapies effective against viral replication in HIV-infected individuals. In 1998, Detels et al. (Detels et al. 1998) determined the effectiveness of the potent antiretroviral therapies introduced in 1995 by showing a doubling of the AIDS-free times under the conditions of the first 2 years (July 1995–July 1997) of the highly active antiretroviral therapy (HAART) era (Detels et al. 1998). In 2005, Schneider et al. (Schneider et al. 2005) determined the population effectiveness of prolonged use of HAART by showing that in the era when HAART was well established (i.e. July 2001–December 2005, 6–10 years after its introduction in July 1995), the median survival time after AIDS diagnosis increased tenfold from the 1.5 years in the era when no therapies were available (Schneider et al. 2005).

In cohort studies, two types of effects of interventions can be measured. The first can be termed ‘individual effectiveness’, which mimics clinical trials by using treatment data at the individual level. These analyses must overcome the lack of randomization and the confounding by indication, whereby those individuals at more advanced disease stages are the ones more likely to receive the therapies (Ahdieh et al. 2000). Measures of individual effectiveness *supplement* the results of clinical trials, but are usually subject to an unknown amount of residual confounding (Phillips et al. 1999). Data analysis methods for individual effectiveness require the use of multivariate methods of survival analysis, including the use of therapy as an internal time-dependent covariate; however, the complexity of the selection of individuals receiving therapies may require the use of more elaborate methods for causal inferences (Robins et al. 2000; Cole et al.

2003). These methods include propensity score matching methods (Stuart 2010), inverse probability weights based on propensity scores (Robins et al. 2000), and marginal structural models (Hernán et al. 2001). The guiding principle of these approaches is to construct a sample in which two or more groups (e.g. exposed/unexposed) have balanced distributions of confounders (Stuart 2010).

There is growing interest in determining the effectiveness of the many therapies participants in cohort studies are observed to receive but there is strong confounding by indication as therapies tend to be given to individuals who fulfil guidelines for who and when to treat. Standard regression adjustments to compare outcomes of treated to those untreated seldom achieve control for the indication for receiving treatment. Alternative approaches include the use of inverse probability weights based on probability of receiving treatment. Inverse probability weights estimators provide a means for estimating the causal effects of treatment among individuals with different covariate values at study baseline (Robins et al. 2000). However, covariates are often dynamic and changing values may alter the impact of therapy on the outcome. Further, marginal structural models are limited in their flexibility, becoming unstable if certain covariate values yield very large or very small probabilities of treatment. Inverse probability weights methods offer powerful tools to deal with complex patterns of confounding, particularly in longitudinal data, where outcomes at one time point may influence both subsequent treatments and outcomes. More elaborate methods such as marginal structural models have been proposed to deal with these types of patterns, whereby the weights in these models are updated longitudinally using the complete past history. In addition, the weights are stabilized, resulting in improved performance. Many scientific initiatives present research questions involving strong confounders for which these approaches may overcome the limitations of classical multivariate regression methods.

The second type of effect that can be measured in a cohort study can be termed ‘population effectiveness’ which quantifies the reduction of disease in the population when (typically) the most ill are treated relative to the occurrence of disease in the population when none or only few are treated. Because the introduction and use of therapies are closely linked to calendar time, the primary comparison may be characterized by time periods. When periods are characterized by differential availability of therapies, they could then play the role of an *instrumental variable* (related to therapy but not to disease progression or markers indicative of therapy need) and thus provide an accurate estimate of the effect of the benefits of therapy at the population level (Greenland 2000; Martens et al. 2006). To control for survival bias and overall disease progression, this approach requires the comparison of groups reaching similar time at risk (e.g. duration of infection or time since disease diagnosis) in different eras of therapy defined by

calendar periods (Muñoz and Hoover 1995; Detels et al. 1998; Schneider et al. 2005). Measures of population effectiveness *complement* the efficacy measured in clinical trials and provide a key public health index: the amount of disease burden that is reduced when only some (typically the most ill) receive the therapy of interest (Muñoz et al. 2000). Comprehensive data collected by cohort studies are essential to eliminate possible ecological fallaciousness (i.e. effectiveness due to changes over time other than changes in the therapies of interest). This includes not only prospectively collected data on therapy use, but also information on access, healthcare utilization and practices, and adherence at the population level.

Measures of exposures

The exposure can be defined as a quantitative (continuous) variable (e.g. blood pressure) or qualitative (categorical) variable (e.g. non-smoker, ex-smoker, current smoker).

When exposures are assessed repeatedly over time, the investigators can take into account not only the amount (dose) but also the duration of the exposure (Armstrong et al. 2008). There are several ways of quantifying dose and duration: (1) cumulative exposure (e.g. number of pack-years of smoking, number of rad-years of exposure to a radioactive compound at work), (2) the average exposure during the latest years (e.g. average number of cigarettes per day, average number of rads in the work environment), or (3) maximum exposure (e.g. maximum number of cigarettes per day, maximum level of radioactivity registered in the industry).

Instruments for the collection of individual data include questionnaires, physical examinations, and registries. Questionnaires allow not only the obtaining of information on demographic data, personal and family history, disease symptoms, behaviours, and attitudes, but also the recording of self-reported physical characteristics such as weight and height. They can be administered through personal, telephone interviews or online, they can be completed by the participants themselves, or they can be administered by a computer-assisted method, which is particularly useful for the collection of sensitive data (e.g. sexual behaviour, drug abuse). Modern technologies are significantly expanding the range of possible modalities for data collection. Web-based instruments, smartphones, and other types of mobile devices are being used to collect information on dietary habits, physical activity, blood pressure and others (Illner et al. 2012). In addition, registries are external sources that can be used to complement the active follow-up and are particularly useful to obtain vital status events or diagnosis of a condition of interest (e.g. cancer registries).

Timescales and types of outcomes

The scientific aims of a cohort study should dictate the type of outcome or measure of disease occurrence that should be collected during follow-up. The most common outcome measure is the time individuals at risk take to develop an end point. To properly describe this time, the following need to be defined: (1) the origin, which marks the time at which individuals are placed at risk for the development of the particular event of interest; (2) the end point, which typically is the onset of a clinical condition or the occurrence of death; and (3) the scale of time.

Time to event

The use of time-to-event outcomes requires that the *time* variable be anchored at the origin, resulting in the characterization of the event incidence across the time since origin. Examples of time-to-event outcomes used in epidemiological research include the following: (1) in clinical epidemiology, the classic time from diagnosis of a clinical condition to death or the time from initiating therapy to response; (2) in infectious disease epidemiology, the time from infection to overt disease (i.e. the incubation period); (3) in cancer epidemiology, the time from remission to relapse; (4) in behavioural epidemiology, the time from enrolment into a smoking cessation programme to the time the individual quits smoking; and (5) in occupational epidemiology, the time from employment to the occurrence of an occupationally related health outcome.

Types of timescales

Traditionally, the timescale used in cohort studies is the time from the beginning of the study (when the cohort is identified and the baseline exam is conducted) until the event of interest (or censoring, as discussed in the next subsection) occurs. For example, in many of the analyses of the Framingham Study data, the origin (time 0) of the follow-up is defined as the date when the baseline interview/exam of each of the participants took place in or at around 1950. The fact that individuals start at different ages is dealt with in the analysis by statistically *controlling* for baseline age.

Whether or not an origin is well defined, the use of *age* as the timescale is an appealing alternative (Korn et al. 1997). The caveat of this approach when applied to a cohort of individuals entering at different ages is that individuals are not under observation during the years from birth to the age at which they are recruited into the cohort. This needs to be handled in the analysis allowing for late

entry (left truncation—see following subsection). This method was used, for example, in a study of the relation between sleep apnoea and cancer mortality in the Wisconsin Sleep Cohort (Nieto et al. 2012) and in a study of life expectancies of HIV-infected individuals in the era of HAART (Wada et al. 2013; Wada et al. 2014).

In most cases, even for groups of individuals with a fixed exposure, the pattern of incidence of disease over the follow-up time is not the same at different durations at risk. An exposure whose deleterious effect monotonically accumulates over time will result in an incidence rate that increases with time (e.g. death after AIDS diagnosis in the absence of treatment). An exposure that first affects susceptible individuals so that those remaining free of the event over time represent resistance (i.e. some degree of immunity to the effects of exposure) will result in an increasing incidence followed by a decreasing incidence rate (e.g. a viral infection to which a subset of individuals are immune). An exposure that initially carries risk that ameliorates over time will result in a decreasing incidence rate (e.g. death after transplantation). A beneficial intervention that decreases the risk of death but whose effect is obliterated by other processes including old age will result in a bathtub hazard (Cox et al. 2013).

Incomplete observation from the origin and to the event

In some cohort studies, not all individuals are observed from the origin, but some enter the study after having been at risk for varying lengths of time. This type of incompleteness in the data is referred to as *late entries* or *staggered entries* and occurs when some individuals have experienced the origin that places them at risk for the event of interest at a date prior to their enrolment into a cohort study. Since these individuals have survived free of the event of interest from the origin to study enrolment, they have peers with similar origins who did not survive event-free and developed the event of interest prior to the cohort study enrolment, precluding their participation in the study. Such unseen individuals are *truncated*, and methods to adjust for these truncated observations need to be implemented to prevent survival bias. The presence of late entries in a study is a case of missing data, where missing data are the number and timing of the events of the truncated peers of those who entered late.

With respect to the event, observations in a cohort study are incomplete because it is usually unfeasible for the investigator to observe the event in all participating individuals. This type of incompleteness in the data is called *censoring* and can be due to any of the following: (1) individuals remaining event-free at the date of analysis, sometimes called *administrative* censoring; (2) individuals being lost to follow-up (prior to the date of analysis) before developing the event (e.g. because

migration or refusal to continue participating); or (3) deaths due to unrelated causes, precluding the observation of the event of interest. In this latter case, it is more appropriate to use methods of analysis based on competing risk models (Fine and Gray 1999; Putter et al. 2007; Checkley et al. 2010; Ng et al. 2016).

For the most part, subjects who are lost to follow-up are *right-censored*, which means that their exit from observation is the last possible time they contributed information to the study (i.e. on the timeline represented by a scale running from left to right, no data are available to the right of the time of censoring). Occasionally, information from sources external to the study (e.g. death certificates) are used to identify the interval of time during which individuals lost to follow-up and free of the event of interest are documented to have had the event because they died of the event of interest at some time point after the censoring. This interval is defined as the time between the date the individual was lost to follow-up and the date of death. Given that the individual died of the event of interest, the event must have occurred during this interval. These observations are called *interval-censored* observations. When using age as the timescale with mortality as the end point, censored observations are all interval-censored as all individuals are expected to die by age 125 (Wada et al. 2013; Wada et al. 2014).

Change of biomarkers

In some cohort studies, the primary event is not an event but whether a marker of disease changes over time differently in individuals exposed to different risk factors. For example, in the cohort study of children with moderate kidney function insufficiency conducted by Furth et al. (Furth et al. 2006), the primary objective was to identify the factors that predicted fast decline of kidney function (Pierce et al. 2011). Another example is the cohort study conducted by Tager et al. (Tager et al. 1983) in East Boston in the 1970s, showing the effect of maternal smoking on slowing the expected increase of pulmonary function in growing children. The study was seminal to the subsequent mounting evidence that second-hand (involuntary) smoking had detrimental health effects and guided the issuing of policies to ban smoking from work and public places as fundamental prevention measures for the health of the public. Furthermore, cohort studies have not only contributed substantially to the elucidation of disease aetiology but have also spurred the development of statistical methods to properly analyse data (Rosner et al. 1985).

Analysis

A fundamental condition for valid epidemiological inferences is that for the disease to be causally linked to a given exposure, the exposed and unexposed groups should be comparable with respect to other factors that are known to explain the heterogeneity of disease occurrence (i.e. absence of confounding). In cohort (observational) studies, comparability needs to be achieved by the use of appropriate analytical methods which often require approaches above and beyond classical stratification and/or regression methods. The goal of causal inference methods is to try to mimic randomization so as to assess the effect of a given exposure in groups of individuals who differ in the exposure of interest, but who are otherwise comparable with respect to all variables known to be associated with disease.

The type of outcome of interest determines the type of analytical technique most appropriate to yield a valid inference. Table 5.5.2 provides a succinct summary of the analytical methods reviewed here.

Table 5.5.2 Main methods for the analysis of cohort studies

Outcome		Summary measure	Comparison		Measure of association
Exposed/unexposed (2-sample)	Multiple (regression)				
I)	Events in person-years	Incidence rate	$(O-E)^2$/variance	Poisson	Relative incidence
II)	Time to event	Kaplan–Meier/ maximum likelihood estimates	Logrank or Mantel–Haenszel/likelihood ratio test	Proportional hazards/parametric	Relative hazard/ relative time
III)	Biomarker repeatedly measured at follow-up visits	Change	t-test for simple measures of change between baseline and last visit	Regression for correlated data; marginal, conditional, random effects	Differences in change over time

When the outcome data are collected as events in person-years, Poisson regression methods are apt for data analysis (outcome I in Table 5.5.2). These methods are particularly useful for the analysis of trends and changes in incidence of disease over calendar time or when the origin is not well defined or not of interest.

When the outcome data are times to event from a well-defined origin (outcome II in Table 5.5.2), the percentage of individuals remaining free of the event of interest at *t* units of time after the origin can be estimated by the Kaplan–Meier (Kaplan and Meier 1958) curve or by maximum likelihood methods for parametric approaches (Cox et al. 2007). Two survival curves can be compared using the Mantel–Haenszel (Mantel and Haenszel 1959) test or the likelihood ratio test (Cox et al. 2007). Regression analysis can be accomplished using semi-parametric methods for hazard functions (Cox 1972) or under richer parametric models (Cox et al. 2007) which lend themselves more directly to estimation of relative times quantifying not only how the hazard is modified by an exposure but also to what extent an exposure shortens (if deleterious) or extends (if beneficial) the event-free times. Software in several statistical packages to incorporate not only censoring but late entries is widely available (Cox et al. 2007).

When the outcome is a biomarker repeatedly measured at follow-up visits (outcome III in Table 5.5.2), regression methods for correlated data need to be used. This is so because the biomarkers measured in the same individual over the follow-up visits are correlated so that the standard methods of regression methods for statistically independent outcomes are inadequate.

Analysis based on person-time

Calculation of person-time and rates

The methods described in this subsection are useful for the analysis of the frequency of events in person-years in groups of individuals with different exposures and when anchoring at the origin is not important. To illustrate the methods, we present data from the Precursors Cohort study. This cohort comprised 1,337 medical students at the Johns Hopkins University, Baltimore, United States, who graduated between 1948 and 1964 (Klag et al. 1993). A total of 1,271 students (95%) completed a questionnaire and were examined during their stay at the school. In order to study the determining factors (‘precursors’) of general mortality and the occurrence of cardiovascular diseases, this cohort was followed up through mailed questionnaires. When the participants reported that they have had a cardiovascular event, the hospital records were requested in order to validate the diagnosis. Table 5.5.3 shows data obtained in the follow-up for each of the groups (smokers and non-smokers), the column named ‘person-years’ showing the totality of time units lived by the members of the cohort between the indicated years of age. Thus, for example, the non-smokers in the cohort lived a total of 862.5 years while being 20–24 years old and 1929.5 years while being 25–29 years of age.

Table 5.5.3 Internal comparison of the rates based on person-years in the Precursors Study. Occurrence of mortality (all-cause) until 1989, as a function of cigarette consumption at the baseline examination

	Non-smokers			Smokers			
Age (years)	Deaths	Person-years	Rate	Deaths	Person-years	Rate	Expected deaths[a]
20–24	1	862.5	0.00116	1	886.5	0.00113	1.0
25–29	2	1,929.5	0.00104	2	2,195.5	0.00091	2.3
30–34	0	2,052	0	1	2,360	0.00042	0
35–39	1	2,064.5	0.00048	4	2,354	0.00170	1.1
40–44	1	2,029.5	0.00049	6	2,280.5	0.00263	1.1
45–49	3	1,940.5	0.00155	2	2,182.5	0.00092	3.4
50–54	5	1,501	0.00333	13	1,819	0.00715	6.1
55–59	5	827	0.00605	11	1,187	0.00927	7.2
60–64	4	370.5	0.01080	13	582	0.02234	6.3
65–69	0	103.5	0	4	106	0.03774	0
70–74	1	17.5	0.05714	0	23	0	1.3
75–79	0	1.5	0	0	0.5	0	0
Total	23			57			29.8

[a] Numbers of deaths that would occur in the group of smokers if they had the age-specific rates observed in the non-smokers

Univariate analysis

Internal comparison

The comparison of exposed and unexposed within a cohort can be done through the calculation of the standardized mortality ratio (SMR). Using data from the Precursors Study, the last column of Table 5.5.3 shows the deaths ‘expected’ in the smokers if they had had the age-specific rates of the non-smokers. For

example, the number of deaths expected in smokers aged 45–49 years old would be 0.00155 (deaths/year) × 2,182.5 (person-years) = 3.4 deaths. The SMR is the ratio of total observed deaths to the total expected deaths in smokers (if the smokers had the same age-specific rates as the non-smokers), which in this case is 57/29.8 = 1.9.

External comparison

In other situations, it can be of interest to compare the mortality in the study group with the mortality of the total population that is used as reference. In this case, it is necessary to obtain the expected number of deaths using population-level rates from demographic statistics. Thus, in the Precursors Study, the observed mortality can be compared with the mortality of the population of white males in the United States, as shown in Table 5.5.4. The total number of observed deaths (23 + 57 = 80) divided by the total number of expected deaths based on the demographic statistics provides the SMR of the cohort in comparison with the general population, which in case of data from Table 5.5.4 is 80/148.1 = 0.54. This result implies that the mortality is almost half of what would be expected if the cohort had the same rates as that of the general population.

Table 5.5.4 External comparison of the rates based on person-years in the Precursors Study. All-cause mortality until 1989, observed and expected according to national rates in 1980

Age (years)	National mortality rate[a]	Study cohort		
		Deaths	Person-years	Expected deaths[b]
20–24	0.001909	2	1,749	3.3
25–29	0.001747	4	4,125	7.2
30–34	0.001676	1	4,412	7.4
35–39	0.002087	5	4,418.5	9.2
40–44	0.003161	7	4,310	13.6
45–49	0.005217	5	4,123	21.5
50–54	0.008668	18	3,320	28.8
55–59	0.013756	16	2,014	27.7
60–64	0.021406	17	952.5	20.4
65–69	0.033121	4	209.5	6.9
70–74	0.050338	1	40.5	2.0
75–79	0.074685	0	2	0.1
Total		80	29,676	148.1

Multivariable analysis

The aim of multivariable analysis is to identify the constellation of exposures that explain the variability of incidence of disease, allowing for random variation under a probability distribution model. The Poisson distribution provides a useful and reasonable model to carry out the multivariable analysis of incidence rates observed in cohort studies. Ideally, the final regression model from a multivariable analysis should have an appropriate goodness of fit and be optimally parsimonious (i.e. with most regression coefficients being statistically significant).

Survival analysis

Time-to-event outcomes are used to accomplish the following epidemiological objectives: estimate the percentage of individuals that survive (i.e. remain event-free) for differing lengths of time from the origin, compare the survival of exposed and unexposed groups, and characterize the possibly multifactorial nature explaining observed heterogeneities in survival of different subgroups of individuals using multivariable analysis and regression methods.

Descriptors of the distribution of times to event

If T denotes the variable of time from origin to event, the simplest descriptor of the distribution of T is the *survival function* at time t (where t is a positive number), which is denoted by $S(t)$ and corresponds to the probability that an individual in the baseline cohort survives beyond time t. The survival function starts with a value of one and monotonically decreases towards zero. Its complement from $1–S(t)$ is the cumulative incidence that an individual in the baseline cohort has the event before or at time t. The *pth percentile*, which is denoted by $t(p)$, is the time by which p per cent develop the event of interest; that is, when $1–p = S(t(p))$. A widely used descriptor of survival times is the median, which is simply the 50th percentile, or the time since origin by which half of the individuals develop the event of interest.

The *hazard function* at t, which is denoted by $h(t)$, corresponds to the proportion of individuals who develop the event in the next unit of time among those who survive event-free until time t. That is, $h(t)$ equals the rate of decline of S at t divided by $S(t)$. It is important to note that $h(t)$ is a conditional probability and refers only to the subset of the cohort that survives event-free by time t.

Figure 5.5.1 depicts the 25th percentile and hazard at $t = 12$ *years* of a survival function. The 25th percentile is 6 years (i.e. $t(0.25) = 6$ years), because it corresponds to the time by which 25% of the individuals develop the event (i.e. 75% survive). The hazard at $t = 12$ years is 10% and corresponds to the ratio of 0.04/0.40, which is the value of the rate of decline of the survival function at $t = 12$ (i.e. 0.04) divided by the value of S at $t = 12$ (i.e. 0.40).

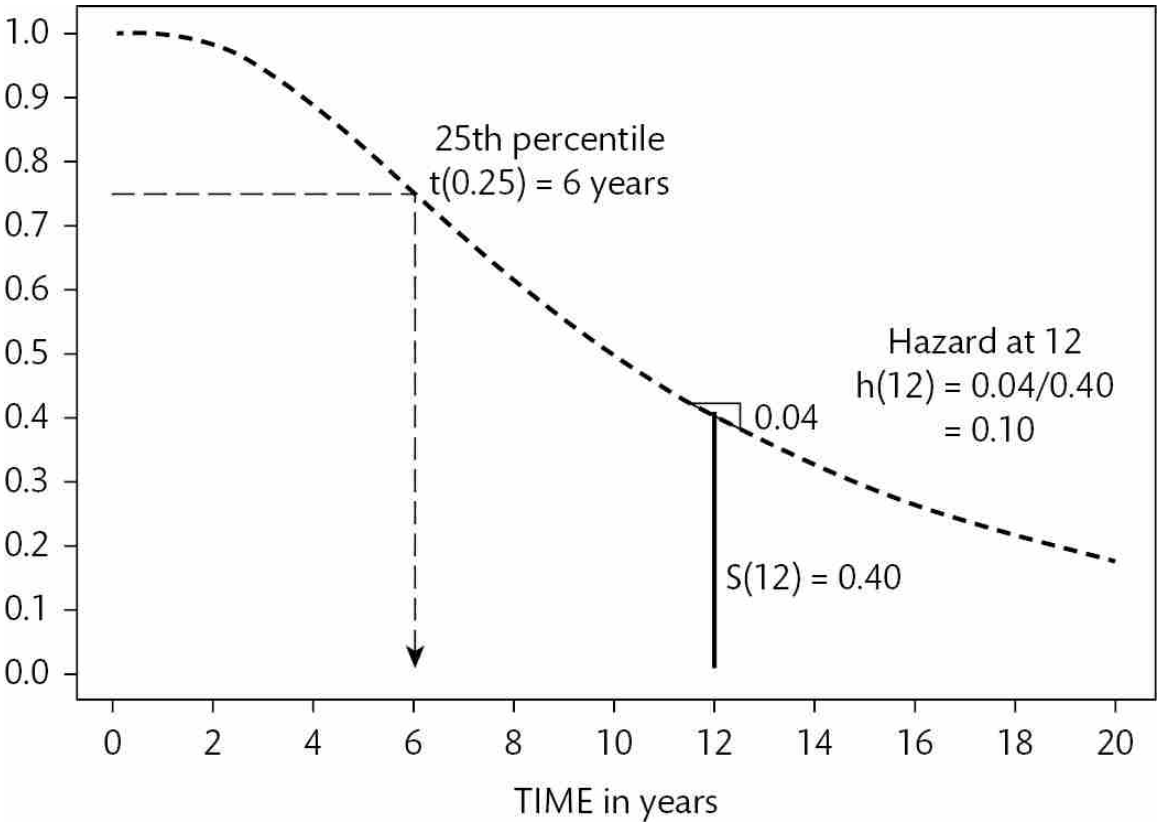

Fig. 5.5.1 Survival function, the 25th percentile ($t(0.25)$) and hazard at $t = 12$ years (h(12)).

Estimation of the survival function

The presence of censored observations is a case of missing data, and the fundamental role of the assumption that censored observations are not a selected subgroup is that, at any time during the study, individuals who remain under observation *represent* those subjects who were censored beforehand. The observation of events beyond the time an individual is censored provides the data to estimate when the censored individual is expected to develop the event had she or he remained in the study. Furthermore, because the individuals who are observed to develop the event are representative of the observations censored before their time of event, estimates of the hazard functions based on the observed individuals are unbiased, and thus they represent the hazards that the censored individuals would have experienced had they remained under observation in the study. Indeed, this forms the basis of the Kaplan–Meier method (Kaplan and Meier 1958), based on the calculation of the survival probability through the product of one minus the observed instantaneous hazards.

Figure 5.5.2 shows five Kaplan–Meier curves according to the number of copies of HIV detected in 500 ml of plasma measured by branched-DNA (bDNA) in HIV-infected individuals followed up in the MACS cohort (Mellors et al. 1997).

It clearly shows the great predictive value that viral load has for the development of AIDS. Indeed, investigators in the MACS have developed methods to quantify the variability of time to AIDS explained by viral load and have shown that it alone explained approximately 50% of the variability of time to AIDS (Mellors et al. 2007).

Univariate analysis

Graphical display of the survival curves is generally quite useful to obtain an overall comparison of the experiences of groups subjected to different exposures (Fig. 5.5.2). There are two different ways to measure the association between exposure and survival, which correspond to horizontal (i.e. relative time) and vertical comparisons (i.e. relative hazard) of survival curves. The first one is the relative times defined as $t_1(p)/t_0(p)$, where $t_i(p)$ corresponds to the time taken by p per cent of group i = (*for* i = 0.1) to develop the event. The second one is the relative hazard, defined as $h_1(t)/h_0(t)$, where $h_i(t)$ is the hazard for the *i*th group

(*for* i = 0.1) at time t. If exposure shortens survival, the relative time will be less than one and the relative hazard will be greater than one. If the relative times are independent of p and/or the relative hazards are independent of t, the times, and/or the hazards are said to be proportional. In such cases, the relative times and/or hazards will be constant across all values of p and/or t, respectively. Since the percentiles are relative to the whole cohort but the hazard function is conditional on survivors, proportionality in one does not imply proportionality in the other. Methods based on parametric models (e.g. lognormal regression) are more amenable to estimation and testing of relative times (e.g. to compare, for instance, the median survival time in exposed and unexposed) and they can also provide measures of relative hazards (Cox et al. 2007). Semi-parametric methods based on the proportionality of hazards focused attention to estimation and testing of relative hazards but caution must be exercised because proportionality of hazards is seldom attained.

There are hypothesis-testing procedures to assess whether the differences between two or more survival curves are statistically significant such as for example the logrank test (Peto et al. 1977).

Multivariable analysis

In the context of survival analysis, the most used method of multivariate analysis is the proportional hazards regression (Cox 1972). The semi-parametric proportional hazards regression model corresponds to the hazard of the group with covariates representing exposures and confounders $x_1 = x_2 = \ldots = x_K = 0$ (i.e. the reference group) being completely arbitrary, and the hazard of the group characterized by any other values of x_1 to x_K being a fixed multiple of the hazard of the reference group according to a linear combination of the covariates. Specifically, the hazard of the group with covariates x_1,
$x_2, \ldots, x_K$ denoted by $h_x(t)$ is $h_0(t)exp(\beta_1$
$x_1 + \beta_2$
$x_2 + \ldots + \beta_K$
x_K). The interpretation of the parameters is directly linked to relative hazards. In particular, if we have two groups of individuals described by the constellation of covariates taking values x for one group and x^* for the other, the hazard at time t of the group described by x^* relative to the hazard at the same time of the group defined by x (i.e. the relative hazards) is given by. $RH(t) \equiv \exp\left[\sum_{i=1}^{k} \beta_i \left(x_i^* - x_i\right)\right]$ Because such an expression does not depend on t, the relative hazard is constant (i.e. the hazards are proportional). In particular, if x and x^* only differ in one unit in the k

th covariate (i.e., $x^* = x_1, x_2, \ldots, x_k + 1, \ldots, x_K$) 1then the relative hazard of the x^* group to the x group is simply $RH(t) \equiv exp(\beta_k)$.

When investigators are not only interested in relative hazards but also in describing the underlying hazard with the aim of characterizing mechanisms and the desire to quantify how exposures modify the magnitude of event-free times, parametric models are a more attractive option (Cox et al. 2007). To carry out parametric analyses of time-to-event data, the generalized gamma distribution offers a succinct yet flexible family of distributions. The generalized gamma distribution GG(β, σ, κ) has three parameters whereby the location parameter β governs the value of the median for fixed values of σ and κ; the scale parameter σ determines the value of the interquartile ratio (i.e. IQR = 3rd quartile/1st quartile) for a fixed value of κ and independently of β; and the parameter κ determines the percentiles of the standard $\beta = 0$, $\sigma = 1$ generalized gamma. The generalized gamma contains commonly used parametric models in that the particular cases when κ is zero and one correspond to the lognormal and Weibull models, respectively. More importantly, the parameters κ and σ together determine the *type* of hazard function and yield a graphical taxonomy of the rich variety of hazards covered by the generalized gamma (Cox et al. 2007). Specifically, the taxonomy shows that the generalized gamma family includes all four of the common types of hazard functions: increasing, decreasing, U or bathtub shape, and inverted U or arch shape. More importantly, the pth percentile of the generalized gamma $t(p;\beta,\sigma,\kappa)$ can be expressed in terms of the three parameters by the simple equation $t(p;\beta,\sigma,\kappa) = e^{\beta}\,[t(p;0.1,\kappa)]^{\sigma}$ which dissects the role of each of the three parameters in determining the percentiles of the distribution.

The conventional generalized gamma regression model corresponds to GG($\beta'x$, σ, κ), whereby the distribution of the times for the group of individuals with covariate vector x has different location parameters but same scale and shape. In this case, the relative times of the group with covariates x^* to the group with covariates x are constant (i.e. proportional times) and are equal to $\exp[\beta'(x^* - x)]$. Lack of proportionality of times can be easily incorporated by allowing σ to depend on covariates and full generalization of the model can be accomplished by further allowing κ to depend on covariates. Software is commonly available to implement generalized gamma regression in its full general form (e.g. streg command in STATA).

An example of the richness of parametric regression analyses for survival data is illustrated by Schneider et al. (Schneider et al. 2005), who used data from the MACS cohort of homosexual men and the WIHS cohort of women to characterize the changing pattern of survival after development of clinical AIDS from 1984 to 2004 when different antiretroviral therapies were introduced. Table 5.5.5 presents the relative hazards obtained from a multivariable Cox proportional hazards

regression model and the relative times obtained from a multivariable Weibull regression model. Substantial differences in survival were seen between the last two HAART eras (July 1998–June 2001 and July 2001–December 2003) and the no/monotherapy era (prior to 1989); the time from AIDS to death (adjusted by age, sex, type of AIDS diagnosis, and CD4 cell count at diagnosis) expanded by eightfold and 11-fold in the two eras with stable HAART, respectively. This analysis illustrates the role that cohort studies can play in providing measures of the effectiveness of interventions at the population level.

Table 5.5.5 Descriptive statistics, adjusted relative hazards, and relative times for survival after an initial AIDS diagnosis in five calendar periods from July 1984 to December 2003. Data from the Multicenter AIDS Cohort Study and The Women Interagency HIV Study

Variable	Calendar period				
	July 1984–Dec 1989	Jan 1990–Dec 1994	Jan 1995–June 1998	July 1998–June 2001	July 2001–Dec 2003
Therapy era	**no/monotherapy**	**monotherapy/ combination therapy**	**HAART introduction**	**short-term stable HAART**	**moderate-term stable HAART**
Number seen	633	660	472	496	464
% women	NA[a]	NA[a]	65%	72%	74%
Incident AIDS	633 (100%)	660 (100%)	472 (100%)	143 (29%)	57 (12%)
Median (IQR)[b] Date of AIDS diagnosis	Oct 1987 (April 1986–Dec 1988)	April 1992 (Feb 1991–June 1993)	Jan 1996 (July 1995–Nov 1996)	Nov 1996 (Dec 1995–Sept 1998)	March 1997 (Jan 1996–Oct 1999)
Median (IQR)[b] Age at AIDS diagnosis	36.5 (32.1–41.1)	39.7 (35.3–43.9)	39.7 (34.5–44.5)	39.8 (35.1–44.8)	40.1 (35.6–45.2)
Median (IQR)[b] CD4 cell count at AIDS diagnosis	141 (64–273)	90 (35–194)	196 (78–390)	241 (117–439)	268 (130–456)
Number of person-years	685	912	796	1,156	992
Deaths Number % of person-years	388 57%	445 49%	109 14%	71 6%	44 4%

Longitudinal data analysis

In cohort studies, it is often the case that the dependent variable of interest in a cohort study is not the occurrence of an event but the trajectory of a determined biomarker such as blood pressure, weight, leucocyte count, viral load, glomerular filtration rate, pulmonary function, C-reactive protein, or CD4 cell count.

To illustrate the power of longitudinal data in cohort studies collecting data at regularly scheduled visits, we used data collected at semi-annual visits by the MACS from 1984 to 2006. The person-visits of interest were those happening after the first time individuals tested positive for antibodies to HIV and with data on therapy received, CD4 cell count (a marker of immunosuppression), and HIV-RNA (copies of HIV per mL of plasma). The objective was to describe the distribution of HIV-RNA in four categories of CD4 cell count using 200, 350, and 500 cells/mm_3 as cut-off values and in four categories of therapy according to whether the participant at a given visit was not on any therapy, was just receiving antiretroviral therapy but not a triple combination, or was receiving triple combination therapy (HAART) and the visit occurred within 3 years or after 3 years from initiation. Two measures of HIV-RNA were used: (1) the median HIV-RNA and (2) the percentage of person-visits in a given category of CD4 cell count and therapy with undetectable HIV-RNA (i.e. <50 copies/ml). Figure 5.5.3 uses a diamond-shaped equiponderant graphical display of the effects of CD4 cell count and therapy on HIV-RNA whereby the shaded area on each square is proportional to the HIV-RNA (Li et al. 2003). Both panels show the great effectiveness of HAART in suppressing viral replication in all categories of CD4 cell count.

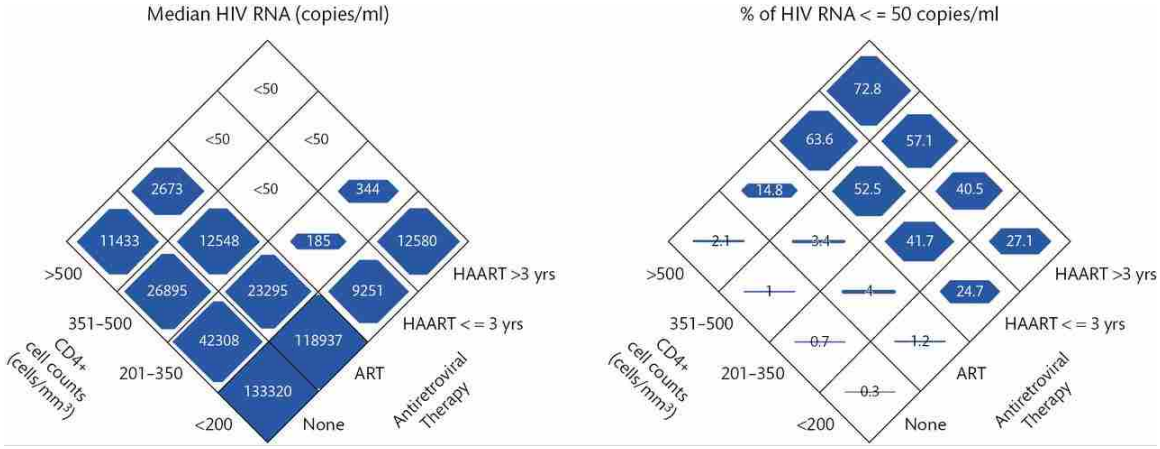

Fig. 5.5.3 Median HIV-RNA (copies/ml) and % with HIV-RNA ≤50 copies/ml in HIV-infected individuals according to CD4 cell count and Antiretroviral Therapy. Multicenter AIDS Cohort Study, 1984–2006.

Methods for the analysis of longitudinal data can be broadly classified in three categories: marginal, conditional, and random effects models. The primary aim of the marginal approach is to combine the multiple cross-sections corresponding to visits so as to provide the most efficient summary of the cross-sectional relationships between exposure and disease. In this approach, the longitudinal component is typically incorporated by including age or time since baseline as a covariate for the regression component of the model. Approaches for the incorporation of the correlation between repeated measurements within individuals include parametric (Jennrich and Schluchter 1986) and non-parametric methods, the latter handling the correlation as a nuisance (Zeger and Liang 1992). The primary aim of conditional models is to regress current outcome on past values of the outcome, and current and previous exposures (Rosner et al. 1985). The primary aim of the random effects models is to allow different individuals to have different intercepts and slopes according to components of variance and to provide direct averages of rates of change across individuals. Figure 5.5.4 depicts the random effects model whereby the population average line has intercept α and slope β and the line for the ith individual has intercept $\alpha + a_i$ and slope $\beta + b_i$ with the departures being random effects (Laird and Ware 1982).

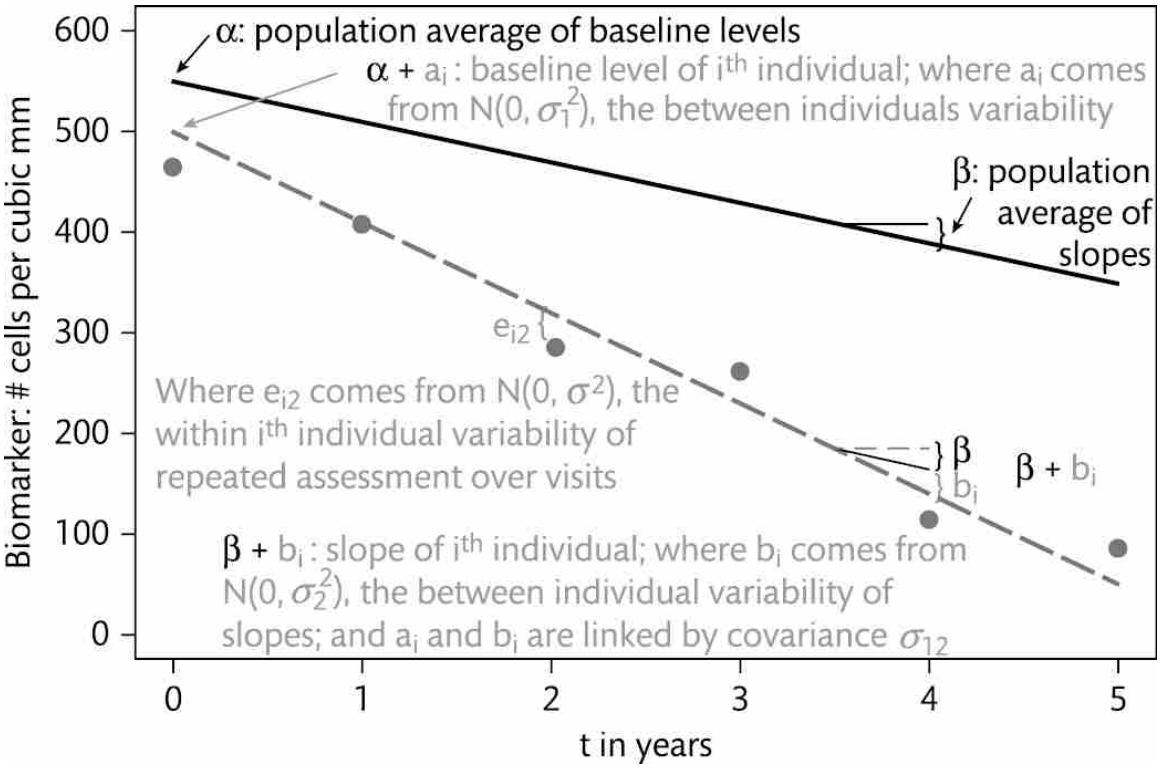

Fig. 5.5.4 Linear model with random intercepts and slopes for the analysis of longitudinal biomarkers data from cohort studies. Population averages in black and random departure of the line of the i^{th} individual in grey.

When data are longitudinal assessments of a biomarker (e.g. pulmonary function, blood pressure, viral load of an infectious agent), linear models for normally distributed biomarkers allowing for both fixed and random effects (i.e. mixed effects) are apt to describe the probabilistic structure of the data. In the simplest case of two groups (i.e. an exposure taking the value zero or one) with linear trends over time, the fixed effects describe the two average lines for each group. That is, for the unexposed group, the average biomarker trajectory is given by $\beta_0 + \beta_1$
t, and for the exposed group the average biomarker trajectory is given by (β0 + β*0) + (β1 + β*1)t. In this case, β*0 represents the fixed effect of exposure on the levels at baseline and β*1 represents the fixed effects of exposure on the rates of change of the biomarker over time. The random effects allow individuals in each of the two groups to vary randomly around the average lines of the fixed effects (i.e. each individual has his or her own line that varies randomly from the average line as depicted in Figure 5.5.4) (Laird and Ware 1982).

Joint analysis of survival and longitudinal data

Since the occurrence of an end point in a cohort study typically marks the end of follow-up in the study, the trajectories of participants who develop end points will typically be shorter than those who remain event-free. When subjects leave the study for reasons related to the effects of exposures and/or the progression of disease, the longitudinal data will be subjected to informative dropout. If the biomarkers of interest have greater changes among those who develop end points, a separate analysis of the longitudinal data may yield biased estimates of the rates of change of the biomarkers as they are unduly weighted towards longer and less changing trajectories. A joint model of the time-to-event data and the longitudinal biomarkers data aims to properly describe the relationships between exposures and the two distinct but related outcome processes. For longitudinal data, a joint model must take into account not only the dependence resulting from repeated measurement of the same outcome, but also the association between the different outcomes, all measured on the same individual. A solution to this problem has been provided by the development of shared-parameter models, in which the necessary dependence structure between the two types of data is provided by a vector of shared random effects that links all the measurements on the same individual. Typically the two outcomes (end point and markers) are assumed to be independent given the random effects, which results in a relatively simple factorization of the joint likelihood. Parametric models for the marginal distributions of each outcome, as well as the standard assumption of a multivariate normal distribution for the random effects, provide a complete description of the joint likelihood. Statistical software to fit these models is available in standard statistical software packages such as SAS and STATA.

Validity and biases

External validity refers to the extent to which the results of a cohort study can be extrapolated or generalized to the reference population. When the cohort is composed of volunteers, representativeness may be limited due to the fact that volunteers tend to be different from the general population. The representativeness or the lack of representativeness of the cohort in relation to the general population is also determined by the inherent characteristics of the sampling framework. Thus, for instance, even in the case that the members of the Framingham cohort were a representative sample of the population of this small town in New England, it is more than dubious that this population was representative of the general population.

Even when the representativeness of the cohort is dubious, it is possible that the internal comparison between cohort subgroups (e.g. exposed and unexposed) may

be valid (*internal validity*). In the Precursors Study, for example, it was observed that the SMR was 54% (see Table 5.5.4), which indicates that the mortality in the cohort of the Precursors Study was almost half that of the general US population of the same sex, race, and age. Obviously, this is due to the fact that this cohort is formed by medical students belonging, in general, to higher socioeconomic strata than the average population, which limits the ability to generalize any estimates of the absolute values of incidence or mortality in this cohort. However, it is reasonable to assume that the *relative* comparison of the mortality in smokers and non-smokers in this population (see Table 5.5.3) is valid, or in other words, that the magnitude of the bias that affects the absolute value of mortality given the lack of representativeness of the cohort is proportionally similar in both groups; under these circumstances, even a non-representative cohort in the strict sense of the word, can yield unbiased estimates of the relative risk (or SMR in this case).

In cohort studies, the internal validity is based not only on the comparability of the selection process of exposed and unexposed when the cohort is established, but also on the comparability between the subjects who are lost to follow-up and those who continue under observation in the study. If the participants who are lost to follow-up have a different survival experience compared to those who remain under observation, the overall estimates of survival are biased (i.e. do not accurately represent the survival experience of the population in the original cohort) and special methods are required to avoid the biases due to informative censoring (Robins and Finkelstein 2000; Howe et al. 2011).

Biases

In the evaluation of the possibility of biases due to the losses to follow-up, it is important to consider which types of losses have occurred. The biases due to differential losses to follow-up in a cohort study are conceptually analogous to the *selection biases* that affect case–control or other types of epidemiological studies.

There are other biases than can affect the internal validity of a cohort study. Among the information biases, one type of bias that could affect these types of studies is *surveillance bias*. This bias is present when the persons exposed to a determined risk factor are more carefully monitored or watched over than the persons without that factor. If the disease has a long subclinical phase, this can exaggerate the apparent magnitude of the association between that factor and the disease outcome. Thus, for example, diabetics are generally subject to periodical check-ups in which blood pressure is taken. Because in the natural history of hypertensive disease there exists a long asymptomatic phase and hypertension is much more likely to be diagnosed in diabetic persons given their periodical clinical assessment, it is possible that part of the strong association that exists

between diabetes and hypertension is due in part to a surveillance bias. Even in cohort studies in which information is collected in a systematic form, if the observer knows the history of the participant, he/she can evaluate the presence of the disease in a biased form (*observer bias*). These biases are removed in large part in cohort studies in which a rigorous protocol for collection of information (preferably blinded with respect to exposure status) and well-trained observers exist.

As in all epidemiological studies, the presence of errors in classification of the participants regarding the presence of the exposure or the occurrence of the disease under study may generate *bias due to misclassification*. When the errors in the determination of disease occurrence are equal in exposed and non-exposed, or when the errors in measurement of the exposure are not differential between diseased and non-diseased, the bias is generally (but not always) conservative; that is, towards the underestimation of the true association (Flegal et al. 1991; Mertens 1993).

Applications and conclusions

Even with the potential limitations regarding internal and external validity discussed in the previous section, the cohort study constitutes the design of reference for all other designs in observational epidemiology. Cohort studies are free from certain types of biases that complicate the interpretation of cross-sectional and case–control studies (Schlesselman 1982), as, for example, recall bias (different recall of the exposure in cases and controls) and cross-sectional bias (when there is a different duration of disease in exposed and unexposed). The cohort design is more powerful for the establishment of the temporal relationship between cause and effect, one of the classical criteria for causality (Hill 1965).

Another advantage of cohort studies is the possibility of studying the occurrence of several events in addition to that initially planned. Thus, for instance, the Framingham cohort has been the basis for the investigation of several hypotheses in addition to those conceived in the initial aims of the study (Kannel 1990) as, for example, the relationship between several factors and cancer (Kreger et al. 1991), senile dementia (Bachman et al. 1993), cognitive function (Elias et al. 1993; Au et al. 2006), osteoporosis (Hannan et al. 1992), hearing loss (Gates et al. 1990), kidney function (Culleton et al. 1999), pulmonary function (Wilk et al. 2009), healthcare preferences, and others. Furthermore, cohort studies are a platform to expand the initial scientific scope of the studies as new knowledge is acquired and new questions arise.

Cohort studies have proven to be extremely valuable in many areas of medical research including cardiovascular disease (Dawber 1980), cancer (Doll and Hill 1952; Doll et al. 2005), and infectious diseases (Samet and Muñoz 1998). Cohort data may also be of great use for the development of public policy, such as treatment guidelines. Follow-up of cohorts before interventions are available provides the most appropriate data for the description of the natural history of disease. Furthermore, if these studies continue to collect data after interventions become available, three uses of these pre-intervention data are apparent: (1) as historical controls for assessing and/or confirming the effectiveness of interventions (Jacobson et al. 2002); (2) as a reference point to establish the effectiveness of interventions at the population level once the interventions have been widely implemented (Detels et al. 1998; Muñoz et al. 2000; Schneider et al. 2005); and (3) as a mechanism to identify the subgroups who should receive treatment once an intervention has been proven efficacious in clinical trials (Cole et al. 2004; Sterne et al. 2009). From the public health perspective, population effectiveness quantifies the reduction of disease achieved by treating the subset of the population that needs therapies the most. In doing so, cohort studies are at the cornerstone of public health and policy (Szklo and Nieto 2018).

5.6

Qualitative research imagination

Jennie Popay and Fran Baum

Introduction

In his classic book The Sociological Imagination C. Wright Mills (1970) argued that ‘imagination’ is the creative force that transforms social enquiry from the mundane application of particular techniques into a process that has the potential to generate new ways of thinking about the social world producing new knowledge of both theoretical and practical use. From this perspective, though it may seem counterintuitive, maximizing the contribution to global public health of any type of research requires imagination alongside technical competencies. Imagination enables scientists to envision the potential impact of their research on policy and practice and to ensure it is relevant and high quality. In this chapter we will consider what the qualitative research imagination ‘is’—touching on key questions that should be addressed by all researchers regardless of their approach (see Box 5.6.1). In the first part of the chapter we will consider the first two questions focusing on the type of ‘knowledge’ generated by qualitative research and in the second part on questions about the range of approaches that can be taken to data collection, analysis and interpretation, and the role of theory.

Box 5.6.1 Four key questions for researchers

1. Ontological perspective: What is the nature of the 'social phenomena' I wish to investigate?
2. Epistemological perspective: What might represent knowledge/evidence about these phenomena?
3. Theoretical perspective: What is the intellectual puzzle I wish to 'explain' and what research questions flow from this?
4. Methodological perspective: What approach should I use to collect and analyses data about these phenomena?

What is the qualitative research imagination?

Qualitative research is underpinned by a social constructivist philosophy. it assumes that the 'reality' or phenomena being studied are subjective: the product of people's interpretations informed by their perceptions, beliefs, and experiences. These subjective phenomena are rich, diverse, and fluid. Rather than trying to control them through experiment and measurement, qualitative research therefore studies social phenomena in naturally occurring settings and seeks to develop concepts and theories that help us to see these phenomena from the point of view of the people being studied.

The central question for qualitative research is why individuals, collectives and/or organizations 'act' or 'behave' as they do (what social scientists refer to as *agency*) (Mallinson et al. 2014). It seeks to answer this question by studying the relationship between 'agency' and social context, including in particular *social structures* associated with social class, gender, ethnicity, sexuality, etc. and by illuminating the understandings and meanings people attach to these actions and experiences. Qualitative research can also illuminate power relationships and how these affect the distribution of resources in a society, including the extent of equality in health status between different groups. Concepts are the basis for analysis of qualitative data, rather than numbers, and theory is the basis for explanation and generalization rather than statistical probability.

Given the assumption that the 'reality' or 'phenomena' being studied is socially constructed, a research event, such as an interview, is not viewed as a method for gaining a 'slice of reality' but as a process of contextually bounded 'meaning-making' between the researcher and the researched. The context, perspective and position of the researcher is therefore understood to be an inevitable influence on the findings of qualitative research. So, rather than seeking to eliminate sources of potential bias, the aim is to make

them visible. Processes of *reflexivity* and *transparency* are used by the qualitative researcher to identify relevant aspects of their beliefs/perceptions etc, to consider how these may have influenced the research process and to record this so that readers can assess the strengths, weaknesses, and relevance of a study.

The rest of this chapter is divided into three parts. First, we discuss the type of knowledge produced by qualitative research. We then discuss the potential for community/public involvement as 'partners' in qualitative research and finally consider key methodological issues in the conduct of qualitative research.

What knowledge or evidence can the qualitative research imagination contribute to public health policy and practice?

Armstrong (2000) has written about the separation of two ways of understanding the world: 'mythos' and 'logos' and the limits this imposes on our ability to 'imagine' action for health. improvement. Logos concerns the rational world—how we might understand how the world works, how we solve problems, and grasp causal processes. It is mundane and concerns both logical argument and the accumulation of facts. Mythos, on the other hand, is concerned with meaning: it is what gives life its *telos* or purpose. It is often expressed in different forms, through metaphor, poetry, visual arts: resources commonly used to express the emotional life and our relationships to others (Richards 2011). The point is not that one 'way of knowing' is better than the other but that knowledge itself becomes impoverished by this separation, often unwittingly, because of the narrow disciplinary confines in which people work and their assumption that their expertise marks them out as separate from the everyday. From this perspective, it is vital that global public health is able to access knowledge about both ways of understanding the world: the quantitative and the qualitative (Baum 2016).

The qualitative research imagination can be used to address a wide range of questions (Popay and Williams 2009). These can be groups into four broad domains critical to global public health policy and practice:

Preparing the ground for other forms of enquiry: addressing different kinds of questions and generating hypothesis to be tested by other study designs.
Adding theoretical and/or empirical depth to understandings of pathways to population health and health equity.
Illuminating barriers and enablers to effective policy and practice.
Contributing to greater social justice by addressing inequities between different forms of knowledge and between researcher and researched and by contributing to critical thinking on action for population health and health equity.

Preparing the ground for other enquiries: Imagining public health evidence beyond lifestyles

A large number of qualitative studies relevant to public health focus on the meanings people attach to behaviours/lifestyle. It has been argued that this research, 'tends to produce bland accounts of social life, in which it is difficult to assess the *import* of things for people' (Sayer 2011, p. 6). To avoid this limitation qualitative research has to provide explanations rather than descriptions: exploring the relationship between the social/material context of people's lives and individual behaviours such as smoking and poor diet and revealing the strategies people develop to cope with risks and exposures over which they may have little control. By doing this the qualitative research imagination provides an understanding of 'private troubles' as 'public issues' and reframes the space for action beyond the individual (Wright Mills 1970); see also, Burawoy (2005) on 'public sociology'. For example, qualitative research embedded in a trial aimed at reducing smoking in early teenage years through a 'peer-led' intervention found that some young people continued to smoke, despite having knowledge of the health risks, in order to maintain social relationships with peers, revealing the complex risks assessments involved in individual decision-making processes (Campbell et al. 2008).

Adding depth to understanding pathways to population health and health equity

A recurring finding from qualitative research into the meanings people attach to their actions is the purposeful development and/or maintenance of

valued social identities in situations that threaten to undermine their moral worth. Importantly this body of research often highlights 'fault lines' between lay and professional understanding about health and illness that can impact adversely on the success of policies/practices. For example, on the basis of a synthesis of multiple qualitative studies Graham and McDermott's (2006) argue that teenagers pursued motherhood as a pathway into a valued adult identity—or social inclusion—in the face of limited alternative pathways to adulthood. In contrast, professionals see education and employment as the pathway to adulthood. They fail to see the positive values and identities affirmed through teenage motherhood constructing it as a pathway to social exclusion and lifelong disadvantage. A more recent qualitative study (Wekesa and Coast 2013) highlighted the extent to which stigma and discrimination affected the responses of people living in an informal settlement in Nairobi to a diagnosis of HIV/AIDS. The study showed the need to ask broad questions about the experience of living with HIV/AIDS and the importance of paying attention to structural factors including poverty, gender, and sociocultural norms.

Illuminating barriers and enablers to effective policy and practice

Qualitative research is now a common element of research evaluating the impact of public health policies and practices and factors impinging on successful implementation: either embedded in a mixed method evaluation or stand alone. The qualitative research by Roberts et al. (2004) embedded in a RCT of the installation and use of domestic smoke alarms explored people's perceptions of the risk of fire and barriers and enablers to the installation and maintenance of domestic smoke alarms. The results revealed, for example, that people disabled alarms because they went off when they were cooking or eating. Similarly, using examples from African research Camlin and Seeley (Camlin and Seeley 2018) illustrate how qualitative research conducted within trials of HIV/AIDS treatments can: (i) reveal vital contextual factors that influence implementation and outcomes; (ii) enable an informed adaptation of trials as they are being conducted; and (iii) can lead to the formulation of theory regarding the social and behavioural pathways to outcomes of interventions. This study design can also enable community engagement in trial design and implementation.

Qualitative research conducted independently has also be used to better understanding the results of multiple RCTs. For example, Noyes and Popay (Noyes and Popay 2007) conducted a systematic review of qualitative research on help seeking behaviour in an effort to explain the diverse results of six trials of TB treatment interventions.

Contributing to greater social justice

Public health research has long mapped the processes of exclusion and privilege that create social inequities in the experience of health and illness across and within societies (Dorling 2011; Thomas and Dorling 2011). However, these maps typically do not capture the 'experiences of hardship, subjugation and alienation which cannot easily be … weighed via ratios, metrics and indices' (Trahair 2014, p. 6), but about which people have points of view. These 'knowledgeable narratives' (Williams 2000) people's 'practical wisdom', as Aristotle described it, can be accessed through qualitative research. For the philosopher Martha Nussbaum (1990, p. 55) people's practical wisdom provides a 'profound alternative' to the power of 'scientific' knowledge that pervades 'almost every area of human social life'. Without an understanding of this knowledge, public health policy/practice risks reducing people to unthinking bearers of various risks, deficits or assets and seriously limits the 'evidence' available to improve health and reduce health inequalities.

A particularly important aspect of the experiential knowledge revealed in qualitative research is the emotion it can embody. Conventionally emotion is seen as antithetical to scientific rationality, whereas the Aristotelian view articulated by Nussbaum is that emotions, and the imagination fed by them, are central to a fuller and more grounded understanding of how knowledge of human predicaments is articulated. Rather than bracketing emotions out as residuals in the analysis of health inequalities, it would be more fully rational to include them as components in a 'passionate epistemology' for a critical public health (Krieger 2000). The emotionality embedded in lay knowledge about the experience and consequences of ill-health points to the significance of these experiences for individuals, but can also highlight causal pathways within which different kinds of intervention or action might be developed (Popay et al. 2003a; Eades et al. 2008).

Finally, qualitative research can contribute to the development of the theory and practice of transformative action by illuminating both the need for, and barriers to, collective action as strategies to improve population health and reduce health inequalities (Elliot et al. 2015). Currently, prominent theories in the public health field focused, for example, on social capital, social cohesion, resilience, community assets, etc, describe the way things *are*, and suggest interventions that help people cope with current conditions but offer limited insight into how to overcome the threats themselves. For example, in their literature review Elliot et al. (2011) found that while most contemporary community-based public health interventions were potentially transformative for individuals they failed to support communities to acquire the collective social/political power they need to change the determinants of health and health inequities.

Recent work by the New Economics Foundation (Coote and Angel 2014) points to the need for further critical qualitative research in this field, arguing that while concepts such as social capital are about 'the glue' that holds people together, 'solidarity' concerns 'momentum' and the conditions for change. This conceptual reframing locates the sources of transformative action in civil society, but also highlights the need for better understanding of barriers and enablers to such action. One important contribution qualitative research has made to this understanding is to reveal how the strategies people develop to manage their lives can undermine solidarity. For example, Popay et al. (2003b) and Ruston (2009) in the United Kingdom and Bustos Castro and Lindbladh (2004) in Sweden have described how residents of low-income neighbourhoods frequently withdraw from the public sphere and adopt strategies of avoidance, surveillance, and fortification in order to distance themselves for the stigma attaching to living in these neighbourhoods.

Public/community involvement in research can also contribute to the development of capabilities for transformative action in public health. Health researchers have argued for decades that, whenever possible, research should be participative (Wadsworth 1984; Feuerstein 1986; Baum 1988; Bruce et al. 1995; de Koning and Martin 1996; Minkler and Wallerstein 2003; Popay 2010). Participative approaches to research have tended to be associated with qualitative research methods. In Australia the National Lowitja Institute—the National Institute for Aboriginal & Torres Strait Islander Health Research—has developed supports to guide

participatory and ethical research with Indigenous peoples (Laycock et al. 2011). Similar participatory approaches have been encouraged in Canada (Canadian Institutes of Health Research 2014).

Minkler and Wallerstein (2003) have developed a practice of community-based participatory research and described its growth and increasing acceptability in the past years. However, as Oakley (1989) has argued, quantitative methodologies, such as randomized control trials, can be emancipatory in practice and could be designed to involve research participants more than at present. Today, though still underdeveloped in the public health field, the active involvement of 'lay people' (e.g. residents of low-income neighbourhoods, users of services, or people with particular health conditions) as partners in research is a requirement of major funding bodies in many countries. In the United Kingdom, for example, the National Institute for Health Research has published National Standards for Public Involvement in research and expects this to be adequately funded in proposals.[1] The Australian National Health and Medical Research Council (NHMRC) requires researchers to demonstrate the degree to which Aboriginal and Torres Strait Islander people have been involved in the planning and will be involved in the execution the research (National Health & Medical Research Council 2003).

The movement for more participative research approaches partly reflects the increasing recognition that lay people can offer unique expertise. In addition, it reflects a growing commitment to democratize the research process. While participants in all types of research have the right to receive information about the research, formally agree to their participation and withdraw at any time, traditional research models involve what Wadsworth (1984) called 'data raids'. In this approach, researchers swooped down from their ivory towers, collected data, returned to their towers, and never communicated the results of the raid to the subjects. In contrast, the new public health is calling for a more meaningful form of involvement, including involving the public/communities in defining research questions, determining methods, collecting and analysing data, interpreting findings, and deciding how they could be reported back in a readily comprehensible way. In particular, there is an increasing emphasis on approaches, such as action research, that enable traditionally marginalized groups and communities to become full partners in gaining and creating knowledge and mobilizing for change. AS we have noted a participative research approach

is essential when conducting Aboriginal research given the history of the use of research as part of the processes of colonization and inhumane treatment of Indigenous peoples. The People's Health Movement conducted participative research to examine its own form of collective action to improved health and has suggested this approach presents particular methodological challenges (Bodini et al. 2019). These concerned the following issues: making meaning; aligning research and action; managing power relations; valuing experiential knowledges, chaos, and contingency; challenging preconceptions. Specific approaches to participative research are discussed in more detail in the next section of the chapter (see also Minkler and Wallerstein 2003, p. 2).

Doing qualitative research

In this section we move on to consider the range of study designs that can be used in qualitative research, the specific methods, or tools, available for data collection, and approaches to analysis. Patton (2014) suggests that qualitative data can be grouped into three categories:

in-depth, open-ended narrative data collected from individuals or groups;
direct observation and description of people's activities, behaviours, actions, and interactions, including audio- and video-taped material. Kellehear (1993) extends the definition to include the study of 'material culture' (graffiti, garbage, cemeteries);
written data, usually excerpts, quotations, or entire passages from organizational, clinical, or programme records, personal diaries, official records or publications, and open-ended written responses to questionnaires.

These data can be collected in the context of different study designs the main ones being:

ethnographies (based on observations);
interview-based studies (individual or group based);
case studies (which may involve both qualitative and quantitative methods and most commonly use in-depth and/or focus group interviews to collect qualitative data);
document-based research and content analyses;
participative action research (using a variety of methods).

Next we discuss the first four of these study designs, the methods available to collect qualitative data, approaches to analysing these data and how 'quality' in qualitative research can be assessed. Approaches to participative action research and then discussed and described in the final section of the chapter.

Study designs and data collection methods

Ethnographic approaches and observation

Ethnographers seek to immerse themselves in a study context to study 'everyday' activities and practices in their natural setting in order to develop a holistic, in-depth, understanding of the 'way of life' of a group, institution, and/or community. Denzin (Denzin 1989, p. 83) described this as producing a 'thick description', which:

> goes beyond mere fact and surface appearances. It presents details, context, emotions, and the webs of social relationships that join persons to one another. Thick description evokes emotionality and self-feeling. It inserts history into experience. It establishes the significance of an experience, or the sequence of events, for the person or persons in question. In thick descriptions, the voices, feelings, actions and meanings of interacting individuals are heard.

Two 'classic' ethnographies in the health field are Asylums (Goffman's (1961) study of a single mental hospital for which he posed as a member of staff for over a year) and Boys in White (Becker et al.'s 1961 study of medical education). Reading these studies, which have had profound impacts on health policy and practice, is a good way of becoming familiar with the methodology.

Ethnographers used a range of methods but participant observation, where the observers are fully active members of the activities being studied is the central method of data collection. Observational approaches to data

collection are, however, used in other study designs, often less intensively when the observer may be non-participant (maintaining distance by not having a formal role in the activities there). Observation typically involves the use of field diaries to record data, though video and audio recording may be used. Field notes are written up as soon as possible after the observation and include description of events that occurred (who, what, when, where, how), theoretical notes that try to derive meaning from the descriptive observation and notes on methodological issues that may impinge on the credibility of the research. As in all qualitative research observers are typically reflecting continually on the meaning of their observations during fieldwork and beginning to analyse by generating categories and ideas.

The ethical challenges of being an observer have been a source of debate as have the methodological issues: researcher presence may change the context under investigation. Building trust between researcher and researched, important to the quality of all empirical research, is vital. However, a balance has to be struck between building trust, understanding issues through the eyes of the researched and maintaining a critical observer stance.

Interview-based studies

Interviews are an almost ubiquitous element of qualitative research but they can take various forms: individuals or groups; short informal conversation or long sessions over many hours; one-off or longitudinal. They are a way of gaining a more ‘in-depth’ perspective on experiences than that provided by more structured forms of research (Olesen 1994). They are typically used to explore people’s understanding or experience of a phenomenon (e.g. poverty or housing quality), the meanings they attach to these experiences and the impact on their lives. An example of this type of research is Williams and Elliot’s Health Impact Analysis (Elliott and Williams 2008) of plans to demolish substandard housing in a South Wales community, which included a qualitative study involving both individual in-depth interviews and focus groups. The qualitative findings revealed that despite recognizing housing problems residents and local professionals were ambivalent and uncertain about the developments because of the potential disruption to social and family networks. Payment of expenses (travel and childcare) may often be necessary, especially for people on low incomes. However,

payment of a fee as an inducement to participate in individual or group interviews, which is becoming more common, raises ethical questions. Some ethics committees are uncomfortable with the practice. In terms of validity, payment may encourage people to take part primarily to earn the money, possibly even claiming membership of a group in order to qualify.

In-depth interviews are either unstructured (e.g. oral history or life history) or guided by a set of topics to be used flexibly with each interviewee. Interviewees are encouraged to express ideas and experiences in their own words, generating. 'textual' or 'narrative' data. Interviews are usually tape recorded and transcribed for analysis. Respondents are often selected purposively or 'theoretically' to reflect a range of experience of the phenomenon of interest (e.g. a health condition, an intervention, a place). Sample sizes vary but typically would be around 20–30 interviewees. Decisions about the style of interview to use will be influenced by the:

Topic of the research. More sensitive research topics (e.g. fertility) demand longer interviews than others.
Resources available. Long, in-depth interviews are costly to conduct, transcribe, and analyse. Tape recording is the preferred option (assuming respondents agree): responses can be handwritten but this is hard work as the interviewer also has to concentrate on maintaining eye contact and responding appropriately.
Tolerance of the interview group. In-depth interviews can be quite intrusive. People also have to give up time, possibly 2 or 3 hours. This may be easier for some people. Health professionals may be less willing, but older people are often more willing to spend time being interviewed.

In-depth interviewing is a skilled process but all members of a team doing research involving in-depth interviews should do at least some of the interviewing. Textbooks dealing with in-depth interviewing contain a considerable amount of advice for researchers (Glesne and Peshkin 1992; Seidman 2005; Minichiello et al. 2008). It is important to consider issues of gender, culture, language, and social class when planning interviews and in addition to establishing rapport, researchers need to: be able to explain the purpose of the research clearly; to keep an open mind and see 'the respondent as teacher' (Glesne and Peshkin 1992, p. 81); to learn and adapt as the interviews proceed; and to adopt an analytical approach from the

beginning of the research. In-depth interviewing has also been used to good effect to study policy processes such as Townsend et al. (2019) study of how paid parental leave was able to get in the policy agenda.

Focus groups are interviews with groups of people on a particular focused issue typically for up to 2 hours. They are often used to develop questionnaires for quantitative research or to obtain participants interpretation of results from the analysis of other data/studies. Increasingly, however, they have been used as a self-contained means of qualitative data collection. For example, Davidson, Kitzinger, and Hunt (2006) used 14 focus group discussions in Scotland and the north of England to explore views on health inequalities among people from different socioeconomic background. Focus groups are also commonly used in health promotion needs assessment. Similarly, Cortie et al. (1996) used four focus groups (stratified according to low and high socioeconomic status and extent of physical activity) to determine the factors in a local community that determine people's decision to exercise or not while Jacobs and Roberts (2004) used focus groups to collect data from health professionals on approaches to addressing malnutrition in Cambodia.

As Brown et al. (1989, p. 40) comment focus group 'are not just a convenient way to accumulate the individual knowledge of their members. They give rise synergistically to insights and solutions that would not come about without them'. They also enable participants to control the agenda and formulate opinions in a way that would not be possible in individual interviews (Morgan 1988, p. 28) and to explore topics in an open format at the beginning of research. Researchers also need to be aware of potential problems including:

'Group think' which may discourage individuals from expressing opinions at odds with the majority: 'devil's advocates' may overcome this tendency (MacDougall and Baum 1997).
Dominant individuals who can influence results: skilful moderation to minimize this risk is vital.
Less control by the researchers over the data that are generated.
Challenges associated with recording discussions.

The number and size of focus groups will be determined by research goals and available resources. Krueger and Casey (2009) recommends using

groups of between 5 and 10 but say size can be as few as 4 to as many as 12: the key point is that the group must be small enough for everyone to have an opportunity to provide insights and yet large enough to give a range of perceptions. As with individual interviews, the number of group interviews required to answer the research question cannot always be predicted in advance. It will also be necessary to decide how to divide the 'population'. For instance, if gender is likely to be a significant variable, it may be appropriate to have separate groups for men and women. In an evaluation, more 'honest' discussion may ensure if for example the providers of services are in a separate group from users. The research topic will usually determine how easy it is to recruit people for focus groups. Generally, the more sensitive the topic, the more challenging is recruitment.

As with all interviews, the quality of data obtained from focus groups is dependent on how they are run. Skills in facilitation, knowledge of groups dynamics and an understanding of the research area (so that interesting 'leads' are followed up in the discussion) are essential. For Morgan (1988) the role of the facilitator is to set up the group with instructions and then move to the side, intervening only if it goes badly off track. The venue will also be important: participants need to feel comfortable and relaxed and it needs to be suitable for achieving high-quality recordings. The data from a focus group are most easily recorded on audio tapes or digital media. It is usual to have one researcher facilitating the group and another taking notes. Depending on the research it may be sufficient to have a co-researcher take notes during the focus group, merely supplementing them with a recording but if more detailed content analysis is required then the recording would be transcribed verbatim. Focus group information, like other textual data, may be analysed according to its content and themes drawn out as discussed in the next section.

Case studies

Case studies involve the systematic study of an individual, group or community, an institution, or an event with a view to understanding why something happens in a particular context. Typically case studies place less emphasis on members' tacit knowledge than in ethnography, involve less intensive fieldwork, and are more likely to combine quantitative and qualitative methods. Data is usually collected from a variety of sources, including in-depth individual or group interviews, self-completion surveys,

and documents. Single or multiple cases can be studied, they can be descriptive or explanatory and may involve testing hypotheses.

Case studies were once seen as an exploratory phase of research, but are now widely accepted as evaluation tools in their own right (Stake 1995; Yin 2018). They are used extensively by development agencies such as the World Bank and US AID because 'it is more desirable to have a few carefully done case studies with results one can trust than to aim for large, probabilistic, and generalizable samples with results that are dubious because of the multitude of technical, logistic and management problems in third world settings' (Patton 1990, p. 100) Policymakers and politicians may relate to a case study and its story better than to a set of statistics so potentially increasing the likelihood that the research will be impactful. Combining statistics with case studies may be a particularly effective way of politicians. The Healthy Cities project is an international initiative based on the evaluation of international case studies. A summary evaluation of The Noarlunga Healthy Cities initiative (Baum et al. 2006a), for example, involving a narrative review of findings from a number of reported qualitative case studies of initiative activities and other project documents identified nine factors that lead to the initiative's sustainability over 18 years. Case studies have also been used to study the extent to which primary healthcare services are comprehensive and highlight the value of comparative case studies (Baum et al. 2013).

According to Yin (2018, pp. 242–7) criteria for exemplary case studies include: significance (i.e. focused on issues that are unusual and of general public interest, or important in theoretical, policy, or practical terms); *c*ompleteness (i.e. having clear boundaries and giving full attention to all relevant evidence); consider alternative perspectives on how the data should be interpreted; provide a *s*ufficiency of evidence to allow readers to judge the quality and robustness of conclusions; and use *e*ngaging approaches to dissemination, *such as videos.*

Document-based research

The collation and analysis of documents (such as minutes of meetings, annual reports, newspapers, etc.) is a valuable method in qualitative research. They can provide a 'particularly rich source of information about many organizations and programs' (Patton 2014, p. 176), and are often used in combination with other methods (Bowen 2009). Document analysis has

been used to assess uptake of research evidence in health policies (Flitcroft et al. 2011; Rosella et al. 2013) and the extent to which health policies address equity issues (Keleher 2013), and is emerging as a method to assess uptake of evidence on social determinants of health and health inequities (Pinto et al. 2012; Borrell et al. 2013; Fisher et al. 2014). Document analysis is also highly relevant to the commercial determinants of health, Anaf et al. (2017; see also Anaf et al. 2019) were able to conduct corporate health impact assessments by referring to company annual reports, other corporate documents, and media analysis.

Diaries/autobiographies are a particular form of documents used in qualitative research. Some studies make use of existing diaries other require participants to keep a diary for a set period focusing on key events they judge to be memorable. The method is particularly good for longitudinal data collection where recall may be a challenge, and where repeated interviews are not feasible. Diaries may be more or less structured and may be paper-based, computer based, or online blogs. The data are likely to be analysed in the same way as an interview transcript.

Sampling in qualitative research

The rationale for sampling in qualitative studies is purposive rather than random as in quantitative research. The aim is to select cases that will provide the most relevant and richest data. For this reason, as Kuzel (1992, p. 41) notes:

the sample can be adjusted as the theory develops, the aim being to thoroughly explore the topic of interest and to consider as many different angles and perspectives as possible. Glaser and Strauss (1967) refer to this as ‘theoretical sampling’;
people/cases are selected serially and sampling continues until little new information is gained (referred to as saturation);
‘negative or deviant cases’ are searched for to test ideas emerging from the analysis.

‘Snowball sampling’ is common. It involves contacting a few members of the group that is the focus of the research, and asking them to help find others. This technique is particularly useful for reaching groups that are not

readily identifiable, such as illicit drug users or voluntarily childless people. Researchers may also have to advertise. As already noted, sample size depends on what you want to know, what will be useful, what will have credibility, and what can be done with available time and resources (Patton 2014, p. 311). However, as a rule of thumb, six to eight data sources or sampling units will often be sufficient where the group is homogeneous, while up to 20 might be needed when looking for disconfirming evidence or trying to achieve maximum variation (Lincoln and Guba 1985; Patton 1990; Kuzel 1992). Qualitative researchers may be asked to specify their sample size in advance because of the requirements of a research funding body. The crucial feature is the logic underlying the sampling strategy, as this is the main criterion used to judge the strength of the sampling method. A proposal should be able to describe the sampling strategy clearly, state the selection criteria and provide an approximation of the sample size (National Health & Medical Research Council 2007).

Analysing qualitative textual data

In qualitative research analysis is the point at which data and theory are brought together to try and generate new understandings and explanations of social phenomena. Two elements in the analysis process can be distinguished: the purpose (what is being sought) and the practice (how it is done).

The purpose of data analysis

Although visual or audio data may be collected most qualitative research produces textual data, which typically comprise a mix of field or observational notes and transcripts from interviews or focus groups. Some examples of different approaches to analysis of these data are summarized next, but the key point is that the choice of approach to data analysis should be driven by the purpose of the research. For example, a narrative, life history, discourse, or conversation analysis can be conducted on the same extract from an interview, hence the importance of surfacing researcher standpoint and the theory driving a particular piece of research.

Content analysis: looks at the way themes and issues arise across texts (including interview transcriptions). Analysis may focus on the context,

frequency, and/or how themes are patterned by e.g. gender or ethnicity. This is a descriptive level of analysis.

Narrative analysis: looks at the way a person constructs a 'story' in the light of the audience and their purpose for giving the account. There is a focus on language, imagery, metaphor, and rhetorical purpose in the story being told.

Conversation analysis (CA): focuses on the structure of communication and conversation management such as turn taking or pausing. The aim is to reveal how meaning is constructed in interaction. CA is very specialized and marks both words spoken and how conversation proceeds (for example intonation).

Discourse analysis: explores the way knowledge is produced in particular contexts through the use of specialized language or theories and through performances, interaction, and rhetorical devices used to persuade. A range of texts can be subjected to discourse analysis (e.g. interview transcripts, video, letters, policy documents).

The practice of data analysis

In the broadest terms qualitative data analysis (QDA) involves the imposition of meaning and interpretation on mainly textual, usually unstructured, and unwieldy data. There are several schools of thought about methods of QDA but three theoretical traditions are particularly significant: interpretivism, social anthropology and collaborative research (Miles and Huberman 1994, p. 8). Interpretivism emphasizes the meaning of the data, and works from the premise that researchers' perceptions and understanding are affected by, and affect, the process of research. Included within this general tradition are ethnomethodologists, phenomenologists, deconstructionists, and discourse analysts. Social anthropology, including ethnography, focuses more on the accuracy of description and less on the conceptual or theoretical meaning of the observations. There is an interest in 'discovering' the underlying patterns or rules in a situation, which often begins with a theory that is tested during analysis. Within this broad tradition come researchers in life history, grounded theory, and much applied qualitative research and evaluation in education and health. Finally, there is collaborative research, in which analysis is either through reflective (questioning) or dialectic (opposing) enquiry with the research participants interspersed with further rounds of data collection.

Not-with-standing these different traditions, QDA always involves two distinct processes: description and interpretation, with the former comprising the identification of themes, concepts and categories in order to develop ideas or 'theories' about the data and relationships within it. There are many textbooks describing specific approaches to qualitative data but the Framework Analysis developed in the 1980s by applied qualitative researchers Ritchie and Spencer (1994) in 1994 and updated in 2011 is now extensively used. This involves the five stages briefly described next.

Familiarization with the range and diversity of data collected. A selection of the data should be read and (if recorded) listened to. Key ideas and themes should be listed.

Identifying a thematic framework within which textual data can be sifted and sorted. The framework should draw upon the original research ideas, theories informing the research, issues raised by respondents and themes identified during familiarization.

Indexing is the process whereby the thematic framework is applied to the data. Each transcript or set of field notes is coded by reference to the themes, usually using a computer package. A commonly used package is NVIVO (Bazeley and Jackson 2013). The system of annotating the text means the process is visible and accessible to others, and can be checked by two or more researchers.

Charting refers to the process of taking the data from its original context and rearranging it according to the appropriate thematic reference. Data are usually analysed by considering each theme across all respondents/cases. Charts can be produced manually but computer packages can also be used to compile all the data relating to a particular theme, which is then available for further analysis.

Mapping and interpretation involve reviewing the themes, comparing accounts and experiences, searching for patterns and connections, and seeking explanations for them within the data: processes that require 'leaps of intuition and imagination' (Ritchie and Spencer 1994, p. 186).

The use of computer packages is now common in QDA. Importantly, however, the intellectual work of description and interpretation is the responsibility of the researcher. Software cannot conduct analysis: it is simply a tool that can help make the analytical process more systematic by helping to:

Manage and keep track of all data including raw data files from interviews, survey and focus groups, or field observations, images, diagrams, audio, video, web pages, policy documents, ideas recorded as memos.
Organize and provide rapid access to conceptual and theoretical knowledge you generate.
Retrieving all relevant information from your data base in response to questions you pose. Queries can be saves and so becomes part of an ongoing enquiry process.
Visualize data to show the content of cases, ideas, concepts timelines, etc. and to represent these relationships visually.
Report from the data: including information about the original data source, the ideas and knowledge developed from them and the processes by which outcomes were reached (Bazeley and Jackson 2013, p. 3).

Assessing the quality of qualitative research

Validity, reliability, and generalisability are concepts that enable the value of positivist research to be judged. There is uncertainty in the literature about the extent to which these concepts can be applied to qualitative research. Kirk and Miller (1986) argue that they can be adapted to qualitative research methods, but others suggest alternative terms. Lincoln and Guba (1985) suggest using the terms ‘credibility’, ‘transferability’, ‘dependability’, and ‘confirmability’.

Credibility: Patton (2014) suggests this can be determined by reference to:

the rigour of the techniques and methods used
the credibility of the researcher (e.g. training, experience, track record, and status)
the philosophical orientation and assumptions that underpinned the study.

Triangulation can be a useful way of increasing the credibility of qualitative research. Denzin (1978) originally defined four types of triangulation:

data source triangulation—the use of a variety of data sources
researcher triangulation—the use of several different researchers or evaluators
theory triangulation—the use of multiple theoretical perspectives to interpret the same data
methodological triangulation—the use of multiple methods to study a particular problem.

To these Janesick (1994) adds a fifth type, which is relevant to public health:

interdisciplinary triangulation—having researchers from a variety of professions. This can be extended to include non-researchers who have an interest in the findings of research, such as residents of neighbourhoods receiving interventions that are being evaluated.

The analysis of negative cases that do not fit broader patterns identified in the data is also an important way of increasing credibility. Patton (2014, p. 656) comments: 'Dealing openly with the complexities and dilemmas posed by negative cases is both intellectually honest and politically strategic.'

Transferability refers to the ability of qualitative researchers to extend their findings to other settings. Lincoln and Guba (1985) suggest that research reports should provide sufficient detail (about methods, parameter, setting) for other researchers and users to make judgements about transferability. The use of theory in qualitative research is central to its transferability: Hilary Graham's (1994) research re-conceptualizing smoking among poor white women in England as a coping mechanism rather than a health damaging behaviour is an example of how the findings from qualitative research can be generalized on the basis of theory.

Dependability and reliability refer to whether the research is likely to be consistent over time and across researchers and methods and should be considered at all stages of the research. The reliability of data depends on skills in interviewing, observing, and recording. Analysis procedures, such as having two people involving in coding of data to themes, are likely to increase the reliability of interpretation.

Confirmability refers to the need to confirm research results with a source outside the research team and overlaps with interdisciplinary triangulation

discussed earlier. De Laine (1997, p. 279) suggests that an 'audit trail' of sampling decisions, methods of recording, analysis, coding, construction of themes, and personal notes would enable an outsider to follow the logic of each stage and understand how and why the researchers had drawn the conclusions they had.

There are, therefore, distinct ways of assessing qualitative research, but it is still common for the validity and reliability of public health qualitative research to be called into question by those who consider it to be subjective, and so invalid and unreliable. The issue of subjectivity and objectivity in science has been extensively debated by science philosophers, and today there are few who still maintain that positivist science is as objective as it was once thought to be, and there is broad acceptance that qualitative data can make a crucial contribution to aspects of public health. Patton (2014, p. 58) takes a pragmatic position that appears also to make sense for public health when he suggests we 'stay out of futile debate about subjectivity versus objectivity'.

Participatory action research

As we discussed earlier, participatory approaches are embedded in a broader movement to democratize the research process and to contribute to greater social justice. These approaches, which are not confined to qualitative research, challenge the privileged position of the professional researcher. They have drawn on the work of the adult educator Paulo Freire (1972) and place as much emphasis on the process as on the product of research.

The term 'action research' is often used interchangeably with participatory research; but sometimes the two are combined into 'participatory action research' (PAR). In medical and public health circles action research has received more attention in recent years but it had its origins in the work of educationists during the 1940s, particularly the work of the North American Kurt Lewin and it is now an accepted and respected research tradition in educational and management research (McTaggart 1991).

Drawing on the work of Minkler and Wallerstein (2003) and Grbich (1999) Baum et al. (2006b) define PAR as an approach that seeks to

understand and improve the world by changing it. At its heart it is collective, self-reflective enquiry that researchers and researched undertake together so they can understand and improve upon the practices in which they participate and/or the situations in which they find themselves. The reflective process is directly linked to action, influenced by understanding of history, culture, and local context and embedded in social relationships. The process of PAR should be empowering and lead to people having increased control over their lives. PAR pay careful attention to power relationships, advocating for power to be deliberately shared between researcher and researched: blurring the line between them until the researched becomes the researcher. The researched cease to be objects and become partners in the whole research process: including selecting the research topic, data collection, and analysis and deciding what action should happen as a result of the research findings. PAR may use a range of qualitative and quantitative approaches to data collection.

PAR is therefore a process that includes the generation of knowledge alongside 'education and development of consciousness and of mobilisation' (Gaventa 1988, p. 19). Some of the most exciting experimentation with participatory research has been in low-income countries where there is a potential to raise people's consciousness and encourage them to become involved in actions that could liberate them from poverty and despair. Bloem and colleagues (1996), for example, describe the development of the People's Participatory Planning (PPP) process by a non-government organization in Bangladesh in 1990. These authors stress that the PPP is not a universal panacea but overall they conclude that 'the continual process of reflection and action can enable people to change and transform from one level of functioning to another' (1996, p. 150). Similar conclusions were reached by Howard-Grabman (1996) in her analysis of a PAR designed to address maternal and neonatal health problems in rural Bolivia. The involvement of men and women in the project led to the development of new reproductive health practices that have seen maternal, perinatal, and neonatal mortality decline in the communities that were part of the project. Similarly, the PAR study by Hague and colleagues (2011), which found that the practice of paying for wives in rural Uganda was associated with increased domestic violence and male power over women, developed skills and capacity at the local level and made recommendations for strategies for action at both the national and the local level.

PAR does not require the researcher to downplay their specialist knowledge but to use that knowledge in dialogue with the expert knowledge of participants in the research process. As Reason (1994, p. 328) argued 'it is through dialogue that the subject–object relationship of traditional science gives way to a subject–subject one, in which the academic knowledge of formally educated people works in a dialectic tension with the popular knowledge of the people to produce a more profound understanding of the situation'. Similarly, PAR must avoid eulogizing the potential contribution of research participants. Just as professional researcher perspectives must be subject to critical reflection, so too must those of participants through a rigorous process of 'critical subjectivity' to arrive at new forms of interpretation and knowledge (Reason 1994, p. 333).

The practice of PAR presents dilemmas in the public health domain as it does in other fields. Boutilier, Mason, and Rootman (1997, p. 76) describe a number of these and suggest that key issues to be resolved in the practice of what they call 'community reflective action research' relate to: whose knowledge is valued; who owns the research; why the research is being done; and recognition of the complementary skills of lay people, researchers, and practitioners. Community participation and control of research processes may also lead to tensions with the demands of scientific rigour (Allison and Rootman 1996), as participants are generally not experts in research or primarily interested in the validity of research. These tensions should be addressed so that evaluations are scientifically acceptable and ethically participatory but they are not easy to reconcile. Inevitably, then, the processes of negotiation in participatory action research can be long and complicated and may in turn conflict with the needs of funding bodies. The key point is that PAR creates new dialogical spaces in which experiential knowledge is taken seriously: contributing to the creation of a democratic public health science that builds knowledge and understanding about population health and health equity through 'narratives of living and being'.

New directions in qualitative research

Qualitative public health researchers have recently begun to think of more creative ways in which to engage with and represent the experiences of people and communities by, for example, working more closely with the

arts and new methods including photovoice, digital storytelling and poetry which have been used to engage homeless women in research (Walsh et al. 2010). These kinds of initiatives are asking us to 'imagine' what cultural representations of population health and health inequity might look like, beyond the graph and the quote and they point to ways in which public health research might take more seriously the knowledge and concerns of local publics (Burawoy 2005). Working inside the fabric of everyday life can reveal the complex relationships between private troubles and local, national, and global public forces more clearly, illuminating the limits of behaviour change and demonstrating the value of experiential knowledge. This surely offers the hope of public health research with a stronger connection to broader social and political action in today's increasingly unequal, unjust social systems.

Conclusion

Qualitative research is vital to the study of global public health. Although primarily emanating from social epidemiology, public health research is increasingly utilizing more integrative approaches to explanation bringing together insights from different disciplines. Qualitative research has a key role to play in this context by opening up new theoretically informed analyses of the relationships between individual lives and social structures, including 'materially-informed' ways of thinking about the contribution of 'individual lifestyle' factors to health inequalities (Bartley 2004). Qualitative data can add depth to our understanding of the nature and impacts of the relationships between the social, commercial, and political determinants of population health and health inequalities described in quantitative research. Qualitative research can open up understanding of what things *mean* to people, what drives them to act (or not) in the situations they are in (Sayer 2011). Much public health research neglects the *particulars* of people's situation and the knowledge they develop and utilize to deal with these situations. Importantly, good quality qualitative research makes theoretical connections from these 'particulars' to more general social structures and processes. This is illustrated by our earlier example of qualitative research in which the concept of smoking as a coping mechanism was developed to demonstrate how white working-class

women caring for children while living in poverty relied on a cigarette to help them manage very stressful situations (Graham 1994). By making these connections (in this case between smoking and coping with poverty) and involving people as partners in the research process qualitative research can support public health practitioners and policymakers and the public more widely to develop new forms of solidarity: to 'imagine' and implement mechanisms for personal and collective change that will contribute to improving health and reducing inequities (Elliot et al. 2015)

Methodological issues in the design and analysis of cluster randomized trials

Kathy J. Baisley, Richard J. Hayes, and Lawrence H. Moulton

Introduction

Randomized controlled trials are the accepted gold standard for evaluating the effects of interventions to improve health. In the majority of such trials, individuals are randomly allocated to the experimental conditions under study, for example, to treatment and control arms. However, in some situations it is more appropriate to randomly allocate groups of individuals to the treatment arms. These groups are referred to as clusters, and trials of this kind are known as cluster randomized trials (CRTs). Examples of clusters include schools, villages, workplaces, or health facilities, but there are many other possible choices. In some CRTs, all individuals within the selected clusters are automatically included. In others, there may be additional eligibility criteria. Similarly, the impact of the intervention may be measured in all individuals in the cluster, or in a random subsample. This chapter aims to discuss methodological issues that arise in the design and analysis of CRTs. Some of the content has been condensed from the textbook by Hayes and Moulton (2017).

There are a number of reasons for using a cluster randomized design. Some interventions by their nature have to be implemented at the cluster level, such as an intervention to improve water supplies in villages. Others could in principle be implemented at the individual level, but cluster randomization may offer greater logistical convenience, or may be more acceptable to the community. Cluster randomization may help avoid contamination, where individuals in one treatment arm are exposed to or receive the treatment assigned to the other arm. CRTs are also the best design to capture the population-level effects of an intervention applied to a

large proportion of a population. For example, a CRT in Uganda evaluated the effect of intermittent preventive treatment (IPT) for malaria in school children (Staedke et al. 2018). Each cluster included one primary school and 100 surrounding households. The main trial outcome was malaria parasite prevalence in the community, measured in a random sample of households in each cluster.

When considering a cluster randomized design, the advantages need to be weighed against the limitations. The power and precision of a CRT is lower than for an individually randomized trial of the same size, and the logistical aspects of working in several different clusters may make a CRT expensive to implement. Other issues to consider are selection bias, imbalance between study arms, and generalisability, which will be discussed in this chapter.

CRTs have become increasingly more common in health research. In the early years, the special design and analysis requirements of these trials were not always understood, and there were many trials that were designed, analysed, or reported inappropriately. However, over the past two decades, much work has been done on methods for CRTs, and the quality of these trials has improved.

Methodological implications of cluster randomization

The design and analysis of individually randomized trials rely on individual observations being independent of one another. However, when observations are naturally grouped within clusters, this assumption of independence is violated, since observations on individuals in the same cluster are usually correlated. That is, responses among individuals in one cluster will tend to resemble each other more than the responses of individuals in different clusters. This phenomenon is termed within-cluster correlation. It can be equivalently viewed as between-cluster variation, which reflects the natural variation among clusters that exists even in the absence of an intervention effect. Therefore, within-cluster correlation and between-cluster variation can be thought of as corresponding concepts that provide two different perspectives on the same underlying phenomenon.

Within-cluster correlation, or equivalently between-cluster variation, can occur in CRTs for three main reasons. The first reason is the most obvious,

which is that health conditions tend to vary between populations, owing to differences in the individuals that make up each cluster or differences in geographical or environmental characteristics of the cluster. A perhaps less obvious point is that different clusters may respond differently to the intervention, so that there may be no between-cluster variation in the outcome of interest before the intervention, but significant between-cluster variation after the intervention is introduced. The final reason that health outcomes may be clustered is due to interactions between members of the cluster. For example, in interventions against infectious diseases, the effect of an intervention in one individual may affect the risk of contracting the disease in other individuals in the same cluster.

The correlated nature of the data from CRTs requires careful thought at the design stage to ensure sufficient information is collected. As a result of this correlation, CRTs require larger sample sizes than conventional individually randomized trials to be adequately powered to detect treatment effects, and to obtain sufficiently precise estimates of the treatment effect.

Since standard statistical techniques rely on the independence of individual observations, we cannot use these methods to analyse data from a CRT. Using standard statistical techniques will result in p-values that are too small and confidence intervals for the treatment effect that are too narrow. Instead, analysis techniques that account for between-cluster variability are required to analyse CRTs.

Measures of between-cluster variability

There are two main measures of between-cluster variability, corresponding to the two ways of viewing this phenomenon: the coefficient of variation between clusters (k) and the intracluster correlation coefficient (ICC).

Consider a CRT in which a quantitative variable, for example systolic blood pressure, is measured on each individual. The parameter of interest is the mean, μ. Suppose there are c clusters, and that the true value of the mean in the jth cluster is given by μ_j. We assume that the μ_j are randomly sampled from a probability distribution with mean $E(\mu_j) = \mu$ and variance $Var(\mu_j) = \sigma_B^2$, where σ_B^2 represents the between-cluster variance. Then the coefficient of variation is defined as:

$$k = \frac{\sigma_B}{\mu}.$$

If the parameter of interest is a proportion or rate, μ is replaced by π or λ, the true value of the proportion or rate, respectively. It is important to recognize that the μ_j represent the true value of the mean in a notional wider population in each of the c clusters. The μ_j are not directly observable, since we collect data only on a finite sample of individuals in each cluster. However, it is possible to use the observed values of the mean in each cluster to obtain valid estimates of σ_B, μ, and hence *k*, as we describe in a later section.

The ICC, usually denoted by the Greek letter *ρ*, represents how much more similar outcomes are in individuals from the same cluster compared with individuals from different cluster. Another way of describing the ICC is to say that it measures the proportion of the total variance in the outcome that may be attributed to between-cluster variation. The ICC is calculated differently depending on the outcome of interest. The methods for quantitative and binary outcomes are described next. The ICC is not defined for a rate; therefore, *k* is used to estimate between-cluster variability when outcomes are event rates.

For quantitative outcomes, the ICC is defined as:

$$\rho = \frac{\sigma_B^2}{\sigma_B^2 + \sigma_W^2},$$

where σ_B^2 is the between-cluster variance and σ_W^2 is the within-cluster variance.

For binary outcomes, where an individual either does or does not satisfy a certain condition (for example, has hypertension or does not), the objective is usually to compare the proportion of individuals with the outcome. The ICC for binary outcomes is defined as:

$$\rho = \frac{\sigma_B^2}{\pi(1-\pi)},$$

where π is the true proportion for the entire population, and σ_B^2 is the variance of the cluster-specific true proportions.

In general the ICC will fall between zero and one. An ICC of zero implies that there is no clustering, so that individuals within the same cluster are no more similar to each other than to individuals from different clusters, in other words, there is no between-cluster variability. An ICC of one implies that individuals in the same cluster are perfectly correlated, in other words they all have the same outcome, and there is no within-cluster variability.

Design effect and effective sample size

A CRT can be considered equivalent to collecting data from a cluster sample of individuals, rather than a simple random sample as in a conventional individually randomized trial. Cluster sampling provides less precise estimates of parameters of interest than simple random sampling. The increase in variance can be measured by the design effect (DEff) (Kish 1965):

$$\mathrm{DEff} = \frac{\text{variance for cluster sampling}}{\text{variance for simple random sampling}}.$$

Since the variance for a simple random sample is inversely proportional to the sample size, the design effect also gives the effective sample size for the cluster sampling design:

$$\mathit{Effective\,sample\,size} = \frac{\mathit{actual\,sample\,size}}{\mathit{DEff}}.$$

For example, if DEff = 2, this means that the cluster sample will provide the same precision as a simple random sample of half the size.
DEff can be calculated from the ICC as follows:

$$\mathrm{DEff} = 1 + (m-1)\rho.$$

where *m* is the number of individuals per cluster.

From this, we can see that the impact of clustering in a trial depends not only on the value of the ICC, but also on the size of the clusters. DEff may be substantial when we have large clusters, even if the ICC is small. A further discussion of the relationship between DEff, the ICC, and *k*, can be found in Hayes and Moulton (2017, pp. 19–22). A detailed discussion of how to account for the impact of clustering in sample size calculations and analyses is presented in later sections of this chapter.

Experimental and observational units

The key difference between a CRT and an individually randomized trial is that the intervention is randomly allocated to clusters of individuals rather than to individual participants. The cluster therefore constitutes the experimental unit in a CRT. While the cluster is always the experimental unit, observations may be made at different levels so there may be several types of observational unit. In the simplest case, observations may be made only on the individual participants in each cluster. More often, data will also be collected on cluster-level variables and, in some CRTs, there may also be intermediate levels of observation. For example, in a CRT of a school-based health education programme, in which the intervention is randomly allocated to schools, units of observation might include the individual student (e.g. age, sex), class (e.g. grade, size, number of students, number of sessions delivered), and school (e.g. urban/rural, type of school, size of school). Data from all these levels may be used when making inferences about the main parameters of interest.

Design considerations in CRTs

Choice of cluster type and size

One of the first decisions when designing a CRT relates to the choice and definition of the clusters that are to be randomized. In practice, trials have used a wide variety of cluster types, ranging from CRTs of families or households, with only a few individuals in each cluster, to CRTs of large geographical regions in which each cluster may include millions of

individuals. While the general principles of CRT design may be similar for these widely varying situations, the practical aspects of implementing such trials are clearly very different.

Having decided on the type of cluster that will be randomized, the investigator may still have some latitude in choosing the cluster size. This is particularly the case with geographical clusters, where arbitrary boundaries may be drawn. Even when we have institutional clusters, however, there may be some flexibility—for example to group neighbouring schools or health facilities into one cluster.

A number of factors may be considered when deciding on cluster size. The formula for DEff shows that, for a given total sample size, precision is maximized with a cluster size of m = 1, corresponding to individual randomization. Assuming the ICC remains constant, DEff increases with cluster size. This implies that a large number of small clusters is statistically more efficient than a small number of larger clusters. By statistical efficiency, we mean that our estimate of the intervention effect will be more precise. However, in practice the ICC may not remain constant, and generally tends to decrease with increasing cluster size. For example, suppose the choice is between randomizing towns or neighbourhoods. There may be substantial variation in health outcomes between neighbourhoods, owing in part to socioeconomic differences. However, since each town is likely to have a mix of neighbourhoods of higher and lower socioeconomic status, the differences may average out so that there is little variation in the outcome between towns. As a result, the ICC may be larger for neighbourhoods than for towns. Thus it is important to have estimates of the ICC or *k* which relate to the types and sizes of cluster under consideration, when estimating the sample size of a CRT.

Statistical issues are not the only consideration when deciding on cluster size. Although designs using a large number of small clusters are statistically more efficient, it may be logistically and financially more feasible to carry out field work in a smaller number of large clusters. The relative cost and feasibility of designs based on different cluster sizes will depend critically on the type of cluster and geographical setting.

Contamination is another consideration in the choice of cluster size. Contamination can occur through contacts between intervention and control clusters, or through contacts between intervention clusters or control clusters and the wider population. In general, contamination is likely to

decrease as cluster size increases. Rates of travel and migration across area boundaries generally decrease as the size of the area increases. Edge effects are also likely to diminish with the size of the cluster, since the proportion of the population living close to the boundary of an area decreases as the area is increased.

One of the main strategies for reducing contamination in a CRT is to select clusters that are well-separated. This is particularly useful for reducing the level of contact between intervention and control clusters. The separation needed will depend on the intervention under study, for example, much greater geographical separation may be needed for a mass media intervention. Investigators have sometimes specified that the trial clusters should be separated by buffer zones, so that there is little or no common boundary between any two clusters. Additional strategies may be needed to reduce contact between trial clusters and the wider population.

For example, a CRT in rural Burkina Faso evaluated the effect of a comprehensive radio campaign on key family behaviours for improving child survival (Sarrassat et al. 2018). Clusters were 14 distinct geographical areas, each centred around a community radio station, and comprising sufficient villages to provide a total population of around 40,000 per cluster. Clusters were identified using digital terrain maps, on-the-ground mapping of radio signal strength, and surveys to assess radio listenership. Clusters were selected based on their high radio listenership (>60% of women listening to the radio in the past week), and to have little or no overlap of radio signal between areas to minimize contamination.

Baseline imbalance between trial arms

In individually randomized trials with a large number of participants, we can rely on the randomization process to provide study arms that are similar with respect to all potential confounding factors. In CRTs, owing to practical and financial constraints, the number of clusters randomized is often quite small, for example, 20 or 30. In these circumstances, randomization still has the advantages of impartiality, transparency, and justification for statistical inference as it does in individually randomized trials. However, with such a small number of randomization units, it is quite likely that there will be some imbalance on one or more potential confounding factors. While these factors can be adjusted for in the analysis,

the credibility of the trial results may be weakened in the presence of such imbalances; therefore investigators may choose to employ matching, stratification, or restricted (covariate-constrained) randomization to improve baseline balance.

Matching

Matching involves grouping clusters that are similar with respect to certain pre-defined characteristics, then randomizing one cluster in each group to each of the treatment arms. If there are two treatment arms in the CRT, clusters are grouped into matched pairs and one cluster in each pair is randomly allocated to each treatment arm. Matched trials with three treatment arms involve identifying matched triplets and so on. Matching can help to minimize differences between treatment arms with respect to baseline characteristics, and can improve the precision and power of a CRT, since it can reduce between-cluster variability in the outcome of interest.

For example, an HIV prevention trial reported by Grosskurth et al. (1995) was carried out in 12 communities in Mwanza, Tanzania that included rural villages, settlements along a major road, and villages along the shore of Lake Victoria. Baseline HIV prevalence in these communities varied from 1.6 to 8.6%, and the primary outcome (HIV incidence) was expected to be similarly variable. When such high levels of between-cluster variability exist, the coefficient of variation in the outcome is large, which reduces the power of the trial for a given sample size. Therefore, the trial communities were grouped into matched pairs, based on baseline HIV prevalence and geographical characteristics. This helped to ensure that the two arms were similar with respect to these factors at baseline, and it was presumed that they would therefore be more similar with respect to the primary outcome. A matched analysis was employed by comparing the outcome between the intervention and control communities within matched pairs. Since the variance in the outcome within matched pairs may be considerably smaller than the overall variance, replacing the overall coefficient of variation k with the coefficient of variation within matched pairs, k_m, may increase the power of a trial to detect a treatment effect.

However, there are several important disadvantages to matching. Matching is most effective if the matching variables are highly correlated with the outcome variable. In the Mwanza trial, the matching correlation

coefficient was 0.94. However, this level of success in pair-matching is unusual, and indeed in some trials, efficiency may even be lost relative to that of an unmatched design. This is because of the loss of degrees of freedom associated with a matched analysis. For example, to test for an effect of the intervention, a CRT with c matched pairs of clusters is typically analysed using a paired t-test with c − 1 degrees of freedom. This is half the 2(c − 1) degrees of freedom available for an unpaired t-test. The power to show an intervention effect will depend on both the value of the t-statistic and the critical value of the *t* distribution, which in turn depends on the degrees of freedom. It has been shown that below a particular break-even value of the matching correlation coefficient, an unmatched design will have higher power than a matched design, because the loss in degrees of freedom will outweigh the reduction in variance (Martin et al. 1993; Hayes and Moulton 2017, pp. 80–1).

Matching may also present problems if an entire cluster drops out of the trial. Such drop-out also reduces the power and precision of an unmatched CRT and raises questions over selection bias. However, in a matched CRT, the entire matched pair is lost, since the remaining cluster no longer has a matched cluster for comparison.

Another disadvantage of the matched design is that it is not possible to assess whether the intervention effect varies between matched sets. This is because the difference in outcomes between clusters in a matched set depends on both the intervention effect and the intrinsic between-cluster variability within that matched set. It is impossible to separate out these two effects without making additional assumptions. This difficulty results from the lack of replication within each matched set, meaning that there is only one cluster per treatment arm in each matched set. Therefore, it is not possible to calculate the ICC or *k* based on data from a matched trial (unless additional assumptions are made), because the between-cluster variability is confounded with variation in the intervention effect. Although matched trials can still be analysed without an estimate of the ICC or k, the lack of a good estimate of between-cluster variation may be a limitation when investigators are calculating sample sizes for future trials.

Stratification

Stratification is a less rigid method than matching for reducing baseline imbalance between treatment arms and reducing between-cluster variability. Stratification involves grouping clusters with similar characteristics into strata, then randomizing more than one cluster in each stratum to each treatment arm. Thus, unlike matching, stratification achieves replication within strata, which overcomes the main disadvantages of matching. For example, the HIV Treatment as Prevention (TasP) trial in rural South Africa used a stratified design to allocate 34 communities to either the intervention or control arms (Iwuji et al. 2013). The investigators created six strata on the basis of antenatal HIV prevalence. Within each stratum, communities were then randomly allocated to the two trial arms.

Restricted randomization

Although matching and stratification may help reduce imbalances between the treatment arms, they are less useful if balance is required on a large number of variables. In these circumstances, restricted (covariate-constrained) randomization can be used to ensure an acceptable level of overall balance on a number of variables. This method uses baseline or pre-existing data from each cluster to generate a subset of possible allocations that satisfy certain predetermined balance criteria (Raab and Butcher 2001; Moulton 2004). One allocation is then randomly selected from this restricted subset. For example, the ZAMSTAR trial of a tuberculosis control intervention in Zambia and South Africa used both restricted randomization and stratification to randomly allocate 24 clusters to four intervention groups (Sismanidis et al. 2008). Stratification was by country and tuberculous infection prevalence and restricted randomization was by tuberculous infection prevalence, HIV prevalence, urban/rural, social context, and geographical location. A further overview of matching, stratification, and restricted randomization for achieving baseline balance in CRTs is provided by Ivers et al. (2012).

Choice of design strategy

Matching and stratification are designed to achieve baseline balance and reduce between-cluster variability, so thus improve power and precision. In

contrast, restricted randomization is mainly intended to achieve baseline balance.

Matching has been most commonly used for CRTs with a small number of clusters per arm (fewer than 10–15). Unfortunately, while matching is likely to improve balance, it may reduce the power and precision of the trial if the matching is ineffective. In contrast, stratification loses fewer degrees of freedom, so power and precision are more likely to be maximized. In trials with a small number of clusters, care should be taken to limit the number of strata: as a general rule, no more than two strata should be used in trials with ≤6 clusters per arm. Although stratification loses fewer degrees of freedom compared with matching, it is less likely to achieve close balance. In particular, if balance is sought on a large number of variables, the number of strata required would result in a large loss of degrees of freedom. In this situation, restricted randomization would be more effective in achieving balance.

Baseline balance is more likely in trials with larger numbers of clusters. However matching and stratification may still be useful to improve power and precision. In trials with many clusters, the loss of degrees of freedom has very little effect, so either method can be an effective design. In most practical situations, it is likely that stratification (with, say, three or four strata) will capture most of the additional power provided by matching unless there are matching factors that are very closely related to the endpoints of interest. Box 5.7.1 provides a summary of important points for CRT design.

Box 5.7.1 Summary of important points for CRT design

- In CRTs, the intervention is randomly allocated to groups of individuals, rather than individual participants
- Observations in the same cluster are correlated; therefore, CRTs require larger overall sample sizes than individually randomized trials
- The degree to which observations are correlated can be measured by k or the ICC
- The design effect (DEff) measures the impact of clustering on sample size
- CRTs often randomize a small number of clusters, so are susceptible to baseline imbalance
- Matching, stratification, and restricted randomization can be used to help ensure balance
- Matching and stratification may also improve power and precision
- However, if the matching is ineffective, power and precision may be reduced in a matched CRT

Alternative trial designs

Most CRTs involve the randomization of clusters to two parallel treatment arms. A number of alternative CRT designs exist, and may be advantageous in certain situations. However, the analysis and interpretation of trials with these alternative designs are not always straightforward. Investigators would generally be advised to use simpler deigns unless there are convincing reasons for using these more complex designs.

Factorial designs allow the study of the independent effects of two interventions in the same trial. This has the advantage of being cost effective, and conserving sample size. The design most commonly used in CRTs takes a 2 × 2 layout resulting in four treatment arms: one arm receiving the first intervention, another receiving the second intervention, an arm receiving both interventions, and a control arm. For example, the ZAMSTAR trial evaluated enhanced tuberculosis (TB) case-finding (ECF) and a household intervention (HH) including TB screening and preventive treatment (Sismanidis et al. 2008). Clusters were randomly allocated to one of four arms: ECF, HH, both ECF and HH (ECF + HH), or control. The effect of ECF was assessed by combining the ECF and ECF + HH arms and comparing them with the combined HH and control arms. The effect of HH was assessed in a similar manner. This approach is only valid if there is no interaction between the interventions. Where interactions are expected, factorial designs can be used to identify the joint effect of two interventions; however, larger sample sizes will be required.

The crossover design is commonly used in individually randomized trials, and has been adopted for CRTs. Each cluster receives two interventions, one after the other, in an order determined at random (Parienti and Kuss 2007). Delivery of the two interventions is separated by a washout period, to avoid any ‘carry-over’ effects. Since each cluster serves as its own control, the design has potentially greater efficiency than a parallel group CRT. However, its validity depends on the assumption that carry-over effects are absent, that is, that the estimated effects of intervention are independent of the order in which they are assigned. Even with the use of

washout periods, crossover trials are still often subject to carry-over effects, particularly for interventions that aim to effect behaviour change.

Crossover trials are also subject to ‘period’ effects, where participants respond differently in one treatment period for reasons unrelated to the intervention (e.g. because their health status has changed). A review of crossover designs is provided in Arnup et al. (2017).

Stepped wedge trials have received increasing attention in the literature. This design is a modification of the crossover design, and involves all of the clusters beginning the trial in the control arm (Hussey and Hughes 2007). After each successive time period of the trial, one or more clusters commences the intervention and remains in the intervention arm for the rest of the trial, so that at the end of the trial all of the clusters are in the intervention arm. The order in which the clusters commence the intervention is decided randomly to avoid confounding by variables related to the order of introduction. For example, a stepped wedge trial of an intervention to reduce the risk of stillbirth was conducted in 33 maternity hospitals in the United Kingdom and Ireland (Norman et al. 2018). Hospitals were randomly allocated to one of nine intervention starting dates, approximately 3 months apart. At baseline, none of the hospitals received the intervention. Every 3 months, the intervention was implemented in the hospitals allocated to that starting date, until all of the hospitals had received the intervention. Although the stepped wedge design is becoming more widespread and there have been recent advances in the methodological literature, it is still viewed as a relatively new design with gaps in knowledge remaining around their uses, ethics, conduct and analysis (e.g. Hargreaves et al. 2015; Thompson et al. 2017).

An important disadvantage of the stepped wedge design is that there is a systematic difference in calendar time of observation between the two treatment arms, so the design is susceptible to bias introduced through secular trends in the outcome. Stepped wedge trials often take place over a period of years, increasing the opportunity for a gradual overall improvement or deterioration in outcomes. Furthermore, it may be difficult to ascribe a particular outcome to the effect of the control or intervention, if the outcome takes a long time to occur. Similarly, there may be difficulties in interpretation when the intervention effect waxes or wanes. Further discussion of the use of stepped wedge designs in CRTs can be found in Rhoda et al. (2011), Copas et al. (2015), and Hemming et al. (2015).

Approaches for impact evaluation

The impact of an intervention in a CRT can be evaluated either through repeated cross-sectional surveys or by following up a cohort of individuals over time. With a cross-sectional survey design, surveys are conducted at different points throughout the trial; either the entire cluster is surveyed or a random sample may be selected. Individuals who enter the cluster during the trial may be included in surveys at later time points. For example, in the CRT of a radio campaign in Burkina Faso mentioned earlier (Sarrassat et al. 2018), trial outcomes were assessed in cross-sectional surveys at 20 months and at 32 months after the trial start. In each survey, a random sample of around 360 mothers per cluster were interviewed regarding their demographic characteristics, radio listenership, and family behaviours of relevance to child survival. Cross-sectional surveys are useful for assessing the effect of an intervention on the prevalence of a binary outcome, such as hypertension prevalence, or on a quantitative outcome, such as serum cholesterol. However they are less useful for measuring incidence rates of an event of interest.

An alternative approach is to enrol a cohort of individuals who are followed over time. Either the entire cluster, or a random sample of each cluster, may be enrolled. If the entire cluster is enrolled, the investigator must specify whether new people entering the cluster during the trial will be included (referred to as an open or ‘dynamic’ cohort) or if the cohort will be limited to those seen at baseline (a closed cohort). Cohort designs are particularly useful for measuring event rates. They also allow direct measurement of change over time, such as a change in serum cholesterol or a change in disease incidence over time. For example, a CRT in rural India of a mobile phone-based system and nurse-managed care for hypertension and diabetes randomly allocated 40 community health clinics to the intervention or control arms (Jha et al. 2017). Individuals with hypertension and/or type 2 diabetes were invited to participate in the trial. A total of 90 individuals were recruited at each clinic and followed for 12 months. The primary outcome was change in systolic blood pressure and glycated haemoglobin (HbA1c) over 1 year. However, cohort designs are subject to selection bias owing to loss to follow-up, are generally more logistically complex, and may not be as generalizable since they represent the effect of the intervention in the subgroup of the population who remain in the cohort

throughout follow-up. In a closed cohort, the disease incidence may decrease over time as the susceptible members acquire the disease early on and only the less susceptible members remain at risk. The choice of design will also depend in part on the primary questions of scientific interest. If interest focuses on change at the broader community level, cross-sectional designs may be the more natural choice, while cohort designs may be more appropriate if focus is on change at the individual level. Further discussion may be found in Feldman and McKinlay (1994).

Sample size determination for CRTs

Statistical approaches to estimating sample size

The formal assessment of statistical power is a fundamental step in the design of any intervention trial. The consequences of trials that are too small for their purpose have been widely discussed in the literature. CRTs are often more costly and logistically complex than individually randomized trials, placing even more responsibility on researchers to ensure that trials are designed with sufficient power to achieve their main objectives. A fundamental principle of randomized trials is that sufficient replication is required to draw reliable conclusions. The correlated nature of the data from CRTs means that the information gained is less than that in an individually randomized trial of the same size. Even if each cluster contains a large number of individuals, the trial may be insufficiently powered if there are too few clusters. We need several clusters in each treatment arm to draw any useful conclusions about the effect of an intervention. For example, imagine an extreme case in which just two clusters are randomly allocated, one to each treatment arm. This is equivalent to a clinical trial in which just two patients are randomly allocated to the two treatment arms. Because there is no replication within each treatment arm, we have no way of measuring and taking account of between-cluster variation, and so no statistical inference is possible. Only by randomizing sufficient clusters to the different treatment arms can we obtain an accurate estimate of average response in each arm, and of differences between arms.

Sample size formulae for CRTs are easily available in journals (e.g. Hemming et al. 2011; Rutterford et al. 2015) and textbooks (e.g. Donner and Klar 2000; Eldridge and Kerry 2012; Hayes and Moulton 2017). In

their simplest form, if we have an estimate of DEff, sample sizes for CRTs can be estimated by calculating a sample size for an individually randomized trial then multiplying this by the DEff (Donner et al. 1981).

Next we give a brief overview of formulae for a standard unmatched CRT design. The formulae assume that the cluster size is fixed, and that we need to calculate the number of clusters required per arm. This is the most useful formulation in CRTs where the sizes of the clusters are defined in advance and the outcome is measured in all individuals in each cluster. If instead the number of clusters is fixed, for example a health service intervention in a fixed number of clinics, the formulae can be rearranged to calculate the required cluster size.

Binary outcomes are usually analysed by comparing the proportions with the outcome in the two arms of the trial. The number of clusters, c, required in each arm can be calculated as:

$$c = 1 + (z_{\alpha/2} + z_{\beta})^2 \frac{\pi_0(1-\pi_0)/m + \pi_1(1-\pi_1)/m + (k_0^2\pi_0^2 + k_1^2\pi_1^2)}{(\pi_0 - \pi_1)^2},$$

where $z_{\alpha/2}$ and z_{β} are standard normal distribution values corresponding to the upper tail probabilities of $\alpha/2$ and β, respectively, k_0 and k_1 are the coefficients of variation in the control and intervention arms, π_0 and π_1 are the true proportions with the outcome in the two arms, and m is the number of individuals per cluster.

If we can assume that the intervention has a similar proportional effect across clusters, then the coefficient of variation for the two arms will be similar and the equation can be simplified to:

$$c = 1 + (z_{\alpha/2} + z_{\beta})^2 \frac{\pi_0(1-\pi_0)/m + \pi_1(1-\pi_1)/m + k^2(\pi_0^2 + \pi_1^2)}{(\pi_0 - \pi_1)^2},$$

where *k* is the common value of the coefficient of variation in the two arms. An important practical point is that, if the expected proportion with the outcome is above 0.50, it is usually better to work in terms of $1-\pi$, rather than π, when calculating the sample size.

We illustrate the calculation of sample size for a CRT using the HIV TasP trial described earlier as an example (Iwuji et al. 2013). The trial's primary outcome was the impact of the intervention on the cumulative incidence of HIV over 24 months in adults aged ≥16 years who were HIV negative at baseline. Clusters comprised contiguous neighbourhoods in a demographic surveillance area (DSA). The study area was mapped before the trial; average cluster size was 1,000 adults. Based on previous HIV surveys in the DSA, HIV prevalence was estimated to be 20%. Allowing for 20% non-participation and loss to follow-up, the estimated mean number of HIV negative adults to be followed over 2 years in each cluster was m = 1,000 × 0.80 × 0.80 = 640.

HIV cumulative incidence over two years in the control communities was estimated to be 5% (π_0), based on surveys in the DSA. On the basis of mathematical modelling, the intervention was expected to reduce cumulative incidence by 30% (i.e. from 5% to 3.5% (π_1)). A value of k = 0.25 was used, based on other studies in the region with HIV incidence as an outcome. The proportional effect of the intervention was assumed to be roughly constant over clusters so that $k_0 \approx k_1 \approx 0.25$. To have 80% power ($z_\beta = 0.84$) to detect a significant difference (2-sided $p < 0.05$, $z_{\alpha/2} = 1.96$), the number of clusters that are needed per arm is:

$$c = 1 + (1.96 + 0.84)^2 \frac{[0.05(1-0.05)]/640 + [0.035(1-0.035)]/640 + 0.25^2(0.05^2 + 0.035^2)}{(0.05-0.035)^2} = 13.5.$$

We would therefore select 28 clusters and randomly allocate 14 to each arm. The investigators decided to randomize 34 clusters (17 per arm), which would give them 88% power to detect an intervention effect.

For trials in which outcomes are expressed as rates per person-year (e.g. incidence rates or mortality rates), the required number of clusters per arm can be calculated as:

$$c = 1 + (z_{\alpha/2} + z_\beta)^2 \frac{(\lambda_0 + \lambda_1)/y + (k_0^2\lambda_0^2 + k_1^2\lambda_1^2)}{(\lambda_0 - \lambda_1)^2},$$

where y is the number of person-years in each cluster, and λ_0 and λ_0 are the true rates in the control and intervention arms, respectively. If the intervention effect is assumed to be similar across all clusters, the equation can be simplified by using a common value of k as above.

For CRTs with quantitative outcomes (e.g. cholesterol levels), the required sample size can be calculated as:

$$c = 1 + (z_{\alpha/2} + z_{\beta})^2 \frac{(\sigma_0^2 + \sigma_1^2)/m + (k_0^2\mu_0^2 + k_1^2\mu_1^2)}{(\mu_0 - \mu_1)^2},$$

where μ_0 and μ_1 are the true means in the control and intervention arms, and σ_0 and σ_1 are the within-cluster standard deviations. Again, the equation can be simplified assuming a common value of k.

Simple extensions of these formulae can be used for matched trials, using the coefficient of variation of the outcome between clusters within matched pairs, k_m, and adding an extra cluster to each treatment arm, to make up for the loss of degrees of freedom when using the paired t-test (Hayes and Moulton 2017, pp.141–2). Sample sizes for stratified trials can be calculated using the same equations as for matched trials. The value of k_m for stratified trials will generally lie between k_m for matched trials and the k for the unmatched design.

Alternative formulae are available for binary and quantitative outcomes based on the ICC (Donner et al. 1981; Donner and Klar 2000). Application of these formulae generally provides very similar results to those based on the coefficient of variation.

Our discussion so far has assumed that the number of individuals or person-years in each cluster is the same. However, in many CRTs, the cluster size may be variable, for example, because villages vary in size, or individuals in some clusters may be lost to follow-up. If the variability in cluster size is large, this should be taken into account in the sample size calculations to ensure that the power is adequate. Methods to account for variable cluster size are reviewed in Rutterford et al. (2015). Sample size calculations for more complex designs are discussed in Hayes and Moulton (2017), Campbell et al. (2007), and Rutterford et al. (2015). Sample size

determination for stepped wedge trials is discussed in Baio et al. (2015), Hemming and Taljaard (2016), and Thompson et al. (2017).

In practice sample size calculations are rarely performed by hand. Statistical packages such as R and Stata have commands to perform sample size calculations that take account of between-cluster variability. Sample size estimation by simulation is an alternative to using an analytical formula, particularly for more complex designs (Reich et al. 2012).

Obtaining estimates of *k* or ICC

Sample size calculations for CRTs require an estimate of between-cluster variation in the outcome of interest. Recall that the coefficient of variation in the i^{th} treatment arm, k_i, is defined as σ_{Bi} $/\lambda_i$, σ_{Bi} $/\pi_i$, or σ_{Bi} $/\mu_i$ for outcomes measured as event rates, proportions, and means, respectively. The values of λ_i, π_i, or μ_i need to be specified in any case, as these are intrinsic to any sample size calculation. In addition, we need an estimate of the between-cluster standard deviation σ_{Bi} in order to obtain a value for k_i.

In many cases, empirical data from which σ_{Bi} can be estimated are not available at the time when a CRT is being designed. In these cases, sample sizes can be calculated using different plausible assumptions regarding *k*. As a rough guideline, experience from field trials suggests that *k* is often ≤0.25, and seldom exceeds 0.5 for most health outcomes. However, values of *k* in excess of 0.5 can occur, especially if the distribution of cluster values is skewed.

Sometimes researchers may have data on between-cluster variation either from previous studies or a baseline survey. A more accurate estimate of σ_B^2 can then be obtained from the empirical variance s^2 of cluster-specific results. The parameter σ_B^2 relates to the true cluster-level values, whereas s^2 relates to the observed cluster-level values and therefore incorporates random sampling error. An estimate of this random sampling error needs to

be subtracted from s^2 to get an estimate of σ_B^2. A detailed explanation of the approach is provided in Hayes and Moulton (2017, pp. 145–7).

As in unmatched trials, there are often no data available on k_m in matched and stratified trials and so a range of plausible values must be used to estimate the required sample size. Occasionally, empirical data are available, and data on the endpoint of interest from clusters grouped according to the matching or stratification variables can be used to estimate k_m.

One advantage of calculating sample sizes based on ρ is that estimates of the ICC have been published for a range of outcome variables and settings, and it is now fairly common for investigators to publish estimates of the ICC when reporting trial results. However, as with k, the ICC will depend on both the study outcome and the setting, so investigators should use caution when using published values to plan studies in different populations or with different outcomes. A range of likely values of the ICC (or k) should be explored, to ascertain the sensitivity of the sample size to these values.

Other considerations for power

CRTs may be particularly vulnerable to problems of low power given the nature of the interventions evaluated and the heterogeneity of the populations in which they are applied. For example, many interventions are delivered to large communities with relatively little attention given to individual study participants. Thus the risk of non-compliance and loss to follow-up may be greater than in individually randomized trials.

Since the power of a given CRT will depend on the degree of between-cluster variation, one strategy for increasing precision is to use relatively narrow cluster-level eligibility criteria. For example, in the Mwanza HIV prevention trial described previously (Grosskurth et al. 1995), clusters were deliberately selected to be similar within pairs in order to increase statistical power.

For trials where there is some latitude in how the primary outcome variable is defined, quantitative endpoints (e.g. cholesterol level) usually lead to more statistical power than their binary counterparts (e.g. high

cholesterol or not), although issues of measurement error and ease of interpretability must also be considered.

As discussed, the statistical efficiency of a CRT is increased if we use a larger number of small clusters rather than a few large clusters. As the value of *k* increases, the number of clusters required increases substantially. The effect of increasing the sample size per cluster is subject to diminishing returns, particularly for large values of *k*. A useful rule of thumb in terms of the ICC is that very little increase in power will be obtained for a fixed number of clusters after the cluster size exceeds the value 1/ρ (Donner and Klar 2004). For example if ρ = 0.01, then the increased power obtained by enrolling more than 100 participants per cluster will be small. However, researchers will often have practical reasons for enrolling large numbers of participants per cluster, even if not needed from a statistical perspective.

Plans to adjust for baseline covariates can lead to reduced sample size requirements. Teerenstra et al. (2012) present a simple formula for quantitative outcomes, that provides a reduction in the sample size depending on the expected correlation between the baseline and follow-up values of the outcome. However, reducing the sample size may not always be advisable, since the degree of correlation may change between the start and end of the trial.

Once the appropriate sample size has been decided, there remains the practical problem of ensuring that recruitment targets can actually be met. Feasibility studies are essential, particularly for CRTs that involve complex intervention components. Box 5.7.2 provides a summary of important points for sample size considerations.

Box 5.7.2 Summary of important points for CRT sample size considerations

- Sample size calculations for CRTs require an estimate of the correlation between observations
- Data from previous studies may be used to estimate k or ICC; however, the value may vary in different settings so a range of likely values should be explored
- In general, power and precision of a CRT will be higher with a large number of small clusters, than with a small number of large clusters
- CRTs tend to have diminishing returns in terms of power and precision as cluster size increases

Analysis strategies in CRTs

A wide range of analytical methods have been proposed for the analysis of CRTs. The aim of this section is not to provide a comprehensive review of all such methods but instead to focus on a limited number of methods that are simple to understand, can be easily applied, and have proven to be robust and efficient. A detailed description of these methods, including examples of all procedures discussed in this section, is given by Hayes and Moulton (2017).

Cluster-level analysis

There are two main approaches to the analysis of data from CRTs: analysis of cluster-level summaries, and analysis of individual-level observations. The cluster-level approach is conceptually very simple, and performs well under a wide range of conditions. It is essentially a two-stage process. In the first stage, a summary measure is obtained for each cluster, based on data collected on the outcome of interest among individuals in that cluster. Thus, the individual observations are reduced to 2c numbers, if there are c clusters in each of two study arms. At the second stage, we compare these two sets of cluster-specific measures using an appropriate statistical method. The most common approach is to use a simple two-sample t-test. Sometimes we start by applying a logarithmic transformation to the cluster-level summaries, especially if these have a skewed distribution. The *t* distribution can be used both to carry out a significance test of the null hypothesis of no intervention effect, and to obtain a confidence interval for the intervention effect. The methods based on the t-test have been shown to be highly robust to departures from the underlying assumptions.

A common objection to cluster-level analysis is that information is wasted when the data are reduced to a set of summary measures. Investigators note that, in a trial with 10 clusters per arm but following many thousands of individuals, the final analysis is based on two columns of 10 numbers. This objection, however, is not valid. The power of the study and the precision of the effect estimates will depend on the observed variability in the outcome between clusters. The observed between-cluster

variance will be reduced if a large number of individuals are studied in each cluster.

As an example, we illustrate the cluster-level approach by considering the comparison of a binary outcome in an unmatched CRT with two arms, although similar equations can be used for event rates or quantitative outcomes. The first step is to calculate the proportion of individuals with the outcome in each cluster (the cluster-level summaries). Suppose that p_{ij} is the observed proportion in the jth cluster of the ith treatment arm (i = 1: intervention; i = 0: control). Then we can estimate the mean proportion in each treatment arm as

$$\bar{P}_i = \frac{\sum p_{ij}}{c_i},$$

where c_i is the number of clusters in the i^{th} treatment arm.

When working with proportions, we are generally interested in the risk difference or risk ratio as a measure of the intervention effect. We can use the observed mean proportions to obtain a *point estimate* of the effect:

Risk difference: $\bar{P}_1 - \bar{P}_0$

Risk ratio: $\frac{\bar{P}_1}{\bar{P}_0}$

We can then use the unpaired t-test to test the null hypothesis of no intervention effect:

$$t = \frac{\bar{P}_1 - \bar{P}_0}{s\sqrt{\frac{1}{c_1} + \frac{1}{c_0}}},$$

where s^2 is the *pooled estimate* of the variance of observed cluster-specific risks (i.e. proportions) within treatment arms, computed as

$$s^2 = \frac{\sum_{ij} (p_{ij} - \bar{P}_i)^2}{c_1 + c_0 - 2},$$

The resulting test statistic is compared with the *t* distribution with ($c_1 + c_0 - 2$) degrees of freedom.

The validity of the t-test depends on the observed cluster proportions being normally distributed. However, simulations have shown that the t-test is remarkably robust to deviations from normality, even for quite small numbers of clusters (e.g. Gail et al. 1996; Bennett et al. 2002). For CRTs with a very small number of clusters, a more conservative option is to use non-parametric methods such as Wilcoxon's rank sum test or a permutation test (Eldridge and Kerry 2012; Hayes and Moulton 2017).

Application of the t-test to cluster-level summaries is robust, in the sense that it provides reliable p-values and confidence intervals with approximately correct coverage. However, it may not be fully efficient in terms of providing optimal power and precision. The t-test described just now gives equal weight to each cluster, even though some clusters may be much larger than others and thus provide more information on the outcome of interest. It is theoretically possible to use a weighted t-test which weights clusters according to the information they provide. However, calculation of the weights depends on having an accurate estimate of the between-cluster variance. If the weights are not estimated accurately, the precision of the weighted analysis may be worse than for an unweighted analysis. Therefore, we would not generally recommend use of the weighted t-test.

In addition to testing the evidence against the null hypothesis, it is important to compute a confidence interval which represents the precision in our estimate of the intervention effect. We can obtain a 95% confidence interval for the true risk difference as:

$$(\bar{p}_1 - \bar{p}_0) \pm t_{v,0.025} \times s\sqrt{\frac{1}{c_1} + \frac{1}{c_0}},$$

where $t_{v,0.025}$ is the upper 2.5% point of the *t* distribution with $v = c_1 + c_0 - 2$ degrees of freedom.

Note that this formula assumes equal variances for the risks in the intervention and control arms. While this assumption is reasonable under the null hypothesis of no intervention effect, it may not be when there is a non-null effect. A robust alternative is to compute the variance of the risk

difference based on separate estimates of the variances in the two treatment arms.

We can also obtain a 95% confidence interval for the risk ratio computed based on cluster-level summaries. Since ratio estimates of this kind tend to have skewed distributions, it is usual to work instead in terms of the logarithm of the risk ratio. The variance of the natural logarithm ln(risk ratio) can be estimated by:

$$V = \frac{s_1^2}{c_1 \bar{p}_1^2} + \frac{s_0^2}{c_0 \bar{p}_0^2}.$$

Then a 95% confidence interval for the logarithm of the risk ratio can be obtained as

$$\log(\text{risk ratio}) \pm t_{v,0.025} \times \sqrt{V}.$$

The confidence interval for the risk ratio can be obtained by dividing and multiplying the estimated risk ratio by the error factor (EF):

$$EF = \exp\left(t_{v,0.025} \times \sqrt{V} \right).$$

We illustrate the cluster-level approach with data from the MEMA kwa Vijana (MkV) trial in Tanzania. In this CRT, 20 rural communities were randomly allocated to an intervention arm receiving an integrated adolescent sexual health programme or a control arm (Ross et al. 2007). The final impact of the intervention was evaluated in a cross-sectional survey of young people aged 15–30 years who had attended the trial schools (Doyle et al. 2010). A range of outcomes were examined, but we shall focus on the effect of the intervention on sexual attitudes. Participants were classed as having a desirable attitude based on their answers to three questions on sexual behaviour and gender norms. The trial used a stratified design to allocate communities to each arm; however, for the purpose of this example, we will ignore the stratification in the analysis.

Table 5.7.1 shows the number of adolescents surveyed, and the number and proportion with a desirable attitude in each cluster. The mean

proportion in the control arm $\bar{p}_0$ is 0.161, and in the intervention arm $\bar{p}_1$ is 0.201. Thus the risk difference is 0.040, and risk ratio is 1.246.

Table 5.7.1 Proportion of participants with desirable sexual attitudes at the final survey in the 20 clusters of the MEMA kwa Vijana trial

Intervention clusters			Control clusters		
N with desirable attitude	Total N	Proportion	N with desirable attitude	Total N	Proportion

Mean		0.201			0.161
SD		0.0556			0.0606

To test the null hypothesis of no intervention effect, we carry out an unpaired t-test. First we compute the pooled variance, using the aforementioned equation. Alternatively, we can take the weighted average of the variance in each treatment arm shown in Table 5.7.1:

$$s^2 = \frac{(c_1 - 1)s_1^2 + (c_2 - 1)s_0^2}{c_1 + c_0 - 2} = \frac{(9 \times 0.0556^2) + (9 \times 0.0606^2)}{10 + 10 - 2} = 0.00338,$$

giving an estimated pooled standard deviation of s = 0.0582. Then we compute the t-test as:

$$t = \frac{0.201 - 0.161}{0.0582\sqrt{\frac{1}{10} + \frac{1}{10}}} = \frac{0.040}{0.0260} = 1.524.$$

Referring this value to tables of the t distribution with ν = 18 degrees of freedom, we obtain a two-sided p-value of 0.14. Thus, while there is a trend towards more desirable attitudes in the intervention arm, this difference may have occurred by chance. A 95% confidence interval for the risk difference is obtained as 0.040 ± 2.101 × 0.0260, or (− 0.0147, 0.0943), where 2.101 is the upper 2.5% point of the t distribution with 18 degrees of freedom.

To obtain the 95% confidence interval for the risk ratio, we first estimate the variance of the log(risk ratio) as

$$V = \frac{0.0556^2}{10 \times 0.201^2} + \frac{0.0606^2}{10 \times 0.161^2} = 0.0218.$$

We can then calculate the error factor as $EF = \exp(2.101 \times \sqrt{0.0218}) = 1.364$ and divide and multiply the risk ratio by the EF to obtain the 95% confidence interval as 1.246/1.364 and 1.246 × 1.364, or (0.914, 1.700).

Using the logarithmic transformation

When using cluster-level summaries to obtain estimates of the intervention effect, it is advisable to inspect the distribution of the summary measures within each treatment arm. These distributions are sometimes markedly skewed, particularly for proportions and rates. Since the statistical inference methods used assume the cluster-level summaries are normally distributed, a logarithmic transformation may be useful before analysis, if the cluster-level summaries are positively skewed. For proportions, this would involve computing the logarithm of the risk for each cluster as $l_{ij} = \log(p_{ij})$, then working with the l_{ij} which are likely to be more symmetrically distributed. It is common in statistical practice to use the natural logarithm (ln),

although the choice of logarithmic base has no effect on the estimates of the intervention effect.

We can then calculate the difference in the mean of the cluster-specific log risks ($\bar{l}_1 - \bar{l}_0$), and apply the t-test to the log-transformed values. The log transformation may help to ensure that the variances of the cluster summaries in the two treatment arms are similar as well as providing a more symmetric distribution of cluster summaries, thus improving the validity of the t-test. We can also calculate a 95% confidence interval for the difference in log risks ($\bar{l}_1 - \bar{l}_0$), and exponentiate to get these estimates on the ratio scale.

Adjusting for covariates

In an individually randomized trial, we can expect that randomization will achieve good baseline balance between the trial arms, and the primary analysis is generally an unadjusted analysis. However, as we have seen, CRTs often randomize a relatively small number of clusters (≤30), so substantial baseline imbalance between arms is not unusual. Thus adjustment is much more important in this context and often the primary analysis would be adjusted. Furthermore, adjustment may also reduce k, by accounting for some of the variation between clusters, so may increase power and precision.

There is limited guidance for choosing which covariates to adjust for in the analysis of CRTs. Ideally they should be covariates considered a priori to be important risk factors for the outcome of interest. These covariates must be specified in advance in a statistical analysis plan, to protect against allegations of data dredging or selective reporting. Crucially, the decision to adjust for baseline variables should not be based on the statistical significance of the imbalance between arms. Instead, the decision should depend on how strong a risk factor a covariate is thought to be, the magnitude of any imbalance, how many variables show an imbalance and the number of clusters randomized. For example, in the HIV TasP trial in South Africa described earlier (Iwuji et al. 2013), the analysis was adjusted for temporal changes in national ART guidelines, and cluster-level measures of sex (proportion female), age (proportion <30 years and >=60 years) estimated HIV prevalence, and estimated population ART coverage

at baseline, all characteristics known to be associated with HIV transmission risk in the population (Iwuji et al. 2018).

Adjustment for covariates in a cluster-level analysis can be done using a two-stage procedure. In the first stage, we carry out a standard individual-level regression analysis of the outcome, including all the covariates of interest, *except for the intervention effect*, in the regression model. At this stage, we ignore the effects of clustering, and use standard logistic regression for binary outcomes, Poisson regression for rates, and linear regression for quantitative outcomes. The regression model is used to obtain the expected number of events (for binary outcomes or rates) or the expected mean in each cluster, ignoring the intervention effect. After fitting the regression model, the expected and observed values are compared and used to calculate a residual for each cluster. For example, if we are interested in estimating the risk difference, we calculate the difference-residual as:

$$R_{Dij} = \frac{d_{ij} - e_{ij}}{m_{ij}},$$

Where d_{ij} is the observed number of events in the *jth* cluster of the *i*th treatment arm, e_{ij} is the expected number of events from the regression model, and m_{ij} is the number of individuals.

If the rate ratio is our parameter of interest, then the ratio-residual is calculated as

$$R_{Rij} = \frac{d_{ij}}{e_{ij}},$$

In the second stage of the analysis, the residuals take the place of the cluster-level summaries when calculating point estimates and performing statistical tests, using the methods described in the previous section. If the intervention has no effect, then the average of the residuals will be zero (for difference-residuals) or 1 (for ratio-residuals), whereas an intervention effect will result in systematic differences in the residuals between the two arms.

Individual-level analysis

As we have discussed, the unpaired t-test is based on the assumption that the cluster summary measures are normally distributed and have equal variance. If cluster sizes vary, this latter assumption is clearly invalid, and greater power and precision would be achieved if the analysis were weighted to take into account the different variances. Such weighting is incorporated automatically when we carry out regression analyses based on individual-level data. It is essential that the regression method takes proper account of between-cluster variation. A wide range of regression methods have been suggested for this purpose, but we will focus on two approaches that have received the most attention and which have advantages over other methods: random effects regression models and generalized estimating equations (GEE).

An advantage of individual-level regression methods over the simpler cluster-level methods is that, in an adjusted analysis, the effects of the covariates are estimated and presented simultaneously with the intervention effects. This is not the case in a cluster-level analysis, since we are comparing cluster-level residuals from which the effects of other covariates have already been removed.

An important disadvantage of individual-level regression methods is that they do not appear to perform robustly when there are a relatively small number of clusters. Formally, both the individual-level and cluster-level methods are valid asymptotically, that is when there are a very large number of clusters per treatment arm. However, the cluster-level methods seem to perform much more robustly for small numbers of clusters.

Random effects models

In random effects models, we take account of between-cluster variation by assuming that there are cluster-level effects (over and above the random sampling variation within each cluster) which follow a specified probability distribution. Random effect models take the general form:

$$\theta_{ijk} = \alpha + \beta_i + \sum_j \gamma_j z_{ijkl} + u_{ij}$$

In this equation, θ_{ijk} is a parameter related to the outcome of interest and refers to the k^{th} individual in the j^{th} cluster in the i^{th} treatment arm. For event rate data, for example, θ might be the logarithm of the rate in that individual. The parameter β_i represents the intervention effect, the γ_l parameters represent the effects of a set of covariates, z_1, z_2, … z_L, each of which may be measured at individual or cluster level, and α is an intercept term representing the expected outcome in individuals in the control arm (I = 0) and with zero values for all the covariates.

The term u_{ij} is a random effect relating to the j^{th} cluster in the i^{th} treatment arm, and takes account of between-cluster variation. Therefore, models of this form are known as random effects models.

The random effects are assumed to be sampled from a probability distribution. To fit a random effects model, we need to make an assumption about the distribution of these effects, which will depend on the outcome of interest. Random effects models represent full probability models for the data and so likelihood inference is used to estimate the parameters associated with the random effects as well as the effects of the intervention and the covariates. These models can be readily fitted using standard statistical software such as R, Stata, or SAS.

We can use random effects Poisson regression for event rates, such as disease incidence, and random effects logistic regression for binary outcomes. For quantitative outcomes, for example systolic blood pressure, these models are known as mixed effect linear regression models, because they have both fixed effects, indicated by the parameters α, β_i and γ_l, as well as the random effects represented by u_{ij}.

Random effect models perform well for event rate data and quantitative (normally distributed) outcomes, since the assumptions that are made about the distribution of the random effects and the variation in the outcome within clusters mean that the likelihood can be written down in analytical form. However, the likelihood for the random effects logistic regression model assumes a mixture of normal and binomial distributions, and the combination of these distributions does not provide a simple composite distribution. Therefore, numerical approximations have to be used to maximize the likelihood, and to obtain parameter estimates, confidence intervals, and significance tests. The numerical procedure used for this purpose is known as quadrature and involves approximating the normal

distribution. With older versions of statistical software, the parameter estimates were not always reliable and were dependent on the number of quadrature points. However, recent advances in statistical software have resulted in significant improvements in the procedure of quadrature, so quadrature problems are rarely encountered.

Generalized estimating equations

GEE provide an alternative method of individual-level regression modelling and make allowance for clustering without incorporating additional terms in the model (Zeger and Liang 1986). They do this by assuming that observations in the same cluster are correlated and using the data to estimate the strength of the correlation.

While GEE models do make allowance for within-cluster correlation, they do not correspond to a full probability model for the data. For this reason, we cannot define the likelihood of the data and so we cannot obtain maximum likelihood estimators of the parameters or use likelihood ratio tests for hypothesis testing. Instead, GEE uses an iterative generalized least squares method to estimate the parameters together with robust standard errors. The Wald test can be used for hypothesis testing. As with random effects models, GEE only works reliably when there are a sufficiently large number of clusters in each treatment arm.

For the analysis of CRTs, the usual assumption in a GEE model is that observations on individuals in different clusters are uncorrelated, while observations on individuals in the same cluster all have the same correlation coefficient ρ. In this situation an exchangeable correlation matrix is specified in the statistical model, although the method is asymptotically robust to this specification. The observed data are used to estimate the value of ρ, and this is used to obtain estimates of the regression coefficients and their standard errors that are adjusted for the correlations in the data. If ρ is large, less weight will be given to each individual in large clusters, since the outcomes within a cluster will tend to be similar. Conversely, if ρ is close to zero, this means that there is little clustering and all individuals will be given similar weight in the analysis. An excellent non-technical discussion of GEE is given in Hanley et al. (2003).

GEE models may be fitted for event rates, binary outcomes, and quantitative outcomes. GEE models are more robust than random effects

models, since they do not rely on assumptions about the distribution of the between-cluster variation. Although GEE and random effects models estimate the same parameter for the intervention effect when the outcome variable is normally distributed or an event rate, this equivalence disappears in the case of a binary outcome, and thus their interpretation is different. In a GEE logistic regression model, we are estimating a population-averaged odds ratio of the outcome, whereas with random effects models we are estimating a cluster-specific odds ratio. The cluster-specific odds ratio represents the effect on the odds of the outcome if the intervention is applied to any given cluster, whereas the population odds ratio represents the effect on the odds in the combined population of all the clusters. In many circumstances, there will be little difference between the cluster-specific and population-averaged estimates. The difference will only be large if there is substantial between-cluster variation and, in at least a proportion of clusters, the outcome is common.

Choosing an appropriate analysis

Individual-level regression methods are popular for analysing CRTs but require a sufficient number of clusters to ensure unbiased estimates. Based on a review of simulation studies, McNeish and Stapleton (2016a) recommended that there are at least 15 clusters (8 per arm) for quantitative outcomes and 30 (15 per arm) for binary outcomes, in order to ensure unbiased estimates of the treatment effect and its standard error with random effects models. The distributional assumptions of random effects models can also be difficult to verify without large numbers of clusters.

GEE models have been shown to have inflated type I error when there are few clusters per arm (Bellamy et al. 2000). That is, we are more likely to reject the null hypothesis, when there is no true underlying effect of the intervention. In contrast, analyses of cluster-level summaries based on the t-test provide reliable p-values, and confidence intervals with approximately correct coverage under a wide range of conditions.

Therefore, for CRTs with a small number of clusters, less than around 15 per arm, we recommend the use of cluster-level analyses. For trials with larger numbers of clusters, either approach can be used but the individual-level regression methods are likely to be statistically more efficient than the cluster-level methods and provide greater convenience when analysing the

effects of covariates. If the assumptions of the random effects models are roughly correct, we advise using these models since they are likely to be the most efficient. Another advantage of random effects models is that they provide direct estimates of the between-cluster variance, and hence the ICC, quantities which are treated as nuisance parameters using the GEE approach. If however, the assumptions of the random effects models are violated, GEE with an exchangeable correlation matrix and robust standard errors should be the method of choice. Box 5.7.3 provides a summary of important points for analysis of CRTs.

New literature on the performance of methods for analysing CRTs is continually emerging, including methods based on restricted maximum likelihood estimation and Bayesian techniques (e.g. McNeish and Stapleton 2016b). Adjustments to GEEs for small number of clusters and variation in cluster sizes are also being investigated (e.g. Huang et al 2016). Therefore, particularly where there are few clusters or very small clusters it may be advisable to seek the advice of a statistician with experience of analysing CRTs.

Box 5.7.3 Summary of important points for CRT analysis

- The analysis of data from CRTs must take clustering into account
- Analyses based on cluster-level summaries are robust and perform well under a wide range of conditions
- Individual-level analyses have greater power and precision, but are generally less reliable when there are relatively few clusters (<15 per arm)
- Matched designs should take account of the matching in the analysis

The matched-pair design

Matched-pair CRTs are generally analysed using cluster-level summaries. Individual-level regression methods are usually not suitable for matched-pair designs, for reasons discussed at the end of this section.

Some investigators have suggested that, in matched-pair CRTs with a small number of clusters, an unmatched analysis may be used, particularly when the matching correlation is not strong. This is known as breaking the

matching, and helps to achieve balance while avoiding loss of degrees of freedom in the analysis. If the matching is broken, we can use either cluster-level or individual-level analytical methods (providing there is a sufficient number of clusters). However, the investigator needs to specify in advance in an analysis plan that an unmatched analysis will be conducted, resulting in a loss of power if it turns out that the matching was highly effective. If instead the investigator makes the decision based on the observed matching correlation after the trial is completed, this increases the type I error (Diehr et al. 1995). Therefore, we do not recommend this approach.

We will begin by considering how to obtain point estimates, confidence intervals, and significance tests for pair-matched CRTs where no adjustment is made for covariates. We use the comparison of proportions as an example, but similar equations can be derived for event rates and quantitative outcomes. The simplest method of obtaining an estimate of the risk difference is to calculate the mean of the pair-wise risk differences, as follows:

$$\frac{1}{c}\sum_{j}(p_{1j}-p_{0j}),$$

where p_{1j} and p_{0j} are the observed proportion with the outcome in the j^{th} matched pair in the intervention and control arms, respectively, and c is the number of matched pairs of clusters.

This can also be written as:

$$\bar{p}_1-\bar{p}_0,$$

so that the point estimate for the risk difference is identical to that obtained from an unmatched analysis.

We can write the observed difference in the risks in the j^{th} matched pair as:

$$p_{1j}-p_{0j}=h_j,$$

A 95% confidence interval for the risk difference can then be obtained as follows:

$$\bar{h} \pm t_{\upsilon,0.025} \times \frac{s_m}{\sqrt{c}},$$

where $\bar{h}$ is the mean of the differences in the risks across matched pairs, $t_{\upsilon,0.025}$ is the t distribution value with one-sided p-value of 0.025 with $\upsilon = (c-1)$ degrees of freedom and $s_m^{\,2}$ is the empirical variance of these differences:

$$s_m^{\,2} = \frac{1}{c-1}\sum_j (h_j - \bar{h})^2.$$

We can perform a paired t-test on the pair-wise differences to test the null hypothesis of no intervention effect:

$$t_m = \frac{\bar{h}}{\sqrt{\frac{s_m^{\,2}}{c}}},$$

The computed value of t_m is referred to tables of the t distribution with $\upsilon = (c-1)$ degrees of freedom. For small numbers of pairs, it may be advisable to additionally carry out a non-parametric test, for example the signed rank test. Note, however, that at least six pairs are needed to achieve a significant result (two-sided $p < 0.05$) when using such a non-parametric test.

If our parameter of interest is the risk ratio, since ratios often have skewed distributions, we may work in terms of the log (risk ratio), and calculate the mean of the log of the pair-wise risk ratios, obtain the 95% confidence interval and apply the paired t-test in a similar manner. As with an unmatched analysis, we can exponentiate our results to obtain an estimate of the risk ratio and its corresponding 95% confidence interval.

If close matching is achieved, the treatment arms will be similar with respect to the variables matched on. However there may be other variables

that are not balanced between arms and we may want to adjust for these in the analysis. For example, in the Mwanza HIV prevention trial reported by Grosskurth et al. (1995), the arms were similar at baseline with respect to HIV prevalence and other factors that were matched on. However, there was some imbalance in reported history of sexually transmitted infections (STIs), travel away from the village, and male circumcision, and so these variables were adjusted for in the analysis. As with analysis of unmatched CRTs, adjustment for covariates is a two-stage process. The first step is to fit a regression model excluding the intervention effect, but including terms for the matched pairs and the covariates we are adjusting for. We then compare the observed and expected numbers of events in the two clusters in each matched pair. If the intervention has a protective effect, then the observed number of events in the intervention arm will tend to be less than the expected number of events, and the observed number of events in the control arm will tend to exceed the expected number.

Individual-level regression methods are generally not suitable for the analysis of pair-matched CRTs when the trial endpoint is an event rate or binary outcome. Both random effects logistic and Poisson regression models are fitted using likelihood inference, which relies on large sample approximations for its validity. More specifically, it assumes that the number of parameters to be estimated is much smaller than the number of data points used to estimate them. However in the pair-matched model, we must estimate a large number of parameters, including a separate parameter for each matched pair, one for the intervention effect, and a parameter for each covariate in our model. Therefore in a pair-matched CRT, the number of parameters to be estimated approaches the number of clusters. Under these conditions the regression analysis cannot be relied upon to give robust results. Other regression methods, such as GEE, are similarly unreliable for the pair-matched design. Cluster-level methods are therefore recommended when analysing proportions or event rates in pair-matched trials.

An exception are matched CRTs with quantitative outcomes, because the analysis does not rely on the approximate methods of likelihood inference. Providing the random effects can be assumed to be normally distributed, valid estimates, confidence intervals, and significance tests can be obtained that do not depend on large sample assumptions. However, if the number of clusters is small, the dependence on assumptions of normality becomes critical, and so individual-level methods are unlikely to be as robust as the

cluster-level methods, even for quantitative outcomes. A more detailed discussion of the analysis of pair-matched CRTs is provided in Hayes and Moulton (2017, pp. 281–93).

Stratified CRTs

Stratified CRTs can be analysed using cluster-level summaries, using extensions of the methods described for matched CRTs (Hayes and Moulton 2017, pp. 293–303). Unlike with matched trials, stratified CRTs can also be analysed using individual-level regression methods with an additional fixed effect parameter for the strata. Stratified designs fall between the extremes of pair-matched and unmatched designs, because there is replication within the strata, and only one parameter is fitted for each stratum rather than one for each matched pair. This replication also allows us to obtain direct estimates of between-cluster variation, and to assess any differences in the intervention effect between strata.

Less research has been conducted on the performance of small stratified CRTs, but as a rough guideline, individual-level regression is not recommended for stratified trials with less than 20 clusters per arm, due to the extra parameters that are fitted. It is also recommended to carry out cluster-level analysis, to check that the conclusions are robust.

Ethical issues in the design of CRTs

The ethical principles underpinning research on human subjects are well recognized, and there are internationally accepted guidelines setting out the minimum requirements for such studies. However, cluster randomization introduces a number of additional ethical issues to which investigators need to give careful consideration when planning a CRT.

Obtaining informed consent is a key ethical requirement in all intervention trials. In individually randomized trials, individuals are asked for consent both to be randomly allocated to one of the treatment arms and to participate in the trial. In CRTs, consent for randomization and for participation generally need to be considered separately. Since randomization is at the cluster level, obtaining individual consent for randomization is rarely possible. Instead, approval is given at the group

level on behalf of the entire cluster, by a person who genuinely represents the interest of cluster members. Investigators need to carefully consider who should provide this approval. It should be noted that while a person may provide approval for randomization on behalf of the individual members of the cluster, they cannot provide formal consent (as defined by good clinical practice, GCP) on behalf of these individuals.

Although cluster randomization may preclude seeking consent from individuals before randomization, it is often possible to obtain individual consent at other stages. In many CRTs, individuals are able to consent to receive the intervention. Even if individuals cannot be asked for consent to receive the intervention, for example, a mass media intervention, most CRTs collect data from individuals in order to evaluate the intervention. Consent to participate must be obtained from these individuals.

For example, in the CRT in Uganda of IPT for malaria described earlier (Staedke et al. 2018), clusters were each a primary school and the surrounding households. Consent for randomization was given by national and district level ministries of health and education. Head teachers were asked for consent to participate in the trial. In the intervention clusters, children and their parents/guardians were asked for consent for the child to receive IPT. The outcome was measured in household surveys, in which all individuals were asked for consent to participate.

Potential benefit and harm also need to be considered at the cluster level. Many CRTs evaluate public health interventions such as educational programmes where the potential for harm may not be obvious, or may be poorly understood. For example, a social marketing intervention aimed at promoting condom use may have an unintended effect of encouraging casual sexual relationships. Another consideration is that the risk/benefit ratio may not be the same for all cluster members. For example, in the CRT of malaria IPT (Staedke et al. 2018), adults in the intervention clusters were expected to benefit from the reduction in malaria transmission, without taking IPT.

Ethical guidelines for CRTs are less readily available than for individually randomized trials. However, the Ottawa Statement on the Ethical Design and Conduct of Cluster Randomized Trials (Weijer et al. 2012) sets out 15 recommendations on the ethical design and conduct of CRTs. Further discussion of ethical issues in the context of CRTs can be found in Hayes and Moulton (2017).

Reporting of CRTs

CRTs are often large studies involving substantial financial, logistical, and human resources. There is perhaps a particular onus on CRT investigators to ensure that the reporting of such trials is carried out to the highest standards, to maximize the chances that the findings are interpreted correctly and the appropriate lessons drawn for future health policy. The Consolidation of Standards for Reporting of Trials (CONSORT) guidelines were developed over 20 years ago as an evidence-based checklist for reporting individually randomized trials (Begg et al. 1996). Subsequently, an extended statement was published that provided guidelines for use with CRTs (Campbell et al. 2004; Campbell et al. 2012).

The results of a CRT refer to the specific set of clusters that are studied. Therefore, when reporting a CRT, the characteristics of the clusters should be carefully described, including a clear definition of a cluster and an explanation of how the specific study clusters were selected. Eligibility criteria and sampling methods should be described at both cluster and individual levels.

A key requirement of the CONSORT guidelines is the provision of a flow diagram showing, by treatment arm, the number of clusters, and the number of individuals, that were eligible, randomized, and lost to follow-up at each stage of the trial, and numbers analysed for the main trial endpoints. This provides useful information for the assessment of selection bias and the generalisability of trial findings.

A clear description of the intervention is also important if the results of the trial are to be put into practice in other settings. This is particularly true for CRTs since they often evaluate complex interventions, comprising a package of measures that may be applied at either the cluster level or individual level or both.

Assumptions made in the sample size calculations should also be reported. This includes the number of individuals per cluster and the values of k or the ICC that were used. In addition, assumptions about the baseline rate, proportion, or mean outcome, as well as the expected intervention effect, should be stated. If matching, stratification, or restricted randomization were used, these aspects of the design need to be described carefully. Since the analysis methods for CRTs are less standardized than for individually randomized trials, it is essential to provide an adequate

description of the analytical methods and reasons for their choice. Any covariates used for adjustment should be described.

The first table in a report of the results of a randomized trial is usually a description of baseline characteristics of each trial arm, which shows whether the randomization has been effective in achieving comparable treatment groups. For a CRT, it is important to present baseline characteristics of both the clusters and individuals. Clearly, the most important table in any trial report is that which shows the estimated effects of the intervention on the main outcome. For a CRT, tables should show the estimated intervention effects and associated confidence intervals, obtained using appropriate statistical methods that take account of between-cluster variability. If there are fewer than 15–20 clusters per arm, we recommend that the cluster-level summary outcomes also be presented, at least as supplementary material, for transparency. It is also good practice to report the level of between-cluster variability in the form of the ICC or k. This provides information on appropriate values of these coefficients for investigators planning new studies.

As with individually randomized trials, the discussion section of a report of a CRT should focus on the analyses of primary endpoints, paying particular attention to the confidence interval associated with the effect estimate. Investigators should also consider the generalisability of trial results, since both the implementation of an intervention and the intervention effects may differ between populations or over time.

Conclusions

CRTs have become increasingly common in the literature in recent years. In this chapter, we have attempted to provide investigators with a practical overview of the special methods of design and analysis that are needed for these trials. Cluster randomization may be preferred over individual randomization in a number of situations; however, the advantages of this design need to be weighed against its limitations. If used appropriately, CRTs have the potential to make an important contribution to the development of evidence-based interventions to improve health.

Community intervention trials in high-income countries

John W. Farquhar and Lawrence W. Green

Introduction to community intervention trials in high-income countries

As background on theories and methods underlying successful multilevel, multimethod, *community-based*, *health promotion intervention trials*, this chapter first reviews community organizational and mass media intervention developments in the first half of the twentieth century and the origin of randomized trials outside laboratory settings early in that century. It then reviews specific health examples from tuberculosis mobile X-ray and immunization campaigns in the 1950s and 1960s, family planning programmes in the 1960s and 1970s, and HIV/AIDS in the 1980s. We then turn to the most prominent and influential community health intervention trials for the remainder of the twentieth century as touchstones for development of twenty-first-century public health challenges, such as obesity and diabetes control, substance abuse prevention, and cancer control. These touchstones were the cardiovascular disease prevention and risk reduction trials (including most notably hypertension, tobacco, dyslipidaemia, and physical inactivity) mounted in California with the Stanford Three-Community Study and in North Karelia, Finland in 1972. Parallel national and state-wide successes in hypertension control in the 1970s, and tobacco control in the 1980s and beyond, have drawn significantly on these and subsequent exemplary trials from North America, Europe, Australia, and elsewhere.

These later trials exemplify the scope and innovation of *experimental* epidemiology in advancing disease prevention and health promotion science, involving total populations of communities, initiated often following insights from *observational* epidemiology, or from *randomized clinical* trials in

smaller populations. Some were derived from ‘natural experiments’ that studied the impact of policies and programmes not initiated by academic investigators.

The earliest of mid-century trials were often in developing countries, designed to reduce social development problems associated with communicable diseases and high birth rates. The communicable disease studies in Western countries gave opportunities to test new polio vaccines and their adoption, and later by emergence of new infectious diseases, particularly HIV/AIDS. Other studies increasingly addressed risk factors for cardiovascular disease (CVD), cancer, and other chronic diseases as the rising mortality curve of chronic diseases crossed the declining curve of communicable diseases in the mid-twentieth century. All relied on locally available mass communication channels, community organizing, and other policy advocacy and educational methods, using relatively low-cost approaches with potentials to change lifestyles or specific behaviours.

One study examined alcohol-involved trauma using only community organizing to promote adherence to existing laws, rather than public education for policy-change advocacy (Holder et al. 1997). Another study, designed to reduce consumption of dietary trans fats, used primarily new laws and regulations (Angell et al. 2009). By community organizing we mean collaborating and seeking support from community leaders and other channels of communication. The World Health Organization characterized this as community participation or participatory planning (Green 1983), and as ‘maximum feasible participation’ (Moynihan 1969) for community projects under President Kennedy’s ‘New Frontier’, and Lyndon Johnson’s ‘New Society’ legislation. But this spin on community organization assumed lay communities set the goals (Green 1989). This orientation was recently termed ‘community-based participatory research’ when organizing was undertaken collaboratively at the initiative of the community or by academic or external health agencies (George et al. 2006; Minkler and Wallerstein 2008). Following further definition of community and community organizing for health, we review this history to identify some prominent precedents in the public health and community health promotion literature.

Definitions of community and community organizing for health

A community-based programme was defined historically as one organized locally, and promoted through the community's institutions and communication channels. '*Community-based*' has become more broadly labelled, including both community-initiated and community-administered following initiation from external agencies. Programmes were termed '*community-placed*' when conceived, sponsored by, or driven from organizations outside the community and applied with or without community participation.

The traditional definition of a 'community' is a residential area with legally defined geographic boundaries, where a *local* governmental system regulates many aspects of schools, businesses, law enforcement, transportation, and recreational activities. A community is usually the last designated jurisdiction in a nation's official or governmental regulatory chain, where education and implementation must ultimately occur. In rural areas the county or district becomes the agent for education and other official governance. For programmes funded by non-governmental organizations, local agencies or branch organizations are the implementing agents within communities.

The following summarizes changing precedents in effectiveness trials of community health promotion, reviewed by twentieth-century decades. It illustrates that technologies for solving emerging public health problems led to research in high-income countries, developing theories, and evidence needed for community interventions for large segments of the population at risk.

Some converging developments for community health trials

Table 5.8.1 summarizes a chronology of community trials that dominated eras of action research across seven decades of the twentieth century, and a few citations of works illustrating trial types and theoretical and epidemiological problems they tested, either as proof-of-concept trials, or as health promotion model evaluations.

The origin of randomized controlled trials (RCTs) is usually attributed to Sir Ronald Fisher (1925) for its application to field trials comparing effectiveness of alternative cultivation methods (Fisher 1926). Some rural sociologists began in the 1930s to study the spread among farmers of new hybrid seeds, providing technical assistance to farmers by agricultural

extension agents. This led to the first publication of the diffusion model describing the normal-curve pattern of adoption of new ideas, behaviour, or innovations in populations (Ryan and Gross 1943). The diffusion model and its theoretical framing of social and behavioural change in populations has been chronicled by the rural sociologist Everett Rogers (2003), through five editions of his book, *Diffusion of Innovations*, and specifically for public health applications (Green et al. 2009). Rogers converged at Stanford with others who brought their various sociobehavioural and health disciplines to bear on development of the first large-scale, interdisciplinary US trial in community-based cardiovascular risk factor reduction. Table 5.8.1 recapitulates this history of community trials leading to and including the cardiovascular trials and beyond to tobacco control and now obesity control.

Tobacco control successes, from the 1960s through to the 1990s

Of all chronic disease prevention and health promotion efforts, tobacco control is the most cited as a great success of health behaviour change on a population scale. Ironically, at least in North America, Europe, Australia, and New Zealand, this success, initially, was not the direct application of controlled trials, either clinical or community. It followed many planned media and educational events, popular media, policy initiatives and the environmental changes associated with them, and their evaluation through yearly measures of tobacco consumption. The mass media ‘softened’ public opinion, denormalizing smoking in public places, and assisting smoking cessation policy changes (Fig. 5.8.1).

Table 5.8.1 Decades in which community trials of particular types dominated in development of a body of evidence, methods, and theories

Decade	Influential community trials	Examples and reviews
1930s	Agricultural extension trials and diffusion studies	Fisher 1926; Ryan and Gross 1943; Rogers 2003; Green et al. 2009
1940s	Mass media and war-years' propaganda studies; advertising, radio, and film studies	Hovland 1948; Maccoby 1951; Michael and Maccoby 1953
1950s	Community mobile X-ray and various immunization studies	Hochbaum 1958; Rosenstock et al. 1959; WHO 1954; Green 1970
1960s	Community family planning and polio immunization campaign trials	Stycos 1962, pp. 481–482; Berelson 1966; Bogue 1962; Northcutt et al. 1964; D'Onofrio 1966; Gray et al. 1966; Green et al. 1972
1970s	The first cardiovascular community risk factor prevention trials	Farquhar et al. 1977; Puska et al. 1981
1980s	The HIV/AIDS and substance abuse prevention trials	Miller et al. 1990; Ruiz et al. 2000; Cain et al. 2001; Darrow et al. 2009; Kagan et al. 2012
1990s	Culmination of four decades of tobacco control	Centers for Disease Control and Prevention 1999; Rogers 2010; Levy et al. 2012
2000s	Obesity control	Institute of Medicine 2010a, 2010b, 2012a, 2012b

These associations offer 'lessons' from tobacco control for chronic disease control at the population level, demonstrating that changing risk *conditions* in the social and physical environment is needed for behaviour change.

In addition to denormalization, research shows other policies and programmes have additive or multiplicative effects on reducing tobacco consumption and its premature mortality. The greatest impacts include tobacco price increases, high-intensity media campaigns, comprehensive cessation treatments, strong health warnings, stricter smoke-free air regulations, advertising bans, and youth access laws (e.g. Levy et al. 2012). Price increases have an independent effect; but the last three depend on both laws and their enforcement. These, in turn, have depended on building an informed and activated electorate through community-level organizing and communications, because community policies controlling tobacco

promotions and smoking in public places could be passed locally when they could not overcome industry lobbying at state and national levels.

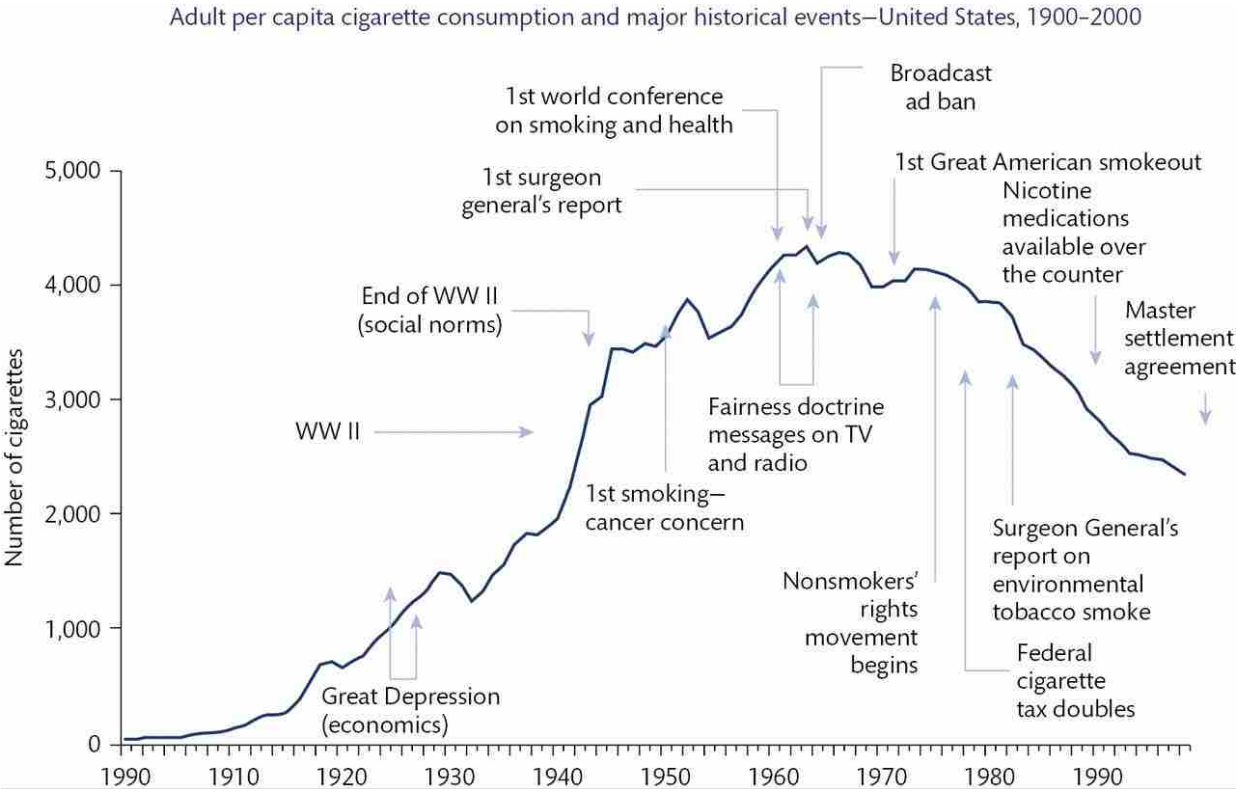

Fig. 5.8.1 Linkage in tobacco consumption trends with historical events in the social, economic, and policy environments.

Adapted from US Department of Health and Human Services, *Reducing Tobacco Use: A Report of the Surgeon General*, US Department of Health and Human Services, Centers for Disease Control and Prevention, National Center for Chronic Disease Prevention and Health Promotion, Office on Smoking and Health, Atlanta, Georgia, USA, 2000, available from http://www.cdc.gov/tobacco/data_statistics/sgr/2000/complete_report/pdfs/fullreport.pdf

Lessons drawn from the last seven decades of the twentieth century

We draw 'lessons' or generalizations for community prevention and health promotion interventions from seven decades of trials and natural experiments just reviewed, drawing especially on CVD trials and adoption and cessation trends of tobacco seen during the twentieth century (Fig.

5.8.1). Many ‘lessons’, derived from the tobacco consumption trends, were more readily adoptable within the CVD community trials, which began in the 1970s, and included smoking prevention and cessation. The tobacco experiences were also then seen as applicable to other risk behaviours at the community level. Finally lessons from these CVD trials lead to a description of the mix and sequence of the intervention steps needed.

The economic imperative

Cigarettes became increasingly popular and inexpensive in the century’s first three decades after manufacturing ‘advances’ reduced mass production costs, accounting for a steep rise in consumption. Consumption plummeted in the late 1920s during the Great Depression. This strong association in usage was early evidence for the wisdom of suppressing consumption through tobacco excise taxation. It demonstrated that even an addictive product is sensitive to price relative to disposable income. The argument for excise taxes gained momentum as evidence accumulated. A 10% increase in cigarette price, on average, reduces consumption by about 4% (Chaloupka et al. 2002), and more for young, lower-income and pregnant smokers (Hyland et al. 2006).

Two other advantages spurred more cigarette tax initiatives. One is that revenues can finance state-wide *and* community tobacco control programmes, making cigarette taxes even more palatable to the public, thus launching and sustaining some very successful programmes. The other is growing evidence that tobacco consumption increases healthcare expenditures, and since taxes decrease tobacco use, healthcare costs may eventually fall by billions of dollars in a state the size of California (Max et al. 2013).

The economic imperative also relates to obesity control and diabetes prevention, partly due to decades of increasing agricultural efficiency, causing progressive food price decreases. Food manufacturers and vendors have increased portion sizes, thus many have become accustomed to consuming larger portions and more frequent indulgences of cheaper, unhealthful food; much of it processed rather than home-cooked, and often with empty calories. These trends have led a contemporary movement advocating taxation of sugar-sweetened beverages (e.g. Novak and Brownell 2011).

The social normative or denormalization imperative

Two early notable changes in the trajectory of tobacco consumption were acceleration during the Second World War, and a less dramatic but significant rise during the First World War (Fig. 5.8.1). These are partly attributable to official condoning, facilitating, and even encouraging of smoking among soldiers to reduce boredom, and cope with stress, and smoking became integrated with their camaraderie. A modest drop in smoking occurs following the Second World War as soldiers' social networks fragment. Later recognition of these social norm changes led to using mass media to portray smoking as less glamorous, less fashionable, less smart, and portrayed the tobacco industry as deceiving and exploiting the public. Experiments within the community CVD trials began to highlight use of social influence strategies and media use to provide role models for changing behaviours, such as smoking (Ramirez et al. 1995).

The public health education and informed electorate imperative

Before mass media were used to create denormalization, most public health education was limited to smoking's health hazards, which had effects as noted. In 1954 a single mass media message created a precipitous drop in tobacco use. That year, *The Reader's Digest*, a popular and credible magazine with the American public, featured an article showing that tar of tobacco residues induced cancerous tumours when painted on mice. Although dramatic in its drop, consumption soon bounced back and continued upwards with continued tobacco industry advertising (Fig. 5.8.1).

As the public became more aware and cautious about tobacco, America was ready for the first Surgeon General's Report on Tobacco and Health in 1965, the peak of tobacco consumption growth. This and subsequent events led to legislation restraining the tobacco industry (e.g. the Fairness Doctrine requiring equal broadcast media time for antitobacco and pro-tobacco advertising). This indicated that public health education's most powerful method, certainly in relation to tobacco, was creation of an informed electorate—more supportive of regulations restraining industry advertising, promotion, and sales of a harmful product, and raising tobacco products' taxes.

The surveillance imperative

The tracking of tobacco consumption illustrates how helpful a consistently measured outcome or risk factor metric related to particular chronic diseases can be. Ideally, such measures should be collected on whole populations and also on smaller subpopulations requiring particular attention. Regrettably, such surveillance—nearly universal for communicable diseases—remains sparse for most chronic disease risk factors. They are usually absent at the community level, so special surveys are needed for community intervention effects on behavioural and environmental issues. This expense alone makes trials prohibitively costly and dependent on a national government's funding.

The comprehensiveness imperative

The major tobacco consumption declines, following the first Surgeon General's Report on Smoking and Health in 1965, reflect the historical creation of national policies and programmes supportive of state and local efforts to create comprehensive programmes (Centers for Disease Control and Prevention 1999, 2007). Two states in particular (California and Massachusetts) in the late 1980s and early 1990s increased tobacco taxes, with a portion of the revenue earmarked for state-wide and community tobacco control, including use of the social normative approach through schools, worksites, and mass media. These programmes achieved tobacco consumption reductions that doubled and then tripled decline rates of the other 48 states within a few years. Given results of these and later state-wide and community trials, and success in measuring and tracking their effects, the Centers for Disease Control and Prevention's Office on Smoking and Health published in 1999 and updated in 2007 the 'Best Practices' document cited earlier, guiding other states' comprehensive state-wide programme development.

The formative evaluation and tailoring imperative

Formative evaluation must begin before and be continued throughout implementation of any planned community intervention campaign. Success requires programmes well designed in mix and sequence, delivered through varied channels, adjusted for audience responses. This integration, with goals set in advance and adjustments from early results, is analogous to a

commercial marketing campaign, hence the term ‘social marketing’. (Ironically, *commercial* marketing has adopted many novel methods from academic research on *social* marketing.) It includes recognition of audience segmentation, or tailoring of messages and appeals to the varied motives, needs, and preferences of subpopulations (Slater and Flora 1991). Needs analysis, message design, and pre-testing are formative evaluation phases. Message sequences should first increase awareness, then knowledge, then motivation, and last provide training in the skills and resources to enable adoption and maintenance of new behaviours (Bandura 1986). Electronic media can furnish the first two parts of this sequence and stimulate use of more information-dense print media of newspapers, booklets, CDs, and websites, which are inherently more effective in *skills training* than are electronic media (Flora et al. 1997).

The ecological imperative

Health behaviours and health status are influenced by economic, political, cultural, and socioeconomic factors, all non-biological (Schooler et al. 1997; Best et al. 2003; Trickett et al. 2011). Healthcare’s reliance on clinical services can neither prevent most chronic disease nor reach large population segments. Therefore, changing behaviour and improving health need to include family, cultural, and social contexts of these populations. A primary tenet of community prevention programmes is the opportunity to intervene in multiple settings and domains (Poland et al. 2000), and at multiple levels from individuals to families, organizations, and whole populations. This ecological approach honours the ‘comprehensiveness imperative’, but also urges communities to encompass interdependencies among environmental, social, and individual factors and the potential for public health strategies to interact with individually tailored therapeutic and medical strategies (Shea and Basch 1990; Schooler et al. 1997; Green et al. 2012; Farquhar in press). This principle is known as the ecological approach to community or population programmes (Green et al. 1996; Kok et al. 2008; Golden and Earp 2012), and has been a central tenet of the Ottawa Charter for Health Promotion (World Health Organization et al. 1986).

Community-based programmes offer opportunities to approximate the ideal multicomponent and multilevel approach by coordinating population-based policy and mass health communication and education strategies with

individual-based clinical intervention. Social norms and community attributes greatly impact health. Community governmental and private institutions influence health behaviours by controlling, for example, health, recreational (e.g. Kokko et al. 2008), and transportation services (Mosquera et al. 2012) and youth access to tobacco. The health and safety policies and worksite health promotion practices of businesses can also affect health. Stores and restaurants also shape health according to the food they sell (Schooler et al. 1997) and whether menus provide information on calories and ingredients.

The ideal programme design, then, would include programmes developed within or channelled through multiple and coordinated worksites, schools, recreation sites, libraries, churches, local business organizations, and other sites to supplement and expand the effects of policy and health education approaches and appropriate delivery of healthcare (Farquhar et al. 1985; Kokko et al. 2006; Dooris 2009). This broad reach into the community is critically appropriate to chronic disease prevention and injury control because most people are at some level of risk for these and will benefit from interventions to predispose, enable, and reinforce healthful behaviour, leading to creating a *population* impact on prevalent risk factors. Indeed, most CVD does not occur among the relatively few adults at highest risk, but among many at moderate risk (Blackburn 1979; Puska et al. 1985; Schooler et al. 1997). Therefore, population health promotion must reach a community's entire population, including those who are neither engaged with the health system nor motivated to reduce a possible distant development of chronic disease.

While some behaviour change reflects individuals recognizing and reducing a risk, a population-wide impact always requires diffusion of behaviour change from a social process—individuals learning about new behaviours from neighbours, or individuals being encouraged to adopt new behaviours by those in their social networks. Such social diffusion results best from increasing opportunities to learn about and implement new behaviours, plus increased social expectations for doing so. The tobacco control literature calls this the social norms approach, 'denormalizing', by making both tobacco smoking and the tobacco industry's practices socially unacceptable, an approach central to California's successful Tobacco Control Program (Rogers et al. 2010).

This social normative and total community approach requires building an environment that coherently and consistently favours behaviour change. In addition to policy changes and mass communications campaigns, this total environmental change may be aided by entrepreneurs recognizing a need and developing products to accelerate behaviour change, through workplaces providing incentives for adherence to wellness programmes (Volpp et al. 2009), through schools that modify food available to children and require physical activity (Lynagh et al. 1997; Michaud 2003; Louriero 2004), through sports clubs (Kokko et al. 2006), and through programmes in other community settings. The goal is to create a behaviour change cascade, arising from synergistic interactive effects when many components are embedded in total community-based programmes that encourage institutional change, leaves space for entrepreneurs, and includes mass media and environmental change (Schooler et al. 1997).

Several synergies arise from combining multicomponent, multilevel (ecological) community intervention approaches with clinical services of physicians and other health professionals (Green et al. 2012). Adherence to dietary and exercise advice is more readily followed when family members, friends, and colleagues are modelling, enabling, and reinforcing these behaviours. Medication adherence improves when others in the patient's social network have learned, for example, about the need to control blood pressure and blood lipids. Health professionals, and their practice sites, potentially contribute to the 'total push' for better health, for example, by supplying print materials on health and alerting their patients to forthcoming community health events.

Comprehensive community-based efforts may modify the environment to support healthful or inhibit unhealthful individual actions, create organizational and institutional support for programmes, and influence the knowledge, attitudes, and behaviours of individuals (Schooler et al. 1997). However, a pragmatic view on implementing community-based programmes includes healthy scepticism about depending on institutions if reducing the CVD burden is not central to their primary missions. For workplaces, schools, and other community organizations the advantages may be made more evident when improved health increases performance or reduces absenteeism, for example, of students or employees.

Committing limited resources from community-level organizations to programmes may be unsustainable if incentives are weak or if interventions

are too complex to implement and maintain, leading to dissipation despite early enthusiasm (Thompson et al. 2000). For example, businesses that have insurance incentives to reduce smoking and obesity might invest in CVD prevention programmes, but few precedents exist for long-term sustainability and effectiveness even in high-income countries—and the potential incentives for businesses in low- and middle-income countries are less certain. However, recent findings suggest that financial incentives increase effectiveness of many worksite programmes, with evidence limited so far to their use in large worksites (Volpp et al. 2009). Similarly, physical activity is greatly needed in schools, but may not be implementable, given competition for limited educational resources and their primary academic mission. The infrastructure and capacity may be even more fragile in less formalized community organizations. More knowledge is needed on methods to create programmes and disseminate or scale them up in low- and middle-income countries.

'Best processes' to complement 'best practices'

Community intervention trials are typically funded to determine *efficacy*; multicommunity trials test *effectiveness*, that is, what might result when applied to different populations with different community structures. The generalizability from these to many varieties of communities and populations involves external validity (Green et al. 2009). Adaptation is an assessment and planning *process* which considers the history, culture, demographic and political structure, attitudes, community needs, and diversity of a particular community.

Features of this planning, implementation, and evaluation process approach are shown procedurally in models such as PRECEDE-PROCEED (Green and Kreuter 2004), which was informed by community trials following on Stanford and North Karelia, and the PATCH programme model of the Centers for Disease Control and Prevention (CDC) (Green and Kreuter 1992).

Message characteristics

Messages must arouse interest in health improvement and disease prevention and appeal to individuals with varied backgrounds and knowledge. They

must surmount indifference caused by the public's exposure to an *extreme* advertising overload. Since the 1990s, the average adult's annual exposure in the United States was 35,000 television advertisements, equalling 292 hours of personal exposure (Fortmann et al. 1995). They must arouse interest and awareness and have production qualities able to capture the public's attention. Formative evaluation must continue to match message content to the population's readiness. Early campaign messages must raise awareness and increase knowledge; later messages should increase motivation, provide direction to access resources, and develop needed skills—with resultant behaviour change (Schooler et al. 1997).

For adolescents, for example, the following enhanced success: parents and teachers whose personal habits were role models; and amount and quality of school-based education on tobacco, fitness, and nutrition. Also, certain personal characteristics were influential—for example, the person's baseline *self-efficacy* towards one's behaviour-change abilities (Fortmann et al. 1995). Finally, as Perry, of the Minnesota Heart Health Project (Perry 2000) explained, if a peer-led smoking prevention curriculum reduced smoking onset among youth, effect preservation required other support: 'The careful links of behavioural curricula, parental involvement, community support, and peer participation and leadership, with messages that are consistent and coordinated, have demonstrated efficacy beyond the implementation of a single strategy' (p. 122). This lesson is very germane for developing countries, given their proportionately high adolescent population.

The multiplicity and multilevel dimensions of community supports are shown in Table 5.9.2 as channels and mediators, referring to the individuals through whom the interventions can be personally or organizationally adopted and converted into reasons to act themselves, and then to influence others to change behaviour. They connect in the third column to the receiver's social cognitive change processes (Bandura 1986).

Prominent theories applied in community-based interventions

Community-based health education carried out by SPRC and some analogous projects has been guided by two major theories (community organizing and health communication–behaviour change), with success depending on their judicious blend (Flora et al. 1989; Farquhar et al. 1991).

Community organizing theory

This describes how to identify the community's health problem (and resources needed or available), and how to mobilize the community's opinion leaders and organizations. It describes the need to form coalitions, begin and maintain educational programmes, achieve regulatory changes, and *empower communities* to reach and maintain their goals. See 'Functions (for the sender)' in Table 5.8.2. Community organizing has elements central to concepts of 'community self-development' (Green and Kreuter 2005; Minkler 2005) and includes elements of diffusion theory (Rogers 2003)—which has shown how innovations are adopted through natural social networks, aided by a community's opinion leaders. Rogers strongly advised to ensure that these leaders play an important role, given their perceived trustworthiness (Rogers 2003).

Health communication–behaviour change theory

Health communication–behaviour change theory describe the basis for educating the population and its subgroups considering their health needs, cultural attributes, social networks, media habits, attitudes, motivation, knowledge, and self-management skills (see Table 5.8.1). It describes principles underlying education's success, including social cognitive theory (Bandura 1986), which emphasizes an individual's capacity for self-directed change. Bandura's research builds on the long-standing educational principle that 'learning by doing' is more effective than 'learning from observing' (modelling a behaviour), and both are more effective than an 'information-only' approach. Bandura described these principles as *social cognitive theory*: proposing that guided practice in a new behaviour can increase self-efficacy and behaviour change beyond the usual (Bandura 1986). The health communication–behaviour change theory includes efficient ways to reach total populations using methods described earlier in this chapter as 'social marketing' (Kotler 1975; Lefebvre and Flora 1988). The goal of a comprehensive, multicomponent, community-based intervention is to achieve 'community efficacy', just as 'self-efficacy' occurs for an individual after a successful behaviour change programme (Bandura 1986).

Specific methods for CVD community-based interventions

Problem identification

The first task is to identify the problem, initiated from within or outside the community. Local (community) interventions ideally interact with national programmes and link to scientific support from national or international levels, as noted with the family planning and HIV/AIDS histories. CVD prevention (WHO 1986) and alcohol sales control (Holder and Wallack 1986) are problems requiring local action, and any chronic disease requiring widespread education for changing 'lifestyle' behaviours (such as exercise, diet, and cigarette use) will require analogous methods.

Table 5.8.2 The components of health communication–behaviour change

Communication inputs	Functions (for the sender)	Behaviour objectives (for the receiver)
Face-to-face messages	Determine receiver's needs	Become aware
Mediated messages	Gain attention (set the agenda)	Increase knowledge
Community events	Provide information	Increase motivation and interest
Environmental cues	Provide incentives	Take action, assess outcomes
Training for community sources of influence (parents, employers, etc.)	Provide training to enable and reinforce others	Maintain action, practise self-management skills
Diffusion and influence beyond the primary receivers	Provide cues to action, including environmental change	Become an opinion leader (exert peer-group influence)

Adapted from Farquhar, J.W. et al., 'Methods of communication to influence behavior' in Holland, W.W., Detels, R., and Knox, G. (eds) *Oxford Textbook of Public Health*, Second Edition, Volume 2, Oxford University Press, Oxford, UK, Copyright © 1991, by permission of Oxford University Press.

Formation of partnerships

Key opinion leaders as well as relevant organizations usually need to form a coalition or at least a network of strategic partnerships (Green et al. 2001) to assure coordinated agreement on needs assessments, planning and

implementation, development of a community resource inventory, and mobilization of populace support for policy changes and enforcement. Relevant organizations, particularly in developed countries, include the following: the County Medical Society, or its equivalent, the local public health department, municipal hospital community affairs departments, city parks and recreation departments and voluntary health agencies (e.g. the local branches of national heart, lung, cancer, and diabetes organizations). Any organization that will act as a conduit for the public's education should also be represented (e.g. television and radio stations, local newspapers, schools, churches, libraries, pharmacies, clinics, and physicians' and dentists' offices). As the coalition-partner numbers proliferate, a 'steering committee', preferably limited to six members, is needed for more detailed planning, including formation of expert groups ('task forces') in education and evaluation and other topics (Flora et al. 1989; Farquhar et al. 1991).

Matching for comparison

Assuming the high likelihood of a non-randomized or cluster-randomized small number of communities, and therefore a 'quasi-experimental' design (Flora et al. 1989; Mercer et al. 2007), successful implementation requires close matching of intervention communities (treatment) with comparison (control) communities on relevant demographic and socioenvironmental factors, while also minimizing shared media channels (Farquhar et al. 1985). Many community trials have not followed these important principles.

Intervention components

The goals include providing behaviour-change skills training, supplementing goals of increasing knowledge. They should enlist multiple sectors beyond health organizations in health improvement campaigns, including changes in social and built environments, and regulations that promote access to facilities and resources needed for healthful physical activity. Multiple communication channels can facilitate reaching subgroups with differing needs. Comprehensive interventions should involve schools, worksites, senior citizens' centres, churches, and facilities for sport, recreation, and health. Voluntary health agencies (such as the local branches of any national organization that deal with cardiovascular disease, diabetes, and cancer) should be involved. These can serve as education conduits, with the

community's electronic and print mass media organizations assisting in message design, content, and delivery. The internet's community education role (digital health) is now a major force (Baker et al. 2003) and can reach and benefit more than traditional channels—an emerging variant of mass media. Interactive computer learning, including hand-held computers (King et al. 2008) ('mobile health') now provides new points of entry.

The intervention 'dose'

For future community intervention planning, an important question is how much amount and duration of intervention (the 'dose') is needed? Although outcome evaluations measure change achieved in health or disease risk, this 'dose' is rarely measured, thus cost-effectiveness remains a mystery. Dose measurement is difficult, the usual report gives only the intervention's duration and a cursory description of the educational inputs (Farquhar 2014), with little attention to reach or intensity (exposures). One can, at least, measure print and electronic media distributed, all converted to time, as was done uniquely in the Stanford Five-City Project (Farquhar et al. 1990). Public health policy would be served if this were done more commonly.

The community transformative phase

This begins early in the community organizing period, preceding the intervention, but accelerates throughout, particularly in the terminal period when external support diminishes or ceases (Farquhar et al. 1985). Enhancing a community's programme adoption for intervention sustenance is a major goal. This begins earlier, but becomes more definitive towards cessation of educational forces extrinsic to the community. A concurrent goal is to facilitate policy and regulatory changes that foster long-term goals and provide supportive physical infrastructures. The preferred outcome sees a continuing role for the original external academic advisors for community assistance, including the county's health agencies, to create new disease prevention programmes, as new technologies emerge. The ideal long-term outcome is that the 'transformed' community will advocate for local, regional, and national governmental regulations and laws increasing local intervention effects, such as smoke-free places, and extend them beyond the community.

The case of comprehensive community health promotion for CVD

The history of seven decades of twentieth-century community trials described has encompassed a mid-twentieth-century shift from public health and medical strategies appropriate to communicable diseases that accounted for the majority of deaths to those appropriate to a growing chronic disease burden. It outlined a series of formal research projects designed to affect health of communities, and illustrative CVD risk factors. The CVD trials have involved entire populations of at least one *education* community, compared to at least one *control* community. Three projects are described in greater detail here as case studies to provide examples of their methods and results. Dissemination worldwide into practical applications of community organizing and mass communication technologies, derived in part from these projects, occurred throughout these decades, with a relatively small number using research methods analogous to those described here.

Two examples: the first decade of CVD community-based projects

The first example is the Stanford Three-Community Study (3CS) in three small agricultural marketing towns in California (total population 45,000). The second is the North Karelia Study (NKS) in two adjoining predominately rural Finnish counties (North Karelia population about 180,000). Both projects began in 1972.

The first of two Stanford projects, 3CS, was carried out from 1972 to 1975 in both English and Spanish, comparing effects of 2 years of mass media plus ten-session risk reduction classes for 1 year for some high-risk adults in one community with the effects in a comparison community having 2 years of mass media alone, and a third as a control having neither (Farquhar et al. 1977; Schooler et al. 1997). Groups exposed to varied education amounts showed a dose–response change in levels of smoking, blood pressure, and blood cholesterol. Spanish-speaking residents had a proportionately larger effect than did the Anglo majority. A composite measure of CVD risk reduction at 2 years of about 23% and 30% occurred in the mass media-only and mass media-plus classroom conditions, respectively. The risk score (a probability) was derived from each adult's 'before–after' risk levels. These risk parameters predicted the 12-year future probability of a coronary heart disease event, using the scoring system

derived from the long-term Framingham Heart Study (Truett et al. 1967). Thus, a relatively modest amount of mass media alone over 2 years (about 30 television and radio ‘spots’, weekly newspaper columns on heart health, and four separate mass mailings of booklets) was sufficient to change the population’s coronary disease risk by 23%. The education followed the principles outlined in the earlier section ‘Prominent theories applied in community-based interventions’ for prominent theories of community organizing and health communication–behaviour change.

In Finland, NKS evaluated two unmatched rural counties that contained many villages with farming and lumbering as their main occupations. North Karelia (which has a population of about 180,000, with the highest CVD rates in Finland) received an education campaign that began in 1972, continuing to the present and expanded to the entire country. After 10 years, CVD risk factor changes comparable to the 3CS occurred, and significant net reductions in CVD events occurred (Puska et al. 1985; Schooler et al. 1997). Extensive community organizing, resulting in strong partnerships with residents and their organizations marked this study. The NKS influence on Finland’s national policies was unequalled among the CVD projects, giving its most important lesson—that a well-executed project led by respected scientists can change an entire country. Examples included Finland’s food and agricultural industries making large changes: fertilizers were supplemented with selenium (a substance needed for health, but low in Finland’s soil), milk pricing previously based on fat content converted to protein-based pricing, programmes were created to replace dairy farms with berry farms, a new canola industry replaced jobs lost in dairying, and increased production of low-saturated fat foods occurred (Puska et al. 1985, 1995). In 1972, population-wide nutrition change and smoking cessation interventions were an innovation internationally, which may partly explain the success of both 3CS and NKS (Green and Richard 1993).

Early international diffusion, 1977–1983

Building on the 3CS and NKS were studies carried out in various countries:

Italy (The Martignacco Project, 1977–1983, one treatment, mass media and screening, one control—coronary heart disease (CHD) risk fell in men only).
Australia (The North Coast Project, 1978–1980, similar to 3CS, one mass media, one mass media plus classes—effects on smoking, greater in the mass media 'plus' community).
Switzerland (two treatment, two control pairs, German and French speaking, with mass media, classes, and environmental changes—small effects on smoking, blood pressure, and obesity).
South Africa (similar to 3CS, one mass media, one mass media plus classes plus community events—decreased CHD risk, blood pressure, smoking; both treatments were equivalent).

All of these studies, reviewed in Schooler et al. (1997), reported significant risk factor changes, adding evidence both for the effectiveness of the 3CS model, and for the external validity of the evidence. In all, a predominately community-wide mass media campaign was effective, but a supplemental face-to-face instruction usually adds effects (Farquhar et al. 1991). A noteworthy qualification is that all these studies were done in rather small communities (population sizes of about 12,000 to 15,000 residents), thus achieving these effects may be more difficult in larger and more complex cities.

The second and third decades—projects begun in the 1980s and 1990s

The third case study, the Stanford Five-City Project (5CP) (California, United States), had an intervention phase of slightly more than 5 years, 1980–1986, and extended 3CS methods to larger populations (total population of about 360,000) with multifactor CVD prevention directed at two northern California cities, no intervention in three control cities (Farquhar et al. 1990). It differed from 3CS in larger community sizes, in greater use of community organizing, in greater collaboration with the communities' health, media and educational organizations in planning and implementing programmes, and in offering extensive continuing collaboration with Stanford. It was similar in its generous use of mass media, both print and electronic. The *proportion* of message sources received by the average adult over 5 years of education included: television and radio 67%, newspaper 28%, other print (such as booklets and 'tip' sheets) 4%, and face-to-face 1%. This dose measurement method, more fully described elsewhere

(Farquhar 2014), was unique among all reported CVD community intervention programmes in measuring total education dose. In the intervention communities this amounted to about 5 hours/year and about 100 exposure episodes/year to all forms of media and classroom education (Flora et al. 1989; Farquhar et al. 1990). This method's use increased evaluation costs, almost two-thirds of total expenses. This expense may explain why others have not used it to similar degrees. Public health education would be served were more campaigns analysed in this way (Brown et al. 2012).

The first year of 5CP's television messages (characterized as 'high reach/low involvement') led to the public's later use of print media, which contained more specific instructions than from television in skills needed for changing smoking, diet, exercise, or weight control (Flora et al. 1997). Television, however, was also quite effective in skills training. For example, the 5CP presented an 8-week 'live' smoking cessation TV programme, demonstrating smoking cessation skills (Altman et al. 1987). The results of an antismoking campaign of a 'quit smoking' contest, the television and face-to-face classes, and a widely distributed print 'Quit Kit' were analysed separately. The highest cost-effectiveness was achieved by the low-cost print component (Altman et al. 1987). Results were comparable to the 3CS (about a 15% fall in Framingham composite risk of CVD) (Truett et al. 1967), with a major impact on blood pressure (4–5%) and smoking (13%) (Farquhar et al. 1990). The usually timid health policy experts might gain courage from the 5CP's evidence that only 3 hours/year of high-quality television health education can counteract the public's relatively intimidating exposure to about 100 hours/year of television advertising devoted to unhealthful nutrition. The US population's exposure is estimated as 292 hours of TV advertisement as measured by the Nielsen monitoring system (Farquhar 2014). Michael Jacobson, from the Center for Science in the Public Interest, identified that one-third of these promoted unhealthful nutrition (personal communication).

Compared to similar projects, 5CP's greater effects at relatively low cost, support that communication–behaviour change theory's predicted effects may be explained by mass media presentation components, including adaptation of skills training aspects of Bandura's social cognitive theory. An important lesson for policymakers is that adult quitters saved over three times more money from their cessation of cigarette purchases (2,860 quitters @ $274/quitter/year) than the cost of the entire population-wide campaign

($4/adult/year), which would justify cigarette taxes as the campaign's payment. Savings are retained life-long by the community's smoker-quitters, not counting long-term health costs' savings, and absenteeism from the individual's employment decreases, all accruing to the whole community. The intervention's relatively low cost is again emphasized, since the total yearly cost of cigarettes to the 22,000 smokers (over $6 million) was 23 times greater than the yearly campaign costs (about $260,000/year). Additionally, the county's Health Department adopted 5CP's technologies, applying them to seatbelt promotion, changing restaurants' saturated fat use, violence prevention, and adolescent pregnancy prevention.

More variably sized CVD projects occurred in the 1980s and 1990s in the United States, Sweden, Denmark, Canada, Germany, the Czech Republic, and China, including World Health Organization-sponsored projects (Schooler et al. 1997). The Minnesota Heart Health Project (MHHP) (Luepker et al. 1994) emerged as an important innovation source, pioneering introduction of antismoking contests (Lando et al. 1990), and demonstrating synergism in school health intervention effects when multiple schools in a community are involved within a comprehensive community intervention (Perry 2000). Many projects borrowed heavily from and often received training from either the Stanford or the North Karelia groups, although changes seen were often less than in those two projects. Reasons for lower success may defy explanations (e.g. the magnitude of the interventions was incompletely described). For many, the cause was likely due to inadequate use of inherently cost-effective mass media.

To summarize lessons learned, a five-step approach emerges from community trials, much derived from the Stanford 5CP, and some from various worldwide trials. Generalizability, of course, has limitations inherent in the nature of such trials, including designs, locales, and methods:

Define the problem. Choose behaviour and environment change goals following community consultation.
Implement a 2-year campaign. Provide 3–5 hours of multichannel education/year. Year 1: 70% electronic media, 15% print, 15% community classes, contests, health fairs. Year 2: change to 40%, 35%, and 25%.
Evaluate. Use formative, process, and summative evaluations, tracking exposure, and effects of each intervention type. Use repeated cohort surveys to best measure effects, avoiding greater variance and in-migration's dilution effect. Repeated independent sample designs are feasible if in-migration dilution is less than 5%/year.
Institutionalize. Continue intervention. Create a community demonstration project as a regional resource centre.
Leverage. Advocate for local, regional, and national governmental regulations to magnify intervention effects.

Conclusions

Six decades of applying the 'total community' health promotion approach in developed countries show unequivocally that considerable change is achievable at reasonable cost. Well-designed projects have transferred educational technologies and social-behavioural intervention skills to a community's infrastructure (public health, media, schools, etc.), resulting in significant improvements in health risk factors and conditions of populations (Schooler et al. 1997). Although many studies were done in small communities, recent successes in New York City (Angell et al. 2009), suggest that success occurs in large urban populations. Adherence to theory is key: gains in self-efficacy of many individuals through education results in *community efficacy*, enhancing changed institutional policy and practice, thus maintaining and extending community change. Changing communities through organizing and education requires *advocacy*, *activism*, *partnership building*, and *leadership*; success is enhanced by *regulatory change*. When needed laws and regulations come from state, provincial, or national governments, local changes are enhanced. Both local and broad governmental approaches are needed to succeed in preventing chronic disease, which is particularly important for developing countries (Institute of Medicine 2010a). Adding well-planned, well-integrated digital health

programmes, as yet untried, can likely increase effectiveness at decreased cost.

5.9

Natural and quasi-experiments

Peter Craig

Introduction

Natural experiments, broadly defined as events or processes outwith the control of a researcher, which divide a population into exposed and unexposed groups (Craig et al. 2012), have long been used in epidemiology and public health. John Snow's studies of cholera in mid-nineteenth century London (Snow 1855), the most celebrated example of early epidemiology (Davey Smith 2002), exploited a natural experiment brought about by a change in domestic water supply between two cholera outbreaks. At the time, cholera was widely believed to be an airborne disease. Snow used information about cholera deaths and water supply at neighbourhood and household level to show that deaths were more likely in households whose water came from a contaminated source. Although he did not use the term, Snow clearly understood his approach as a natural experiment:

> No fewer than 300 000 people of both sexes, of every age and occupation and every rank and station, from gentle folks down to the very poor, were divided into two groups without their choice, and in most cases without their knowledge; one group being supplied with water containing the sewage of London … , the other group having water quite free from such impurity. To turn this grand experiment into account all that was required was to learn the supply of water to each individual house, where a fatal attack of cholera may occur. (Snow 1855)

What makes this 'grand experiment' useful is that the change in exposure was well-characterized and independent of other factors that may influence the health outcome. In another important early example of turning natural experiments into account, GCM M'Gonigle compared changes in death rates among residents of an 'Unhealthy Area' of a town in the North East of England who were rehoused following a survey of housing conditions, with

changes among residents who remained in their original houses (M'Gonigle 1933). The division of the area was, according to M'Gonigle, purely administrative, and death rates prior to rehousing in 1927 were similar among the two groups of households. In the five years following the rehousing, the death rate was markedly higher among the rehoused residents, but declined slightly in those who remained. Further investigation suggested that increased rents leading to inadequate diets among adults in the rehoused families was the probable cause.

Despite these early demonstrations of the potential of natural experiments for addressing important public health questions, and a substantial body of epidemiological work from the 1940s onwards, including influential studies of famines and mass migrations, the methodology of evaluating natural experiments has developed piecemeal across a range of subject areas and disciplines, including psychology, economics and political science (Bärnighausen et al. 2017b). Developments in these other disciplines have been slow to permeate public health. It is only in the last ten years or so that attempts have been made to pull together the range of methods available to study the different kinds of natural experiments that are of interest to public health, and to identify the circumstances in which each method works best (Craig et al., 2012; Bärnighausen et al. 2017b; Basu et al., 2017; Craig et al., 2017). This chapter introduces the main approaches that researchers can use to evaluate natural experiments, and provides examples of their application in a wide range of contexts. It begins by setting out the advantages, and also the limitations, of a natural experimental approach. The term *quasi-experiment* is often used interchangeably with *natural experiment*, but is also used to refer to true experiments (in which there is manipulation of exposure by the researcher) which are non-randomized. To avoid confusion, the preferred term in this chapter is *natural experiment*.

Trials, observational studies, and natural experiments

Randomized controlled trials and syntheses of evidence from trials occupy the top steps of the conventional hierarchy of evidence (Concato et al. 2000). The hierarchy is organized according to risk of bias, with observational studies regarded as being at higher risk because of the difficulty of isolating the effect of the exposure of interest from other

factors that might affect outcomes. In a trial, random assignment of participants to treatment and control groups, plus a number of other methodological safeguards such as blinding of participants and assessors, and concealment of the allocation sequence, generates exposed and unexposed groups that are, in expectation, balanced in terms of all the factors that may influence outcomes other than exposure to the treatment. Differences in outcomes between the groups can therefore be interpreted as effects of the treatment. Outside an experimental setting, such balance is rare: individuals may be selected for treatment, or may self-select, according to characteristics that influence outcomes, leading to confounding of the treatment effect. In an observational study, statistical adjustment may be used to address such confounding, but only works to the extent that the confounders are known and accurately measured. Estimates of the treatment effect will be biased if there is 'residual confounding' due to unknown or imperfectly measured confounders (see Chapter 5.13). Natural experimental studies are a subset of observational studies that use the process by which exposure is determined to identify treatment effects. Understanding this process is therefore key to the design of a good natural experimental study. Because such processes rarely give rise to exposed and unexposed groups that are perfectly balanced on all of the characteristics that may affect outcomes, natural experiments also rely on statistical models that take into account both the allocation process and any observed differences between the groups in characteristics that may affect outcomes.

Given that randomized controlled trials are such an effective way of eliminating bias associated with selective exposure to treatment, why should natural experiments be considered a useful alternative? One reason is that for many interventions a trial may not be feasible, for ethical, political, or practical reasons (Craig et al. 2012; Bärnighausen et al. 2017b; Derzon 2018). It may be regarded as unethical to withhold a treatment in order to identify its effect on health, if it clearly provides other benefits. This particularly applies to non-healthcare interventions whose main purpose is to influence some other outcome such as participation in education or in the labour market. Recipients of a conditional cash transfer benefit directly from receiving the money. If the purpose of the scheme is to reduce poverty, withholding payments from some potential recipients to study its effect on health, once its effectiveness in alleviating poverty has been established, is unlikely to be seen as fair by the losers, and may also be

unacceptable to other stakeholders. Similar arguments apply to evaluating the wider, non-health-related, or long-term impacts of health interventions. The design of the intervention may make randomization impractical, at least at an individual level—as in the case of international treaties, national legislation, or taxation policies—or stakeholders may be unwilling to selectively withhold an intervention once it has been implemented, even if its effectiveness in delivering its primary outcome is uncertain.

Natural experimental studies, which involve no manipulation of exposure by the researcher and which can be conducted retrospectively, may therefore be feasible when a prospective randomized controlled trial would not. Natural experiments may also avoid threats to validity that are specific to trials. One is the confounding of trial procedures with treatment. This may occur when methods for retaining participants in the trial also improve retention in care among patients in the control arm, leading to an underestimate of the effectiveness of treatment (Bor et al. 2017). Another is that effects on individuals observed in a trial may differ from the effect of exposing the whole population to the intervention. This may occur when interactions between recipients contribute to the overall treatment effect. To use the conditional cash transfer example again, treating a whole population may change social norms regarding the behavioural conditions, strengthening the individual incentive of the cash transfer.

Another reason for considering alternatives to randomized trials is that minimizing bias is not the only aim of good research design. The strength of randomized controlled trials is that they permit strong causal inference with a minimum of assumptions. But additional assumptions are always needed to apply the evidence to a particular context, if it differs in any way from the settings in which the trials were conducted (Deaton and Cartwright 2018). Researchers evaluate public health interventions to provide information that is useful for decision-makers, as well as to contribute to a scientific evidence base. Precise estimates with a small amount of bias from a large natural experimental study, conducted in a relevant context, may be more useful than unbiased but imprecise estimates from an experimental study conducted in a highly artificial setting. Whether this, or any of the other reasons for considering natural experimental approach, is persuasive will depend on the details of the case. Rather than seeing trials and natural experiments as competing for position at the top of a hierarchy of evidence,

researchers and evidence users should see them as belonging to a common methodological toolkit for answering important public health questions.

Natural experimental study designs

The key methodological problem that all natural experimental studies must solve is that of selective exposure to the intervention, and the designs summarized in this section can be seen as alternative solutions to this challenge. They include some that would be ruled out by definitions that restrict natural experiments to cases where a process of 'as-if randomization' determines exposure (Dunning 2012), or to methods that deal with unobserved confounding as well as with confounding by observables (Tugwell et al. 2017). 'As-if randomization' is difficult to define, and rules out cases where the assignment process is clearly non-random, but amenable to modelling. Non-random assignment can provide useful opportunities for natural experimental studies, so long as the assignment process is well understood. None of the available methods automatically solves the selection problem. How far they do so depends on how well their underlying assumptions are met (Bärnighausen et al. 2017a). As this is unlikely to be perfect, or completely demonstrable from available data, a hard and fast distinction between methods that control for both unobserved and observed confounders, and those that only deal with observables, is unhelpful. A more inclusive list is also in keeping with the idea that the value of natural experimental approaches is that they widen the range of public health interventions that can usefully be evaluated. Because the methods originated in a number of different disciplines, terms that are readily understood by some researchers may be unfamiliar or puzzling to others. Definitions of some key terms, according to their usage in this chapter, are provided in Table 5.9.1.

'Real-world' randomization

Sometimes, lotteries or ballots are used in the delivery of an intervention or implementation of a policy. A well-known example is the Vietnam-era draft lottery which has been used to identify the effects of military service on

earnings (Angrist 1990). Another is the practice of reserving council seats for women in a randomly selected proportion of village elections in the Indian states of Rajasthan and West Bengal. Researchers have used the system to study the effects of women's involvement in local government on the provision of public goods (Chattopadhyay and Duflo 2004). An example in the health field is the Oregon Health Plan Lottery in which randomly selected entrants to a public lottery were eligible to apply for health insurance. The lottery broke the link between income, prior health status and health insurance, enabling researchers to identify the effect of health insurance on use of health services and on health outcomes (Baicker et al. 2013).

Randomization may also come about inadvertently, as a consequence of errors in policy implementation. Database errors led to some families being randomly excluded from Brazil's *Bolsa Alimentação*, a conditional cash transfer programme that sought to improve child nutrition. Researchers compared the growth of children in households that were accidentally excluded from the programme and in matched households which received the payments (Morris et al. 2004). Resource constraints may sometimes limit programme reach in arbitrary ways that approximate random assignment. In Scotland's Family Nurse Partnership, which provides teenage first-time mothers with additional support pre-natally and in the first few years of the child's life, access to the programme is determined by the availability of specially trained nurses. When all the trained nurses have a full caseload, recruitment to the programme stops. Assignment should therefore be unrelated to characteristics of the mothers that might affect outcomes (Wimbush et al. 2015). Real-world randomization is rare, but may offer valuable opportunities for natural experiments. In studies that seek to exploit such opportunities, it is important to understand in detail how the assignment process works, and to check for self-selection by potential recipients, or manipulation of assignment by those delivering the programme.

Table 5.9.1 Glossary

Term	Usage
Assignment, allocation	The process that determines whether units (which may be individual people, or aggregates of some kind) are exposed to the intervention that is being studied. Also referred to as the data generating process.
Confounding, confounder (observed, unobserved)	Confounding refers to the mixing up of the effects of the intervention with the effects of characteristics associated with exposure. Confounding by observed characteristics (i.e. those on which data is available) can be addressed using a statistical model. Some natural experimental study designs go a step further, and use a combination of assumptions about the assignment process and statistical modelling to address confounding by unobservables.
Control, counterfactual	Controls are unexposed units. Outcomes among the controls constitute the counterfactual, in the sense that they represent the outcomes that would occur in the absence of exposure.
Exposure	A general term for receipt of an intervention; effectively synonymous with treatment in natural experimental studies.
Identification, identifying assumption	Identification refers to the method used to obtain an estimate of the effect of the intervention. All such methods rely on identifying assumptions, such as the assumption that pre-intervention trends in outcomes will continue in the absence of intervention. Testing how well the assumptions are met is an important element of good natural experimental study design.
Intervention	A general term for any policy, programme, service, or treatment that is being evaluated.
Natural experiment	An event or process that divides a population into exposed and unexposed subpopulations. The division may be spatial, temporal, or based on the characteristics of individual units, such as test scores.
Observational study	A study that does not involve any manipulation of exposure for research purposes. Natural experimental studies are a subset of observational studies.
Outcome, potential outcome	Outcome is used as a general term for the effect of treatment or exposure to the intervention being studied. Potential outcomes are the outcomes that would occur in the absence of treatment. Comparison of actual with potential outcomes is the basis for identifying treatment effects in a natural experimental study, with potential outcomes measured in a group that is not exposed to the intervention but is otherwise similar to the exposed group.
Quasi-experiment	Natural experimental studies are often referred to as quasi-experiments, but quasi-experiment is also sometimes used to refer to non-randomized experiments. To avoid confusion, the term natural experiment is preferred in this chapter.

Term	Usage
Selection	A process that leads exposed and unexposed units to differ in ways other than exposure to the intervention that are associated with differences in outcome. Selection is the source of confounding in natural experimental studies.
Treatment	Treatment is often used as a general term for exposure to an intervention, rather than to denote a medical treatment.

Controlling for observables: regression adjustment and propensity scores

When it is plausible to expect that there are no important differences between exposed and unexposed groups a standard regression model may be sufficient to identify the effect of the intervention. The real-world randomization examples discussed in the previous section are one kind of situation in which this assumption is reasonable. Another is when randomization is built into the timing of data-gathering rather than the timing of exposure. Goodman and colleagues used this approach to evaluate a school-based cycle training scheme (Goodman et al. 2016). Parents of some children in participating schools were interviewed as part of a long-running birth cohort study before the training was implemented in their school; parents of other children in the same schools were interviewed after the training had been delivered. The researchers used Poisson regression to estimate the effects of training on cycling behaviour, with adjustment for a wide range of potential confounders. Unlike previous evaluations which compared children in participating and non-participating schools, the study found no effect of the training on cycling behaviour.

As with real-world randomization, such opportunities are scarce but potentially highly valuable. In the example, data were gathered only from participating schools so selective participation cannot bias the estimate of effect of the programme (though may limit its generalisability). The key identifying assumption is that the timing of interviews was unrelated to delivery of training, a reasonable assumption given that the survey and the training were planned and conducted independently of one another.

When random allocation cannot be assumed, or is known not to occur, as in the case of many social interventions that are targeted at poorer households or poorer neighbourhoods, an alternative is to model the

allocation mechanism using a propensity score, defined as the conditional probability of exposure, given a number of covariates. The propensity score is usually estimated using a logistic regression model. It can be used to match exposed with unexposed units, to stratify analyses of outcomes, or as a covariate in an outcomes model. Propensity score-based methods have been extensively used to evaluate the impacts of targeted social programmes. In their evaluation of the Sure Start programme, an area-based intervention to improve the health and wellbeing of young children in England, Melhuish and colleagues calculated a propensity score from 85 area-level variables, which they used to stratify their analyses of the effects on individuals of exposure to the programme (Melhuish et al. 2008). The key identifying assumption is that the propensity score fully accounts for exposure to the programme—a strong assumption when data are sparse. Although propensity score-based methods will produce effect estimates similar to those of conventional regressions using the same covariates, they encourage a clearer conceptualization of the assignment process. A disadvantage is that units that cannot be matched on the propensity score must be omitted from the analyses.

Difference in differences and fixed effects models

When data are available on exposed and unexposed units before and after the introduction of an intervention, the difference in the change in outcomes can be used to identify the effect of the intervention. This difference in differences (DiD) approach is one of the most widely used natural experimental study designs. Its key assumption, known as the common trends assumption, is that any group specific confounders are time invariant, and any time-varying confounders are common to all groups. Effect estimates can be obtained from a regression model with dummy variables for group (exposed, unexposed) and period (pre/post-intervention), and a group-by-period interaction term that serves as the DiD estimator. The model takes account of any differences in unobserved fixed characteristics of the groups. Additional covariates can be added to take account of observed characteristics of the groups that vary over time. Researchers have developed a range of ways in which the common trends assumption can be tested (Wing et al. 2018). With data on covariates, the

standard model can be fitted with the outcome replaced by each covariate in turn to test for changes in the composition of the groups. With data on multiple time points, the outcome model can be fitted to the pre-intervention data with time as a continuous variable, to identify differences between the groups in the pre-intervention trends. The common trends assumption may also be violated by other interventions introduced at the same time as the intervention under study that affect one or other of the groups. This cannot be dealt with statistically. Instead, researchers should use specialist knowledge of the subject area to identify such threats.

DiD methods are widely applied to the evaluation of national programmes or policies, or interventions introduced at state level within federal jurisdictions. Schram and colleagues used a DiD approach to estimate the effect of joining the World Trade Organization, and subsequent removal of controls on foreign direct investment, on sugar-sweetened beverage (SSB) consumption in Vietnam (Schram et al. 2015). Models comparing SSB consumption in Vietnam and the Philippines in the pre- and post-accession periods indicated a substantially greater increase in Vietnam. The authors included gross domestic product (GDP) as a covariate in the models and fitted further models for foreign company sales growth and consumption of unprocessed foods. They found that the increase in soft drink consumption was not explained by economic growth, and was specific to products manufactured and marketed by foreign companies. The additional analyses support the conclusion that increased consumption of SSBs was the result of trade and investment liberalization.

The two-group, two-period DiD described here can be extended to situations where there are data on multiple groups and multiple time periods. The standard approach is to estimate a regression model with a variable denoting exposure and a complete set of group and time fixed effects to take account of unobserved time invariant characteristics of the groups, and temporal trends that apply to all groups. Nandi and colleagues used this approach to evaluate the effects of paid maternity leave on infant mortality in low- and middle-income countries (Nandi et al. 2016). Their models included fixed effects of country and year, a term indicating whether countries had changed their maternity leave policies in the previous year, plus additional covariates to take account of characteristics of countries that could vary over time, such as the level of wage replacement

and spending in healthcare. The research found that each month of paid maternity leave was associated with a 13% fall in infant mortality.

Webster and colleagues used a similar approach to evaluate the impact on murder rates of withdrawing a restriction on the purchase of handguns in the US State of Missouri (Webster et al. 2014). The researchers fitted models comparing Missouri with all other US states, with fixed effects for state and year, and a range of covariates including unemployment, burglary, and incarceration rates, levels of policing, and other firearm-related legislation. They found a 16–23% increase in gun-related murders associated with withdrawal, but no change in murders by other means. As with the study of trade liberalization and soft drink consumption, this use of outcomes that are not expected to respond to the intervention in order to test the specificity of the effects helps to strengthen confidence in the conclusions.

Synthetic controls

DiD and fixed effects approaches allow the effects of an intervention to be identified under the assumption that any differences between the exposed and unexposed groups other than the intervention are stable over time, or can be modelled using information on covariates. Choosing a comparator which is similar to the exposed group, such as a neighbouring state, or excluding groups that are known to have been affected by other interventions, can increase confidence in this assumption. An alternative approach is to create a synthetic control from a pool of potential comparators (Abadie et al. 2015). A synthetic control is a weighted composite of control units that matches the pre-intervention trend in the outcome in the exposed unit. The weights are constructed to minimize the pre-intervention differences in the outcome and observed predictors of the outcome in the exposed unit and the synthetic control. Matching on the pre-intervention outcome should also minimize differences in unobserved time-varying characteristics associated with the outcome. The difference in the post-intervention trend between the exposed unit and its synthetic control provides the effect estimate. Although standard statistical inference is not possible with this method, the estimated effect can be compared with a distribution of ‘placebo’ effect estimates obtained by swapping the

intervention unit with each control unit in turn and constructing a synthetic control for each.

The first application of synthetic control methods in public health was in a study of a tobacco control programme introduced in California (Abadie et al. 2010). Abadie and colleagues derived their synthetic control from a donor pool of other US states. After excluding those that had implemented similar programmes, the synthetic control was constructed from a weighted combination of five states. The difference in the post-intervention trend in cigarette sales between California and its synthetic control was greater than differences between the other states and their synthetic counterparts, suggesting that the programme was effective. Since that study was published, the use of synthetic control methods, often applied in conjunction with other methods, has grown rapidly (Bouttell et al. 2018). Comparing results of approaches that rely on differing assumptions is a useful way both of strengthening confidence in findings when no single method is unambiguously better, and of learning about the strengths and weaknesses of the methods.

Interrupted time series

Alongside DiD, interrupted time series (ITS) methods are among the most widely used approaches to evaluating natural experiments. They can be used to evaluate the effect of interventions that take place at a well-defined timepoint, and affect a population for whom outcome data are available at regularly spaced intervals. Whereas in DiD studies, the pre-intervention data are used to test whether the common trends assumption is reasonable, ITS studies incorporate the data directly into the outcome model. The simplest approach is to fit a segmented regression model to the sequence of outcome data, with terms for time since start of the observation period, time period (pre/post-intervention) and time post-intervention (Bernal et al. 2017). The coefficients of these terms estimate the pre-intervention trend in the outcome, the change in level of the outcome at the point at which the intervention is introduced, and the change in trend post-intervention.

Inclusion of the pre-intervention trend in the time series model controls for fixed characteristics of the exposed population. Additional covariates can be added and interacted with the time variables to account for observed

characteristics that change more quickly, or for other interventions that might affect the outcome of interest. An unexposed group can be added to control for unobserved time-varying confounders. Outcomes that are not expected to change as a result of the intervention, but may be affected by unobserved underlying trends, can be modelled in the same way as the outcome of interest to test for specificity of effects. Similar changes seen across all the outcomes are likely to represent unobserved confounding rather than an intervention effect. Other modifications can be made to account for seasonal patterns and other forms of serial correlation which are common in time series data. Whatever approach is taken, choosing an appropriate outcome model, based on reasonable assumptions about how the intervention is likely to impact on the outcome, and what other factors need to be taken into account, is key to obtaining useful results. For example, if the effect is expected to take place after a lag, observations in the lag period can be omitted or modelled as a separate segment of the series.

Humphreys and colleagues used a controlled ITS approach to evaluate the impact on homicide rates of a ‘stand your ground’ law enacted in the US State of Florida in 2005 (Humphreys et al. 2017a, b). Such laws, which permit the use of lethal force in self-defence, have been enacted in a number of US states, but previous evaluations had produced conflicting findings. The study used segmented regression models to analyse trends in homicide and suicide rates in Florida and four other US states for which comparable data were available, but which did not have stand your ground laws. The models assumed an immediate and permanent impact of the new law, and allowed for seasonal effects and serial correlation in the data. An interaction term was included to identify changes in homicide and suicide rates in Florida, relative to the control states. Results suggested a 24.4% increase in the monthly homicide rate but no increase in suicide rates in Florida, and no increase in either homicide or suicide rates in the control states. The specificity of the increase strongly suggests a causal interpretation.

Regression discontinuity

DiD, fixed effects, synthetic controls, and ITS methods can be used when the introduction or, more rarely, withdrawal (Craig et al. 2018) of an intervention divides a population into unexposed (i.e. pre-intervention or post-withdrawal) and exposed subpopulations. Other approaches can be applied when the assignment process operates at an individual level, the most widely used being regression discontinuity (RD) designs and instrumental variables (IVs). RD designs can be applied when a cut-off in a continuous variable, such as age or income, is used to determine exposure. Such methods of assignment are commonly used in public policy. Examples include social security benefits awarded on the basis of a means test, school places allocated using a test of cognitive ability, and laws that define a minimum age at which people can hold a driving licence or buy alcohol. The identifying assumption is that individuals with values of the assignment variable close to the cut-off will be similar in terms of other characteristics, both observed and unobserved, that may affect outcomes, especially if there is random error in the measurement of the assignment variable. Differences in outcomes for individuals either side of the cut-off can therefore be used to estimate a treatment effect (Bor et al. 2014).

When probability of exposure changes abruptly at the cut-off from close to zero to close to one, treatment effects can be estimated from a regression of outcomes on the assignment variable (known as the ‘forcing variable’ in RD studies), with a dummy variable denoting exposure. The coefficient of the dummy variable is the RD estimator. Additional terms may be included to allow the slopes to vary above and below the cut-off, and to control for confounders on which information is available. This is known as a sharp RD design. In many cases, known as fuzzy RD designs, probability of exposure takes intermediate values within a range of values of the forcing variable either side of the cut-off, and a two-stage approach to estimation is needed. In the first stage, probability of exposure is estimated from a regression of actual treatment on the cut-off and the forcing variable. In the second stage, the estimated probabilities of exposure replace the dummy exposure variable in the outcomes model.

Care is needed in the interpretation of effect estimates from RD studies. In both sharp and fuzzy RD designs, the effect of exposure to the intervention is identified at the cut-off. In a sharp RD design, the effect estimate can be interpreted as the average effect of treatment across the whole population, so long as it is independent of the forcing variable. In

practice, RD estimates are obtained from local regressions, using observations drawn from a narrow range of values of the forcing variable around the cut-off where the assumption of near-random assignment is most plausible. The effect estimated in a fuzzy RD design is known as a complier average causal effect because it represents the effect of exposure on those who comply with their assignment.

A strength of the RD design is that the key identifying assumption can be tested empirically. A histogram of the assignment variable and scatterplots of the forcing variable against other covariates can be used to identify any bunching either side of the cut-off that would indicate manipulation of treatment assignment (for example, by under-reporting of income or misrepresentation of age). A scatter plot of the outcome against the forcing variable can also be used to inform decisions about the modelling approach, such as what range of data should be used, whether additional terms are needed to take account of non-linearities or changes in slopes at the cut-off. Drawbacks are that additional assumptions are needed to extrapolate effect estimates to populations far from the cut-off, and the need to restrict analyses to a subset of observations close to the cut-off, which reduces statistical power. The latter problem is less serious in studies where the effect close to the cut-off is most relevant to the research questions, such as those where the focus is on a small change in the assignment rule (Moscoe et al. 2015).

Hainmueller and colleagues used a sharp RD design to identify the impact on child mental health of protection against deportation under the US Deferred Action on Childhood Arrivals (DACA) programme (Hainmueller et al. 2017). DACA provided renewable temporary work permits and protection against deportation for unauthorized immigrants who arrived in the US as children, and who were aged under 31 in 2012, the year in which the programme was introduced. The age cut-off determining eligibility for DACA provided the basis for a sharp RD design. Using a sample of unauthorized immigrant mothers with birthdays within 150 days of the age cut-off, drawn from Emergency Medicaid records in Oregon, the researchers found that following the introduction of the programme, children of DACA-eligible mothers were less likely than children of ineligible mothers to be diagnosed with adjustment or anxiety disorders. There was no such difference prior to the introduction of the programme. Robustness checks indicated no discontinuities in measured background

characteristics, and no bunching of mothers' birthdates around the age cut-off which would suggest manipulation of the forcing variable.

Andalón used a fuzzy RD design to investigate the impact of Mexico's *Opportunidades* programme on obesity and overweight among adolescents (Andalón 2011). *Opportunidades* provided cash transfers to households in rural communities below a poverty threshold, conditional on school and health attendance, plus a number of other eligibility criteria, leading to a fuzzy rather than a sharp discontinuity at the poverty threshold. Andalón used two-stage least squares regression to estimate the probability of receipt of the cash transfer as a function of poverty scores and the cut-off, and then to predict obesity and overweight as a function of the estimated probability of receipt. She found that obesity and overweight decreased among female but not among male participants. Note the difference in the interpretation of the two studies: the first estimates the effect of the DACA programme on the children of eligible mothers; the second estimates the impact on programme recipients, rather than all households below the poverty threshold.

Instrumental variables

Fuzzy RD designs are closely related to instrumental variable (IV) methods. Both methods use the same two-stage approach to estimating treatment effects. In IV studies a potentially confounded direct measure of exposure is replaced by an unconfounded proxy measure. To solve the problem of confounding, the instrumental variable must be associated with exposure to the intervention, have no association with other factors associated with exposure, and no association with outcomes other than through its association with exposure to the intervention. Effects are estimated by first obtaining a prediction of the probability of treatment from a regression of treatment status on the instrument, plus any observed confounders. The predicted probabilities of treatment are then fitted in an outcomes model, which also includes any confounders used in the first stage model. As in the fuzzy RD design, the effect estimated is the complier average causal effect, rather than the average treatment effect across the whole exposed population.

Reinhard and colleagues used this approach to evaluate the impact of a policy of providing free bus travel on loneliness and mental health among older people in England (Reinhard et al. 2018). Use of public transport is socially patterned but under the policy, eligibility for free travel depended solely on age. The researchers estimated the impact of the policy by regressing use of public transport on the age cut-off determining eligibility for free travel plus a range of covariates, such as employment status and pension receipt, then regressed the mental health and social outcomes on the predicted probabilities of public transport use plus the same range of covariates. They found that use of public transport was associated with fewer depression symptoms and feelings of loneliness, and higher levels of social engagement.

The key strength of IV methods is that if the three assumptions outlined are met, the instrument controls for unobserved as well as observed confounders. The drawback is that although the first assumption can be tested empirically, it is difficult to show that the instrument has no association with any other factors that may be associated with the outcome of interest, or that it has no direct relation with outcomes other than through its association with exposure to the intervention. Critics of the use of IVs point to the lack of either an empirical or a good theoretical justification for the identifying assumptions in some applications of the method (Deaton 2010).

Conclusion—making good use of natural experiments

Until recently, natural experiments were regarded primarily as a historical curiosity. That view no longer prevails, and natural experimental approaches are now widely, but not universally, seen as central to efforts to improve the evidence base for large-scale public health interventions. Leading national and international public health agencies have invested in initiatives to promote the use of natural experiments (Emmons et al. 2018; National Institutes of Health Office of Disease Prevention 2018; Snell et al. 2018).

This chapter has set out the case for seeing trials and natural experimental methods as belonging to a common toolkit of approaches available to researchers, rather than as occupying separate levels of an

evidence hierarchy that is stratified only by risk of bias. Exactly the same reasoning applies to the different natural experimental approaches described in this chapter. There is no single approach that is best in all circumstances. Instead, there is a range of methods that provide researchers with tools to tackle a wide array of evaluation problems. Choice of methods should depend on the specific details of the evaluation problem, rather than on more general assumptions about the superiority of some methods over others.

Good natural experimental studies require a clear understanding of how the intervention works, and in particular of the processes that determine exposure. An explicit logic model or programme theory is a useful way of capturing this. Whatever method is chosen for identifying the effects of the intervention, careful testing of assumptions and, where possible, the comparison of results from alternative methods helps to build confidence in conclusions. Prior publication or registration of study protocols, so that it is clear which questions were theoretically motivated, rather than driven by the data, is also useful—and increasingly a requirement of journal publication.

A key advantage of natural experimental approaches is that they can be applied retrospectively. A corollary is that they often rely on routinely collected data, from Censuses, long-running surveys, vital events registration, or monitoring carried out in the course of programme implementation. Investment in infrastructure for linking exposure and outcomes data at an individual level is opening up new opportunities for both trials and natural experiments. To enable researchers to make the most of these opportunities, information governance processes need to be rigorous, but also efficient and proportionate to the real risk of disclosure. For their part, researchers need to be alert to the opportunities provided by the withdrawal or scaling back of existing interventions, the fine details of assignment rules, or by imperfections in programme delivery, as well as by the implementation of large-scale policies or programmes.

Clinical epidemiology

Fiona F. Stanaway, Naomi Noguchi, Clement Loy, Sharon Reid, and Jonathan C. Craig

Introduction

Clinical epidemiology is a science that extends the principles and methods of epidemiology to clinical practice and clinical research. It incorporates the location, evaluation, and application of the best evidence to patient care by clinicians as well as the generation of high-quality research evidence by clinical researchers. Rather than being focused on health at the population level, clinical epidemiology focuses on individual patients and groups of patients. The application of the science of clinical epidemiology to patient care and its' integration with clinical expertise and patient values is also often referred to as evidence-based medicine or evidence-based practice.

Clinical epidemiology can make an important contribution to global public health through the application of relevant methods to public health decision-making. The field of clinical epidemiology has driven changes in the way in which evidence is generated and synthesized, and has led to more efficient approaches to the identification, retrieval, and appraisal of evidence (Sackett 2002). These methods make an important contribution to evidence-based public health, the term used to describe public health decision-making that is based on the best available evidence, availability of resources, and population needs, values, and preferences (Brownson et al. 2009). Clinical epidemiology has also contributed to the development of methods for research translation, also known as implementation science, to facilitate the rapid uptake of scientific evidence into clinical decision-making (Woolf 2008). These same approaches are being applied to the field of public health, ensuring that public health research evidence is translated into effective interventions and policies.

Clinical epidemiology benefits global public health by its impact on improving healthcare. By providing better diagnostic and therapeutic care to individual patients and groups of patients, clinical epidemiology can contribute to health improvement at the population level. These improvements can come about through better evidence-based decision-making on the part of individual clinicians as well as health system wide approaches.

In this chapter, we provide an overview of clinical epidemiological methods and how these approaches can be used to improve global public health. We have focused primarily on using evidence in decision-making in this chapter, rather than study design and conduct elements, such as randomized controlled trials, which are covered in detail elsewhere. Consequently, we have provided a framework for critical appraisal and reporting of relevant study designs (how to use and report), rather than a detailed discussion about how such studies should be designed and conducted (how to do).

Clinical epidemiological methods

Efficient location of research evidence

Locating a relevant piece of evidence is the first step behind evidence-based decision-making. An important principle behind making a search for evidence efficient is starting the search with higher levels of evidence (primarily systematic reviews) and resources that have already been appraised for quality (Alper and Haynes 2016). In these 'pre-appraised' sources of evidence, the information has been critically appraised and filtered by experts, meaning that it has been appraised for risk of bias. Table 5.10.1 shows the hierarchy in terms of locating pre-appraised evidence. The highest level referred to as 'systems' is currently not applicable to public health decision-making as it involves integration of an individual's electronic health records with computerized decision support systems. However, all of the other levels of pre-appraised evidence can be useful for answering public health questions. The second level of synthesized summaries for clinical reference, also referred to as point-of-care tools, although specifically aimed at clinical decision-making at the point of care, can contain useful summaries of public health-related evidence. However, an important barrier to the use of these resources is their cost as they are all subscription-based tools.

Within the lower three levels of pre-appraised evidence, available content can include original reports that have been pre-appraised by experts (filtered content) and appraisal and extraction of key content of original reports (synopses) (Alper and Haynes 2016). Table 5.10.1 shows resources that can provide these various forms of pre-appraised evidence to aid public health decision-making. In addition to sites that provide one type of pre-appraised resource such as the Cochrane Library for systematic reviews, there are a number of search engines that search simultaneously across multiple sources and organize results according to level or quality of evidence (e.g. TRIP database and Health Evidence).

An efficient search would start at the highest level (point-of-care tools if available) and then work down based on the availability of sources and the success of the search. Within each level, the more pre-appraised the material the better. For example, if searching for evidence from a guideline, a guideline that has been rated as high quality by experts would be a better start than a guideline that has not been appraised. Results of single primary studies such as a single randomized controlled trial, cohort, or case–control study should only be used to inform decision-making when no other higher-level sources are available.

Evidence synthesis

An important part of being able to locate pre-appraised evidence for health decision-making is the creation of pre-appraised resources. A key component to this is the methodological approach to synthesizing evidence that has been developed through clinical epidemiology. ‘Evidence synthesis’ refers to the creation of an unbiased summary

of all the available evidence relevant to a specific question. It involves locating all the relevant evidence for a particular question or topic, and using rigorous methods to appraise, synthesize, and present summarized information in a concise, transparent, and accessible way to inform decision-making. Synthesized summaries for clinical reference, guidelines and systematic reviews are important forms of evidence synthesis used in clinical epidemiology and the practice of evidence-based medicine. These are also important sources of pre-appraised information for evidence-based public health

Synthesized summaries for clinical reference

These types of resources are also referred to as point-of-care tools (as they facilitate evidence-based decision-making at the point of care) and online, evidence-driven, clinical textbooks. A large number of these resources are available and examples are listed in Table 5.10.1. While these resources are aimed at clinical decision-making, they also provide summaries of evidence that can be relevant for public health decision-making such as evidence around smoking cessation, diabetes prevention, and vaccine effectiveness.

Ideally, these resources should provide clear descriptions of the processes that are used to locate and appraise the evidence that forms the basis for the summarized information. In addition, there needs to be a clear process of regular updates to the resources as well as the provision of information to users about the recency of the evidence. A recent review of these resources found variation in terms of editorial quality (including items such as disclosure of conflicts of interest and regularity of updates to summaries), evidence-based methodology, and breadth of diseases covered (Kwag et al. 2016). Only three resources received scores in the top quartile across all three domains and these were BMJ Best Practice, DynaMed, and UpToDate.

Guidelines

Clinical practice guidelines (CPGs) are evidence-based statements including recommendations that aim to optimize patient care and guide healthcare decision-making for specific clinical circumstances (National Health and Medical Research Council (NHMRC)). CPGs typically integrate evidence from a number of different systematic reviews to assess the benefits and harms of different management options (AGREE 2018). The CPG development process involves specific methodology including a systematic method of searching for and selecting evidence, involvement of target populations so that their views and preferences can be incorporated, appraisal of the quality of evidence collected, declaration of any conflicts of interest, and clear recommendations for management based on the evidence located.

Although developed specifically for clinical practice, CPGs can also have a public health focus such as guidelines regarding alcohol consumption and dietary recommendations. In addition to CPGs, an increasing number of guidelines are developed specifically for public health and to this end organizations such as the World Health Organization (WHO 2014) and the National Institute for Health and Care Excellence (NICE 2012) have developed manuals outlining the methodological approaches to guideline development for public health decision-making. Both WHO and NICE use the Grading of Recommendations Assessment, Development and Evaluation (GRADE) approach for rating evidence quality.

An important tool for assessing the quality of guidelines is the Appraisal of Guidelines for Research and Evaluation (AGREE) II instrument. AGREE II provides a framework to assess the quality, development and reporting of CPGs and emphasizes the important contribution of systematic reviews in the rigour of CPG development (AGREE 2018). Although developed for appraisal of CPGs, AGREE II is a useful tool for appraising public health guidelines.

Systematic reviews

A systematic review is an evidence synthesis of primary research studies using rigorous and clearly defined methodology. A systematic review aims to collate all empirical evidence that meets pre-specified eligibility criteria, to answer a specific research question. Systematic reviews use explicit, systematic methods to minimize the risk of bias, and aim to provide reliable findings from which conclusions can be drawn and decisions made. There are two organizations, the Cochrane Collaboration (Cochrane) and the Campbell Collaboration that produce high-quality systematic reviews that are useful for evidence-based decision-making.

Cochrane provides an invaluable contribution to the methodological standards and dissemination of systematic reviews. The original focus of Cochrane was on systematic reviews of randomized controlled trials but over recent years the Cochrane Database of Systematic Reviews (CDSR) has expanded to include: intervention reviews

(randomized and non-randomized studies) to assess the benefits and harms of healthcare and health policy interventions; diagnostic test accuracy reviews to assess how well a test diagnoses and detects a particular disease; methodology reviews which assess issues relevant to the conduct and reporting of systematic reviews and clinical trials; qualitative reviews which consider aspects of interventions other than effectiveness; and prognosis reviews which assess the course and future outcomes for people with a particular health outcome. The Cochrane public health and health systems network includes the Cochrane public health review group which focusses on topics that address health and other outcomes at the population level and aim to help government and non-government agencies achieve population-level health, well-being, learning, and social outcomes.

The Campbell Collaboration is a 'sister' organization to Cochrane for the purpose of producing systematic reviews of research evidence on the effectiveness of social interventions. Campbell systematic reviews address the effectiveness of programmes, policies, and practices in the areas of crime and justice, education, international development, and social welfare. In addition to the systematic reviews series, the Campbell Collaboration also includes: the policies and guidelines series; the methods series; and a collection of resources and tools for researchers.

GRADE and assessment of evidence quality

Both systematic reviews and CPGs use the GRADE approach to 'grading' the confidence (or certainty) of evidence. GRADE classifies the quality of evidence for each outcome at one of four levels: high, moderate, low, and very low. In the GRADE approach, the certainty of evidence refers to more than the risk of bias domain (internal validity) of a study. GRADE quality assessment includes consideration of the following five components.:

Study limitations or risk of bias;
Inconsistency of results;
Indirectness of evidence;
Imprecision; and
Other considerations such as publication bias (Guyatt et al. 2008).

Risk of bias

Bias is a kind of systematic error that leads to the results being different from the truth. Risk of bias assessment refers to the process where the risk of bias of a study is assessed in order to judge if the study's results are trustworthy. If there is a systematic difference between the study groups not due to the intervention being studied, the truth may be distorted towards a particular direction. The domains and specific items that are important in terms of risk of bias vary between study types and the type of research question. For example, a cohort study may be used to examine questions of causality (e.g. the link between high blood pressure and stroke) and prognosis (e.g. survival following stroke), but the risks of bias domains are study design/question specific. Epidemiological study types, clinical question types, and examples of tools that can be used to appraise them are provided in Table 5.10.2.

In general, when appraising the risk of bias of primary studies, we need to assess if: (1) the study groups remain comparable to each other throughout the research study (selection bias); (2) the participants are treated equally and their outcomes are measured in the same manner between groups (performance bias and measurement bias); and (3) if there are systematic differences in participant characteristics that can impact on the outcomes, these are taken into account (adjustment for potential confounders). Taking randomized controlled trials (RCTs) as an example, for the study groups to remain equal throughout a RCT, the study should begin with comparable groups by using an appropriate randomization method and ensuring there is allocation concealment to prevent researchers interfering with the randomization process. The groups can then be kept balanced by ensuring that loss to follow-up is minimized throughout the study and by conducting analyses by intention-to-treat, or as randomized, to preserve the effect of the randomization. Blinding is an essential component of RCTs that enables equal treatment of participants during the study and equal outcome measurement regardless of study group allocation. Confounders are factors associated with the outcome that are distributed unevenly between study groups. As randomization should ensure equal distribution of characteristics between study groups, the management of confounding is usually not needed in a RCT.

The approach to risk of bias assessment of systematic reviews, which would be an essential part of guidelines development, is somewhat different to that of primary studies. Some of the key points in assessing risk of bias in systematic reviews are: the comprehensiveness of the search for studies including both published and unpublished research; risk of bias assessment of included primary studies; and appropriate numerical synthesis of included studies (meta-analysis).

An important and common barrier to critical appraisal is that sufficient information may not be reported in the article to allow assessment of the risk of bias. As a result, a number of reporting guidelines have been developed that specify a set of items that authors need to report for each study type to enable risk of bias assessment. These reporting guidelines have also been listed in Table 5.10.2. It is important to note that these guidelines are reporting checklists for authors to use when preparing a manuscript and are frequently mandated by journals. They are not suitable to use as critical appraisal checklists to assess risk of bias.

Inconsistency of results

Within GRADE, confidence is also downgraded in the presence of unexplained inconsistency or heterogeneity in relative effects between studies (Guyatt et al. 2011c). The quality of evidence is rated down if: there is great variation in point estimates between studies; the confidence intervals around these point estimates demonstrate minimal or no overlap; and there is evidence of statistical heterogeneity in the meta-analysis through a significant statistical test for heterogeneity and a large I^2 value. Inconsistency is particularly important when the variability in results would lead to different decisions. For example, it would be important to rate down evidence quality for inconsistency if some studies demonstrated large beneficial effects while other studies demonstrated large harmful effects, and there was no apparent reason for such discordance. In contrast, inconsistency would have less impact on decision-making if the inconsistency observed was quantitative only, when all studies showed benefit but varied regarding the magnitude of the benefit.

Indirectness of evidence

Indirectness refers to the situation where the research that is being summarized in the systematic review or guideline does not directly answer the question we are interested in. This might be because the population or patients included in the study is not the population of interest. For example, studies may have all been conducted on young or middle-aged people whereas the population of interest is older people. Or, for example, in the development of the WHO guideline regarding avian influenza, evidence about the effectiveness of antivirals for avian influenza was rated down as it was based on evidence of the effectiveness of antivirals for seasonal influenza and it is possible that the avian influenza virus may not respond in the same way to antivirals (Schunemann et al. 2007; Guyatt et al. 2011b).

Another potential reason for indirectness concerns the intervention itself. This could include consideration of situations where the same intervention may be implemented differently due to variation in the availability of technical expertise or other resources. The latter is a particularly important consideration for low- and middle-income countries.

A third cause of indirectness is a lack of outcomes that are considered most important to patients, which may include the timing (long term versus short term) or domain (surrogate versus patient reported outcome). For example, in assessing evidence around a health condition like cardiovascular disease, outcomes such as the incidence of myocardial infarction, stroke, and overall mortality would be considered more important and relevant to patients than cholesterol levels.

Imprecision

Assessment of imprecision in GRADE is based on confidence intervals (Guyatt et al. 2011a). However, rather than considering the width of the confidence interval alone in determining whether or not precision is sufficient, the confidence intervals relative to decision-making thresholds are regarded as more important. When the entire confidence interval lies to either side of a threshold, the imprecision has no impact on decision-making as at either extreme of the confidence interval the clinical decision would be the same—to either use or not use the intervention. However, if a confidence interval crosses the treatment threshold it would mean that decisions may be different at either extreme of the confidence interval and as a result, the quality of the evidence would be rated down for imprecision. The impact of confidence intervals on clinical decision-making in relationship to thresholds is shown in Figure 5.10.1. In study 1, the entire confidence interval is to the left of the threshold of clinical importance and therefore is sufficiently precise for decision-making. In study 2, as the confidence interval crosses

the threshold of clinical importance there is a possibility that while the intervention is likely beneficial that the benefit may not be large enough to be clinically important. In this situation, therefore, we would rate down for imprecision. In study 4, even though the confidence interval is quite wide and crosses the line of no effect indicating lack of statistical significance, the entire confidence interval is to the right of the threshold of clinical importance. This means that we are confident that there is no clinically important effect and would not recommend the intervention.

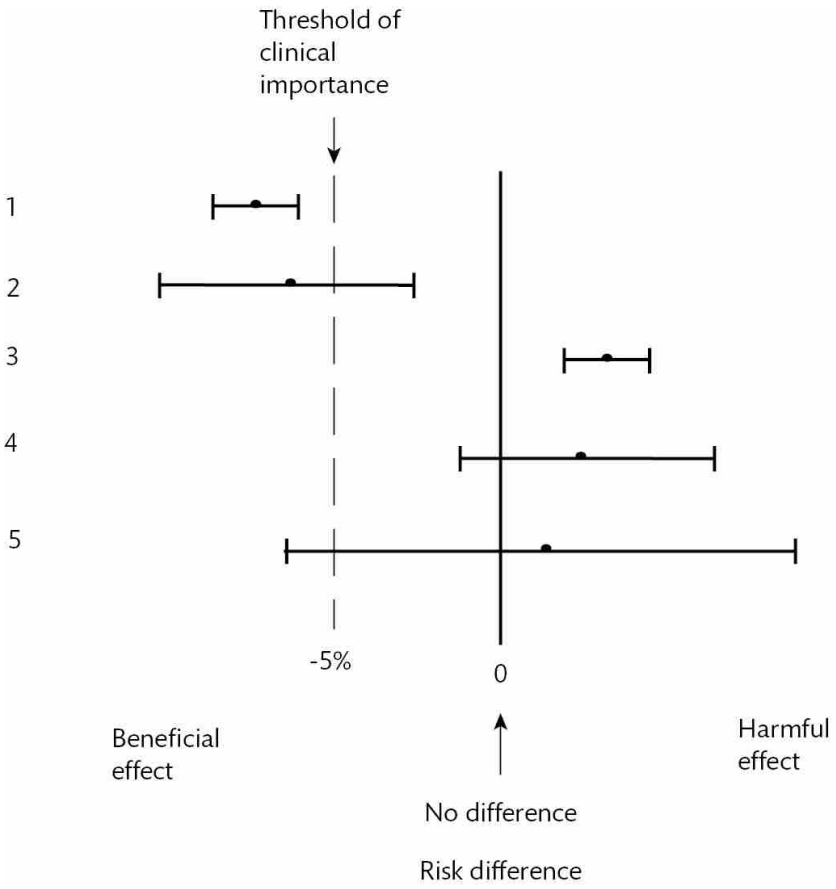

Fig. 5.10.1 Judging precision of confidence intervals in relation to clinically important thresholds
Studies 1 and 3 are sufficiently precise as the entire confidence intervals are to one side of the threshold of clinical importance.
Study 4 is also sufficiently precise as despite lacking statistical significance, the entire confidence interval lies to one side of the threshold of clinical importance.
Studies 2 and 5 are insufficiently precise as the confidence intervals cross the threshold of clinical importance.

Publication bias

Studies that have statistically significant results are more likely to be published than those with non-significant results. Therefore, relying solely on published studies in a systematic review may be misleading (in favour of the intervention) due to such publication bias. In addition, studies with non-significant results that are published are more likely to experience delayed publication which means that an early systematic review of a particular topic may have biased results as the negative results of these later publications will be excluded—a phenomenon described as lag bias (Hopewell et al. 2007). Publication bias can be associated with industry funding as industry sponsored trials may be less likely to publish negative or null results. A high likelihood of publication bias means that the confidence in a body of evidence about a particular topic would be rated down.

Strength of recommendations

Using the GRADE approach, recommendations made in guidelines collapse down into two categories, ‘strong’ or ‘weak’ (also known as conditional). In addition to the confidence in the evidence determined as described earlier, the strength of recommendations also involves consideration of: uncertainty about the balance between benefits and harms associated with an intervention; uncertainty about values and preferences of target populations; and uncertainty about whether the intervention is a wise use of resources (Guyatt et al. 2008; Andrews et al. 2013). The GRADE strength of recommendations are presented in the following four categories:

Strong recommendation against using the intervention
Weak recommendations against using the intervention
Weak recommendation for using the intervention
Strong recommendation for using the intervention.

GRADE and public health guidelines

The GRADE approach is readily applicable to assessment of the quality of evidence in systematic reviews and guidelines developed for public health questions and is being increasingly used in public health guidelines. WHO has adopted the use of GRADE for guidelines and NICE also uses GRADE for determining evidence certainty. However, despite this, there are still some concerns in the public health community about using GRADE (Burford et al. 2012; Rehfuess and Akl 2013). Many of the concerns are to do with the frequent need to use lower levels of evidence in public health decision-making due to the lack of availability and/or lack of feasibility of RCTs. However, it should be noted that although observational studies default to a low-confidence rating, they can be rated up if the size of the effect is large, if there is evidence of a dose-response gradient, and if all the impact of possible confounding is in the direction of reducing the observed effect (Guyatt et al. 2011d). One such example would be rating up the body of evidence from observational studies supporting smoking as a risk factor for lung cancer due to the large size of effect (RR of 5.5 overall and 16.9 for squamous cell carcinoma) and a clear dose-response gradient with greater cancer risk with the amount smoked, duration of smoking, tar level and fraction smoked (Lee et al. 2012). Moreover, many public health questions can be addressed by randomized studies, particularly with the increased use of pragmatic trials and methods such as cluster randomization or stepped wedge design.

Other concerns about the use of GRADE in public health include the importance of taking into consideration other aspects such as cost and the legal implications of particular public health approaches. NICE, although adopting GRADE for assessment of evidence quality, also incorporates the quality of cost-effectiveness studies in the review and uses a different approach for the wording of recommendations (Thornton et al. 2013).

The GRADE working group has taken many of these considerations into account in the development of the GRADE Evidence to Decision (EtD) framework for health system and public health decisions. In this framework, consideration is also given to the priority given to a particular problem, the impact of the proposed option on equity, and the acceptability and feasibility of the proposed public health approach (Moberg et al. 2018).

Research translation

It has been increasingly recognized that the results of medical research are often not translated into patient care, or when they are, it is delayed. For example, as many as 8 years after a large trial demonstrated a 40% reduction in mortality from using beta blockers post myocardial infarction, this treatment was prescribed in only one-third of relevant patients in the United States. It took 20 years from the publication of the study until the rate of prescribing reached high levels and this was only after this was included as a recommendation in guidelines and became part of accreditation standards (Glasziou et al. 2017).

The role of clinical epidemiology methods in evidence synthesis in the form of systematic reviews, meta-analyses, and clinical practice guideline development has been outlined, but alone is not sufficient to change practice. Translating research into individual clinical practice needs to be an active process. Passive uptake of guideline recommendations can be low, even in well-resourced health systems.

As well as failing to use interventions with strong evidence of net benefit in routine clinical care (underuse), overuse of inappropriate healthcare is also common. Overuse refers to the provision of healthcare where the harms to patients outweigh the benefits. For example, in Thailand and China, an estimated 55% of children with acute diarrhoea are reported to receive inappropriate antibiotic prescriptions (Brownlee et al. 2017). As well as non-

evidence-based use of treatments, inappropriate use of diagnostic tests is also very common. For example, in the United States an estimated 36% of patients had a repeat colonoscopy that was not recommended based on guidelines and 40% had inappropriate imaging for low back pain (Brownlee et al. 2017). Research translation is concerned with both the lack of use of effective interventions and tests as well as the use of interventions and tests that are ineffective or unnecessary.

Models of change have been developed to assist the translation of evidence into practice. These models include steps that help integrate theory with interventions to encourage change. The following steps are from a modified version of the model developed by Grol (Grol and Wensing 2004):

Identify and measure an evidence practice gap—it is useful to choose an area of practice that is important clinically, has a good evidence base to support a particular management approach, and where current practice can be easily measured
Conduct a cause analysis to determine reasons for the evidence practice gap—this can be done using tools such as fishbone diagrams or a theoretical domain framework
Choose an intervention aimed at changing practice
Evaluate the effectiveness of the intervention using an appropriate indicator of quality improvement
Sustainability—a plan for sustainability should be incorporated into project planning from the outset as well as how sustainability will be assessed

Optimizing use of health resources

Another area where clinical epidemiology can contribute to the functioning of the health system, is through the interpretation of evidence and, in partnership with health economists, optimization of resource use. Critical evaluation of trial data and meta-analytical techniques form the backbone of decision-making for health technology agencies. Some additional techniques used in this context include network meta-analysis (Lumley 2002) (to estimate the relative efficacy of more than two treatments to determine which intervention is likely to be the best), and a ‘linked evidence approach’ to assessing diagnostic tests (Merlin et al. 2013).

Evaluation reports from health technology agencies not only provide local guidance, but also form a rich resource for other health systems considering adoption of new medicines. These include reports from the Food and Drug Administration in the United States (McDonagh et al. 2013), the European Medicines Agency (European Medicines Agency 2018), the National Institute for Health and Care Excellence in the United Kingdom (National Institute for Health and Care Excellence UK), and the Medicare Benefits Schedule and Pharmaceutical Benefits Scheme in Australia (Pharmaceutical Benefits Scheme 2018).

Applying evidence to individual patients

As well as contributing to system wide approaches to optimizing health resource use, clinical epidemiology methods may optimize resource use through providing clinicians with skills to tailor management decisions according to the circumstances of individual patients. This process has been variously called applicability and transferability of evidence, individualizing therapy, precision medicine, and stratified care. The importance of this approach comes from an understanding that even when there is strong evidence from a trial or meta-analysis of trials that a treatment on average produces a net benefit, there may not be a net beneficial effect from the treatment in every patient in the trial(s) or in every patient in clinical practice (Glasziou and Irwig 1995). Traditionally, it has been common to use the inclusion and exclusion criteria of a trial to decide whether or not an intervention will have a net benefit in a patient. However, these inclusion and exclusion criteria for trials are primarily based upon separate considerations such as improving the power of a study to detect an effect and to maximize safety. There will be patients who meet inclusion criteria for the trial who would not receive a net benefit from the intervention and there will be those who do not meet inclusion criteria who would receive a net benefit.

A more appropriate approach to determining which patients should receive particular interventions is a risk-benefit model approach. This process has several steps which are:

Listing all of the benefits and harms of the intervention
Determining if there is any heterogeneity or effect modification of the relative treatment effect and/or harms
Considering the impact of baseline risk on absolute benefits and harms
Weighing up benefits and harms taking into consideration patient values

In the first step, a list of all patient-relevant outcomes that the intervention will have an impact on should be generated. Evidence about efficacy should come from a systematic review of RCTs. However, it may be necessary to use a cohort study or systematic review of cohort studies to obtain sufficient data about harms.

In the second step, it is important to consider if there are subgroups of patients or particular settings in which the treatment might work differently to the estimate of effect given in the systematic review or RCT. This difference in effect can occur not only for the benefits of an intervention but also for the harms. One important cause of effect modification is socio-economic status which can be a source of variability in observed treatment effects due to resource constraints acting at the individual and/or community level. This variation in treatment effects and harms by patient subgroups will impact on the trade-off between benefits and harms.

The next consideration is the impact of baseline risk on the benefit to harm trade-off. An important part of this step is understanding the difference between relative and absolute measures of effect. Relative risks tend to be less dependent upon baseline risk and so are commonly the measure of effect reported in clinical trials. However, the risk difference which refers to the absolute difference in incidence between groups is more useful for determining benefit to harm trade-off as illustrated in Figure 5.10.2. This figure demonstrates how the baseline risk of disease determines the size of the absolute difference given a stable relative risk. This means that if harms are constant, in those patients with a high baseline risk of disease the benefit to harm trade-off will be greater. Therefore, focussing therapy on this high-risk group would result in both better patient care and more efficient use of resources, at an individual and group level.

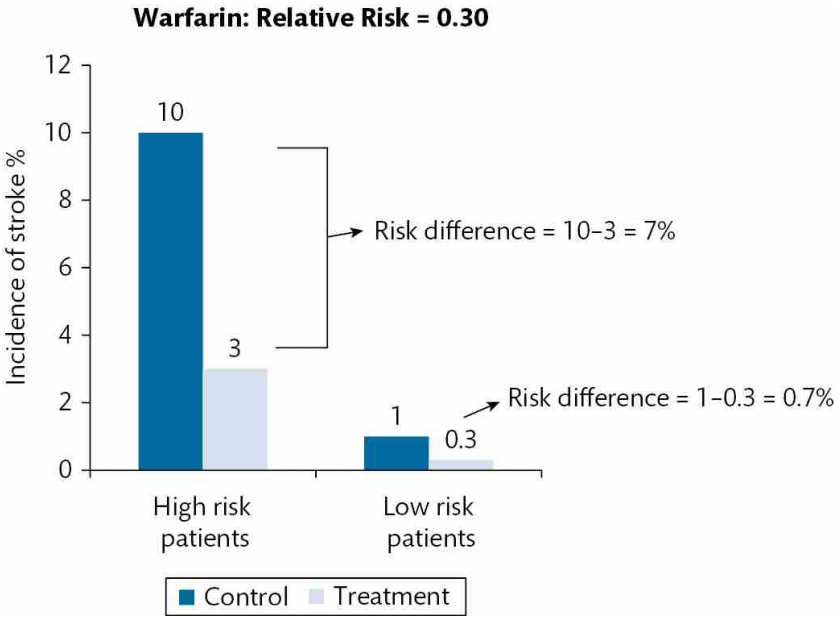

Fig. 5.10.2 Change in absolute risk difference by baseline risk.

This approach of estimating total or absolute risk of disease and tailoring management strategies accordingly is incorporated in many guidelines, such as the current WHO guidelines for cardiovascular disease (WHO 2007). It has been estimated that targeting high-risk individuals in low- and middle-income countries with evidence-based interventions to prevent cardiovascular disease could avert 17.9 million deaths from cardiovascular disease over 10 years (Lim et al. 2007).

An essential part of a risk-benefit model approach to individualizing healthcare is having access to evidence-based information that allows clinicians to estimate absolute risk. A key part of this process is the development of valid prognostic models (variously referred to by other names including prognostic index, prediction rule, risk, or clinical prediction model and predictive model). These models can be turned into scoring systems or 'risk calculator' tools that are increasingly web-based and allow clinicians to estimate a patient's absolute risk of a particular disease or outcome based on a number of predictive clinical features and test results.

Methodological standards in prognosis research studies have lagged behind those of other areas such as RCTs and to this end the PROGnosis RESearch Strategy (PROGRESS) partnership has proposed a framework for

research themes in prognosis research as well as guidance in terms of methodology. There are three main phases essential to development of prognostic models which include: development of the model, external validation of the model (ideally in a different setting), and assessment of the impact of using the model on clinical practice. Unfortunately, it is very common for only the first step to be carried out. The importance of external validation in other settings is emphasized by a study examining the performance of four commonly used cardiovascular risk prediction models in Malaysia where the performance of one of the models was found to be poor (Selvarajah et al. 2014).

The final step of the process considers the values of individual patients as they consider potential benefits and harms. This is an essential step given existing evidence for substantial variation in patient preferences for particular treatment approaches and the varying importance placed on particular benefits and harms. For example, in a systematic review of patient preferences regarding antithrombotic therapy, included studies found substantial variation in how study participants considered the trade-off between benefits such as stroke prevention and the harm of bleeding. There was also variability in the decisions patients made when provided with evidence about the benefits and harms of treatment options (MacLean et al. 2012).

Applying evidence to individual settings

The approach used to optimize the care of individual patients by considering benefit to harm trade-off can readily be adapted to how public health evidence can be applied to different settings. Benefits and harms of implementing a public health intervention could be considered at the country level where, in addition to benefits and harms related to the outcomes of the specific intervention, the impact on resource use also needs consideration given the constraint of fixed resources and opportunity cost. Assessing the likelihood of effect modification of the effectiveness of an intervention is a critical consideration, particularly in low- and middle-income countries. There is potential for variation in benefits and harms due to population characteristics such as socio-economic status and nutrition as well as potential variation in effectiveness due to staff training and availability and differences in infrastructure. In terms of baseline risk, rather than considering the baseline risk of an individual patient, the prevalence of disease in a particular country would provide a firm basis for determining the absolute benefit for the country in terms of health improvement that would be gained from the intervention. In the presence of a constant relative measure of effectiveness, a country with a high burden of disease will stand to receive a greater absolute benefit from an intervention targeting this disease. Finally, different values in a particular country or setting could impact on the importance placed on the potential benefits and harms of a given public health intervention, thereby influencing the benefit to harm trade-off.

Many of these ideas are covered in the GRADE EtD framework discussed in the section ‘GRADE and public health guidelines’ in this chapter. For example, the priority given to a public health problem would be closely tied to the burden of disease. Considering the impact of the proposal on equity and considering the feasibility of the public health intervention would be considering the potential for variability in effectiveness or effect modification of the intervention. And considering the acceptability of the public health approach would involve considering the values of the population including how these impact on the benefit to harm trade-off.

Evaluation of the health system

Clinical epidemiology methods can contribute to improved health system design. As well as optimization of resource allocation, they are also useful in health system evaluation. Analogous to methods in evaluating effectiveness of treatments for individuals, these same methods can be extended to assess system wide interventions. These methods are also frequently used in the assessment of many public health interventions that due to their complexity and breadth of focus can be difficult to evaluate using the traditional randomized controlled trial approach.

Cluster RCTs

There are situations where a health system may wish to evaluate or randomize interventions on a work unit basis (by ‘clusters’ such as clinic, area health service or school), but also measure outcomes based on individual participant/patient outcome. These cluster RCTs may be the study design of choice because (1) the intervention applies to the entire cluster (e.g. whole-school health promotion programmes), or (2) the intervention is likely to ‘overflow’ or ‘contaminate’ non-intervention units (e.g. an educational intervention for handwashing may affect

this behaviour in both the targeted health workers, as well as their colleagues who were not allocated to the intervention). An important consideration for cluster RCTs is that individual participant outcomes are likely to be correlated within each cluster. For example, patients attending the same clinic may have more similar health outcomes than patients across different clinics. This needs to be taken into account for in the planning and analysis of the study, and there are established statistical methods for doing so (Hemming et al. 2017). Protopopoff et al. is an example where the cluster randomized controlled trial design was used to evaluate insecticidal nets and indoor residual spraying, randomized to Tanzanian villages as clusters, with childhood malaria as the outcome measure (Protopopoff et al. 2018).

Stepped wedge design

One variation to the cluster randomized trial is the stepped wedge cluster randomized trial design. This is a useful design when a health system has already decided to roll out an intervention programme, but for pragmatic reasons may only be able to roll out at one site/cluster at a time. This presents an opportunity to collect evaluation data. The stepped wedge design involves collecting outcome data at regular intervals (steps) for all clusters, starting to do so before any of the clusters has started on the intervention programme. Then at each subsequent 'step', a cluster is randomly assigned to commence on the intervention programme, thus adding a cluster at each step until all clusters are in the intervention programme. Analysis for stepped wedge cluster randomized trials is complex but good introductions are available (Hemming et al. 2015). Betran et al. is an example where the stepped wedge design was used to evaluate whether provision of medical supply kits improved quality of antenatal care, across 10 antenatal care clinics in Mozambique (Betran et al. 2018).

Population screening

Population screening is defined as offering a test to all individuals in a target group in the population (e.g. a mammogram every two years, for all women aged 50–74 years) to identify people with pre-symptomatic, early disease, and offer early intervention. Recommendations for screening should be based on RCT evidence demonstrating that offering such early intervention improves outcomes (Barratt et al. 1999). The RCT design avoids two common biases that can occur in observational studies of screening: lead-time bias and length-time bias. Lead-time bias refers to the apparent longer survival of patients identified through screening due to their identification at an earlier point in their disease with a resulting longer period of follow-up. Length-time bias refers to the bias that arises due to the greater propensity of screening to identify slowly progressive disease, which will be associated with better survival. In addition to potential benefits in terms of prolonged life and improved quality of life, screening can also be associated with harms including complications from investigations, adverse effects of treatments, and psychological harms. Another harm of screening, both at the individual and population level, is the potential for overdiagnosis. This refers to the identification of disease that is inconsequential and would not have resulted in any harm if left untreated. Randomized controlled trial data may also help indicate the possibility of overdiagnosis in the screening setting (Moynihan et al. 2012).

Challenges in low- and middle-income country settings

In this final section, some key challenges faced in terms of using the methodological approaches highlighted in this chapter are discussed along with current strategies being used to alleviate them.

Access to evidence

An important barrier to the efficient location of research evidence in low- and middle-income settings is poor access to such evidence. This is the result of a combination of infrastructure issues around the availability of reliable internet and electricity supply in addition to reduced availability of evidence sources that are subscription based. Hinari is a programme established by the WHO that provides low- and middle-income countries (LMICs) with access to a large number of journals, ebooks, and information resources including sources of synthesized evidence such as the Cochrane Library. Hinari facilitates either full or partial access to over 250 publishers to more than 5,000 different institutions in LMICs. There are also a number of freely available sites that provide synthesized evidence for policy makers such as SUPPORT summaries that provide policy makers with structured summaries of systematic reviews of ways to organize, finance, and govern the delivery of healthcare interventions

in LMIC settings and PDQ-Evidence that provides systematic reviews, syntheses of reviews, evidence-based policy briefs, primary studies, and structured summaries.

Research capacity building

Training in clinical epidemiology provides clinicians and clinical researchers with the skills they need to effectively use and produce high-quality evidence to guide clinical decision-making. As illustrated in this chapter, training in clinical epidemiological skills also provides public health practitioners with important skills and approaches that can be used in evidence-based public health decision-making. Improving research capacity within a country or region not only increases the volume and quality of research produced but can also facilitate the setting of research priorities that are driven by local rather than global priorities.

One important strategy to strengthen capacity in clinical epidemiology and research training in LMICs has been the establishment of the International Clinical Epidemiology Network (INCLEN) in 1982. This network has established Clinical Epidemiology Units (CEUs) and Clinical Epidemiology Research Training Centres (CERTCs) in 89 academic institutions across 39 countries. The aim of the network has been to develop and upskill patient-orientated researchers and clinician investigators, enabling them to undertake high-quality clinical research. INCLEN scholars in CEUs received training in the fields of Clinical Epidemiology, Biostatistics, Health Social Sciences, and Health Economics. Initial training was conducted at established clinical epidemiology training centres such as McMaster University in Canada, the University of Pennsylvania, and University of North Carolina in the United States, and the University of Newcastle in Australia. However, many of the originally established CEUs have now gone on to become training centres themselves. These units and centres have played a vital role in strengthening clinical research capacity, the creation of a network of researchers, and increased research output including the development of CPGs.

The Cochrane and Campbell Collaborations also have a major focus on improving capacity in LMICs. Both have established a large network of skilled researchers and centres for producing high-quality systematic reviews that can be used to support and mentor researchers in LMICs. The Cochrane effective practice and organization of care (EPOC), equity, and public health groups are all quite involved in capacity building of LMIC researchers. For example, the Norwegian satellite of EPOC provides support to Cochrane authors in LMICs in the form of training stipends for review authors and the provision of support and instruction from the editorial team throughout the systematic review process. This satellite also helps build the capacity of policy makers to appropriately interpret research evidence for decision-making

Indirectness of evidence and transferability of guidelines

At the present time, the majority of research evidence continues to be produced in high income settings and not all of the results will be readily applicable to LMICs. As the guideline development process is both time consuming and resource intensive, a more efficient approach would be to adapt existing guidelines to different settings. The GRADE EtD framework provides a good basis for understanding what additional pieces of evidence would be required to ensure an evidence-based adaptation process. This would include burden of disease studies that are essential for priority setting, cost-effectiveness data to quantify the impact on health resources, pilot study data examining issues of feasibility and an understanding of values in terms of the importance of particular benefits and harms.

Owalabi et al. (2016) provides a useful example of how cardiovascular disease recommendations can be adapted for LMICs by presenting both an implementation cycle and translatable scale that is a useful approach to ranking recommendations according to how readily they may be implemented according to considerations of cost and personnel.

Conclusion

Based on methods developed within public health, clinical epidemiology has extended these methods into new areas aimed at improving both the use of evidence in clinical decision-making and the production of high-quality evidence. Despite the clinical focus of clinical epidemiology, many of the methods are of value to public health decision-making and are being increasingly adopted by public health professionals.

Validity and bias in epidemiological research

Sander Greenland and Tyler J. VanderWeele

Introduction to validity and bias in epidemiological research

Some of the major concepts of validity and bias in epidemiological research are outlined in this chapter. The contents are organized in four main sections: validity in statistical interpretation, validity in prediction problems, validity in causal inference, and special validity problems in case–control and retrospective cohort studies. Familiarity with the basics of epidemiological study design and a number of terms of epidemiological theory, among them risk, competing risks, average risk, population at risk, and rate, is assumed. A number of textbooks provide more background and depth than can be given here; see, for example, Kelsey et al. (1996), Koepsell and Weiss (2003), Checkoway et al. (2004), and Rothman et al. (2008).

Despite similarities, there is considerable diversity and conflict among the classification schemes and terminologies employed in various textbooks. This diversity reflects that there is no unique way of classifying validity conditions, biases, and errors. It follows that the classification schemes employed here and elsewhere should not be regarded as anything more than convenient frameworks for organizing discussions of validity and bias in epidemiological inference. Many types of bias can be qualitatively illustrated with causal diagrams, which reveal the relationships among confounding and selection bias; for example, see Greenland et al. (1999), Cole and Hermán (2002), Hernán et al. (2004), Glymour and Greenland (2008), and Pearl (2009).

Several important study designs, including randomized trials, prevalence (cross-sectional) studies, and ecological studies, are not discussed in this chapter. Such studies require consideration of the validity conditions

mentioned earlier and also require special considerations of their own. Further details of these and other designs can be found in the general textbooks cited in the preceding paragraphs. For discussions of the problems of ecological studies, see Greenland (2001, 2002a, 2004a) and Morgenstern (2008). Meta-analytic methods are discussed by Eddy et al. (1992), Greenland and O'Rourke (2008), and Borenstein et al. (2009). A number of central problems of epidemiological inference are also not covered, including choice of effect measures, problems of induction, and causal modelling. For critical discussions of effect measures by the present authors, see Greenland et al. (1986, 1991, 1999), Greenland (1987, 1999, 2002b), Greenland and Robins (1988), Rothman et al. (2008, chapter 4), and VanderWeele (2012). Greenland (1998a, 1998b) and Rothman et al. (2008, chapter 2) discuss problems of inductive and probabilistic inference, Greenland and Brumback (2002) review causal modelling in epidemiology, and Rothman et al. (2008, chapter 2) discuss broader issues in causal inference and philosophy.

Among the deeper problems not discussed here are the failure of conventional statistical methods to account for non-random sources of uncertainty, and the tendency of people (including scientists) to make overconfident and biased inferences in the face of uncertainty (Gilovich et al. 2002). Analytical approaches to these problems are discussed by Eddy et al. (1992), Greenland (2005), Greenland and Lash (2008), and Lash et al. (2009, 2014).

Inference and validity

Epidemiological inference is the process of drawing inferences from epidemiological data, such as prediction of disease patterns or identification of causes of diseases or epidemics. These inferences must often be made without the benefits of direct experimental evidence or established theory about disease aetiology. Consider the problem of predicting the risk and incubation (induction) time for acquired immunodeficiency syndrome (AIDS) among persons infected with type 1 human immunodeficiency virus (HIV-1). Unlike an experiment, in which the exposure is administered by the investigator, the date of HIV-1 infection cannot be accurately estimated in most cases; furthermore, the mechanism by which 'silent' HIV-1

infection progresses to AIDS is not known with certainty. Nevertheless, some prediction must be made from the available data if one is to prepare effectively for future healthcare needs.

As another example, consider the problem of estimating how much excess risk of coronary heart disease (if any) is produced by coffee drinking. Unlike an experimental exposure, coffee drinking is self-selected; it appears that persons who drink coffee are more likely to smoke than non-drinkers and probably tend to differ in many other behaviours as well (Greenland 1993). As a result, even if coffee use is harmless, we should not expect to observe the same pattern of heart disease in users and non-users. Thus, small effects of coffee drinking are very difficult to disentangle from the effects of other behaviours. Nevertheless, because of the high prevalence of coffee use and the high incidence of heart disease, any effect of coffee on heart disease risk may be of considerable public health importance.

In both these examples, and in general, inferences will depend on evaluating the validity of the available studies; that is, the degree to which the studies meet basic logical criteria for absence of bias. When (as is usually the case) aspects of validity cannot be guaranteed by successful design strategies, such as blinded random assignment (which ensures that baseline non-comparability is random), we must evaluate the magnitude of bias that would arise from plausible violations of validity conditions.

Because biases due to misinterpretation of statistics are often neglected in textbooks yet pervade the health-sciences literature, the next subsection will describe common misinterpretations to be alert for when examining reports or analysing data. The remaining subsections will outline and illustrate major concepts of validity and bias in epidemiological research as applied in three settings: prediction from one population to another, causal inference from cohort studies, and causal inference from case–control and retrospective cohort studies. Parallel aspects of each application will be emphasized. In particular, each problem requires the consideration of comparison bias (better known as confounding), follow-up bias (i.e. loss-to-follow-up or censoring bias), bias due to mismeasurement, bias due to erroneous statistical models, and bias due to erroneous statistical interpretation. (The term ‘bias’ is, here, used in the informal epidemiological sense, and corresponds to the formal statistical concept of inconsistency.) Case–control studies require the additional consideration of

case-selection bias and control-selection bias, and are often subject to additional sources of measurement error beyond those occurring in prospective cohort studies. Similar problems arise in retrospective cohort studies.

Misinterpretations of statistics

Severe consequences can arise from failure to properly interpret statistical outputs, and failure to recognize when the output is the result of a statistical method breaking down. Unfortunately, few textbooks discuss these problems in detail, even though they can result in inferential errors as severe as those from the more familiar biases discussed in the following subsections.

Two problems very common in the health-sciences literature are briefly described here. Both problems as well as many others can be avoided with certain Bayesian statistical approaches. Detailed arguments for Bayesian approaches can be found in Berger and Berry (1988), Greenland (1998b, 2006), and Thomas et al. (2007). For an introduction to Bayesian methods that can be carried out with ordinary software, see Greenland (2007) and Sullivan and Greenland (2013). The remainder of this subsection concerns only conventional 'frequentist' methods of significance tests, confidence intervals (CIs), *p*-values, and model fitting.

Misinterpretations of statistical significance

Many authors have noted that significance testing is very difficult to interpret correctly, so difficult that otherwise expert epidemiologists and even statisticians routinely make dramatic mistakes (Altman et al. 2000; Greenland 2004b, 2011, 2012a; Greenland and Poole 2011). Perhaps the largest source of misreporting and misjudgement in the scientific literature, however, is the simple confusion of presence or absence of an association with presence or absence of statistical significance (Altman and Bland 1995; Rothman et al. 2008, chapter 10; Greenland 2011). A common consequence of this confusion is the mistaken reporting of non-significant results as 'confirming' the null, when in reality the results are completely ambiguous. For example, a study that results in 95% confidence limits for a

relative risk (RR) of 0.80 and 2.0 is non-significant. Even if perfectly valid, however, it would not support the null hypothesis any more than it would support the hypothesis that the true RR is 1.5 (a 50% increase in risk). Misinterpreting non-significant results as null is easily avoided by paying attention to the confidence limits (Rothman 1978; Altman et al. 2000; Poole, 2001; Rothman et al. 2008, chapter 10). The limits of 0.80 and 2.0 show that the results are not 'significantly' different at the 0.05 level from any RR between 0.80 and 2.0. Unfortunately, mistaken claims that non-significant results support the null hypothesis of no association still pervade the field, especially in important policy and legal applications of statistics to epidemiology (Greenland 2004b, 2011, 2012a; Greenland and Poole 2011).

A converse misinterpretation is to say that two groups showed different results because they had different statistical significance. As an example, one article abstract (Park et al. 2007) reported that an inverse association with colorectal cancer was 'seen for total vitamin D intake in men (RR = 0.72, 95% CI: 0.51, 1.00; *p* for trend = 0.03) but not in women' (the estimate compares the highest quintile of vitamin D intake to the lowest). Examination of table 3 of the paper reveals, however, that the corresponding RR for women was 0.89 with 95% confidence limits of 0.63 and 1.27, which means that the association for women was in fact inverse, just as in men (0.89 = 11% lower risk in the highest quintile than in the lowest). Although it was not significantly different at the 0.05 level from 1 (the null), it was also not significantly different from the RR of 0.72 seen for men; nor was it significantly different from any RR from 0.63 to 1.27. One way to summarize these results would have been to state that an inverse association was observed in both men and women, but that it was weaker and non-significant for women. An even better interpretation is that the study had too few subjects to detect whether men and women actually differ with respect to the relation of vitamin D to colorectal cancer. Such honest reports of study weaknesses are not common, however. This issue is especially problematic in the interpretation of subgroup analyses in randomized trials (Rothwell 2005; Wang et al. 2007).

An opposite misinterpretation of the one just illustrated is to claim that two results are not significantly different because their confidence intervals overlap. It is true that they will not be significantly different if the interval from either group contains the point estimate from the other group (as in the preceding example, in which the men's point estimate of 0.72 falls within

the women's limits of 0.63 and 1.27), and that the two groups will be significantly different if their confidence intervals do not overlap. Nonetheless, if the intervals overlap but neither interval contains both point estimates, one cannot determine significance without conducting a direct test of the difference in results.

Misinterpretations such as just described arise in part from the conventional use of a cut-off value such as 0.05 to declare presence or absence of significance, and the corresponding use of 95% to determine the width of a confidence interval (which is just the collection of all values that are not significant at the 0.05 level). In reality, there is a continuum of degrees of significance, as measured by the *p*-value ('significance level'), and any cut-off value is both arbitrary and distortive (Rothman et al. 2008, chapter 10). Thus, some authors have encouraged a movement away from classifying associations 'significant' or 'non-significant', towards presenting instead the actual *p*-value for the tested hypothesis and for other values of interest (see Poole 1987a, 1987b; Goodman 1993; Greenland and Poole 2013a, 2013b).

Even if one presents *p*-values, however, the complexities and subtleties of determining and interpreting significance become even worse when multiple tests are involved (the 'multiple comparisons' problem). Here, adjustments for the multiplicity of tests can worsen certain problems even as they address others, for example, by worsening power even as it protects the validity (alpha level) of the tests. They may also shift the null hypothesis being tested to one that, if understood, might be seen as irrelevant to the scientific question at hand. For a discussion of these issues and further references, see Rothman et al. (2008, chapter 10) and Greenland and Poole (2011). Many of these problems can be avoided by shifting to a multilevel (hierarchical) approach for the analysis (Greenland 2000a, 2000b).

Sparse-data bias

Most epidemiological studies collect data on so many variables that any thorough stratification (tabulation) of the data on those variables will result in 'sparse data', in which many if not most cell counts may be very small. Classical epidemiological methods such as standardization break down in the face of this sparsity. Although modelling was developed to address

problems of sparse data, it is not a sure fix. Conventional methods for fitting risk and rate models such as maximum likelihood (ML), weighted least squares, and generalized estimating equations are ‘large-sample’ (asymptotic) techniques, meaning that they have sample-size requirements for valid performance. In the context of say logistic regression (the most common method in epidemiology), this means that among other things there are sufficient numbers of cases and non-cases observed at all levels of categorical variables in the model.

A serious problem is that when there are too few cases or non-cases in a given category a coefficient estimate based on that category may ‘blow up’, taking on a value that is much too large in absolute magnitude. This problem can arise in both unconditional and conditional logistic regression (Greenland et al. 2000). In a similar fashion, certain estimates may become inflated when there are too many variables in the model relative to the number of cases and non-cases. This hazard is especially severe when the data are divided into subgroups for separate analysis, for example, separating men and women instead of modelling effects with a variable for gender, or when ‘interaction’ (product) terms are used in the model. In almost all reports, the inflated estimates if ‘statistically significant’ are misinterpreted as representing strong effects rather than being recognized as statistical artefacts.

To spot these problems, investigators should check tables of the variables in the model against the outcome, and beware of estimates obtained when the observed numbers in each category fall below 4 or 5, or when the ratios of the number of cases and non-cases to the number of variables in the model fall below 4 or 5. Various methods for shrinkage estimation (including random-coefficient, hierarchical, multilevel, ridge, penalized, and Bayesian regression) can be used as an alternative to collapsing categories or deleting variables from the model to avoid sparse-data bias (Greenland 2000b, 2007; Sullivan and Greenland 2013).

Validity and bias in prediction problems

Turning now to more traditional topics, the following prediction problem will be used to illustrate several basic concepts of validity. A health clinic for homosexual men is about to begin enrolling HIV-l-negative men in an

unrestricted programme that will involve retesting each participant for HIV-1 antibodies at 6-month intervals. We can expect that, in the course of the programme, many participants will seroconvert to positive HIV-1 status. Such participants will invariably ask difficult questions, such as: What are my chances of developing AIDS over the next 5 years? How many years do I have before I develop AIDS? In attempting to answer these questions, it will be convenient to refer to such participants (i.e. those who seroconvert) as the target cohort. Even though membership of this cohort is not determined in advance, it will be the target of our predictions. It will also be convenient to refer to the time from HIV-1 infection until the onset of clinical AIDS as the AIDS incubation time. We could provide reasonable answers to a participant's questions if we could accurately predict AIDS incubation times, although we would also have to estimate the time elapsed between infection and the first positive test.

There might be someone who responds to the questions posed here with the following anecdote: 'I've known several men just like the ones in this cohort, and they all developed AIDS within 5 years after a positive HIV-1 test.' No trained scientist would conclude from this anecdote that all or most of the target cohort will develop AIDS within 5 years of seroconversion. Of course, one reason is that the men in the anecdote cannot be 'just like' men in our cohort in every respect: they may have been older or younger when they were infected; they may have experienced a greater degree of stress following their infection; they may have been heavier smokers, drinkers, or drug users; and so on. In other words, we know that the anecdotal men and their post-infection life events could not have been exactly the same as the men in our target cohort with respect to all factors that affect AIDS incubation time, including measured, unmeasured, and unknown factors. Furthermore, it may be that some or all of the men referred to in the anecdote had been infected long before they were first tested, so that (unlike men in our target cohort) the time from their first positive test to AIDS onset was much shorter than the time from seroconversion to AIDS onset.

Any reasonable predictions must be based on observing the distribution of AIDS incubation times in another cohort. Suppose that we obtain data from a study of homosexual men who underwent regular HIV-1 testing, and we then assemble from these data a study cohort of men who were observed to seroconvert. Suppose also that most of these men were followed for at

least 5 years after seroconversion. We cannot expect any member of this study to be ‘just like’ any member of our target cohort in every respect. Nevertheless, if we could identify no differences between the two cohorts with respect to factors that affect incubation time, we might argue that the study cohort could serve as a point of reference for predicting incubation times in the target cohort. Thus, we shall henceforth refer to the study cohort as our reference cohort.

Note that our reference and target cohorts may have originated from different populations; for example, the clinic generating the target cohort could be in New York, but the study that generated the reference cohort may have been in San Francisco. Of course, for both the target and reference cohorts, the actual times of HIV-1 infection will have to be imputed, based on the dates of the last negative and the first positive tests.

Suppose that our statistical analysis of data from the reference cohort produces estimates of 0.05, 0.25, and 0.45 for the average risk of contracting AIDS within 2, 5, and 8 years of HIV-1 infection. What conditions would be sufficient to guarantee the validity of these figures as estimates or predictions of the proportion of the target cohort that would develop AIDS within 2, 5, and 8 years of infection? If by ‘valid’ we mean that any discrepancy between our predictions and the true target proportions is unbiased or purely random (unpredictable in principle), the following conditions would be sufficient:

Comparison validity—the distribution of incubation times in the target cohort will be approximately the same as the distribution in the reference cohort.
Follow-up validity—within the reference cohort, the risk of censoring (i.e. follow-up ended by an event other than AIDS) is not associated with risk of AIDS.
Measurement validity—all measurements of variables used in the analysis closely approximate the true values of the variables. In particular, each imputed time of HIV-1 infection closely approximates the true infection time, and each reported time of AIDS onset closely approximates a clinical event defined as AIDS onset.
Specification validity—the distribution of incubation times in the reference cohort can be closely approximated by the statistical model used to compute the estimates. For example, if one employs a lognormal distribution to model the distribution of incubation times in the reference cohort, this model should be approximately correct.

The first condition concerns the external validity of making predictions about the target cohort based on the reference cohort. The remaining conditions concern the internal validity of the predictions as estimates of average risk in the reference cohort. The following subsections will explore the meaning of these conditions in prediction problems.

Comparison validity

Comparison validity is probably the easiest condition to describe, although it is difficult to evaluate. Intuitively, it simply means that the distribution of incubation times in the target cohort could be almost perfectly predicted from the distribution of incubation times in the reference cohort, if the incubation times were observed without error and there was no loss to follow-up. Other ways of stating this condition are that the two cohorts are comparable or exchangeable with respect to incubation times, or that the AIDS experience of the target cohort can be predicted from the experience of the reference cohort.

Confounding

If the two cohorts are not comparable, some or all of our risk estimates for the target cohort based on the reference cohort will be biased as a result. This bias is sometimes called *confounding*. There has been much research on methods for identifying and adjusting for such bias; see the textbooks cited earlier.

To evaluate comparison validity, we must investigate whether the two cohorts differ on any factors that influence incubation time. If so, we cannot reasonably expect the incubation time distributions of the two cohorts to be comparable. A factor responsible for some or all of the confounding in an estimate is called a confounder or confounding variable, the estimate is said to be confounded by the factor, and the factor is said to confound the estimate.

To illustrate these concepts, suppose that men infected at younger ages tend to have longer incubation times and that the members of the reference cohort are on average younger than members of the target cohort. If there were no other differences to counterbalance this age difference, we should then expect that members of the reference cohort will on average have longer incubation times than members of the target cohort. Consequently, unadjusted predictions of risk for the target cohort derived from the reference cohort would be biased (confounded) by age in a downward direction. In other words, age would be a confounder for estimating risk in the target cohort, and confounding by age would result in underestimation of the proportion of men in the target cohort who will develop AIDS within 5 years.

Now suppose that we can compute the age at infection of men in the reference cohort, and that within 1-year strata of age, for instance, the target and reference cohorts had virtually identical distributions of incubation times. The age-specific estimates of risk derived from the reference cohort would then be free of age confounding and so could be used as unconfounded estimates of age-specific risk for men in the target cohort. Also, if we wished to construct unconfounded estimates of average risk in the entire target cohort, we could do so via the technique of age standardization.

To illustrate, let Px denote our estimate of the average risk of AIDS within 5 years of infection among members of the reference cohort who become infected at age x. Let Wx denote the proportion of men in the target cohort who are infected at age x. Then the estimated average risk of AIDS

within 5 years of infection, standardized to the target cohort's age distribution, is simply the average of the age-specific reference estimates *Px* weighted by the age distribution (at infection) of the target cohort; algebraically, this average is the sum of the products *WxPx* over all ages and is denoted by *ΣxWxPx*. Considered as an estimate of the overall proportion of the target cohort that will contract AIDS within 5 years of HIV-1 infection, the standardized proportion *ΣxWxPx* will be free of age confounding.

The preceding illustration brings forth an important and often overlooked point: when one employs standardization to adjust for potential biases, the choice of standard distribution should never be considered arbitrary. In fact, the standard distribution should always be taken from the target cohort or the population about which inferences will be made. If inferences are to be made about several different groups, it may be necessary to compute several different standardized estimates.

Methods for removing bias in estimates by taking account of variables responsible for some or all of the bias are known as adjustment or covariate control methods. Standardization is perhaps the oldest and simplest example of such a method; methods based on multivariate models are more complex. See also Cole and Stuart (2010) for an alternative approach to such adjustment using weighting.

Unmeasured confounders

If all confounders were measured accurately, comparison validity could be achieved simply by adjusting for these confounders (although various technical problems might arise when attempting to do so). Nevertheless, in any non-randomized study, we would ordinarily be able to think of a number of possible confounders that had not been measured or had been measured only in a very poor fashion. In such cases, it may still be possible to predict the direction of uncontrolled confounding by examining the manner in which persons were selected into the target and reference cohorts from the population at large. If the cohorts are derived from populations with different distributions of predictors of the outcome, or the predictors themselves are associated with admission differentially across the cohorts, these predictors will become confounders in the analysis.

To illustrate this approach, suppose that HIV-1 infection via an intravenous route (e.g. through needle sharing) leads to shorter incubation times than HIV-1 infection through sexual activity. Suppose also that the reference cohort had excluded all or most intravenous drug users, whereas the target cohort was non-selective in this regard. Then incubation times in the target cohort will on average be shorter than times in the reference cohort owing to the presence of intravenously infected persons in the target cohort. Thus we should expect the results from the reference cohort to underestimate average risks of AIDS onset in the target cohort.

Random sampling and confounding

Suppose, for the moment, that our reference cohort had been formed by taking a random sample of the target cohort. Can predictions about the target made from such a random sample still be confounded? With the definition of confounding given here, the answer is yes. To see this, note for example that by chance alone men in our sample reference cohort could be younger on average than the total target; this age difference would in turn downwardly bias the unadjusted risk predictions if men had longer incubation times at younger ages.

Nevertheless, random sampling can help to ensure that the distribution of the reference cohort is not too far from the distribution of the target cohort. In essence, the probability of severe confounding can be made as small as necessary by increasing the sample size. Furthermore, if random sampling is used, any confounding left after adjustment will be accounted for by the standard errors of the estimates, provided that the correct statistical model is used to compute the estimates and standard errors. We shall examine the latter condition under the subsection on specification validity.

Follow-up validity

In any cohort study covering an extended period of risk, subjects will be followed for different lengths of time. Some subjects will be lost to follow-up before the study ends. Others will be removed from the study by an event that precludes AIDS onset, which in this setting is death before AIDS onset from fatal accidents, fatal myocardial infarctions, and so on. Because subjects come under study at different times, those who are not lost to

follow-up or who die before developing AIDS will still have had different lengths of follow-up when the study ends; traditionally, a subject still under follow-up at the end of study is said to have been ‘withdrawn from study’ at this time.

Suppose that we wish to estimate the average risk of AIDS onset within 5 years of infection. The data from a member of the reference cohort who is not observed to develop AIDS but is also not followed for the full 5 years from infection are said to be censored for the outcome of interest (AIDS within 5 years of infection). Consider, for example, a subject killed in a car crash 2 years after infection but before contracting AIDS: the incubation time of this subject was censored at 2 years of follow-up.

Follow-up validity means that over any span of follow-up time, risk of censoring is unassociated with risk of the outcome of interest. In our example, follow-up validity means that over any span of time following infection, risk of censoring (loss, withdrawal, or death before AIDS) is unassociated with risk of AIDS. All common methods for estimating risk from situations in which censoring occurs (e.g. person-years, life table, and Kaplan–Meier methods) are based on the assumption of follow-up validity. Given follow-up validity, we can expect that, at any time *t* after infection, the distribution of incubation times will be the same for subjects lost or withdrawn at *t* and for subjects whose follow-up continues beyond *t*.

Violations of follow-up validity can result in biased estimates of risk; such violations are referred to as follow-up bias or biased censoring. To illustrate, suppose that younger reference subjects tend to have longer incubation times (i.e. lower risks) and are lost to follow-up at a higher rate than older reference subjects. In other words, lower-risk subjects are lost at a higher rate than higher-risk subjects. Then, after enough time, the average risk of AIDS in the observed portion of the reference cohort will tend to be overestimated; that is, higher than the average risk occurring in the full reference cohort (as the latter includes both censored and uncensored subject experience).

The follow-up bias in the last illustration would not affect the age-specific estimates of risk (where age refers to age at infection). Consequently, the age bias in follow-up would not produce bias in age-standardized estimates of risk. More generally, if follow-up bias can be traced to a particular variable that is a predictor of both the outcome of interest and censoring, bias in the estimates can be removed by adjusting for

that variable. Thus, some forms of follow-up bias can be dealt with in the same manner as confounding.

Measurement validity

An estimate from a study can be said to have measurement validity if it suffers from no bias due to errors in measuring the study variables. Unfortunately, there are sources of measurement error in nearly all epidemiological studies, and nearly all sources of measurement error will contribute to bias in estimates. Thus, evaluation of measurement validity primarily focuses on identifying sources of measurement error and attempting to deduce the direction and magnitude of bias produced by these sources.

To aid in the task of identifying sources of measurement error, it can be useful to classify such errors according to their source. Errors from specific sources can then be further classified according to characteristics that are predictive of the direction of the bias they produce. One classification scheme divides errors into three major categories, according to their source:

Procedural error: arising from mistakes or defects in measurement procedures
Proxy-variable error: arising from using a 'proxy' variable as a substitute for an actual variable of interest
Construct error: arising from ambiguities in the definition of the variables.

Regardless of their source, errors can be divided into two basic types, differential and non-differential, according to whether the direction or magnitude of error depends on the true values of the study variables. Two different sources of error may be classified as dependent or independent, according to whether or not the direction or magnitude of the error from one source depends on the direction or magnitude of the error from the other source. Finally, errors in continuous measurements can be factored into systematic and random components. As described in the following subsections, these classifications have important implications for bias.

Procedural error

Procedural error is the most straightforward to imagine. It includes errors in recall when variables are measured through retrospective interview (e.g. mistakes in remembering all medications taken during pregnancy). It also includes coding errors, errors in calibration of instruments, and all other errors in which the target of measurement is well defined and the attempts at measurement are direct but the method of measurement is faulty. In our example, one target of measurement is HIV-1 antibody presence in blood. All available tests for antibody presence are subject to error (false negatives and false positives), and these errors can be considered to be procedural errors of measurement.

Proxy-variable error

Proxy-variable error is distinguished from procedural error in that use of proxies necessitates imputation and hence virtually guarantees that there will be measurement error. In our example, we must impute the time of HIV-1 infection. For instance, we might take as a proxy the infection time computed as 6 weeks before the midpoint between the last negative test and the first positive test for HIV-1 antibodies. Even if our HIV-1 tests are perfect, this measurement incorporates error if (as is certainly the case) time of infection does not always occur 6 weeks before the midpoint between the last negative and first positive tests.

Construct error

Construct error is often overlooked, although it may be a major source of error. Consider our example in which the ultimate target of measurement is the time between HIV-1 infection and onset of AIDS. Before attempting to measure this time span, we must unambiguously define the events that mark the beginning and end of the span. While it may be reasonable to think of HIV-1 infection as a point event, the same cannot be said of AIDS onset. Symptoms and signs may gradually accumulate, and then it is only by convention that some point in time is declared the start of the disease. If this convention cannot be translated into reasonably precise clinical criteria for diagnosing the onset of AIDS, the construct of incubation time (the time span between infection and AIDS onset) will not be well defined let alone accurately measurable. In such situations, it may be left to various clinicians

to improvise answers to the question of time of AIDS onset, and this will introduce another source of extraneous variation into the final 'measurement' of incubation time.

Differential and non-differential error

Errors in measuring a variable are said to be differential when the direction or magnitude of the errors tend to vary across the true values of other variables. Suppose, for example, that recall of drug use during pregnancy is enhanced among mothers of children with birth defects. Then, a retrospective interview about drug use during pregnancy will yield results with differential error, as false-negative error will occur more frequently among mothers whose children have no birth defects.

Another type of differential error occurs in the measurement of continuous variables when the distribution of errors varies with the true value of the variable. Suppose, for example, that women more accurately recall the date of a recent cervical smear (Papanicolaou) test than the date of a more distant test. Then, a retrospective interview to determine length of time since a woman's last cervical smear test would tend to suffer from larger errors when measuring longer times.

Errors in measuring a variable are said to be non-differential with respect to another variable if the magnitudes of errors do not tend to vary with the true values of the other variable. Measurements are usually assumed to be non-differential if neither the subject nor the person taking the measurement knows the values of other variables. For example, if drug use during pregnancy is measured by examining pre-partum prescription records for the mother, it would ordinarily be assumed that the error will be non-differential with respect to birth defects discovered postnatally. Nevertheless, such 'blind' assessments will not guarantee non-differential error if the measurement scale is not as fine as the scale of the original variable (Flegal et al. 1991; Wacholder et al. 1991) or if there is a third uncontrolled variable that affects both the measurement and the other study variables.

Dependent and independent error

Errors in measuring two variables are said to be dependent if the direction or magnitude of the errors made in measuring one of the variables is associated with the direction or magnitude of the errors made in measuring the other variable, conditional on the true variables. If there is no such association of errors, the errors are said to be independent.

In our example, errors in measuring age at HIV-1 infection and AIDS incubation time are dependent. Our measure of incubation time is equal to our measure of age at AIDS onset minus our measure of age at infection; hence, overestimation of age at infection will contribute to underestimation of incubation time, and underestimation of age at infection will contribute to overestimation of incubation time. In contrast, in the same example, it is plausible that the errors in measuring age at infection and age at onset are independent.

Systematic and random components of error

For well-defined measurement procedures on continuous variables, measurement errors can be subdivided into systematic and random components. The systematic component (sometimes called the bias of the measurement) measures the degree to which the procedure tends to underestimate or overestimate the true value on repeated application. The random component is the residual error left after subtracting the systematic component from the total error.

To illustrate, suppose that in our study HIV-1 infection time was unrelated to time of antibody testing and that the average time of HIV-1 seroconversion was 8 weeks after infection. Then, even if one used a perfect HIV-1 test, a procedure that estimated infection time as 6 weeks before the midpoint between the last negative and first positive test would on average yield an estimated infection time that was 2 weeks later than the true time. Thus, the systematic component of the error of this procedure would be +2 weeks. Because AIDS incubation time is AIDS onset time minus HIV-1 infection time, use of this procedure would add –2 weeks (i.e. a 2-week underestimation) to the systematic component of error in estimating incubation time.

Each of the components of an error, systematic and random, may be differential (i.e. may vary with other variable values) or non-differential, and may or may not be independent of the error components in other

variables. We shall not explore the consequences of the numerous possibilities. However, one important (but semantically confusing) fact is that, for certain quantities, independent and non-differential systematic components of error will not harm measurement validity in that they will produce no bias in estimation (Poole 1985).

To illustrate, suppose that in our example we wish to estimate the degree to which AIDS incubation time depends on age at HIV-1 infection. Suppose also that the systematic components of the measurements of incubation time and age of infection are –2 weeks and +2 weeks (as mentioned), and do not vary with true incubation time or age at measurement (i.e. the systematic components are non-differential). Then, the systematic components, being equal, will cancel out when we compute differences in incubation time and differences in age at infection. Because only these differences are used to estimate the association, the observed dependence of incubation time on age at infection will not be affected by the systematic components of error (although it may be biased by the random components of error).

Specification validity

All statistical techniques, including so-called ‘distribution-free’ or ‘non-parametric’ methods as well as basic contingency table methods, are derived by assuming the validity of a sampling model or error distribution. A common example is the binomial model, which is discussed in all the textbooks cited in the introduction. For parametric methods, the sampling model is a mathematical formula that expresses the probability of observing the various possible data patterns as a function of certain unknown constants (parameters). Although the parameters of this model may be unknown, the mathematical form of this model incorporates only known or purely random aspects of the data-generation process; unknown systematic aspects of this process (such as most follow-up and selection biases) will not be accounted for by the model.

All parametric statistical techniques also assume a structural model, which is a mathematical formula that expresses the parameters of the sampling model as a function of study variables. A common example is the logistic model (Kelsey et al. 1996; Hosmer and Lemeshow 2000; Checkoway et al. 2004; Jewell 2004; Greenland 2008a, 2008b). The structural model is most often incorporated into the sampling model, and

the combination is referred to as the statistical model. An estimate can be said to have specification validity if it is derived using a statistical model that is correct or nearly so.

If either the sampling model or the structural model used for analysis is incorrect, the resulting estimates may be biased. Such bias is sometimes called specification bias, and the use of an incorrect model is known as model misspecification or specification error. Even when misspecification does not lead to bias, it can lead to invalidity of statistical tests and confidence intervals.

The true structural relation among the study variables is almost never known in studies of human disease. Furthermore, in the absence of random sampling and randomization, the true sampling process (i.e. the exact process leading people to enter and stay in the study groups) will also be unknown. It follows that we should ordinarily expect some degree of specification error in an epidemiological analysis. Minimizing such error largely consists of contrasting the statistical model against the data and against any available information about the processes that generated the data, such as prior information on demographic patterns of incidence.

Many statistical techniques in epidemiology are based on assuming some type of logistic model. Examples include all the popular adjusted odds ratios, such as the Woolf, ML, and Mantel–Haenszel estimates, as well as tests for odds ratio heterogeneity. Classical ‘indirect’ adjustment of rates and other comparisons of standardized morbidity ratios depend on similar multiplicative models for their validity (Breslow and Day 1987; VanderWeele and Vansteelandt 2010).

The degree of bias in traditional epidemiological analysis methods when the model assumptions fail has not been extensively studied. A few traditional methods, such as directly standardized comparisons and the Mantel–Haenszel test, remain valid under a wide variety of structural models. In addition, risk regression has been extended to situations involving more general models than assumed in classical theory (Breslow and Day 1987; Hastie and Tibshirani 1990). Leamer (1978) and White (1993) give more details on the effects of specification error in multiple regression problems, and Maldonado and Greenland (1994) and Greenland and Maldonado (1994) examine the implications of specification error in epidemiology.

Summary of prediction example

The example in this subsection provides an illustration of the most common threats to the validity of predictions. The unadjusted estimates of AIDS risk may be confounded if the target and reference cohorts differ in composition, and may also be biased by losses to follow-up or use of an incorrect statistical model. Finally, our predictions are likely to be compromised by errors in measurements. These sources of error should be borne in mind in any attempt to predict AIDS incidence.

Validity and bias in causal inference

All the bias problems in prediction arise in studies of causation; confounding, follow-up bias, measurement errors, and specification errors must be considered. In fact, as we shall see, problems of causal inference can be viewed as a special type of prediction problem, namely prediction of what would happen (or what would have happened) to a population if certain characteristics of the population were (or had been) altered (Greenland 2012b).

To illustrate the validity issues in causal inference, we shall consider the hypothesis that coffee drinking causes acute myocardial infarction. This hypothesis can be operationally interpreted in a number of ways, such as:

There are people for whom the consumption of coffee results in their experiencing a myocardial infarction sooner than they might have, had they avoided coffee.

Although this hypothesis is appealingly precise, it offers little practical guidance to an epidemiological researcher. The problem lies in our inability to recognize an individual whose myocardial infarction was caused by coffee drinking. It is quite possible that myocardial infarctions precipitated by coffee use are clinically and pathologically indistinguishable from myocardial infarctions due to other causes. If so, the prospect of testing this hypothesis with purely physiological evidence is not good.

We could overcome this impasse by examining a related epidemiological hypothesis; that is, a hypothesis that refers to the distribution of disease in populations. One of many such hypotheses is:

Among five-cup-a-day coffee drinkers, cessation of coffee use will lower the frequency of myocardial infarction.

This form not only involves a population (five-cup-a-day coffee drinkers) but also asserts that a mass action (coffee cessation) will reduce the frequency of the study disease. Thus, the form of the hypothesis immediately suggests a strong test of the hypothesis: conduct a randomized intervention trial to examine the impact of coffee cessation on myocardial infarction frequency. This solution has some profound practical limitations, not least of which would be persuading anyone to give up or take up coffee drinking to test a speculative hypothesis.

Having ruled out intervention, we might consider an observational cohort study. In this case, our epidemiological hypothesis must refer to natural conditions, rather than intervention. One such hypothesis is:

Among five-cup-a-day coffee drinkers, coffee use has elevated the frequency of myocardial infarction.

There have been many conflicting cohort and case–control studies of coffee and myocardial infarction. The present discussion will be confined to the issues arising in the analysis of a single study. For a review of issues arising in the analysis of multiple studies (meta-analysis) see Greenland (1994) and Greenland and O'Rourke (2008).

Consider a cohort study of coffee and first myocardial infarction. At baseline, a cohort of people with no history of myocardial infarction is assembled and classified into subcohorts according to coffee use (e.g.

never-drinkers, ex-drinkers, occasional drinkers, one-cup-a-day drinkers, two-cup-a-day drinkers, etc.). Other variables are measured as well: age, gender, smoking habits, blood pressure, and serum cholesterol. Suppose that at the end of 10 years of monitoring this cohort for myocardial infarction events, we compare the five-cup-a-day and never-drinker subcohorts, and obtain an unadjusted estimate of 1.22 for the ratio of the person-time incidence rates of first myocardial infarction among five-cup-a-day drinkers and never-drinkers (with 95% CIs of 1.00 and 1.49). In other words, it appears that the rate of first myocardial infarction among five-cup-a-day drinkers was 1.22 times higher than the rate among never-drinkers. (Hereafter, myocardial infarction means first myocardial infarction, risk means average risk, and rate means person-time incidence rate.)

The estimated rate ratio of 1.22 may not seem large. Nevertheless, if it accurately reflects the impact of coffee use on the five-cup-a-day subcohort, this estimate implies that persons drinking five cups a day at baseline suffered a 22% increase in their myocardial infarction rate as a result of their coffee use. Given the high frequency of both coffee use and myocardial infarction in many populations, this could represent a substantial health impact. Therefore, we would want to perform a careful evaluation of possible bias in the estimate.

As in the AIDS example, we can proceed by examining a series of conditions sufficient for validity of the estimate as a measure of the effect of coffee:

Comparison validity (no confounding)—if the members of the five-cup-a-day subcohort had instead never drunk coffee, their distribution of myocardial infarction events over time would have been approximately the same as the distribution among the never-drinkers.
Follow-up validity—within each subcohort, the risk of censoring (i.e. follow-up ended by an event other than myocardial infarction) is not associated with the risk of myocardial infarction.
Measurement validity—all measurements of variables used in the analysis closely approximate the true values of the variables.
Specification validity—the distribution of myocardial infarction events over time in the subcohorts can be closely approximated by the statistical model on which the estimates are based.

These four conditions are sometimes called *internal validity conditions* because they pertain only to estimating effects within the study cohort rather than to generalizing results to other cohorts. They are sufficient but not necessary for validity, in that certain violations of the conditions will not produce bias in the effect estimate (although most violations will produce some bias).

The meaning of these conditions for an observational cohort study of a causal hypothesis is explored in the following subsections. An important phenomenon known as *effect modification*, which is relevant to both internal validity and generalizability, will also be discussed following comparison validity.

Comparison validity

In our example, comparison validity means that the distribution of myocardial infarctions among never-drinkers accurately predicts what would have happened in the coffee drinking groups had the members of these groups never drunk coffee. Another way of stating condition C is that the five-cup-a-day and never-drinker subcohorts would be comparable or exchangeable with respect to myocardial infarction times if no one had ever drunk coffee, or that there is no confounding (Greenland et al. 1991; Rothman et al. 2008, chapter 4).

Despite its simplicity, comparison validity depends on the hypothesis of interest in a very precise way. In particular, the research hypothesis (hypothesis 3 in the preceding subsection) is a statement about the impact of coffee among five-cup-a-day drinkers. Thus, this subcohort is the target cohort, and never-drinkers serve as the reference cohort for making predictions about this target.

To illustrate further the correspondence between comparison validity and the hypothesis at issue, suppose for the moment that our research hypothesis was:

> 4. Among never-drinkers, five-cup-a-day coffee use would elevate the frequency of myocardial infarction.

In examining this hypothesis, the never-drinkers would be the target cohort and the coffee drinkers would be the reference cohort. Thus, the comparison validity condition would have to be replaced by a condition such as

(C') If the never-drinkers had drunk five cups of coffee per day, their distribution of myocardial infarctions would have been approximately the same as the distribution among five-cup-a-day drinkers.

Other ways of stating condition C' are that the five-cup-a-day and never-drinker subcohorts would be comparable or exchangeable with respect to time to myocardial infarction if everyone had been five-cup-a-day drinkers, and that the myocardial infarction experience of five-cup-a-day drinkers accurately predicts what would have happened to the never-drinkers if the latter had drunk five cups a day.

Confounding

Failure to meet condition C results in a biased estimate of the effect of five-cup-a-day coffee drinking on five-cup-a-day drinkers, a condition sometimes referred to as confounding of the estimate. Similarly, failure to meet condition C' results in a biased estimate of the effect that five-cup-a-day drinking would have had on never-drinkers.

To evaluate potential confounding, we must check whether the subcohorts differed at baseline on any factors that influence time to myocardial infarction. If so, we could not reasonably expect the myocardial infarction distributions of the subcohorts to be comparable, even if the subcohorts had the same level of coffee use. In other words, we could not expect condition C (or C') to hold, and so we should expect our estimates to suffer from confounding. This is so, regardless of whether adjustment appears to change the association of coffee use and myocardial infarction (Greenland et al. 1999).

Some studies have found a positive association between cigarette smoking (an established risk factor for myocardial infarction) and coffee use (Greenland 1993). It also seems a priori sensible that a person habituated to a stimulant such as nicotine would be attracted to coffee use as well. Thus, we should expect to see a higher prevalence of smoking among coffee users in our study.

Suppose then that, in our cohort, smoking is more prevalent among five-cup-a-day subjects than never-drinkers. This elevated smoking prevalence should have led to elevated myocardial infarction rates among five-cup-a-day drinkers, even if coffee had no effect. More generally, we should expect the myocardial infarction rate among never-drinkers to underestimate the

myocardial infarction rate that five-cup-a-day drinkers would have had if they had never drunk coffee. The result would be an inflated estimate of the impact of coffee on the myocardial infarction rate of five-cup-a-day drinkers. Similarly, we should expect the myocardial infarction rate among five-cup-a-day drinkers to overestimate the myocardial infarction rate that never-drinkers would have had if they had drunk five cups a day.

Adjustment for measured confounders

As in the prediction problem, we can stratify the data on potential confounders with the objective of creating strata within which confounding is minimal or absent. We can also employ standardization to remove confounding from estimates of overall effect. Again, some care in the selection of the standard is required.

To illustrate, let R_{xz} denote the estimated rate of myocardial infarction among cohort members who drank x cups of coffee per day and smoked z cigarettes per day at baseline, with R_{0z} denoting the estimated rate among never-drinkers. Let W_{xz} denote the proportion of person-time among x-cup-per-day drinkers that was contributed by z-cigarette-per-day smokers. Finally, let R_{xc} be the unadjusted rate observed among cohort members who drank x cups per day at baseline, with R_{0c} denoting the estimated unadjusted rate among never-drinkers.

Suppose for the moment that any change in coffee-use patterns would have negligible impact on the person-time distribution of smoking in the cohort. The predicted (i.e. expected) rate among five-cup-a-day drinkers had they never drunk coffee, adjusted for confounding by smoking, is the average of the smoking-specific estimates from the never-drinker (reference) subcohort weighted by the smoking distribution of the five-cup-per-day (target) cohort. Algebraically, this average is the following sum (over z):

This sum is commonly termed the rate in the never-drinkers standardized to the distribution of smoking among five-cup-a-day drinkers. Such

terminology obscures the fact that the sum is a prediction about the five-cup-a-day drinkers, not the never-drinkers.

Given the last computation, a smoking-standardized estimate of the increase in myocardial infarction rate produced by coffee drinking among five-cup-per-day drinkers is the rate ratio standardized to the five-cup-per-day smoking distribution:

$$\sum_z W_{5z} R_{5z} / \sum_z W_{5z} R_{0z},$$

This formula reveals a property common to a simple standardized rate ratio: the same weights W_{xz} must be used in the numerator and denominator sums. Some insight into this formula can be obtained by noting that the unadjusted rate R_{5c}, among the five-cup-a-day drinkers, is equal to:

$$\sum_z W_{5z} R_{5z},$$

so that the standardized rate ratio can be rewritten as:

$$R_c \sum_z W_{5z} R_{0z} / \sum_z W_{5z} R_{0z},$$

This version shows that the ratio is a classical observed unadjusted rate over the rate expected without exposure, or standardized morbidity ratio (SMR). Another standardized rate ratio is:

$$\sum_z W_{0z} R_{5z} / \sum_z W_{0z} R_{0z},$$

This differs from the previous standardized ratio in that the weights are taken from the never-drinkers (W_{0z}) instead of five-cup-a-day drinkers (W_{5z}). Insight into this formula can be obtained by noting that the numerator sum is simply a prediction (expectation) of what would have happened to the never-drinkers if they had been five-cup-a-day drinkers, and the denominator sum is equal to the unadjusted rate R_{0c}, among never-drinkers. Thus, the last standardized ratio is a smoking-standardized estimate of the

increase in the myocardial infarction rate that five-cup-a-day drinking would have produced among the never-drinkers.

Standardization is appealingly simple in both justification and computation. Unfortunately, if the number of cases occurring within the confounder categories tends to be small (under five or so), the technique will be subject to various technical problems including possible bias. These problems can be avoided by broadening confounder categories or by not adjusting for some of the measured confounders. Unfortunately, both these strategies are likely to result in incomplete control of confounding. To avoid having to adopt these strategies, many researchers attempt to control confounding by using a multivariate model. This remedy has problems of its own, some of which we shall address in the subsection on specification validity.

Another problem is that standardized procedures (as well as typical modelling procedures) take no account of potential exposure effects on the adjustment variables or their distribution. Thus, in the preceding example, to justify use of the fixed weights W_{xz} we had to invoke the dubious assumption that changes in coffee use would only negligibly affect the smoking distribution. We shall briefly discuss this issue in the subsection on intermediate variables.

Unmeasured confounders

Among the possible confounders not measured in our hypothetical study are diet and exercise. Suppose that ‘health conscious’ subjects who exercise regularly and eat low-fat diets also avoid coffee. The result will be a concentration of these lower-risk subjects among coffee non-users and a consequent overestimation of coffee’s effect on risk.

Confounding by unmeasured confounders can sometimes be minimized by controlling variables along the pathways of their effect. For example, if exercise and a low-fat diet lowered myocardial infarction risk only by lowering serum cholesterol and blood pressure, control of serum cholesterol and blood pressure would remove confounding by exercise and dietary fat. Unfortunately, such control may also generate bias if the controlled variables are intermediates between our study variable and our outcome variable.

If external information is available to indicate the relationship in our study between an unmeasured confounder and the study variables, we can attempt to use an indirect method to adjust for the confounder; even if external information is unreliable or unavailable, we can examine the sensitivity of our results to unmeasured confounders (Greenland and Lash 2008; VanderWeele and Arah 2011). Sometimes we can also predict the direction of the bias resulting from confounding (VanderWeele 2008; VanderWeele et al. 2008). Finally, we can evaluate the impact that uncertainty about unmeasured confounders should have on our final inferences about the effect (Greenland and Lash 2008; Lash et al. 2009).

Randomization and confounding

Suppose, for the moment, that the level of coffee use in our cohort had been assigned by randomization and that the participants diligently consumed only their assigned amount of coffee. Could our estimates of coffee effects from such a randomized trial still be confounded? By our earlier definition of confounding, the answer is yes. To see this, note for example that by chance alone the five-cup-a-day drinkers could be older on average than the never-drinkers; this difference would in turn result in an upward bias in the unadjusted estimate of the effect of five cups a day, because age is an important risk factor for myocardial infarction.

Nevertheless, randomization can help to ensure that the distributions of confounders in the different exposure groups are not too far apart. In essence, the probability of severe confounding can be made as small as necessary by increasing the size of the randomized groups. Furthermore, if randomization is used and subjects comply with their assigned treatments, any confounding left after adjustment will be accounted for by the standard errors of the estimates, provided that the correct statistical model is used to compute the effect estimates and their standard errors (Robins 1988; Greenland 1990).

Intermediate variables

In effect estimation, we must take care to distinguish intermediate variables from confounding variables. Intermediate variables represent steps in the causal pathway from the study exposure to the outcome event. The

distinction is essential, for control of intermediate variables can increase the bias of estimates.

To illustrate, suppose that coffee use affects serum cholesterol levels (as suggested by the results of Curb et al. 1986). Then, given that serum cholesterol affects myocardial infarction risk, serum cholesterol is an intermediate variable for the study of the effects of coffee on this risk. Now suppose that we stratify our cohort data on serum cholesterol levels. Some coffee drinkers will be in elevated cholesterol categories because of coffee use and so will have an elevated risk of myocardial infarction, yet these subjects will be compared with never-drinkers in the same stratum who are also at elevated risk due to their elevated cholesterol. Therefore, the effect of coffee on the risk of myocardial infarction via the cholesterol pathway will not be apparent within the cholesterol strata, and so cholesterol adjustment will contribute to underestimation of the effect of coffee on risk of myocardial infarction. Analogously, if coffee affected the risk of myocardial infarction by elevating blood pressure, blood pressure adjustment will contribute to underestimation of the effect of coffee. Such underestimation can be termed overadjustment bias.

Intermediate variables may also be confounders and thus present the investigator with a severe dilemma. Consider that most of the variation in serum cholesterol levels is not due to coffee use and that much (perhaps most) of the association between coffee use and cholesterol is not due to the effects of coffee, but rather to factors associated with both coffee and cholesterol (such as exercise and dietary fat). This means that serum cholesterol may also be viewed as a confounder for the coffee–myocardial infarction study and that estimates unadjusted for serum cholesterol will be biased unless they are also adjusted for the factors contributing to the coffee–cholesterol association.

Suppose that a variable is both an intermediate and a confounder. It will usually be impossible to determine how much of the change in the effect estimate produced by adjusting for the variable is due to introduction of overadjustment bias and how much is due to removal of confounding. Nevertheless, a qualitative assessment may be possible in some situations. For example, if we know that the effects of coffee on serum cholesterol are weak and that most of the association between coffee and serum cholesterol is due to confounding of this association by uncontrolled factors (such as exercise and diet), we can conclude that the cholesterol-adjusted estimate is

probably the less biased of the two. Alternatively, if we have accurately measured all the factors that confound the coffee–cholesterol association, we can control these factors instead of cholesterol to obtain an estimate free of both overadjustment bias and confounding by cholesterol. Finally, if we have multiple measurements of coffee use and cholesterol over time, techniques are available that adjust for the confounding effects of cholesterol but do not introduce overadjustment (Hernán et al. 2000; Robins et al. 2000).

Direct and indirect effects

Often, one may wish to estimate how much of the effect under study is indirect relative to an intermediate variable (in the sense of being transmitted through the intermediate), or how much of the effect is direct relative to the intermediate (i.e. not mediated by the intermediate). For example, we might wish to estimate how much of the effect of coffee on myocardial infarction risk is due to its effect on serum cholesterol, or how much is due to the effects of coffee on cardiovascular variables other than cholesterol.

One common approach to this problem is to adjust the coffee–myocardial infarction association for serum cholesterol level via ordinary stratification or regression methods and then use the resulting estimate as the estimate of the direct effect of coffee. This procedure is potentially biased as it may introduce new confounding by determinants of serum cholesterol, even if these determinants did not confound the total (unadjusted) association (Robins and Greenland 1992, 1994; Cole and Hermán 2002; Glymour and Greenland 2008). Nonetheless, given sufficient data, it is possible to obtain separate estimates for direct and indirect effects using special stratification or modelling techniques (Robins and Greenland 1994; Kaufman et al. 2005; Vansteelandt 2012; Valeri and VanderWeele 2013), but again these techniques make much stronger assumptions than those for total effects. These assumptions can be assessed to a certain extent using sensitivity analysis (VanderWeele 2010).

Effect modification (heterogeneity of effect)

Estimation of effects usually requires consideration of effect-measure modification, which is also known as effect modification, effect variation, or heterogeneity of effect. As an example, suppose that drinking five cups of coffee a day elevated the myocardial infarction rate of men in our cohort by a factor of 1.40 (i.e. a 40% increase), but elevated the myocardial infarction rate of women by a factor of only 1.10 (i.e. a 10% increase). This situation would be termed modification (or variation or heterogeneity) of the rate ratio by gender, and gender would be called a modifier of the coffee–myocardial infarction rate ratio.

As another example, suppose that drinking five cups of coffee a day elevated the myocardial infarction rate in men in our cohort by a factor of 400 cases per 100,000 person-years but elevated the rate in women by a factor of only 40 cases per 100,000 person-years. This situation would be termed modification of the rate difference by gender, and gender would be called a modifier of the coffee–myocardial infarction rate difference.

As a final example, suppose that drinking five cups of coffee per day elevated the myocardial infarction rate in our cohort by a factor of 1.22 in both men and women. This situation would be termed homogeneity of the rate ratios across gender.

Effect modification and homogeneity are not absolute properties of an effect, but instead are properties of the way that the effect is measured. For example, suppose that drinking five cups of coffee per day elevated the myocardial infarction rate in men from 1,000 cases per 100,000 person-years to 1,220 cases per 100,000 person-years, but elevated the rate in women from 400 cases per 100,000 person-years to 488 cases per 100,000 person-years. Then the gender-specific rate ratios would both be 1.22, homogeneous across gender. In contrast, the gender-specific rate differences would be 220 cases per 100,000 person-years for males and 88 cases per 100,000 person-years for females, and so are heterogeneous or ‘modified’ by gender. Examples such as this one show that one should not equate effect modification with biological concepts of interaction such as synergy or antagonism (Greenland and O’Rourke 2008; VanderWeele 2009).

Effect modification can be analysed by stratifying the data on the potential effect modifier under study, estimating the effect within each stratum, and comparing the estimates across strata. There are several potential problems with this approach. The number of subjects in each stratum may be too small to produce stable estimates of stratum-specific

effects, particularly after adjustment for confounder effects. Estimates may fluctuate wildly from stratum to stratum owing to random error. A related problem is that statistical tests for heterogeneity in stratified data have extremely low power in many situations, and therefore are likely to miss much if not most of the heterogeneity when used with conventional significance levels (such as 0.05). Finally, the amount of bias from confounding, loss to follow-up, measurement error, and other sources may vary from stratum to stratum, in which case the observed pattern of modification will be biased.

Effect modification and generalizability

Suppose that we succeed in obtaining approximately unbiased (internally valid) estimates from our study. We can then confront the issues of generalizability (external validity) of our results. For example, we can ask whether they accurately reflect the effect of coffee on myocardial infarction rates in a new target cohort. We can view such a question as a prediction problem in which the objective is to predict the strength of the effects of coffee in the new target cohort. From this perspective, generalizability of an effect estimate involves just one additional validity issue, namely confounding of the predicted effect by effect modifiers.

Suppose that the rate increase (in cases per 100,000 person-years) produced by coffee use is 400 for males and 40 for females among five-cup-a-day drinkers in both our study cohort and the new target. If our study cohort is 70% male, while the new target is only 30% male, the average increase among five-cup-a-day drinkers in our study cohort would be $0.7 \times 400 + 0.3 \times 40 = 292$, whereas the average increase in the new target would be only $0.3 \times 400 + 0.7 \times 40 = 148$. Thus, any valid estimate of the average increase in our study cohort will tend to overestimate greatly the average increase in the new target. In other words, modification of the effect of coffee by gender confounds the prediction of its effect in the new target. This bias can be avoided by making only gender-specific predictions of effect or by standardizing the study results to the gender distribution of the new target population.

Follow-up validity

In our example, follow-up validity means that follow-up is valid within every subcohort being compared. In other words, over any span of time during follow-up, risk of myocardial infarction within a subcohort is unassociated with censoring risk in the subcohort. Given follow-up validity, we can expect that, at any follow-up time *t*, the myocardial infarction rates in a subcohort will be the same for subjects lost or withdrawn at *t* and subjects whose follow-up continues beyond *t*.

In fact, we should expect follow-up to be biased by cigarette smoking: smoking is associated with mortality from myocardial infarction and from many other causes; the association of smoking with socioeconomic status might also produce an association between smoking and loss to follow-up. The result would be elevated censoring among high-risk (smoking) subjects. As a consequence, unadjusted estimates of the risks of myocardial infarction will underestimate those risks in the complete subcohorts (as the latter includes both censored and uncensored subject experience). If the degree of underestimation varies across subcohorts, bias in the relative-risk estimates will result.

In fact, the degree of underestimation should vary in this example because of the variation in the prevalence of smoking across subcohorts. Nevertheless, this variation is not necessary for smoking-related censoring to produce biased estimates of absolute effect. For example, if smoking-related censoring produced a uniform 15% underestimation of the myocardial infarction rate in each subcohort, all rate differences would also be underestimated by 15%.

Analogous to control of confounding, any bias produced by the association of smoking with myocardial infarction and censoring can be removed by smoking adjustment. As before, if adjustment is by standardization, the standard distribution should be chosen from the target subcohort.

Because the same correction methods can sometimes be applied, some authors classify follow-up bias as a form of confounding. Nevertheless, the two phenomena are reversed with respect to the causal ordering of the third variable responsible for the bias: confounding arises from an association of the study exposure (coffee use) with other exposures (such as smoking) that affect outcome risk; in contrast, follow-up bias arises from an association between the risk of the study outcome (myocardial infarction) and risks of other end points (such as other-cause mortality or loss to follow-up) that are

affected by exposure, and thus is classified as a form of selection bias by many authors (Kelsey et al. 1996; Hernán et al. 2004). In this regard, note that certain forms of follow-up bias cannot be removed by adjustment, and thus do not resemble confounding (Hernán et al. 2004; Glymour and Greenland 2008). These problems are discussed in the statistics literature under the topic of dependent competing risks (Slud and Byar 1988) and resemble the selection-bias problems of case–control studies, which are discussed later.

Measurement validity

Unlike gender, the continuous variables of coffee use, cigarette use, blood pressure, cholesterol, and age are time-dependent covariates. With the exception of age (whose value at any time can be computed from birth date), this fact adds considerable complexity to measuring these variables and estimating their effects.

Consider that we cannot reasonably expect a single baseline measurement, no matter how accurate, to summarize adequately a subject's entire history of coffee drinking, smoking, blood pressure, or cholesterol. Even if the effect of a subject's history could be largely captured by using a single summary number (e.g. total number of cigarettes smoked), the baseline measurement may well be a poor proxy for this ideal and unknown summary. For these reasons, we should expect proxy-variable errors to be very large in our example.

Proxy-variable error in the study variables

The degree of proxy-variable error in measuring the study variables depends on the exact definitions of the variables that we wish to study. In turn, this definition should reflect the hypothesized effect that we wish to study. To illustrate, consider the following acute-effect hypothesis:

> Drinking a cup of coffee produces an immediate rise in short-term myocardial infarction risk. In other words, coffee consumption is an acute risk factor.

This hypothesis does not exclude the possibility that coffee use also elevates long-term risk of myocardial infarction, perhaps through some other mechanism; it simply does not address the issue of chronic effects.

One way to examine the hypothesis would be to compare the myocardial infarction rates among person-days in which one, two, three, or more cups were drunk with the rate among person-days in which no coffee was drunk (adjusting for confounding and follow-up bias). If we had only baseline data, baseline daily consumption would have to serve as the proxy for consumption on every day of follow-up. This would probably be a poor proxy for daily consumption at later follow-up times where more outcome events occur. A 'standard' analysis, which only examines the association of baseline coffee use with myocardial infarction rates, is equivalent to an analysis that uses baseline consumption as a proxy for consumption on all later days. Thus, estimates from a standard analysis would suffer large bias if considered as estimates of the acute effects of coffee.

The proxy-variable error in this example could easily be differential with respect to the outcome: person-days accumulate more rapidly in early follow-up, where the error from using baseline consumption as the proxy is relatively low; in contrast, myocardial infarction events accumulate more rapidly in later follow-up, where the error is probably higher. This difference in accumulation illustrates an important general point: errors in variables can be differential, even if the variables are measured before the outcome event. Such phenomena occur when errors are associated with risk factors for the outcome; in our example, the error is associated with follow-up time and hence age. In turn, such associations are likely to occur when measurements are based on proxy variables.

Suppose now that we examine the following chronic-effect hypothesis:

> Each cup of coffee drunk eventually results in a long-term elevation of myocardial infarction risk.

This hypothesis was suggested by reports that coffee drinking produces a rise in serum lipid levels (Curb et al. 1986); it does not address the issue of acute effects. One way to examine the hypothesis would be to compare the myocardial infarction rates among person-months with different cumulative doses of coffee (perhaps using a lag period in calculating dose; e.g. one might ignore the most recent month of consumption). If we had only baseline data, however, baseline daily consumption would have to be used to construct a proxy for cumulative consumption at every month of follow-up. This construction could be done in several different ways. For example, we could estimate the subjects' cumulative doses up to a particular date by

multiplying their baseline daily consumption by the number of days that they had lived between age 18 and the date in question. This estimate assumes that coffee drinking began at age 18 and the baseline daily consumption is the average daily consumption since that age. We should expect considerable error in such a crude measure of cumulative consumption.

The degree of bias in estimating chronic effects could be quite different from the degree of bias in estimating acute effects. Furthermore, as discussed in the following, the errors in each proxy will make it virtually impossible to discriminate between acute and chronic effects.

Misclassification and bias towards the null

Although measurement errors can bias effect estimates, in some cases one may be able to predict the direction of the bias. Measurement of a binary (dichotomous) variable is called better than random if, regardless of the true value, the probability that the measurement yields the true value is higher than the probability that it does not. In other words, the measurement is better than random if it is more likely to be correct than incorrect, no matter what the true value is. Given two binary variables, better-than-random measurements with independent non-differential errors cannot inflate or reverse the association observed between the variables. In other words, any bias produced by independent non-differential error in better-than-random measurements can only be towards the null value of the association (which is one for a relative-risk measure) and not beyond.

If either variable has more than two levels, then (contrary to assertions in most pre-1990 literature) the preceding conditions are not sufficient to guarantee that the resulting bias will only be towards the null and not beyond (Dosemeci et al. 1990). Despite this insufficiency, knowing that errors are independent and non-differential can increase the plausibility that any resulting bias is towards the null, although it should not increase the plausibility that the observed association is in the correct direction (Weinberg et al. 1994). For further discussions of measurement error and bias towards the null, see Flegal et al. (1991), Wacholder et al. (1991), Weinberg et al. (1994), Rothman et al. (2008, chapter 9), VanderWeele and Hernán (2012), and Gustafson and Greenland (2017).

There is one important situation in which the assumption of independent non-differential measurement error and hence bias towards the null have particularly high plausibility: in a double-blind clinical trial with a dichotomous treatment and outcome, successful blinding of treatment status during outcome evaluation should lead to independence and non-differentiality of treatment and outcome measurement errors. Successful blinding thus helps to ensure (although it does not guarantee) that any bias produced by measurement error contributes to underestimation of treatment differences (conservative bias).

Measurement error and confounding

If a variable is measured with error, estimates adjusted for the variable as measured will still be somewhat confounded by the variable. This residual confounding arises because measurement error prevents construction of strata that are internally homogeneous with respect to the true confounding variable (Greenland 1980).

To illustrate, consider baseline daily cigarette consumption. This variable can be considered a proxy for consumption on each day of follow-up or can be used to construct an estimate of cumulative consumption (analogous to the cumulative coffee variable discussed in the preceding). Suppose that we stratify the data on a cumulative smoking index constructed from the baseline smoking measurement. Within any stratum of the index, there would remain a broad range of cumulative cigarette consumption. For example, two subjects who were age 40 and smoked one pack a day at baseline would receive the same value for the smoking index and so end up in the same stratum. However, if one of them stopped smoking immediately after baseline, while the other continued to smoke a pack a day, after 10 years of follow-up the former subject would have ten fewer pack-years of cigarette consumption than the continuing smoker.

Suppose now that cumulative cigarette consumption is positively associated with cumulative coffee consumption. Then, even within strata of the smoking index, we should expect subjects with high coffee consumption to exhibit elevated myocardial infarction rates simply by virtue of having higher levels of cigarette consumption. As a consequence, the estimate of the effect of coffee adjusted for the smoking index would still be confounded by cumulative cigarette consumption.

In some cases, a study variable may appear to have an effect (or no effect) only because of poor measurement of an apparently unimportant confounder. This can occur, for example, when an important confounding variable is measured with a large amount of non-differential error. Such an error would ordinarily reduce the apparent association of the variable with the exposure, and would also make the variable appear to be a weak risk factor, perhaps weaker than the study exposure. This in turn would make the variable appear to be only weakly confounding, in that adjustment for the variable as measured would produce little change in the result. However, this appearance would be deceptive because adjustment for the variable as measured would eliminate little of the actual confounding by the variable.

As an example, suppose that coronary proneness of personality was measured only by the baseline yes or no question: Do you consider yourself a hard-driving person? Such a crude measure of the original construct would be unlikely to show more than a weak association with either coffee use or myocardial infarction, and adjusting for it would produce little change in our estimate of the effect of coffee. Suppose, however, that coronary-prone personalities have an elevated preference for coffee. Such a phenomenon would lead to a concentration of coronary-prone persons (and hence, a spuriously elevated myocardial infarction rate) among coffee drinkers, even after stratification on the response to the question.

One would ordinarily expect adjustment for a non-differentially misclassified confounder to produce an estimate lying somewhere between the unadjusted estimate and the estimate adjusted for the true values of the confounder (Greenland 1980). Unfortunately, if the true confounder has more than two levels, it is possible for adjustment by the misclassified confounder to be more biased than the unadjusted estimate (Brenner 1993); this can even happen with confounders with two levels if the confounder affects the exposed and unexposed subjects in opposite directions (Ogburn and VanderWeele 2012). It is also possible for adjustment by factors that affect misclassification to worsen bias (Greenland and Robins 1985). If however the effect of the confounder is in the same direction regardless of exposure, and its misclassification is independent and non-differential with respect to the exposure and outcome, adjustment for the misclassified confounder will on average produce an estimate between the unadjusted

estimate and the estimate adjusted for the true confounder values (Ogburn and VanderWeele 2012, 2013).

Measurement error and separation of effects

Because of their impact on the effectiveness of adjustment procedures, measurement errors can severely reduce our ability to separate different effects of the study variable. Suppose in our example that we wished to estimate the relative strength of acute and chronic effects of coffee. To do so, we must take account of the fact that acute and chronic effects will be confounded. When examining acute effects, person-days with high coffee consumption will occur most frequently among persons with high cumulative coffee consumption. As a consequence, if cumulative coffee consumption is a risk factor, it will be a confounder for estimating the acute effects of coffee consumption. By similar arguments, if coffee consumption has acute effects, these will confound estimates of the chronic effects of cumulative consumption.

Unfortunately, both cumulative and daily consumption are measured with considerable error. As a result, any effect observed for one may be wholly or partially due to the other, even if the other has little or no apparent effect.

Repeated measures

One costly but effective method for reducing the degree of proxy-variable error in measuring time-dependent variables is to take repeated (serial) measurements over the follow-up period and ask subjects to report their pre-baseline history of such variables at the baseline interview. In our example, subjects could be asked about their age at first use and level of consumption at different ages for coffee and cigarettes; they could then be recontacted every year or two to assess their current consumption. Of course, not all subjects may be willing to cooperate with such active follow-up, but the penalties of some extra loss may be far outweighed by the benefit of improved measurement accuracy.

Errors in assessing incidence

An important form of measurement error in assessing incidence is misdiagnosis of the outcome event. In the AIDS example, a false-positive diagnosis of AIDS would result in underestimation of incubation time, whereas a false-negative diagnosis would result in overestimation. In the present example, false-positive errors would result in overestimation of myocardial infarction rates, whereas false-negative errors would result in underestimation. These errors will be of particular concern when the study depends on existing surveillance systems or records for detection of outcome events.

There are special cases in which the errors will induce little or no bias in estimates, provided the errors have little effect on the person-time observed. If the only form of misdiagnosis is false-negative error, the proportion of outcome events missed in this fashion is the same across cohorts, and if there is no follow-up bias, then the relative-risk estimates will not be distorted by the underdiagnosis. Suppose in our example that all recorded myocardial infarction events are true myocardial infarctions, but that in each subcohort 10% of myocardial infarctions are missed. The myocardial infarction rates in each subcohort will then be underestimated by 10%; nevertheless, if we consider any two of these rates, say R_0 and R_5, the observed rate ratio will be:

$$\frac{0.9R_5}{0.9R_0} = \frac{R_5}{R_0}$$

which is undistorted by the underdiagnosis of myocardial infarction. Nonetheless, if coffee primarily induced ‘silent’ myocardial infarctions and these were the most frequently undiagnosed events, the effect of coffee would be underestimated.

Analogously, if the only form of misdiagnosis is false-positive error, the rate of false positives is the same across cohorts, and if there is no follow-up bias, then rate differences will not be distorted by the overdiagnosis. Suppose that the rate of false positives in our example is R_f in all subcohorts; then, if we consider any two true rates, say R_0 and R_5, the observed rate difference will be:

$$(R_c + R_f) - (R_u + R_f) = R_c + R_u$$

which is undistorted by the overdiagnosis of myocardial infarction. However, if there is non-differential underdiagnosis of myocardial infarction, as is probably the case in our example, the rate difference will be underestimated.

Specification validity

As noted earlier, the use of a statistical method based on an incorrect model (specification error) can lead to bias in estimates and improper performance of statistical tests and interval estimates. All statistical techniques, including non-parametric methods, must assume some sort of model for the process generating the data; however, in the absence of randomization or random sampling, it will rarely be possible to identify a 'correct' sampling model. In addition, structural assumptions are rarely (if ever) exactly satisfied. Thus, some specification error should be expected. As before, minimization of specification error must rely on checking the model against the data and against background information about the processes generating the data.

Recall that the unadjusted rate ratio estimates for five-cup-a-day versus never-drinkers is 1.22 in the present example, with 95% confidence limits of 1.00 and 1.49, and a *p*-value of 0.05. Suppose that these figures were obtained by conventional person-time methods (Rothman et al. 2008, chapter 14). These methods are based on a binomial sampling model for the number of cases who drank five cups a day at baseline, given the combined total number of cases among five-cup-a-day and never-drinkers. In our example, the validity of this model depends on the assumption that the myocardial infarction rate remains constant within subcohorts over the follow-up period. It follows that the model (and hence the statistics given earlier) cannot be valid in our example; the subcohort members grow older over the follow-up period, and hence the myocardial infarction rates must increase with follow-up time.

The invalidity just noted can be rectified by stratifying either on follow-up time or the variable responsible for the change in rates over follow-up time (here, age). The stratification need only be fine enough to ensure that the myocardial infarction rate change within strata is negligible over follow-up. As noted earlier, however, we must also adjust for smoking and

perhaps other factors responsible for confounding or follow-up bias. If we stratify finely enough to remove all the bias from these sources, the resulting estimates would be undefined or so unstable that they would tell us nothing about the association of coffee and myocardial infarction.

The standard solution to such problems is to compute adjusted estimates using regression models. These are structural models representing a set of assumptions (usually rather strong ones) about the joint effects of the study variables. Such models allow estimates and tests to be extracted from what would otherwise be hopelessly sparse data, at a cost of a greater risk of bias arising from violations of the assumptions underlying the models (Robins and Greenland 1986). For further details of cohort modelling, see Breslow and Day (1987), Hosmer and Lemeshow (2000), Kelsey et al. (1996), Checkoway et al. (2004), Jewell (2004), and Greenland (2008a, 2008b).

Summary of cohort example

The example used in this subsection provides an illustration of the most common threats to the validity of effect estimates from cohort studies. The unadjusted estimates of the effect of coffee on myocardial infarction will be confounded by many variables (such as smoking), and there will be follow-up bias. As a result, the number of variables that must be controlled is too large to allow adequate control using only stratification. The true functional dependence of myocardial infarction rates on coffee and the confounder is unknown, so that estimates based on multivariate models are likely to be biased. Even if this bias is unimportant, our estimates will remain confounded because of our inability to measure the key confounders accurately. Finally, our inability to summarize coffee consumption accurately would further bias our estimates, making it impossible to separate acute and chronic effects of coffee use reliably.

Given that there are several sources of bias of unknown magnitude and different directions, it would appear that no conclusions about the effect of coffee could be drawn from a study such as the one described in the preceding, other than that coffee does not appear to have a large effect. This type of result—inconclusive, other than to rule out very large effects—is common in thorough epidemiological analyses of observational data. In particular, inconclusive results are common when the data being analysed

were collected for purposes other than to address the hypothesis at issue, for such data often lack accurate measurements of key variables.

Special issues in case–control studies

The practical difficulties of cohort studies have led to extensive development of case–control study designs. The distinguishing feature of such designs is that sampling is intentionally based on the outcome of individuals. In a population-based or population-initiated case–control study, one first identifies a population at risk of the outcome of interest, which is to be studied over a specified period of time or risk period. As in a cohort study, one attempts to ascertain outcome events in the population at risk. Nevertheless, unlike a cohort study, one selects persons experiencing the outcome event (cases) and a 'control' sample of the entire population at risk for ascertainment of exposure and covariate status.

In a case-initiated case–control study, one starts by identifying a source of study cases (e.g. a hospital emergency room is a source of myocardial infarction cases). One then attempts to identify a population at risk such that the source of cases provides a random or complete sample of all cases occurring in this population. Study cases recruited from the source occur over a risk period; controls are selected in order to ascertain the distribution of exposure in the population at risk over that period. Case–control studies may also begin with an existing series of controls (Greenland, 1985). Regardless of how a case–control study is initiated, evaluation of validity must ultimately refer to a population at risk that represents the target of inference for the study.

Relative-risk estimation in case–control studies

The control sample may or may not be selected in a manner that excludes cases. If persons who become cases over the risk period are ineligible for inclusion in the control group (as in traditional case–control designs), a 'rare disease' assumption may be needed to estimate RRs from the case–control data. In contrast, if persons who become cases over the risk period are also eligible for inclusion in the control group (as in newer case–control designs), the rare disease assumption can be discarded. These points are discussed in the textbooks cited at the beginning of this chapter.

The basics of case–control estimation will be illustrated using the following example. We wish to study the effect of coffee drinking on rates of first myocardial infarction and we have selected a population for study (e.g. all residents aged 40–64 in a particular town) over a 1-year risk period. At any point during the risk period, the population at risk comprises persons in this selected population who have not yet had a myocardial infarction.

Suppose that the average number of never-drinkers in the population at risk was 20,000 over the risk period, the average number of five-cup-a-day drinkers was 10,000, there were 120 first myocardial infarctions among never-drinkers, and there were 90 first myocardial infarctions among five-cup-a-day drinkers. Then, if one observed the entire population without error, the estimated rates among never-drinkers and five-cup-a-day drinkers would be:

$$\frac{120}{20{,}000\text{Person-years}} = \frac{90}{10{,}000\text{Person-years}}.$$

Thus, if we observed the entire population, the estimated rate ratio would be:

$$\frac{90/10{,}000\text{Person-years}}{20{,}000\text{Person-years}} = \frac{90/120}{10{,}000/20{,}000\text{Person-years}} = 1.50.$$

This estimate depends on only two figures: the relative prevalence of five-cup-a-day versus never-drinkers among cases (90/120), and the same relative prevalence in the person-years at risk (10,000/20,000). These two relative prevalences are often called the case exposure odds and the population exposure odds.

The first relative prevalence (numerator) could be estimated by interviewing an unbiased sample of all the new myocardial infarction cases that occur over the risk period, and the second relative prevalence (denominator) could be estimated by interviewing an unbiased sample of the population at risk over the risk period. The ratio of relative prevalences from the case– and control–sample interviews would then be an unbiased estimate of the population rate ratio of 1.50. This estimate is called the sample odds ratio.

Three points about the preceding argument should be carefully noted. First, no rare disease assumption was made. Second, the control sample of the population at risk was accumulated over the entire risk period (rather than at the end of the risk period); such sampling is called density sampling (Rothman et al. 2008, chapter 8) or risk-set sampling (Breslow and Day 1987). Third, because of the density sampling, someone may be selected for the control sample, and yet have a myocardial infarction later in the risk period and become part of the case sample as well. Methods for carrying out density sampling can be found in the textbooks cited at the beginning of this chapter.

Validity conditions in case–control studies

The primary advantages of case–control studies are their short timeframe and the large reduction in the number of subjects needed to achieve the same statistical power as a cohort study. The primary disadvantage is that more conditions must be met to ensure their validity (in addition to the four listed in the cohort study example), and hence, there are more opportunities for bias to arise.

Suppose that our case–control study data yield an unadjusted rate ratio estimate (odds ratio) of 1.50, with 95% confidence limits of 1.00 and 2.25. The following series of conditions would be sufficient for the validity of this figure as an estimate of the effect of drinking five cups of coffee a day (versus none) on the myocardial infarction rate:

Comparison validity—if five-cup-a-day drinkers in the population at risk had instead drunk no coffee, their distribution of myocardial infarction events over time would have been approximately the same as the distribution among never-drinkers.
Follow-up validity—within each subpopulation defined by coffee use, censoring risk (i.e. population membership ended by an event other than myocardial infarction, such as emigration or death from another cause) is not associated with myocardial infarction risk.
Selection validity—this has two components:

1. *Case-selection validity*—if one studies only a subset of the myocardial infarction cases occurring in the population over the risk period (e.g. because of failure to detect all cases), this subset provides unbiased estimates of the prevalence of different levels of coffee use among all cases occurring in the population over the risk period.
2. *Control-selection validity*—the control sample provides unbiased estimates of the prevalences of different levels of coffee use in the population at risk over the risk period.

Specification validity—the distribution of myocardial infarction events over time in the subpopulations can be closely approximated by the statistical model on which the estimates are based.
Measurement validity—all measurements of variables used in the analysis closely approximate the true values of the variables.

Issues of comparison validity, follow-up validity, specification validity, effect modification, and generalizability in case–control studies parallel those in follow-up studies, and so will not be discussed here. Case–control studies are vulnerable to certain problems of measurement error that are less severe or do not exist in prospective cohort studies. We shall discuss these problems first, and then examine selection validity and modelling. Finally, we shall briefly discuss analogous issues in retrospective cohort studies.

Retrospective ascertainment

A special class of measurement errors arises from the retrospective ascertainment of time-dependent variables; that is, attempting to measure past values of the variables. Retrospective ascertainment must be based on

individual memories, existing records of past values, or some combination of the two. Therefore, such ascertainment usually suffers from faulty recall, missing or mistaken records, or lack of direct measurements in existing records.

Retrospective ascertainment may be an important component of a cohort study. For example, the cohort study of coffee and myocardial infarction discussed earlier could have been improved by asking subjects about their coffee use and smoking prior to the start of follow-up. This information would allow one to construct better cumulative indices than could be constructed from baseline consumption alone, although the resulting indices would still incorporate error due to faulty recall.

Unless records of past measurements are available for all subjects, measurements on cases and controls must be made after the time period under study as subjects are not selected for study until after that period. Thus, unlike cohort studies, most case–control studies of time-dependent variables depend on retrospective ascertainment. Considering our example, there may be much more error in determining daily coffee consumption ten years before interview than one month before interview; one might then expect case–control studies to be more accurate for studying acute effects than for studying chronic effects. Nonetheless, if acute and chronic effects are heavily confounded, the elevated inaccuracies of long-term recall will make it impossible to disentangle short-term from long-term effects. As illustrated earlier, this confounding can arise in a cohort study. Nevertheless, in a cohort study, such confounding can be minimized by taking repeated measurements. In contrast, such confounding would be unavoidable in a case–control study based on recall, even if detailed longitudinal histories were requested from the subjects.

The preceding observations should be tempered by noting that some case–control studies have access to exposure measurements of the same quality as found in cohort studies and that the exposure measurements in some cohort studies may be no better than those used in some case–control studies. For example, a cohort study in which measurements are derived by abstracting routine medical records would suffer from no less measurement error than a case–control study in which measurements are derived by abstracting the same records.

Outcome-affected measurements

One common potential problem in case–control studies is outcome-affected recall, often termed *recall bias*. This term refers to the differential measurement error that originates when the outcome event affects recall of past events. Examples arise in case– control studies of birth defects, for instance. If the trauma of having an affected child either enhances recall of prenatal exposures among case mothers or increases the frequency of false-positive reports among them, estimates of RR will be upwardly biased by effects of the outcome on case recall. This bias may be counterbalanced by other biases, such as recall bias among controls, making the final direction and magnitude of bias due to faulty measurements hard to predict (Drews and Greenland 1990).

One method commonly proposed for preventing bias due to outcome-affected recall is to restrict controls to a group believed to have recall similar to the cases. Unfortunately, one usually cannot tell to what degree this restricted selection corrects the bias from outcome-affected recall. Even more unfortunately, one usually cannot tell if the selection bias produced by such restriction is worse than the recall bias one is attempting to correct (Swan et al. 1992; Drews et al. 1993).

A problem similar to outcome-affected recall can occur when the outcome event affects a psychological or physiological measurement. This is of particular concern in case–control studies of nutrient levels and chronic disease. For example, if colon cancer leads to a drop in serum retinol levels, the RR for the effect of serum retinol will be underestimated if serum retinol is measured after the cancer develops. Errors of this type can be viewed as proxy-variable errors in which the post-outcome value is a poor proxy for the pre-outcome value of interest.

Selection validity

Selection validity is straightforward to understand but can be extraordinarily difficult to verify. A violation of the selection validity conditions is known as selection bias. Many case–control designs and field methods are devoted to avoiding such bias (Kelsey et al. 1996; Koepsell and Weiss 2003; Rothman et al. 2008, chapter 8).

In some instances, it may be possible to identify a factor or factors that affect the chance of selection into the study. If in such instances we have accurate measurements of one of these factors, we can stratify on (or

otherwise adjust for) the factor and thereby remove the selection bias due to the factor. Because of this possibility, some authors classify selection bias as a form of confounding. Nevertheless, there are some forms of selection bias that cannot be removed by adjustment. These points will be illustrated in the following subsections.

Case-selection validity

Case-selection bias can be minimized (although may still be large due to non-participation) if one can identify every case that occurs in the population at risk over the risk period. This requires a surveillance system for the outcome of interest, such as a population-based disease registry. In our coffee–myocardial infarction example, we would probably have to construct a myocardial infarction surveillance system from existing resources, such as emergency room admission records, ambulance service records, and paramedic records.

Even if all cases of interest can be identified, selection bias may arise from failure to obtain information on all the cases. In our example, many cases would be dead before interview was possible. For such cases, there are only two alternatives: attempt to obtain information from some other source, such as next of kin or co-workers, or exclude such cases from the study. The first alternative increases measurement error in the study. The second alternative will introduce bias if coffee affects risk of fatal and non-fatal myocardial infarction differently, or if coffee affects risk of myocardial infarction survivorship. To illustrate, suppose that coffee drinking reduced one's chance of reaching the hospital alive when a myocardial infarction occurred. Then, the prevalence of coffee use among myocardial infarction survivors would under-represent the prevalence among all myocardial infarction cases. Underestimation of the rate ratio would result if fatal myocardial infarction cases were excluded from the study.

It might seem possible to remove the case-selection bias in this example by redefining the study outcome as non-fatal myocardial infarction. This does not remove the bias, however; it only leads to its reclassification as a bias due to differential censoring (here classified as a form of follow-up bias). In a study of non-fatal myocardial infarction, fatal myocardial infarction is a censoring event associated with risk of non-fatal myocardial infarction; if fatal myocardial infarction is also associated with coffee use,

the result will be underestimation of the rate ratio for non-fatal myocardial infarction. More generally, it is usually not possible to remove bias by placing restrictions on admissible outcomes.

Unfortunately, exclusion is the only alternative for cases that refuse to participate or cannot be located. In our example, if such cases tend to be heavier coffee users than others, underestimation of the rate ratio would result. However, suppose that, within levels of cigarette use, such cases were no different from other cases with respect to coffee use. Then, adjustment for smoking would remove the selection bias induced by refusals and failures to locate cases. (Of course, such adjustment would require accurate smoking measurement, which is a problem in itself.)

Bias that arises from failure to detect certain cases is sometimes called detection bias. If our surveillance system used only hospital admissions, many out-of-hospital myocardial infarction deaths would be excluded, and a detection bias of the sort described here could result.

Control-selection validity

Control-selection bias can be minimized (although may still be large due to non-participation) if one can potentially identify every member of the population at risk at every time during the risk period. In such a situation, one could select controls with one of many available probability sampling techniques, using the entire population at risk as the sampling frame. Unfortunately, such situations are exceptional.

Many studies attempt to approximate the ideal sampling situation through use of existing population lists. An example is control selection by random digit dialling; here, the list (of residential telephone numbers) is not used directly but nevertheless serves as a partial enumeration of the population at risk. This list excludes people without telephone numbers. In our example, if people without telephones drink less coffee than people with telephones, a control group selected by random digit dialling would over-represent coffee use in the population at risk. The result would be underestimation of the rate ratio.

One could redefine the population at risk in the previous example so that the telephone-related selection bias did not exist by restricting the study to persons with telephones. This would require excluding persons without telephones from the case series. The resulting relative-risk estimate would

suffer no selection bias. The only important penalty from this restriction is that the resulting estimate might apply only to the population of persons with telephones, which is a problem of generalizability rather than a problem of selection validity. In a similar fashion, it is often possible to prevent confounding or selection bias by placing restrictions on the population at risk (and hence, the control group). In such instances, however, one must take care to apply the same restrictions to the case series and avoid using restrictions based on events that occur after exposure (Poole 1999; Rothman et al. 2008, chapter 8).

Even if all members of the population at risk can be identified, selection bias may arise from failure to obtain information on all people selected as controls. The implications are the reverse of those for case-selection bias. In our example, if controls who refuse to participate or cannot be located tend to be heavier coffee users than other controls, overestimation of the rate ratio would result. This should be contrasted with the underestimation that results from the same tendency among cases.

More generally, one might expect an association of selection probabilities with the study variable to be in the same direction for both cases and controls. If so, the resulting case- and control-selection biases would be in opposite directions and so, to some extent, they would cancel one another out, although not completely. To illustrate, suppose that among cases the proportions who refuse to participate are 0.05 for five-cup-a-day drinkers and 0.02 for never-drinkers, and among controls the analogous proportions are 0.20 and 0.10. These refusals will result in the odds of five-cup-a-day versus never-drinkers among cases being underestimated by a factor of 0.95/0.98 = 0.97; this in turn results in a 3% underestimation of the rate ratio. Among controls, the odds will be underestimated by a factor of 0.80/0.90 = 0.89; this results in a 1/0.89 = 1.12, or a 12% overestimation of the rate ratio. The net selection bias in the rate ratio estimate will then be 0.97/0.89 = 1.09, or 9% overestimation.

For further discussions of control-selection validity, see the textbooks cited in the beginning of this chapter, and also Savitz and Pearce (1988), Schlesselman (1992), Swan et al. (1992), and Wacholder et al. (1992).

Matching

In cohort studies, matching refers to selection of exposure subcohorts in a manner that forces the matched factors to have similar distributions across the subcohorts. If the matched factors are accurately measured and the proportion lost to follow-up does not depend on the matched factors, cohort matching can prevent confounding by the matched factors, although there are statistical reasons to control the matched factors in the analysis (Weinberg 1985).

In case–control studies, however, matching refers to selection of subjects in a manner that forces the distribution of certain factors to be similar in cases and controls. Because the population at risk is not changed by case–control matching, such matching does not by itself prevent confounding by the matched factors. In fact, it is now widely recognized that case–control matching is a form of selection bias (Glymour and Greenland 2008; Rothman et al. 2008, chapter 11). This bias can be removed by adjusting for the matching factor; to the extent the factor has been closely matched and accurately measured, this adjustment also controls for confounding by the factor.

As an example, suppose that our population at risk is half male, that the men tend to drink less coffee than the women, and that about 75% of our cases are men. Unbiased control selection should yield about 50% men in the control group. However, if we matched controls to cases on gender, about 75% of our controls would be men. Because men drink less coffee than women and men would be over-represented in the matched control group, the matched control group would under-represent coffee use in the population at risk. Note, however, that matching does not affect the gender-specific prevalence of coffee use among controls, and so the gender-specific and gender-adjusted estimates would be unaffected by matching. In other words, the selection bias produced by matching could be removed by adjustment for the matching factor.

The conclusion to be drawn is that matching can necessitate control of the matching factors. Thus, in order to avoid increasing the number of factors requiring control unnecessarily, one should limit matching to factors for which control would probably be necessary anyway. In particular, matching is usually best limited to known strong confounders, such as age and gender in the preceding example (Rothman et al. 2008, chapter 11).

More generally, the primary theoretical value of matching is that it can sometimes reduce the variance of adjusted estimators. However, there are

circumstances in which matching can facilitate control selection and so is justified on practical grounds. For example, neighbourhood controls may be far easier to obtain than unmatched general population controls. In addition, although neighbourhood matching would necessitate use of a matched analysis method, the neighbourhood-matched results would incorporate some control of confounding by factors associated with the neighbourhood (such as socioeconomic status and air pollution).

Special control groups

It is not unusual for investigators to select a special control group that is clearly not representative of the population at risk if they can argue that: (1) the group will adequately reflect the distribution of the study factor in the population at risk; or (2) that the selection bias in the control group is of the same magnitude of (and so will cancel with) the selection bias in the case group. The first rationale is common in case–control studies of mortality in which persons dying of other selected causes of death are used as controls; in such studies, selection validity can be assured only if the causes of death of controls are unrelated to the study factor. The second rationale is common in studies using hospital cases and controls; in particular, selection validity can be assured in such studies if the control conditions are unrelated to the study factor, and the study disease and the control conditions have proportional exposure-specific rates of hospital admission (Schlesselman 1992).

Selection into a special control group usually requires membership in a small and highly select subset of the population at risk. Thus, use of a special control group requires careful scrutiny for mechanisms by which the study factor may influence entry into the subset. See Schlesselman (1992) and Kelsey et al. (1996) for discussions of practical issues in evaluating special control groups, and Rothman et al. (Rothman et al. 2008, chapter 8) for validity principles in mortality case–control studies (so-called proportionate mortality studies).

Case–control modelling

The most popular model for case–control analysis is the logistic model. Details of logistic modelling for case–control analysis are covered in many

textbooks, including Breslow and Day (1980), Schlesselman (1992), Kelsey et al. (1996), Hosmer and Lemeshow (2000), and Jewell (2004), and Greenland (2008b).

One important aspect of case–control modelling is that matched factors require special treatment. For example, suppose that matching is done on age in 5-year categories and age is associated with the study exposure. To control for the selection bias produced by matching, one must either employ conditional logistic regression with age as a stratifying factor, or else enter indicator variables for each age-matching category into an ordinary logistic regression (the latter strategy has the drawback of requiring about ten or more subjects per age stratum to produce valid estimates). Simply entering age into the model as a continuous variable may not adequately control for the matching-induced bias.

Summary of case–control example

The example in this subsection provides an illustration of the most common threats to validity in case–control studies (beyond those already discussed for cohort studies). After adjustments for possible confounding and follow-up bias (along the lines described for the cohort study), there may still be irremediable selection bias, especially if we use only select case groups (e.g. myocardial infarction survivors) or control groups (e.g. hospital controls). In addition, retrospective ascertainment will lead to greater measurement error than prospective ascertainment, and some of this additional error may be differential.

Given the even greater number of potential biases of unknown magnitude and different directions, it would appear that (as in the cohort example) no conclusions about the effect of coffee could be drawn from a study such as the one described, other than that coffee does not have a large effect. Again, this is a common result in thorough epidemiological analyses of observational data.

Special issues in retrospective cohort studies

Two major types of cohort studies can be distinguished depending on whether members of the study cohort are identified before or after the

follow-up period under study. Studies in which all members are identified before their follow-up period are called *concurrent* or *prospective* cohort studies, and studies in which all members are identified after their follow-up period are called *historical* or *retrospective* cohort studies.

Similar to case–control studies, retrospective cohort studies often require special consideration of retrospective ascertainment and selection validity. In particular, retrospective cohort studies that obtain exposure or covariate histories from post-event reconstructions are vulnerable to bias from outcome-affected measurements. Suppose, for example, that a study of cancer incidence at an industrial facility had to rely on company personnel to determine the location and nature of various exposures in the plant during the relevant exposure periods. If these personnel were aware of the locations at which cases worked (as when a publicized ‘cluster’ of cases has occurred), biased exposure assessment could result. Such problems can also occur in a prospective cohort study if exposure or covariate histories are based on post-event reconstructions.

Retrospective cohort studies can also suffer from selection biases analogous to those found in case–control studies. Suppose, for example, that a retrospective cohort study relied on company records to identify members of the cohort of plant employees. If retention of an employee’s records (and hence identification of the employee as a cohort member) were associated with both the exposure and outcome status of the employee, the exposure–outcome association observed in the incomplete study cohort could poorly represent the exposure–outcome association in the complete cohort of plant employees.

Conclusion

Uncertainty about validity conditions is responsible for most of the inconclusiveness inherent in epidemiological studies. This inconclusiveness can be partially overcome when multiple complementary studies are conducted; that is, when new studies are conducted under conditions that effectively limit bias from one or more of the sources present in earlier studies. Ideally, after enough complementary studies have been conducted, each known or suspected source of bias might have been rendered unimportant in at least one study. If at this point all the study results appear

consistent with one another (which is not the case for coffee and myocardial infarction, although the studies of smoking and lung cancer provide a good example), the epidemiological community may reach some consensus about the existence and strength of an effect.

Even in such ideal situations, however, one should bear in mind that consistency is not validity. For example, there may be some unsuspected source of bias present in all the studies, so that they are all consistently biased in the same direction. Alternatively, all the known sources of bias may be in the same direction, so that all the studies remain biased in the same direction if no one study eliminates all known sources of bias. Such problems can be addressed tentatively via sensitivity analysis or the more elaborate methods of risk analysis and bias analysis (Eddy et al. 1992; Greenland and Lash 2008; Lash et al. 2009; VanderWeele and Arah 2011; Greenland 2014). For these and other reasons, many authors have warned that all causal inferences should be considered tentative, at least if drawn from observational epidemiological data alone, although such tentativeness does not in any way rule out interventions when it is clear that the probable cost of failing to act far outweighs the probable cost of intervention (Rothman 1988; Rothman et al. 2008, chapter 2).

ACKNOWLEDGEMENTS

The authors wish to thank I. Hertz-Picciotto, K. Hoggatt, P. Kass, J. Kelsey, G. Maldonado, S. Norrell, J. Schlesselman, and A. Walker for their helpful comments on earlier versions of this chapter.

Causation and causal inference

Katherine J. Hoggatt, Tyler J. VanderWeele, and Sander Greenland

Introduction to causation and causal inference

This chapter offers an introduction to causal inference theory for public health research. Causal inference can be viewed as a prediction problem, addressing the question of what the likely outcome will be under one action versus an alternative action. Although asking these types of questions is very natural, useful answers require a high degree of precision in both the statement of the causal questions and the description of analysis techniques and limitations. This chapter focuses on formulation of causal hypotheses and considerations in answering them. More thorough coverage of these issues can be found in chapters 2, 4, 9, and 19 of Rothman et al. (2008) and in the book by Hernán and Robins (2020).

We first review considerations for evaluating evidence of causality, then describe the potential-outcome (counterfactual) framework for cause and effect, showing how measures of effect and association are distinguished in that framework. The potential-outcome framework illustrates problems inherent in attempts to quantify the changes in health expected under different actions or interventions. We conclude with a discussion of how research findings may be translated into policy.

The study of cause and effect

The emergence of modern science has led to increasingly sophisticated methods to distinguish causal effect from non-causal association, aided by formal theories of causation. A formal theory of causation facilitates application of deductive reasoning to the process of causal inference. Of

great importance, it allows us to define precisely the difference between causation and association and gives guidance on how to pose causal questions and test causal hypotheses. It does not, however, provide a basis for 'proving' causality, nor can it model the entire process of causal inference (Greenland 2017a).

That process begins in early childhood, in which we acquire a notion of cause and effect that is based on the observation of one event always or often following another. We observe that flipping a switch consistently results in a light going on and off, and readily assign a cause and effect interpretation to these relations. Nonetheless, such naïve equation of 'variation in tandem' with causation will too often conflate causation with mere association. The key observation cementing our inference that a given switch controls the light is that we see how flipping the switch is followed immediately by the light change—in other words, we repeatedly witness that an *intervention*, or an event we believe shares no important causes with the light, is followed by the light.

A key feature of modern theories of causation is that they formalize these early beginnings by providing comparative predictions about the consequences of alternative interventions (e.g. dietary supplementation versus none) rather than singular predictions of events assuming no intervention (e.g. forecasts of flu epidemics) (Greenland 2012). Nonetheless, as Hume (1739) realized and discussed at length, there is no deductive way to prove causality. Thus, causal inference can only be a speculative, inductive process whose output is a theory of cause and effect. Indeed, the history of science shows that all theories, including causal ones, are necessarily provisional and that future evidence may lead to rejecting previously 'established' relations (Popper 1968; Kuhn 1970).

Those working in public health or policy must often make decisions on how to proceed in the face of equivocal evidence. The question then arises of how to weigh the evidence in favour of cause and effect to determine, say, whether smoking should be banned in bars to prevent lung cancer in bar workers, whether pregnant women should be told to take folate to prevent neural tube defects in their offspring, or whether postmenopausal women should be prescribed hormone replacement therapy (HRT) to prevent heart disease. In each of these cases, the final decision by health or policy professionals was made in the absence of definitive proof of

causality, relying instead on the imperfect evidence gleaned from available studies.

Because of its central importance, causal inference is often confused with the more complex process of rational decision-making. While causal inference is a crucial input to decision-making, decision-making also depends on the costs and benefits of the outcomes. For example, policy makers believed that a ban on smoking in bars and pubs was likely to have health benefits that outweigh any negative economic impacts. This perceived imbalance favouring benefits over costs would be a key basis for a proposed ban. In contrast, recommendations that doctors prescribe HRT for the prevention of heart disease must acknowledge that HRT could have serious side effects on women's health. The recommendations are easily challenged if the costs are shifted according to individual preferences and values.

Such examples show that multiple effects should be considered when policymakers evaluate the evidence of cause and effect based on epidemiological studies. Nonetheless, most attempts to formalize the process of causal inference focus on single endpoints. This single-endpoint view must be understood thoroughly before considering multiple endpoints.

Hill's considerations

Many authors have attempted to list considerations that should be weighed when advancing causal arguments. Best known are those by Sir Austin Bradford Hill (Hill 1965), which are closely related to the considerations found in the first US Surgeon General's report on smoking and health (United States Department of Health, Education and Welfare 1964). Hill's article has been widely misinterpreted as providing necessary conditions ('criteria') for causation to be inferred; see Phillips and Goodman (2004) for a discussion of this and other misinterpretations. In Hill's own words, the considerations were *not* meant to be a checklist or set of criteria, but, rather, simply 'points to consider', namely: (1) strength, (2) consistency, (3) specificity, (4) temporality, (5) biological gradient, (6) plausibility, (7) coherence, (8) experimental evidence, and (9) analogy; we shall discuss each of these in turn. Of these considerations or 'viewpoints' (as Hill called them), the only one necessary for inferring causation is temporality (time

order). The other considerations have been debated at length, with various calls for amendment and caution, e.g. see Weiss (1981, 2002), Maclure (1985); Weed (1986); Susser (1991), Kaufman and Poole (2000), Phillips and Goodman (2004, 2006), Höfler (2005, 2006), and Rothman et al. (2008, ch. 2).

Strength

The strength of an association may be considered important because it is harder to explain away strong effects as complete artefacts of biases such as confounding. There is no general rule for how large an association needs to be to provide compelling evidence for an effect, although a risk or rate ratio of 2 is sometimes taken as a boundary below which bias as a complete explanation of an association starts to become plausible. Nonetheless, there are many smaller associations that are generally agreed to reflect causal effects, in part because they have been replicated in a variety of populations using different designs and in part because of considerations other than strength, such as dose–response (biological gradient). As an example, the rate ratio associating environmental tobacco smoke with lung cancer is below 2, but its causal nature is supported by interpolation between the low rates seen in unexposed non-smokers and the much higher rates seen among direct smokers.

On the other hand, relatively strong non-causal associations have been observed. One example is the association between birth order and Down syndrome: maternal ageing, which is strongly associated with infant birth order, has since been accepted as the actual cause of Down's syndrome and the source of the association. In the absence of information on actual causes, sensitivity and bias analysis can be used along with external information to estimate or quantitatively speculate on the extent to which possible bias sources have affected the strength of an observed association (Greenland and Lash 2008; Lash et al. 2009; VanderWeele and Arah 2011; Greenland 2014; Hernán and Robins 2020).

Consistency

A consistent finding is an association reported across populations, time, and study designs. Although the presence of a consistent result is often taken as

a compelling argument for causality, it can be misleading; for example, an inverse association of beta-carotene with cancer was seen across epidemiological studies but not in subsequent randomized trials. Conversely, the absence of consistency does not imply the absence of a causal effect. For example, acute effects may be submerged in studies that examine only chronic exposure, chronic effects may be submerged in studies that involve only short follow-up or one-time exposure measurement, and some agents may operate only in highly-susceptible subpopulations. Nonetheless, consistency across studies helps rule out chance as an explanation for an observed association. Consistency across studies of different designs can provide important evidence against specific biases that have been controlled by design; for example randomization allows for statistical control of unmeasured confounders, and complete follow-up prevents important bias from non-random losses.

Specificity

In Hill's formulation, specificity can refer either to a cause having a single effect or an effect having a single cause. The limitations of this consideration are apparent even in the case of smoking and lung cancer. Although the smoking and lung cancer association is stronger (on the ratio scale) than the association between smoking and heart disease, there is general agreement today that smoking can increase the risk of many diseases, including heart disease and other cancers.

Specificity can however strengthen a causal inference if a competing non-causal hypothesis would predict a non-specific association (Weiss 2002). For example, some have argued that screening for certain cancers is ineffective in and of itself for reducing cancer mortality, and that the apparent protective effect after adjustment for lead-time reflects the fact that those people who choose to undergo regular screenings are generally more health conscious and therefore at a lower risk for cancer due to their 'healthy lifestyle'. If a specific screening instrument, say a mammogram, were shown to be associated with lower mortality from breast cancer but *not* lower mortality from cancers in other sites, it could strengthen the inference that mammography is indeed useful in preventing deaths from breast cancer; this approach is sometimes described as using 'negative controls' (Lipsitch et al. 2010).

Temporality

Temporality means that a cause must necessarily precede its effect. This positive assertion is inarguable, but it is also possible that in some instances a putative cause (X) may be observed to follow the hypothesized effect (Y), whereas in other instances the putative cause (X) precedes and does in fact cause the effect (Y). Thus an observation that Y preceded X in a specific case (reverse order) is not an argument against causality in cases where Y follows X.

Reverse time order is thus a definitive argument against causality only if we know that X *cannot* come before Y. Establishing the correct temporal order between X and Y would, however, be a necessary condition for inferring causality in a given case. If X and Y vary over time, it is also possible that there is feedback between them such that X and Y both affect each other. If data are available on multiple measurements of these variables, longitudinal causal modelling can help evaluate such feedback (Hernán and Robins 2020).

Biological gradient (dose–response)

A biological gradient is a dose–response relation between an exposure and an outcome. Though most epidemiologists think of a ‘linear’ or monotonic dose–response association as strengthening a causal inference, this need not be the case. There may be a sharp increase in risk for specific outcomes at low to moderate doses of a given exposure that tapers off at higher doses, or there may be no adverse effect until saturation of detoxification mechanisms is reached, resulting in increased risk only at higher doses.

Many substances show non-monotonic trends with outcomes in a manner consistent with their hypothesized biological effects. For example, both very low and very high doses of certain vitamins may increase the risk of death, a fact consistent with what we know about the biological properties of these vitamins. In addition, an apparent monotonic dose–response relation (risk always increasing with greater exposure or risk always decreasing with greater exposure) does not prove the observed associations are genuine rather than artefacts of confounding. If an uncontrolled confounder is monotonically associated with the exposure and monotonically associated with the outcome, an apparent dose–response

relation between exposure and outcome could simply reflect the dose–response relation between the confounder and outcome (Weiss 1981). Sensitivity analysis can clarify the extent to which an observed dose–response relation contributes to evidence of causality (Rosenbaum 2003).

Plausibility

A plausible association is one that conforms to the current scientific understanding of the relation between a putative cause and its effect. This understanding can be informed by other epidemiological studies, animal studies, biology, toxicology, etc. As Hill noted, a limitation of plausibility in assessing causality is that current scientific understanding can be incomplete or wrong. For example, the higher malaria rates seen in lowland and swampy areas made plausible the idea that the disease was caused by 'bad air' (Medieval Italian *mala aria*), but was instead simply an artefact of those areas supporting higher densities of *Anopheles* mosquitos. Conversely, it was once deemed implausible or even impossible that genes could 'jump' across genome locations, yet this phenomenon is now well documented.

Coherence

Hill used the term 'coherence' to mean that the hypothesized causal relation of exposure to outcome is not in conflict with current scientific understanding of the disease process. Hill emphasized that an absence of coherence was not a strong argument against causality. If an observed association apparently conflicts with current scientific understanding of a disease process, it may be that the understanding is mistaken rather than that the association is non-causal. For example, at the time it was made, the observation that shallow inhalers of cigarette smoke had increased rates of lung cancer relative to deep inhalers seemed to contradict the understanding of lung cancer aetiology. Subsequent research on lung cancer, however, found that the cells affected by cigarette smoke tended to be in the upper lung and respiratory tract, which was in fact consistent with the observation of an elevated association for shallow inhalers (Wald 1985).

Conversely, coherence alone does not supply strong support of causality. The theory that the inverse association of beta-carotene with cancers

observed in epidemiological studies represented a preventive effect was quite coherent with contemporary theories of antioxidants and cancer, but the theory that this association reflected a causal effect of beta-carotene was nonetheless refuted by subsequent randomized trials.

Experimental evidence

In modern discussions, ‘experimental evidence’ often refers to either human or animal experiments, which are themselves very different categories of evidence. In practice, experimental evidence for a specific causal relation may be limited or absent: for many exposures, human experimentation is impractical or unethical, and, for many disease processes, no suitable animal model exists.

Hill seemed to have a notion of ‘experiment’ that was broader than randomized trials, however, and more akin to the notions of classical writers such as Mill (1862) in which an experiment involves an intervention that largely determines who is exposed. Hill discussed the evidence obtained by examining the change in disease frequency when the potentially harmful exposure has been reduced or removed, as in certain natural experiments. These types of before-and-after comparisons may provide compelling evidence, although they can mislead if there are uncontrolled time-varying confounders that drive the observed associations. For example, the steep rise in lung-cancer rates seen in Western countries in the first half of the 20th century coincided with many changes including the spread of electrical service, indoor plumbing, and telephones, as well as the increased use of cigarettes.

Randomized experiments are sometimes claimed as necessary or even sufficient evidence for or against an effect. Such extreme views are simply wrong (Hill 1965; Pearl 2009; Deaton and Cartwright 2018). Failure to detect an effect in a randomized experiment may reflect only lack of sensitivity or power, and effects generally agreed to have been ‘detected’ may still be controversial. The history of screening mammography (Biller-Adorno and Jüni 2014) shows that even randomized trial evidence need not be definitive or settle issues. Among the many reasons is that trial populations can be quite different from those exposed in everyday life (e.g. trial population are often specially selected for being thought likely to respond positively to treatment, without severe side effects). Then too, trials

can have their own defects and limitations such as noncompliance and drop-out that diminish the advantages conferred by initial randomization (although these problems can be partially adjusted for using special techniques; Greenland 2002, 2005; Hernán and Robins 2020). In addition, because of their much higher expense per participant, randomized trials tend to have smaller sample sizes than other studies, thus limiting their precision and power for detecting effects. Finally, for studies of medical procedures such as mammography the treatment itself may change considerably over time with improved equipment and training, or may be used more poorly in practice than in trials with strictly enforced protocols; in either case, results from even the best trials may be misleading for current practice.

Analogy

Analogy refers to drawing inferences about the association between a given exposure and disease based on what is known about other exposure–disease relations. From the known effects of cigarette smoking on lung cancer, we might expect that inhalation of other combustibles (e.g. cannabis) would have similar effects, even in the absence of studies on the subject. Analogy can be a useful scientific tool for generating new hypotheses about disease processes; however, its utility for assessing causality is limited by the understanding, imagination, and knowledge of the scientist.

Statistical significance

Notably absent from Hill's list is 'statistical significance' or the like. Hill (1965) prefaced his considerations with the supposition that '[o]ur observations reveal an association between two variables, perfectly clear-cut and beyond what we would care to attribute to the play of chance'. This initial statement led some to claim that Hill considered 'statistical significance' a necessary condition. However, such claims ignore Hill's failure to mention any criterion for a 'statistical significance' condition and his devoting a whole section to expressing scepticism about significance tests. Notably, Hill concluded that 'too often I suspect we waste a deal of time, we grasp the shadow and lose the substance, we weaken our capacity to interpret data and to take reasonable decisions whatever the value of P.

And far too often we deduce ‘no difference’ from ‘no significant difference’.’ It appears, then, that Hill was wary of making too much of the absence as well as the presence of ‘statistical significance’ when forming inferences.

Regardless of Hill’s precise views, today it is widely recognized that ‘statistical significance’ is a controversial concept whose presence or absence should never be confused with presence or absence of an effect: if a statistical hypothesis test is desired one should present the actual resulting p-value for consideration, not whether the p-value crossed a threshold (Greenland et al. 2016; Wasserstein and Lazar 2016; Amrhein et al. 2017, 2019; Greenland 2017b; Wassertein et al. 2019; McShane et al. 2019; Rafi and Greenland 2020). Furthermore, in presenting such p-values for associations or effects, is essential that they be accompanied by a p-value for an alternative hypothesis or an interval estimate, with thorough recognition of the many assumptions on which all statistics depend (Greenland 2017b; Rafi and Greenland 2020).

Summary

For reasons such as those just discussed, Hill and other critical thinkers have discouraged taking his ‘viewpoints’ as a checklist for causality. Despite the ongoing popularity of Hill’s considerations—sometimes in modified form—there is no general agreement on which of them should be used or how they should be used in making causal inferences (Weed and Gorelic 1996; Kaufman and Poole 2000; Holman et al. 2001; Höfler 2005, 2006; Rothman et al. 2008). Some have argued that such aids to inference amount to refined common sense, which if taken as rigid criteria may harm the inferential process (Lanes and Poole 1984; Phillips and Goodman 2004, 2006; Rothman et al. 2008, ch. 2). Others have used the considerations to develop general deductive formats for evaluating causal hypotheses (Maclure 1985; Weed 1986; Susser 1991). Finally, researchers may use different considerations or deploy them differently based on the specifics of the inferences being made, suggesting that, in practice, most of the considerations reflect values rather than objective inferential tools (Poole 2001).

Formal approaches to causal inference

Implicit in the discussion of causal considerations is the idea that there is a well-defined notion of what constitutes cause and effect. Perhaps the oldest non-circular set of definitions arises from the *potential-outcome* or *counterfactual* framework. The potential-outcome or counterfactual model (Rosenbaum 2002; Morgan and Winship 2007; Rothman et al. 2008 ch. 4; Pearl 2009; VanderWeele 2015; Hernán and Robins 2020) specifies what happens to individuals or populations under alternative actions or interventions and also makes explicit the problems in operationally defining causes (Greenland 2002, 2005; Hernán 2005). This model of causation is also useful in defining methodological concepts such as confounding (as discussed in Rothman et al. 2008, ch. 4). Causal diagrams are a useful and closely related tool that enables quick visualization of the assumptions used in causal models; for basic introductions see Glymour and Greenland (2008), Pearl (2009), Elwert (2013), and Pearl and Mackenzie (2018).

Potential outcomes and counterfactual causality

To see how causal inference can be viewed as a prediction problem, consider that we may wish to predict how the rates of lung cancer among bar workers would change if an indoor smoking ban was enacted. The potential-outcome model allows us to formalize questions such as 'Will a smoking ban decrease the rates of lung cancer in 10 years beyond what can be expected in the absence of a ban?'

In discussions of potential outcomes, three components must be defined:

A target of interest that will be the subject of the study of causation. This target may be an individual, a group, or any other unit of study.
A list of possible interventions or actions x_0, x_1,… that could have been applied to the target over some time span of interest.
An outcome measure (Y) taken after implementation of the intervention or action.

If x_a is the action taken from among possible actions x_0 and x_1, a potential-outcome model posits that there is a well-defined outcome, $Y(x_a)$, that would have followed from that specific action x_a. This outcome is often termed a 'potential outcome'.

As an example, suppose the treatment of interest is sending to members of an insurance plan, on their fiftieth birthday, a mail-in home sampling kit to screen for stool blood, a possible indicator of colon cancer. Suppose $X = 1$ if the kit is supplied to a person, and $X = 0$ if not. Ordinary analyses might examine one outcome variable, such as $Y = 1$ if the person dies of colon cancer by age 60 and $Y = 0$ if the person does not die by this age. In contrast, a potential-outcome analysis imagines a separate outcome variable for every treatment being compared: for $X = 1$, we imagine the outcome $Y(1) = 1$ if the person dies of colon cancer by age 60 *when sent the kit* and $Y(1) = 0$ if the person does not die *when sent the kit*. Similarly, for $X = 0$ we consider the outcome $Y(0) = 1$ if the person dies of colon cancer by age 60 *when not sent the kit* and $Y(0) = 0$ if the person does not die when not sent the kit. Offering the kit is then beneficial for the person with respect to these outcomes if $Y(1) = 0$ but $Y(0) = 1$, which is to say if the person would not die of colon cancer by age 60 if sent the kit but *would so die* if the kit *was not sent*. Presumably, such a benefit would arise because the kit, if sent, would be received, used, and would lead to detection of and intervention for an otherwise fatal tumour.

The potential-outcome model is widely used in statistical discussions of causality and has become increasingly popular in epidemiology and other fields. Yet it is not without controversy, largely because *at most* one potential-outcome variable can be observed for each person. That observable potential outcome is the one corresponding to the treatment actually received; all the other potential outcomes are unobserved and hence are ‘missing data’. Understandably, the incompleteness of the data under the model is upsetting to practitioners, and the inevitable missingness requires reconsideration of many conventional statistical methods. Such reconsiderations have, however, led to innovative methods for previously intractable problems, such as the estimation of effects of time-varying treatment regimens (Hernán and Robins 2020).

There are also a number of aspects of the model that are often misrepresented as limitations but are not. For example, the model does *not* require that outcomes be well defined for any possible intervention; it simply requires that the outcomes be well defined for those interventions of interest. If, in a study of motorcycle crash fatalities, we wish to estimate the effect of a helmet law that fines riders who do not use helmets, versus no law, we do not need to specify the outcomes any other actions (such as a

law mandating jail time for non-use). Also, contrary to some misunderstandings, the potential-outcome model is not inherently deterministic: although the model is quite often introduced and taught using deterministic language, a potential outcome could instead be the parameter of a probability distribution, for example the probability of disease (Rothman et al. 2008, ch. 4).

Causes and effects

The term ‘effect’ is sometimes used to specify the outcome of a causal process. A researcher may describe lung cancer or heart disease as two possible effects of cigarette smoking. A quantitative definition of an effect is a numerical contrast in outcome measures corresponding to different actions or interventions, for example, $Y(x_1)$ and $Y(x_0)$; the numerical contrast is then called a *measure of effect*. In the earlier example, if x_1 is the presence of a helmet law and x_0 is the absence of a helmet law, then $Y(x_1)$—$Y(x_0)$ could be the fatality-rate difference for motorcycle crashes and $Y(x_1)/Y(x_0)$ could be the fatality-rate ratio.

Thus, under a potential-outcome model, an effect is a contrast in outcomes corresponding to *two* different actions in *one* single target population (where the population could comprise a single individual). Effects must be defined with respect to a clearly specified alternative or reference condition. To say that smoking one pack of cigarettes a day increases the risk for lung cancer and heart disease would be incorrect without specifying the alternative: smoking one pack a day may be harmful relative to not smoking, the implicit reference condition, but may be protective relative to smoking two packs a day. Statements about the effects of causes may be ambiguous or meaningless unless both the index and reference actions are stated explicitly.

It follows that an action cannot be considered inherently causal—it can only be deemed causal when the outcome associated with it is compared to the outcome associated with an alternative action. Consider a person with depression who is prescribed an antidepressant medication. The weeks following initiation of treatment are thought to be periods of increased risk for suicide. If this person commits suicide in the period following treatment initiation, some would say the antidepressant caused the suicide. Given that

the person was depressed to begin with, it is possible that they would have committed suicide even if they had not been prescribed the medication, in which case the antidepressant did not cause the suicide in reference to the alternative of no prescription. If instead of being prescribed an antidepressant, however, the person had been hospitalized, they may not have committed suicide, in which case the antidepressant treatment may be considered a cause of their suicide, but only in reference to the alternative action of hospitalization.

A second important point is that an effect is a contrast in outcomes for one target population, but, for that single population, we can observe *at most* one of the actions and its corresponding outcome. The other actions, which are not observed, are *counterfactual* (contrary to fact), and as a consequence their corresponding potential outcomes are not observed. For example, $Y(x0)$ would be unobserved (missing data) for all persons who in fact received treatment $x1$. Thus, potential outcomes for counterfactual actions can only be estimated, not observed.

If the index and reference actions lead to identical outcomes, then the index action is said to have no effect on the target population. When an action has an effect, describing it as causal or preventive depends on which outcome we are referring to. If smoking a pack a day for 20 years (versus none) causes an individual to die at age 70, then this smoking also prevents survival past age 70. In parallel, if not smoking prevents death at age 70 relative to smoking a pack a day for 20 years, it causes that individual to survive past age 70.

Confounding and measures of association

Our inability to observe the potential outcome of more than one action fundamentally limits our ability to make causal inferences. In any attempt to estimate a causal effect, at least one potential outcome, corresponding to a counterfactual action, must be estimated or predicted rather than measured. In practice, this is accomplished by measuring outcomes in other individuals who in fact experience the reference action. In experiments and in cohort studies, these individuals are often called the control subjects.

As an example, on 1 July 2000, Florida weakened its existing motorcycle helmet use law to exempt individuals over the age of 21 who had at least US$10,000 in insurance in case of an accident. To estimate the effect of

weakening the helmet law in Florida, we could compare (contrast) the rates of motorcycle crash fatalities before and after the change. Specifically, we use the fatality rate in 1999 as a substitute for the unobserved (counterfactual) fatality rate in 2001 had the law not been changed. The resulting contrast is no longer a measure of effect, because it is not a contrast of the outcomes of two different actions in a single target population. Instead, it is a *measure of association*, which is a contrast of outcomes across groups exposed to different actions. We use this measure of association as a substitute for or estimate of the corresponding measure of effect. The amount of *confounding* can be quantified as the difference or ratio between the measure of association and the measure of effect that the association is intended to estimate.

Although confounding is a serious threat to our ability to make causal inferences, we can often determine factors that contribute to the disparity between the measure of association and the measure of effect. In our example, these factors, commonly referred to as *confounders*, would be the reasons why the motorcycle fatality rates in 1999 would differ from those in 2001 had the helmet law not changed. When confounders are measured, analytic methods can be used to minimize the amount of confounding due to those factors and thus strengthen our causal inferences. The most basic methods for confounding control are based on stratifying the observations on values of the confounders. Summary comparisons can be obtained, e.g. via *standardization*, which averages outcomes in the index and reference groups using a shared weighting scheme or standard (Rothman et al. 2008, ch. 4). Other methods for obtaining summary comparisons make special assumptions to combine measures of association across confounder levels (e.g. logistic regression on exposure and confounders assumes the exposure-outcome odds ratios are constant across levels of the confounders). In all these approaches, the resulting summary comparison across confounder levels is said to be *adjusted* for the confounders.

An adjusted measure of association will be a good estimate for the desired measure of effect only insofar as we have controlled for (e.g. stratified on or modelled) the important confounders. If there are other factors that contribute to important differences between the counterfactual (alternative) outcome and the observed outcome used as its substitute, then the measure of association will remain a biased estimate of the measure of effect. In the case of the helmet law and the motorcycle crash fatalities, one

would have to ask if all the important factors contributing to changes in the rate of crash fatalities *other than the change to the helmet law* had been measured and properly controlled. To the extent we are uncertain or doubtful about our measurement and control of important confounders, we would have to doubt the validity of the adjusted association as an estimate of the measure of effect.

Practical uses of causal inference

Academic discussions of cause and effect often focus on the 'effects' of changes that have no realistic interpretation as actions (e.g. elimination of lung cancer) or actions that are not realistic options (e.g. achieving a 'smoke-free society'). Even when discussions focus on the impact of feasible interventions, they are often based on unrealistic assumptions about their consequences, for example, assuming 100% compliance with a given treatment or behaviour-modification programme.

Discussions of the expected health impact if a given disease or outcome could be removed are irrelevant and often misleading for policy formulation. For example, consider the 'burden of disease due to lung cancer'. A rough ranking of actions and questions from irrelevant and unrealistic to most relevant would be:

Directly eliminating lung cancer (e.g. 'How many deaths could be prevented if we could eliminate lung cancer?').
Removing risk factors for lung cancer (e.g. 'How many deaths could be prevented if we could eliminate cigarette smoking?').
Applying an intervention to change risk behaviours for an entire population (e.g. 'If we could implement a given smoking-cessation programme to the entire smoking population of a nation, how many deaths could be prevented?').
Applying an intervention that will change in risk behaviours in a specially targeted segment of a population (e.g. 'If we could implement a given smoking-cessation programme in a targeted group of motivated individuals, how many deaths could be prevented?').

We will discuss each of these actions in turn.

Removing outcomes

When the outcomes are not directly manipulable, any prediction based on the hypothesized removal of the outcomes needs to consider not just the fact of the outcome removal but also the method used to remove it (Greenland 2002, 2005; Kalbfleisch and Prentice 2002; Hernán 2005; Hernán and VanderWeele 2011). Even if we can define a realistic intervention for removal of the outcome, we cannot assume that removal of the outcome will leave our population with a risk profile similar to that for another population that did not experience the intervention or outcome. Unfortunately, standard statistical procedures for analysing these types of data make the assumption that the risk profiles across these populations (intervention and no outcome vs. no intervention and no outcome) are similar (an assumption of 'independent competing risks'). Thus, it is reasonable to expect that even if we can conceive of an intervention that will prevent a specific outcome, estimates of effect in light of this outcome removal will likely be biased if based on the experience of those who do not experience the intervention or the outcome.

To estimate the effects of outcome removal, one must compare successfully treated individuals. To illustrate, suppose Y represents cause of death, with $Y = y_1$ for death from myocardial infarction (MI) and $Y = y_0$ for death from other causes ('competing risks'). An individual will eventually experience one but not both of these outcomes, so at least one must be counterfactual. Now suppose T represents years of survival past age 50. The value T will take depends not only on the value of Y but also on how that value (y_1 or y_0) is brought about. Suppose a man with a sedentary lifestyle and poor diet died from an MI at age 54, so that we observe $T(y_1) = 4$ (the number of years lived past the age of 50). The value of $T(y_0)$ would then be the number of years lived past age 50 *if the MI death had been prevented*. This value would depend critically on how the MI death was prevented. If the man had taken up a regimen of physical activity and a healthy diet in his twenties, $T(y_0)$ could be considerably larger than $T(y_1)$ because the regimen would lower his risk of many causes of death besides MI. If instead the MI death was prevented by medical care at the time the MI occurred, $T(y_0)$ and $T(y_1)$ may not differ by much because the man would remain at an increased risk for stroke, cancer, and other potentially fatal events.

Removing risk factors

Consider the debate on obesity and mortality. Numerous studies have reported increases in mortality associated with having a body mass index (BMI) over 30 (the cutpoint for obesity) relative to a 'normal' BMI of 20–24.9. Some have used these findings to assert that obesity causes early mortality and that getting people to lose weight will save lives. But suppose not all individuals who go from a BMI of over 30 to a BMI of (say) 24 lose weight in the same way. Some might start exercising and eating more healthfully, in which case lower mortality may in fact result. Others might undergo gastric bypass surgery or become chronic users of amphetamines, each of which are known to confer some risk for early mortality.

Unfortunately, studies that examine only the association of BMI with mortality tell us nothing about the impact of different interventions to change BMI. To make a relevant causal inference, one must specify an intervention aimed at reducing BMI and then compare the mortality outcomes under that intervention to outcomes under a reference intervention (such as no intervention). The resulting measure of association, as an estimate of a measure of effect, would *not* be a contrast in outcomes of persons at different levels of BMI; it would be a contrast in outcomes under *specific interventions* among persons who started with the same BMI.

The very idea of the 'health effects of BMI' suffers from confusion of the effects of interventions (e.g. a diet and exercise regimen) with the downstream results of intermediate outcomes (e.g. changes in BMI). At best, mortality rates across BMI groups are averages taken across a range of *unknown* interventions that brought about the observed BMI levels. As a consequence, comparisons of these rates correspond to comparing average outcomes under differing distributions of unknown interventions (VanderWeele and Hernán 2013), and even this limited interpretation holds only under very strong assumptions. A change in BMI is not an intervention, thus one cannot unambiguously define the causal effect of a change in BMI. A similar problem arises if one considers the effect on lung cancer incidence if more people quit smoking. As with BMI, a researcher would need to specify an intervention (e.g. nicotine patches, hypnotherapy, medication, etc.) before discussing the effect of getting smokers to quit.

When conceptualizing exposures in observational studies as interventions, as opposed to protocols in clinical trials, there are limitations

to how detailed the description can be, making vagueness about the hypothetical intervention unavoidable (Robins and Greenland 2000). Nevertheless, moving away from thinking of outcomes such as BMI as potential causes—as opposed to intermediates—is necessary for making policy-relevant causal inferences from observational data. A related problem arises in discussing the causal effects of personal characteristics. For example, considerable debate has surrounded the question of whether it is meaningful to speak about factors such as race or sex as being possible causes of effects (Holland 1986; Greenland 2005; Kaufman 2008; VanderWeele and Hernán 2012).

Although it might seem natural to ask whether the risk of a disease like hypertension is affected by a person's race, studies that contrast rates of hypertension in different racial groups do not adequately address this question. To ameliorate the racial disparities in hypertension, we would first need to identify feasible interventions. For this goal, discussing race as a cause is of no help, because changing the race of individuals is not a clearly defined action, let alone a feasible or desirable intervention. Observed associations between race and hypertension indicate the disparities that exist, but these associations generally do not pinpoint underlying causes and are thus insufficient to inform efforts to mitigate disparities (Kaufman 2008).

Finally, when considering effects of baseline characteristics it is important to remember that later events may be affected by those characteristics and thus adjustment for those events will bias the resulting effect estimate. This is important to bear in mind as modern estimates may involve adjustment for many variables, some of which should not be included based on causal analysis (Rothman et al. 2008 chapter 9; Glymour and Greenland 2008; Westreich and Greenland 2013).

Identifying and evaluating feasible interventions

Even when an exposure is an intervention, the discussion of its effects can be complicated if there is treatment non-compliance, the intervention is not randomized, or if the researcher wishes to generalize effect estimates to different target populations.

In practice, apart from occasional mandates, treatments are only prescribed or recommended, therefore prescription or recommendation is all

that can be unambiguously studied and implemented. What a subject actually chooses to do in response to the assigned treatment is a function not only of the assignment but also of other factors, most of which are either infeasible to modify (such as the subject's age) or for which modification introduces further treatment (e.g. side effects). If the researcher wishes to understand the effects of received treatment rather than treatment assignment, it is important to realize that received treatment is an *outcome*, not an intervention, and is thus subject to the problems described earlier for intermediate outcomes such as BMI. Special techniques are available for studying the effects of received treatment (e.g. instrumental variables, g-estimation; see Hernán and Robins (2020) for introductions to these topics). Nonetheless, effects estimated by these techniques are those expected under ideal conditions and will likely overestimate the effects that will be seen in field implementation.

The most relevant causal hypotheses for policymakers and health practitioners concern the changes in outcome to be expected under the implementation of feasible interventions, subject to all their compliance problems. Estimating field effects of feasible interventions is difficult, but doing so at least avoids the unrealism and biases that arise from pretending that subject characteristics or behaviour are under direct or perfect control of health practitioners or society. In studying these types of interventions, the effect measure of interest will be a contrast in outcomes corresponding to different levels of the intervention (e.g. whether or not to fund a given programme), rather than the 'received treatment' discussed earlier. Thus the question is not what would happen if people were to comply with the intervention they were assigned, but rather what would result if people were offered a given treatment at a given cost.

Studies that address causal hypotheses about feasible interventions face profound methodological difficulties. If the intervention is not assigned at random (e.g. if individuals who participate in a given intervention are volunteers, and their outcomes are compared to those who chose not to participate), the resulting measure of association is likely to be confounded and will therefore be a poor estimate of the desired measure of effect. The association can also be distorted due to refusals, loss to follow-up, and measurement error, among other things. These threats to validity are discussed in epidemiological methods texts such as Rothman et al. (2008).

Problems in generalizing or transporting the results from a particular study to a target population of interest are often not given detailed attention, yet they are of great concern for policymaking. The target populations for policy are always different from study populations, for at the very least the target population is defined in terms of future experience, whereas study results are always based on the past. Even if there are no time trends, however, factors such as the compliance rate and response to the intervention depend on the characteristics of the individuals involved in a given study. The results from a study may therefore not be applicable to other populations, each of which may be composed of a different mix of individuals.

This problem of population heterogeneity of effect is sometimes framed as an issue of 'effect measure modification', meaning that the measure of the intervention effect depends on characteristics of the individual or the population (see Rothman et al. 2008, ch. 4; Hernán and Robins 2020). In theory, the solution is to identify factors responsible for the heterogeneity, stratify on these factors, estimate effect measures within the stratified groups, and predict the likely impact of an intervention in a target population by standardizing the stratified estimates based on the distribution of the factors in the target population. Extensions based on sample reweighting are also available (Cole and Stuart 2010; Westreich et al. 2017). Nonetheless, it can be difficult to identify all the important sources of heterogeneity, and there are always severe data limitations on the number of factors that can be studied in this fashion.

From research to policy and beyond

This chapter has reviewed some of the considerations necessary in making causal inferences relevant to public health. If the explicit goal of the study is to report associations and thus provide data for subsequent evaluations, rather than to estimate causal effects, these considerations can be deferred to research-synthesis reports (Greenland et al. 2004). In fact, causal inferences from single epidemiological studies are rarely justified (with exceptions typically characterized by enormous risk or rate ratios), and epidemiology is almost never the sole basis for policy decisions, although epidemiological results are important inputs for those decisions.

To name just a few examples, studies on the link between smoking and lung cancer have led to labelling of cigarette packs and bans on indoor smoking; results linking air pollutants to disease and mortality have informed emissions standards; and findings on the connection between vitamin deficiencies and adverse health outcomes have led to fortification of milk, cereals, and flour. In all these examples, decisions were based not only on multiple epidemiological studies but also on evidence from laboratory and clinical studies and considerations of mechanistic theories.

It is thus important for health researchers as well as policymakers to understand the fundamentals of causal inference, especially the often neglected issues of defining meaningful and feasible interventions. It is equally important for researchers to understand that research is done to inform policymaking, not to set policy, and that causal inference represents a synthesis of multiple evidence streams. Apart from perhaps outbreak investigations or large, well-executed randomized trials, no single study is capable of establishing a causal relation. Furthermore, randomized trial populations must be reasonably representative of the intended target populations in order to fully inform clinical or policy decisions, yet trial and target populations are usually quite different. Thus, decisions should be based on a careful consideration of the entire relevant scientific and policy literature and must address cost–benefit considerations as well as purely scientific issues.

5.13

Systematic reviews and meta-analysis

Nandi Siegfried and Lawrence Mbuagbaw

Introduction

Systematic reviews use systematic, explicit, and reproducible methods to identify relevant studies, assess the risk of bias in these studies, extract information, and synthesize findings. Systematic reviews often employ statistical methods (known as meta-analysis) to combine data from similar studies in order to obtain more precise estimates than those derived from the individual studies included in the review.

Systematic reviews play a critical role in guiding practitioners, policymakers, and consumers to make well-informed decisions and choices about healthcare. The massive expansion in the volume of biomedical literature, beginning in the middle of the twentieth century, has made it increasingly difficult for healthcare decision-makers to keep up with the findings of individual studies. Reviews of the literature are thus important for taking stock of existing knowledge and making informed choices about healthcare and resource allocation (Chalmers et al. 2014). Poorly conducted reviews drawing incorrect conclusions from the literature have the potential to cause serious harm to patients and populations, and waste resources (Chalmers and Glasziou 2009). This is especially important in situations where health problems are severe and the scarcity of resources makes it vital that they are not wasted (Chinnock et al. 2005).

In this chapter we focus our discussions on the methodology of systematic reviews to evaluate the effectiveness of healthcare interventions. Reviews of effectiveness preferentially include randomized controlled trials (RCTs) and as such, most of our descriptions and examples relate to systematic reviews of RCTs. The utility of the systematic review method is increasingly applied to synthesize results from observational studies and more recently,

qualitative data. The specificities related to the methods required to conduct such reviews are not covered in any detail in this chapter, and readers interested in the broader applicability of reviews are advised to expand their reading beyond what is included here. In the following pages, we outline the key steps involved in planning and executing a typical systematic review.

What is a systematic review?

An up-to-date synthesis of the results from relevant primary studies should provide healthcare decision-makers with a strong foundation on which to base their policy and practice decisions. If due care is not paid to the methods used during the collection, identification, and analysis of results from individual studies, the final synthesis may be at risk of bias. Bias includes any distortions that occur during the investigation process and may lead to overestimating or underestimating the strength of the observed effect. The methods of a systematic review aim to reduce the risk of biases that may be present in a traditional literature review. The main biases that can affect a review are outlined next and the differences between systematic and traditional literature reviews are presented in Table 5.13.1.

Bias that may affect reviews

Selection bias

Selection bias may occur in a review when the collection of primary studies systematically favours the identification of some studies over others. The main types of selection bias encountered in reviews are publication and language bias.

There is robust research evidence to indicate that studies with positive results are more likely to be published than those with neutral or negative results (Hopewell et al. 2009). If unpublished, negative studies are not identified and included in a review, the synthesized results will be at risk of publication bias and may yield a false positive result (Hopewell et al. 2007). A well-conducted systematic review will attempt to seek out unpublished studies, within resource and time constraints, to reduce potential publication bias.

English is the dominant language of publication in the biomedical literature and many authors seek to publish their work first in English-language journals. There is evidence that trials published in English are more likely to have statistically significant, positive results than studies published in German-language journals (Egger et al. 1997). Failing to include studies which are written in languages other than English, be they published or not, may lead to language bias which may affect the final synthesized results of the review, although this has not been shown consistently (Morrison et al. 2012). A well-conducted systematic review will not limit the search to a single language and review authors should recognize the need to budget for translation of articles where necessary.

Indexing bias

Access to large volumes of literature via electronic databases has streamlined the conduct of reviews and greatly reduced the time required to conduct a systematic review of high quality. In order to accurately identify a primary study of a specific study design, the terms of the search strategy must match that of the database record. For example, for a search strategy to find a randomized controlled trial in a database, the original record must have been clearly identified or indexed as such when the record was created. An initiative to increase the precision of searches for RCTs in MEDLINE was initiated by the Cochrane Collaboration in the 1990s leading to greater accuracy when searching for RCTs in MEDLINE and Embase (Glanville et al. 2006). Systematic review team authors should note that indexing bias is likely to remain a concern when searching across other databases and when searching for observational studies and other non-randomized designs.

Information bias

A review is dependent on the quality of the reporting of the included studies. Where reporting of a study is poor or data is lacking, a review may be at risk of information bias. During the conduct of a systematic review, the author team is encouraged to actively seek out the missing data by contacting the authors of the primary study (Young and Hopewell 2011). Where this is not possible, the systematic review team will be required to transparently report any assumptions made about the missing data and should indicate to the reader the possible effects of the missing data on the synthesized results.

Table 5.13.1 A comparison of the typical characteristics of systematic versus more traditional literature reviews

Systematic review	Literature review
States the methods of the review in a protocol	Often does not state the methods of the review
Answers a focused question or tests a hypothesis; usually narrow in scope	May have a clear question but it often involves general discussion with no stated hypothesis; often very broad in scope
Attempts to locate all relevant studies to minimize publication and other biases	Usually does not attempt to locate all relevant studies
Uses explicit eligibility criteria to determine which studies will be included in the review to prevent selection bias on behalf of the reviewer	Usually does not specify why some studies are included and others excluded
Systematically appraises the methods of the included studies to determine possibility of bias in these studies and sources of heterogeneity between the study results	Often does not assess the risk of bias in the studies or acknowledge differences in their methods
Bases results on studies that are methodologically sound	Often does not distinguish between methodologically sound and unsound studies
May combine study results statistically in a meta-analysis	Often does not pool results in a meta-analysis
Results illustrate level of heterogeneity of data, allowing quantification of uncertainty	Results often presented in certain terms without indicating uncertainty or variability

Developing a protocol

A systematic review is classified as secondary research, but it is nevertheless an original study which collects, appraises, and combines results from primary studies. For this reason, a research protocol is developed prior to the conduct of the review to ensure that the study objectives and methods are stated explicitly and to provide a template for the team to follow.

The protocol should contain the following sections:

Background to the clinical problem and intervention under study
Formulation of the review question (using the PICO structure, see next)
Inclusion and exclusion criteria
Search strategy
Methods of study selection, data extraction, and quality appraisal
Methods of analysis
Methods of overall quality assessment (e.g. Grading of Recommendations Assessment, Development, and Evaluation, GRADE)

Ideally the protocol should undergo peer review to ensure that it is rigorous and meets acceptable standards.

Registration of a review on a publicly accessible platform is encouraged and is mandatory for some funders. This improves transparency and allows detection of any changes to the protocol that may have occurred during the process of the review. It may also reduce the likelihood of unnecessary duplication of effort (Straus and Moher 2010). Review protocols can be registered publicly on the freely available platform, PROSPERO (https://www.crd.york.ac.uk/prospero/). PROSPERO includes protocol details for systematic reviews relevant to health and social care, welfare, public health, education, crime, justice, and international development, where there is a health-related outcome. Systematic review protocols on PROSPERO can include any type of any study design. Reviews of reviews and reviews of methodological issues that contain at least one outcome of direct patient or clinical relevance are also accepted.

Key point: The methods of a good systematic review should be described in a protocol which is registered publicly in advance of the conduct of the review.

Formulating the review question

The first step in conducting a systematic review is to clearly formulate the research question. A focused review question guides the selection of terms to include in the search strategy and narrows the scope of the inclusion criteria. The PICO-ST structure provides a useful framework for developing the review question:

P Populations
I Intervention
C Comparison
O Outcome
S Study design
T Timeframe

The minimum structure of a PICO question is as follows:

> [**Intervention**] compared with [**Comparison**] for preventing/treating [**Outcome**] in [**Populations**]

The study design (S) and timeframe (T) are optional additional components to the PICO. These allow the reader to immediately discern the design(s) of the studies included in the review (e.g. if the included studies are limited to RCTs). The timeframe component refers either to the time-point at which the primary outcome is measured, e.g. death at 1-year follow-up, or the time span of the studies included in the review, e.g. RCTs published between 1990 and 2010.

The O in the PICO refers to the outcome designated as the primary outcome(s) in the review question. The review team should carefully consider which outcome is the most meaningful to measure for answering the clinical question and denote this as the primary outcome. Note that this may differ from the outcome(s) designated as primary outcomes across the included studies.

Key point: The systematic review question is best formulated using the PICO structure.

Searching for studies

The search strategy forms the foundation of a systematic review and is best prepared by a trained librarian or information specialist. A comprehensive search should be highly sensitive, aiming to identify and locate as many of the eligible studies as is feasible within the timeframe and available resources. A search should also be precise in order to reduce the need to screen vast quantities of irrelevant material. Precision is a measure of the number of records that require screening to identify a single eligible study.

In practice the balance between sensitivity and precision is weighted towards high sensitivity to reduce selection bias (including language and publication bias), with low precision. Systematic review teams should generally expect to screen large numbers of records even if they will only a few studies.

Data sources to search

Published reports

An experienced information specialist will develop a search strategy using database-specific syntax including the keywords related to the review PICO. Examples of databases are listed next. At a minimum a well-conducted review of the effects of healthcare interventions should include the first three databases.

General electronic journal databases of published reports:

- European and North American focus:
  - MEDLINE (http://www.ncbi.nlm.nih.gov/pubmed)
  - EMBASE (http://www.elsevier.com/online-tools/embase)
  - CENTRAL (Cochrane Central Register of Controlled Trials) (http://www.cochranelibrary.com)
- South American focus
  - LILACS (Latin American Caribbean Health Sciences Literature) (http://lilacs.bvsalud.org/en/)
- African focus
  - African Journals Online (https://www.ajol.info/)

Subject-specific electronic journal databases:

- Databases will be dependent on the review topic, e.g. a review of behavioural interventions may include PsycINFO (https://www.apa.org/pubs/databases/psycinfo/index.aspx)

Unpublished reports

The so-called grey literature, such as conference abstracts, research reports, policy documents, dissertations, book chapters, and personal

correspondence, should be sought by contacting authors of identified papers, experts in the field, and relevant organizations, including pharmaceutical and medical device companies, and by searching pertinent websites. These sources should be identified at the protocol stage.

Ongoing studies

There are several prospective trials registries available which publish trial protocols and status updates of trial progress. These provide a useful source to identify ongoing studies and studies which are recently completed but not yet published. The choice of registry will be dependent on the topic.

Global focus (supported by World Health Organization)

- http://apps.who.int/trialsearch/AdvSearch.aspx

American and global focus

- https://www.clinicaltrials.gov

African focus

- http://www.pactr.org

Australasian focus

- http://www.anzctr.org.au/

Within the field of observational studies, there is increasing recognition that prospective registries are important, and several small registries do exist. Review teams are encouraged to seek these out in their chosen field should they wish to include observational studies.

Methods to screen for studies

At least two members of the review team should independently screen the titles and abstracts of the records yielded by the search and select all potentially eligible studies. The full-text article or report should then be obtained for each agreed potentially eligible study. Where disagreement or uncertainty occurs, it is advisable to adopt a conservative approach and obtain the full-text report.

Two investigators then apply an eligibility rule based on the PICO to each full-text manuscript and determine if the inclusion criteria are met. A third member of the team can act as arbiter where there is disagreement or uncertainty. The number of records at each stage of the screening, eligibility assessment, and inclusion process must be recorded in order to populate the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) flow diagram in the final report (see section 'Reporting a systematic review', later in this chapter). Reasons for excluding studies after reading the full text should also be recorded and provided in the final report.

It is worth noting that a single study may be reported in more than one article or conference proceeding. For example, a trial protocol and a paper outlining the preliminary results of a trial may be published or presented at a conference prior to the publication of a final report of the trial results. This is viewed as legitimate publication practice. However, sometimes results are published in different articles with no cross-referencing to other relevant reports and can lead to double counting of results in meta-analyses (Abraham 2000). This phenomenon has been labelled 'salami publication' and is to be discouraged. The final number of included studies should therefore refer to the number of discrete studies and not the number of articles or reports identified.

Key point: The search strategy of a systematic review requires the expertise of an information specialist and should be sufficiently comprehensive to ensure that as many eligible studies as possible are included in the review.

Data extraction

What data to collect

The specific items of data to be collected from included studies will be influenced by the objectives of the systematic review. In general the following items should be collected:

Eligibility of the study for inclusion or reason for exclusion.
Study methods, such as study design and duration, as well as items that will be used to assess the risk of bias, such as sequence generation, allocation concealment, and blinding.
Data regarding participants (e.g. sex, age, ethnicity, and education level) and setting (e.g. institution and geographic location) which may influence the size of the effect estimate or assist in assessing the applicability of results.
The number of intervention groups and the details of the specific interventions involved. Any information relating to the fidelity with which the intervention was administered (i.e. the extent to which it was implemented as planned) should be obtained. This is particularly important in preventive or complex interventions, which are usually implemented under ‘real-world’ conditions.
Information regarding the outcomes such as their definitions, time points at which they were measured, and units of measurement should be collected. Usually, this is done only for those outcomes prespecified in the review protocol. However, listing all other outcomes reported in the included study may enable analysis of risk of bias due to selective outcome reporting.
Results should be collected only for those outcomes prespecified in the protocol. For a meta-analysis it is also necessary to collect the numerical data for analysis.
Other information to be collected could include funding source, details of ethics approval, name or contact details of authors, and citations.

How to collect the data

Once the data to be collected have been determined, it is necessary to design appropriate data collection forms. These may be electronic or paper-based, depending on the preference of reviewers.

Data extraction refers to the process of recording all the relevant data from the included studies onto data collection forms. Piloting data collection forms using a representative sample of studies is recommended. To reduce the risk of errors during data extraction, it is advisable that at least two reviewers, working independently, are involved in extracting the data. Any disagreements between the reviewers should be resolved through consensus or arbitration by a third person.

Key point: Selection of what data to extract is guided by the objectives of the review question. Two independent investigators should extract data in duplicate to avoid errors.

Evaluation of the risk of bias

Interpretation of the results of any type of study is dependent on how well the study was conducted. For example, a randomized controlled trial may yield a significant beneficial result, but if a large proportion of the trial participants failed to complete the trial and outcomes were not available for those lost to follow-up, we may be less likely to believe the result. Similarly, if results from several poorly conducted studies are synthesized in a systematic review, we should be concerned about the effect of the potential risk of bias on the pooled results. An evaluation of the risk of bias present in individual included studies is therefore a key part of the systematic review method.

Risk of bias is assessed based on the information in the reports of studies. Sometimes, the reported information may be insufficient to make critical judgements about the methods of a study. In these cases, it is important to contact the study authors to clarify any issues regarding study design or missing data that are not described clearly in the report.

There are several methods for assessing the risk of bias related to study design as outlined next.

Randomized controlled trials

For RCTs, the Risk of Bias domain-based evaluation tool developed by the Cochrane Collaboration is in widespread use (Higgins et al. 2011). The tool requires a judgement regarding the level of risk of bias (low, high, or unclear) for each of the following six domains:

Sequence generation
Allocation concealment
Blinding or masking of participants, providers, and assessors
Size of, and differential loss, to follow-up
Selective outcome reporting
Other biases such as publication bias

In the past, quality scales which provided an overall score or quality rating were in widespread use. The limitations of such scales include unreliable assessments of validity and difficulty in assigning weights to items in the scale. We mention the use of scales only to provide a complete picture for readers, but would discourage their use.

Non-randomized and observational studies

For observational studies of interventions, the Cochrane ROBINS-I tool (Risk Of Bias In Non-randomized Studies—of Interventions) is available for the appraisal of risk of bias in estimates of the effectiveness or safety of an intervention from studies that did not use randomization to allocate interventions (Sterne et al. 2016). Studies may include observational studies such as cohort studies and case-control studies in which intervention groups are allocated during the course of usual treatment decisions, and so-called quasi-randomized studies where allocation is not fully randomized. It addresses bias due to confounding, selection of participants, misclassification of the intervention, deviations from the intervention, missing data, measurement of the outcomes, and selection of the reported result. Assessment of bias can be rated as low, moderate, serious, or critical.

The Newcastle-Ottawa Scale (NOS) is another popular tool which can be used for appraising longitudinal and cross-sectional studies (Wells et al. 2018). Risk of bias is assessed in three domains: selection of participants, comparability of the cohorts, and outcomes. The scale is based on a star system and a total of nine stars can be allocated to a study with no concerns.

Key point: The risk of bias is essential to evaluate in the studies included in a systematic review to indicate the robustness of the results. Tools should employ a domain approach and scores from scales are to be avoided.

Data synthesis

A good systematic review includes a detailed synthesis of the results from included studies. Synthesis may be narrative, meta-analytical, or a combination of both. The protocol of the review must identify a priori the threshold(s) for determining if a meta-analysis should be undertaken. In addition, the team should indicate in the protocol if there are important

subgroups expected between studies and within the data which warrant separate analyses.

Meta-analysis

Meta-analysis is the statistical pooling of estimates of effect from individual studies to create an overall estimate of effect from the combined studies.

There are several benefits of doing a meta-analysis if it is appropriate so to do. It provides a more precise estimate of the treatment effect, helping one to be more confident about the size of any effect. There is more statistical power to detect small effects, which may be clinically significant; and it helps in the evaluation of the applicability of the results to other settings.

Meta-analysis should only be conducted when the included studies are considered sufficiently similar (or homogenous) to combine together. This is a matter of judgement and systematic review teams familiar with the data should ask the following:

Are the interventions, populations, and outcomes similar across studies or do they differ markedly? (Clinical heterogeneity)
Are the methods of the studies similar or different across studies? (Methodological heterogeneity)
Is there a small or large degree of variation between the results of the individual studies? (Statistical heterogeneity)

If the studies are indeed considered sufficiently similar both methodologically and clinically, then further testing for the presence of statistical heterogeneity can be conducted during the meta-analytical procedure to assess the degree of statistical heterogeneity present. Statistical heterogeneity is quantified with the I^2 statistic, which ranges from 0 to 100% (Higgins et al. 2003). The I^2 statistic represents the proportion of variability between the studies that cannot be explained by chance. Higher values of I^2 indicate more statistical heterogeneity.

Meta-analyses would require the use of either the fixed effects or the random effects model, each with its own assumptions and approaches to weighting studies and generating confidence intervals.

Measures of effect

The decision on which effect measure to use should, ideally, be taken when the systematic review is being planned. It should be based on the mathematical appropriateness of the effect measure for the type of data to be analysed. Review teams should select effect measures that are meaningful to clinicians and patients and are commonly used. For example, in a meta-analysis of studies of people living with HIV, the dichotomous outcome measure of undetectable viral load is a preferred measure to change in viral load, which requires log transformation and may not translate into a clinical benefit.

The team should avoid conducting multiple exploratory analyses using different effect measures and then focusing on the analysis that generates their preferred result (Bender et al. 2008). However, in rare instances changing the effect measure can reduce some heterogeneity.

For effectiveness data, combined estimates of dichotomous data are generally expressed as relative risks or odds ratios with associated 95% confidence intervals. The risk difference is an alternative which might be more appealing to a lay audience.

Combined estimates of continuous data are generally expressed as mean differences and associated confidence intervals. Where different scales are used to measure outcomes across studies, the means and standard deviations from the different scales can be combined into a standardized mean difference (SMD) and associated confidence interval. However, the latter can be difficult to interpret clinically and review teams should endeavour to provide the reader with some indication of the clinical significance of the SMD.

Time-to-event data (hazard ratios) can also be pooled using the generic inverse variance (GIV) method which accommodates other forms of non-standard data. The GIV uses the log transformed versions of the data to place them on a similar and symmetric scale.

At times, data may not be usable in the reported format and it may be necessary to contact the authors of a study to obtain disaggregated data, or data may require transformation (for example, using logs, estimating means from medians and confidence intervals from p-values) to facilitate meta-analysis. In such cases, transparent reporting of changes to the planned analysis is required in the final report.

Subgroup analysis

When statistical heterogeneity is present, this should be interrogated further according to the possible subgroups identified in the protocol. Conducting a subgroup analysis may reveal true differences in the data and provide an explanation for the observed heterogeneity. If no explanation is forthcoming, caution is required in interpreting the pooled results and a meta-analysis may not be appropriate.

Even if there is an a priori reason to expect a subgroup analysis to show something different to the overall result, this is no guarantee that a statistically significant difference is reliable clinically. This is because the more analyses are done, the more likely it is that statistically significant results will be found, even when there is truly no difference between the subgroups. Subgroup analyses in a systematic review should be regarded as a way of showing that the direction of effect is the same across different types of patient or as a generator of a hypothesis for testing in future research. The results of subgroup analyses should be treated with caution because the effect of chance will be larger for the subgroup than for the overall result.

It is recommended that the sources of clinical heterogeneity be determined a priori, based on clinical expertise and scientific rationale, and only focusing on variables related to the research question (participants, interventions, comparisons, outcomes). There is extensive guidance on how to conduct and interpret subgroup analyses (Higgins et al. 2002; Gagnier et al. 2013; Sun et al. 2014). Most statistical packages incorporate a formal test for subgroup effects or test of interaction. This test tells you how likely it is that the difference in effect estimates from the subgroups is due to chance.

Sensitivity analysis

Like all statistical analyses, meta-analysis is dependent on underlying assumptions. Once the decision to conduct a meta-analysis has been made, investigators select a statistical model to underpin the analysis. Both the random and fixed effects models are widely used, with the use of a Bayesian approach also recommended for addressing heterogeneity and missing data (Higgins et al. 2009; Moreno et al. 2018). At the protocol stage, reviewers should identify the preferred model and their reasons for its selection.

At analysis stage, a sensitivity analysis can be conducted comparing the results obtained from different models. Consistent results between models provide greater confidence in the overall pooled result; where results differ

between models, investigators need to consider the underlying reasons for this and exhibit caution in interpreting the final result.

Sensitivity analyses can also be conducted on other parameters, such as study quality. A meta-analysis of all eligible studies can be compared with a meta-analysis limited to those studies which are rated at low risk of bias. Again, investigators should think carefully about the interpretation of inconsistent results and how the inclusion of studies at high risk of bias affects the results.

Unit of analysis errors

Trials can employ randomization at an individual, cluster, or crossover level. Combining studies with different levels of randomization in a meta-analysis can lead to unit of analysis errors and yield potentially spurious results. Analytical approaches for such data must account for the correlation between participants in the same cluster and for participants who contribute control and intervention data on crossover designs (Donner et al. 2001; Elbourne et al. 2002).

Meta-regression

Meta-regression is another way of exploring or explaining heterogeneity in meta-analyses (Thompson and Higgins 2002). It allows us to investigate the effects of more than one categorical or continuous variable on the outcome. It is an extension of simple regression in which the outcome variable is the measure of effect and the explanatory variables are the covariates that might influence the measure of effect. Meta-regression is not recommended when there are fewer than ten studies (Thompson and Higgins 2002). The findings from meta-regression are observational and should be treated as such.

Publication bias (Funnel plots)

Despite reviewers' efforts to conduct exhaustive and comprehensive searches of published and unpublished data, some relevant data sources may be missed (Sedgwick 2015). The presence of publication bias plays an important role in how we appraise the completeness of a body of evidence and its quality. The presence of publication bias can be investigated using a graphical test called a funnel plot, or be statistically tested using Egger's and Begg's significance tests (Thornton and Lee 2000).

The funnel plot is a plot of sample size against the effect size of the included studies. If publication bias is absent, the points on the plot would look like a funnel, with the smaller studies spread widely at the base of the funnel and the larger studies spread narrowly closer to the top. Asymmetry in the funnel plot is indicative of publication bias (Song et al. 2013) but observed asymmetry may be present for other reasons. Egger's and Beggs's significance tests investigate whether the study estimate is related to its size and are regression- and correlation-based, respectively (Thornton and Lee 2000).

In Figure 5.13.1 we illustrate a forest plot of invented data. This meta-analysis includes ten studies conducted in low-income and high-income settings comparing text messaging (SMS) and cash transfers to a text messaging alone on the outcome of treatment adherence.

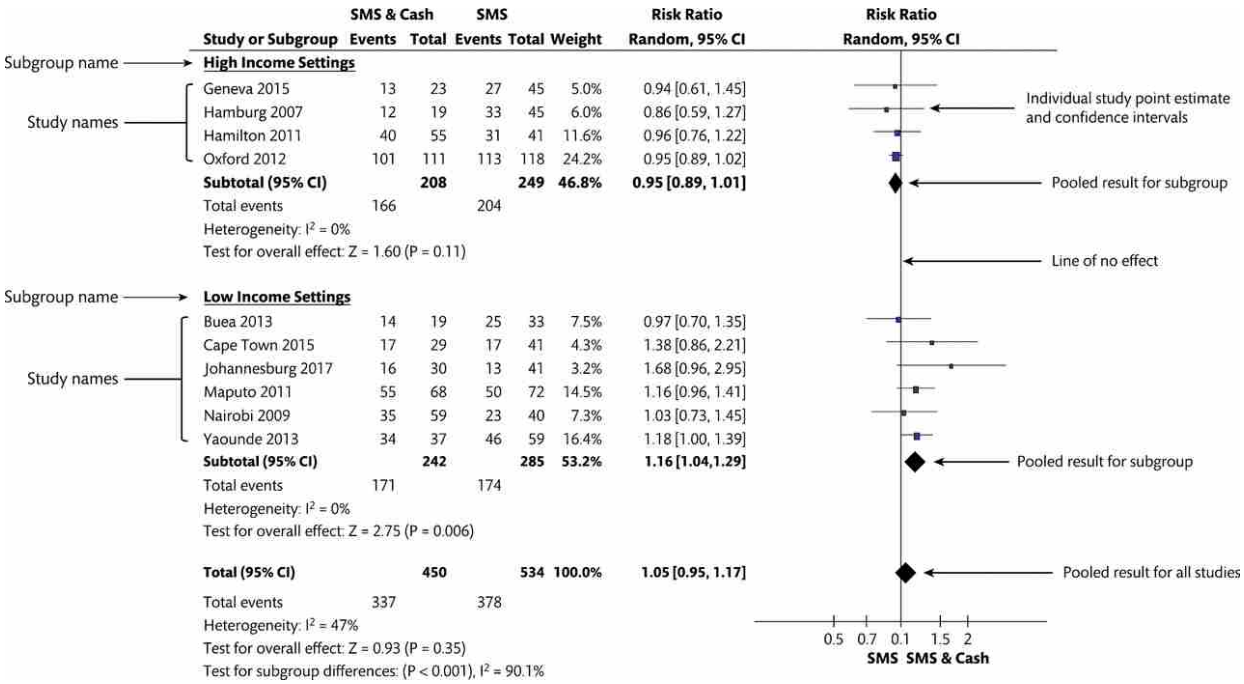

Fig. 5.13.1 Forest plot of invented data, from a meta-analysis of ten studies in high- and low-income settings, comparing text messaging and cash transfers to text messaging alone on the outcome of virologic success.

The outcome is dichotomous and measured as a relative risk. The data are pooled using the random effects approach and 95% confidence intervals are reported.

The vertical line is the line of no difference or a relative risk = 1.

A subgroup analyses is conducted to compare the relative merits of SMS & cash to the SMS alone, separately in the high-income and low-income settings.

The squares represent the point estimates and the horizontal line going across them represents the breadth of the confidence interval for each estimate.

The size of each square is proportional to the weight allocated to the study in the meta-analysis. The weight is derived from the inverse of the variance. In other words, the less precise, smaller studies with wider confidence intervals would have smaller squares.

The diamond represents the pooled estimate. For a positive outcome, like adherence, a diamond to the right of the line of no effect would indicate that the outcome is more likely to occur in the participants who receive SMS and Cash.

The amount of heterogeneity between all ten studies is reported as 47%; between the subgroups as 90.1%; in the high-income subgroup 0% and in the low-income subgroup 0%. The test for subgroup differences is statistically significant ($p<0.001$).

Narrative syntheses

When a meta-analysis is judged to be inappropriate due to significant heterogeneity, authors are advised to present a comprehensive narrative synthesis. Presentation of the study characteristics and the data should be given the same consideration as if a numerical synthesis were conducted. Note that a narrative synthesis is not a synonym for a ‘traditional literature review’. A narrative synthesis refers to the reporting of results in a systematic review where a meta-analysis is not appropriate or possible, and employs the same rigorous systematic review methods as a review which includes a meta-analysis (Popay et al. 2006).

Methodological and clinical heterogeneity should be reported with risk of bias and consistency in direction of estimates described. It is important to recognize that formulation of a single overall statement of the direction of benefit (or harm, or no effect) may not be possible, and caution is advised against counting studies with significant findings versus those without. Narrative syntheses contribute to the delineation of the current evidence base

and can inform and influence primary studies to provide more standardized reporting of outcomes to allow for future meta-analysis.

Key point: Meta-analysis should only be conducted when included studies are judged to be sufficiently similar, both methodologically and clinically. During meta-analysis, tests for statistical heterogeneity indicate whether the pooled results are statistically homogenous. If not, consider whether subgroup differences identified a priori explain the observed heterogeneity. Where meta-analysis is not appropriate, a detailed narrative synthesis should be reported.

Summarizing the overall quality of the evidence

Once the results of a systematic review are available, decision-makers need to know how much confidence to place in the evidence arising from the review. This need to integrate the review results with a quality measure led to the development of several methods to present review evidence graded by a measure of strength. Current hierarchical evidence rating systems include the A to D approach used by the United States Preventive Services Task Force (U.S. Preventive Services Task Force), the Oxford Centre for Evidence-based Medicine Levels 1 to 5 (Centre for Evidence-based Medicine 2016), and the GRADE approach (Guyatt et al. 2011a). We report here in detail on the GRADE method for interventions.

GRADE (Grading of Recommendations Assessment, Development, and Evaluation) provides a method to classify the overall quality of evidence arising from a systematic review as *high*, *moderate*, *low*, or *very low* (Guyatt et al. 2011a). Reviews which include several RCTs are initially graded as *high* quality given that the randomized design provides the highest level of evidence to support effectiveness. This level of quality may then be downgraded dependent on limitations in the included studies which include the presence of risk of bias, inconsistency, indirectness, imprecision, and/or publication bias. Down-grading by a single level takes place when the limitations are judged as ‘serious’, and by two levels when judged as ‘very serious’. On the other hand, a review of observational studies is initially graded as providing *low* quality evidence and can in turn be downgraded for the same reasons as RCTs, or upgraded if circumstances permit (Guyatt et al. 2011e).

Results for a maximum of seven critical outcomes are presented in a GRADE Summary of Findings table. Critical outcomes refer to those outcomes which consumers of the review—those who will be directly impacted by the results—consider most important to their health. For example, trial investigators may measure a biomarker to evaluate efficacy of a medication, but patients may be more interested in the impact of potential adverse effects of the medication on their quality of life. The systematic review team may wish to consult with consumer associations to best reflect their needs in the selection of critical outcomes.

For each of the seven critical outcomes, the systematic review team will assess whether there is an overall risk of bias across the included studies. If a risk of bias is judged to be present, the overall quality will be downgraded (Guyatt et al. 2011f).

When grading indirectness, the team must judge whether or not the included studies match the PICO of the systematic review, either directly or indirectly. For example, evidence may need to be extrapolated from adult studies to a PICO focused on children, where no trials of children exist. In such a case, the results would be downgraded for indirectness (Guyatt et al. 2011c).

Results are downgraded for inconsistency where heterogeneity is present and it cannot be explained e.g. by subgroup differences. The presence of heterogeneity alone is insufficient to down-grade the results; it is the presence of unexplained heterogeneity that drives a decision to down-grade (Guyatt et al. 2011d).

When considering imprecision, authors need to consider the width of the confidence interval around the effect estimate and determine whether this is precise or not by considering the sample size and event rate (Guyatt et al. 2011b).

Note that judgement is required for all of the aforementioned domains, and the review team must record the rationale for each judgement in a footnote in the GRADE Summary of Findings table. This ensures transparency and allows the reader to understand the reasons for each decision.

Once all the domains are graded, an overall quality of evidence per outcome is generated. The levels of quality are interpreted as follows:

High: We are very confident that the true effect lies close to that of the estimate of the effect.
Moderate: We are moderately confident in the estimate of effect: the true effect is likely to be close to the estimate of effect, but possibly to be substantially different.
Low: Our confidence in the effect is limited: the true effect may be substantially different from the estimate of the effect.
Very low: We have very little confidence in the effect estimate: any estimate of effect is very uncertain.

It is important to recognize that the results for different outcomes may arise from pooling the results from different studies and as a result, the quality of evidence may differ across outcomes.

Key point: GRADE is a system of quality assessment which incorporates the risk of bias, indirectness, imprecision, and inconsistency to determine the overall quality of evidence arising in a systematic review. Quality is graded as high, moderate, low, or very low.

Reporting a systematic review

The PRISMA for reporting systematic reviews is the equivalent of CONSORT for reporting randomized trials (Moher et al. 2010) and was first published in 2009 (Liberati et al. 2009) building on the earlier QUOROM statement (Moher et al. 1999). PRISMA is an evidence-based minimum set of items for reporting in systematic reviews and meta-analyses. Although PRISMA focuses on the reporting of reviews evaluating randomized trials, it can be extended to reporting systematic reviews of other types of research, particularly evaluations of interventions.

PRISMA provides a checklist for authors to ensure that the following items are comprehensively and transparently reported:

Title
Abstract
Introduction
Methods
Results
Discussion
Funding

The PRISMA checklist is explained in a detailed Explanation and Elaboration document which has been published in several journals (Liberati et al. 2009). A mandatory component of reporting in a systematic review is the PRISMA flow diagram which documents the stages and resultant yield of records of the search strategy.

Several extensions to the PRISMA Statement have been developed and include PRISMA for Network Meta-analysis and PRISMA for Diagnostic Test Accuracy (see http://prisma-statement.org). Authors of systematic reviews are encouraged to report their methods and results according to the relevant PRISMA Statement.

Key point: Systematic reviews should be reported using the structure recommended in the PRISMA Statement.

Appraising the quality of a systematic review

A systematic review which conforms to the methods outlined in this chapter would be considered well-conducted. However, similar to the quality assessment of included studies, the quality of a systematic review can also be categorized according to whether or not a risk of bias is present. It is particularly helpful for healthcare decision-makers to know how much confidence to place in the results of a systematic review.

Several tools exist to assess the quality of the conduct of a systematic review. The AMSTAR-2 critical appraisal tool provides a 16-item checklist incorporating the key methodological components of a review (Shea et al. 2017). The AMSTAR-2 tool does not provide a score but a rating of confidence in the results of the review based on the presence of weaknesses in critical items. It can be applied to reviews of randomized and non-randomized studies of healthcare interventions.

The ROBIS tool was developed in 2016 to evaluate the risk of bias in reviews of most types of research questions including diagnosis, prognosis, and treatment (Whiting et al. 2016). It provides a similar judgement-based domain approach to the Cochrane Risk of Bias tool for trials. Four domains include multiple questions related to the methods and the appropriateness of the study eligibility criteria, identification, and selection of studies, data collection and study appraisal, and synthesis and findings. An overall risk of bias (high, low, or unclear) is then derived from an assessment of whether the concerns raised in the four domains are addressed in the interpretation of findings, combined with an evaluation of the relevance of the included studies to the review question, and the degree to which the reviewers avoid emphasizing statistical significance.

AMSTAR-2 and ROBIS are designed to provide a structured approach to evaluating risk of bias in systematic reviews which requires judgement. Many may find this difficult to do, and it is recommended that evaluation is completed independently by at least two investigators who have methodological and content expertise.

Key point: The quality of a systematic review can be evaluated using a tool such as AMSTAR-2 or ROBIS, to indicate the robustness of the synthesized results.

Related approaches to evidence synthesis

Scoping reviews

Scoping reviews are variably defined in the literature. In 2005, Arksey and O'Malley described four aims of scoping reviews viz. (1) to examine the extent, range and nature of research activity; (2) to determine the value of undertaking a systematic review; (3) to summarize and disseminate research findings; and (4) to identify research gaps in the literature (Arksey and OMalley 2005). A scoping review will generally have a broad focus compared with a systematic review which adopts a narrow focus defined by a PICO question. Given that a scoping review aims to 'map' the current research base on a topic, the type of included study will not be limited to RCTs but may include all forms of studies to the topic. Clearly, use of robust systematic methods would enhance the quality of a scoping review, but a scoping review may follow a more traditional review approach and

categorize the results by topic area rather than present a quantitative summary or an assessment of the study quality. A 2014 scoping review of 344 scoping reviews described variability in the methodological process, terminology, and reporting of scoping reviews. The authors identified a need for methodological standardization to increase the use and the relevance of findings derived from scoping reviews (Pham et al. 2014).

Overviews of reviews

An overview of reviews aims to identify and collate the results from relevant reviews on a specific topic (Thomson et al. 2010). An overview, also known as an umbrella review, may be conducted for several reasons. Firstly, when several systematic reviews on distinct interventions exist for the same condition, decision-makers may wish to summarize the evidence base on all relevant treatment modalities and present this in a single report. Secondly, when the number and focus of reviews on a relevant topic is not known, an overview can aid in identifying the scope of the current evidence which has undergone review.

In an overview, the review is the type of included study design. Note that an overview may include only systematic reviews, or may include both systematic and literature reviews. Regardless of the type of included review, the methods of an overview mirror those of a systematic review with the exception that the risk of bias assessment uses the ROBIS (or similar) tool, instead of the ROB tool. There is currently no consensus regarding the application of GRADE or other ranking systems to produce an overall quality assessment in an overview.

Individual patient or participant data analysis

This is a form of meta-analysis in which trial investigators collaborate to share individual level data from their trials, instead of aggregated data, in order to ensure that the pooled results mimic a single large trial. This allows for standardization of analyses across studies independent of how the aggregated analysis was conducted (although clustering of each individual trial must be retained rather than treated as coming from one large trial) (Riley et al. 2010). Individual participant data analysis can be very resource-intensive and is dependent on close collaboration of trial investigators, but

arguably produces a more reliable estimate than a meta-analysis of aggregated data.

Prospective meta-analysis

There is debate in the literature as to whether a single large ‘mega-trial’ conducted in trial sites around the world following an identical protocol provides better evidence than several smaller regional trials combined in a meta-analysis (Shrier et al. 2007). Concerns have been raised about the potential of increasing error when pooling aggregated results from small underpowered trials even if precision is increased. One possible solution is prospective meta-analysis in which trials are identified, evaluated, and determined to be eligible before the results of any included studies are known or published, thereby avoiding some of the potential biases inherent in standard, retrospective meta-analyses (Askie et al. 2011). This methodology provides the same strengths as a single large-scale multicentre randomized study while allowing greater pragmatic flexibility. The combined meta-analytic results using individual patient data from each trial is published when all the trials are complete.

Network meta-analysis

Simple meta-analysis compares one intervention to another. This is a direct pairwise comparison. However, reviewers may be interested in comparing more than two treatment options. Trials may compare two treatments with each other or the treatments may have both been compared to placebo. In this instance a multiple treatment comparison, or a network meta-analysis (NMA), is possible. A NMA has the advantage of being able to provide information on the relative merits of interventions that have never been compared directly. A NMA can also increase the precision of effect estimates by using two sources of data: the direct pairwise comparisons and the indirect comparisons based on the comparisons to placebo (Mills et al. 2011; Mbuagbaw et al. 2017). Three key assumption underlie NMAs. The first is homogeneity, which simply refers to the absence of heterogeneity. The second is transitivity, which examines the validity of making indirect comparisons as all the control groups may not be identical. The third is consistency between the direct and indirect evidence (Mills et al. 2013). The

results may be presented graphically or as ranks that represent the probability of an intervention being first or second and so on. NMA is a fairly novel field and guidance on how to conduct, interpret, appraise the quality of the evidence and report NMAs is becoming more available.

Diagnostic test accuracy reviews

Reviewers may be interested in summarizing the accuracy of a diagnostic test. The searching and screening would be similar to a typical interventional systematic review, but in this case the data extracted would be the sensitivities and specificities of the diagnostic test in question as reported by the included studies (Leeflang 2014; Campbell et al. 2015). Many reviewers use the Quality Assessment of Diagnostic Accuracy Studies (QUADAS) tool to appraise the quality of the included studies. There are two important analytical considerations with diagnostic test accuracy (DTA) reviews. The first is the threshold effect. Tests based on continuous data (e.g. haemoglobin) require a threshold above (or below) which the test is positive. If different studies use different thresholds, this introduces heterogeneity in the review. The second issue is that sensitivity and specificity are correlated and therefore must be modelled together. The hierarchical summary ROC (HSROC) model and the bivariate model random effects model are used to address the first and second issues, respectively. Both models allow for covariate adjustment (Leeflang 2014).

Rapid reviews

No consistent definition for rapid reviews exists in the literature and methodologies differ across published rapid reviews (Tricco et al. 2015). However, the hallmark of a rapid review is acceleration of the systematic review process, usually by simplifying or leaving out methodological stages. This allows evidence to be quickly produced for time-sensitive decision-making. Conduct of a rapid review is dependent on a highly skilled review team and urgent provision of necessary resources. With the availability of electronic database searching, computerized study selection, and shared analytical tools, stages of a review can be sped up significantly. A rapid review need not, and arguably should not, compromise on rigorous methodology, but this remains a risk when urgency prevails. We suggest that

protocol templates for systematic reviews based on categories of interventions be developed in anticipation and utilized when a rapid review is required. Research to delineate the consequences of methodological shortcuts is warranted (Tricco et al. 2015).

Qualitative reviews and CERQual

Systematic review methodology has been successfully applied to identifying and synthesizing qualitative study data. Unlike an interventional review, the aims of a systematic review of qualitative data include providing greater in-depth understanding of an issue, informing theory development, and describing major themes related to a topic. CERQual is an approach to providing a confidence rating in the synthesized qualitative evidence, based on the GRADE approach to judging overall quality (Lewin et al. 2015). Methodological limitations, relevance, coherence, and adequacy of data are considered and an overall summary of the level of confidence regarding the representation of the phenomenon of interest is produced.

Use of systematic reviews in practice guidelines

Guidelines development should be based on evidence derived from systematic reviews. In 2007, the World Health Organization was criticised for failing to base global clinical recommendations on systematic review evidence and for an over-reliance on experts with limited methodological expertise (Oxman et al. 2007). In response, the World Health Organization (WHO) actively developed a rigorous approach to guidelines development based on the GRADE framework and outlined in the WHO Handbook for Guideline Development (WHO 2014). Evidence derived from systematic reviews forms the foundation of the GRADE framework for decision-making, which is further supplemented by values and preferences, and issues of acceptability, feasibility, resource use, and equity. The process is transparent and the quality of evidence underpinning a recommendation is clearly reported as part of the overall recommendation (Andrews et al. 2013).

Subsequent research to evaluate guidelines development within WHO has indicated that recommendations are increasingly based on systematic review evidence (Sinclair et al. 2013) but challenges remain. Active engagement

between guidelines developers and systematic reviewers is to be encouraged and a certain level of tension is anticipated. Critics have identified that at times strong recommendations have been inappropriately based on low quality evidence and advocate for further training in GRADE methods for guideline panellists (Alexander et al. 2014).

What does the future hold for systematic reviews?

Living systematic reviews and artificial intelligence

The concept of a 'living' systematic review grew out of the recognition that the value of a systematic review lies not only in its accuracy, but also in its currency. A living systematic review aims to continually update the evidence as new data becomes available (Elliott et al. 2017). It requires a pre-determined frequency of searching which is predictable, allowing for updating of guidelines in real time. New technologies to speed up the review process are available, for example, through machine-learning of screening for references for eligibility assessment. The accuracy of such screening classifiers can be improved by feedback models from human identification which can further be enhanced by using citizen science via crowd-funding initiatives (Thomas et al. 2017). The potential and limitations of harnessing automation to increase human responsiveness need to be carefully considered and tested to ensure the validity of results from living reviews, but offers great promise.

Mining big data

Big data in the form of biobank development integrated with clinical data (Bouzille et al. 2018) may offer robust longitudinal data which may in time provide a substitute for data derived from RCTs. The utility may be greatest for treatment of rare diseases. However, ethical issues regarding access to the data and consent remain a subject of ongoing debate (Lipworth et al. 2017) and statistical modelling will be required to determine the key criteria for drawing causality inferences from longitudinal data derived from such databanks.

Advancing systematic review methodology

Current efforts are underway to determine the most appropriate ways to conduct systematic reviews. In addition to independently-led methodological reviews of systematic review practices, the Cochrane Methods Groups (https://methods.cochrane.org/) and the Northern Ireland Network for Trials Methodology Research (https://www.qub.ac.uk/sites/TheNorthernIrelandNetworkforTrialsMethodologyResearch/) are actively engaged in this process.

Software and resources for systematic reviews

Several resources exist for the conduct of systematic reviews, some of which are commercial (not reported here) and some are not-for-profit. We present a selection which readers may find useful as starting points.

Cochrane

Cochrane (formerly, the Cochrane Collaboration) is an international voluntary organization which generates and compiles Cochrane systematic reviews, considered the gold standard of reviews. Several helpful resources are available for review authors:

The Cochrane Library

Cochrane reviews are published on an electronic database, *The Cochrane Library.* Many countries provide national subscriptions to medical professionals and the general public. See http://www.cochranelibrary.com/

The Cochrane Handbook for Systematic Reviews of Interventions

This handbook is a step-by-step guide to writing, analysing, and reporting a Cochrane review. See http://handbook-5-1.cochrane.org/

REVMAN

This software is free and provides a text-based review template and built-in meta-analytic software. It also contains links to the Cochrane Handbook. See

http://community.cochrane.org/help/tools-and-software/revman-5

The GRADE Working Group

The GRADE Working Group continues to develop the GRADE approach and software for reviews, health technology assessment and guidelines. See http://www.gradeworkinggroup.org/

GRADEPro

This software is free and produces Summary of Findings tables to present the overall quality of evidence based on meta-analysis. The software interfaces directly with REVMAN. See https://gradepro.org/

Rayyan QCI

Rayyan offers free support for reference management, screening, and storage. See: https://rayyan.qcri.org/welcome

Conclusions

In this chapter, we have provided the reader with a comprehensive approach to systematic review methodology, a guide to understanding and interpreting meta-analysis, and a synopsis of the many applications of systematic reviews and related syntheses. Although the science of systematic reviews is relatively new within epidemiology, the impact of systematic review and meta-analytic methodology has been considerable: evidence from reviews informs the direction of primary research, underpins guidelines, and provides patients, clinicians, and the general public with greater certainty regarding treatment and prevention choices. Yet it is important to remember that systematic reviews, like all studies, are subject to biases. The data generated from a review is secondary to that reported in the included studies and is thus totally dependent on the quality of the individual research studies used in the review. Users of evidence derived from systematic reviews should remember that critical appraisal remains an essential tool for the thoughtful researcher, clinician, and policymaker.

ACKNOWLEDGEMENTS

We are grateful to the original authors of the chapter, Jimmy Volmink and Mike Clarke, for their permission to replicate sections of the original chapter.

Statistical methods

Gail Williams and Robert S. Ware

Introduction to statistical methods

Statistics is the study of mathematically based techniques used to collect, analyse, and interpret quantitative data. In public health, this occurs in a complex of biological, clinical, epidemiological, social, ecological, and administrative systems. Sometimes we want to describe, explore, or summarize data without extending our findings beyond the coverage of the data we have—that is, the sample. More usually, however, we want to extend, or generalize, our findings from the sample to a larger group, sometimes called the 'target' population. In this situation, we need to consider carefully two aspects of our data collection. Firstly, what was the actual source of our data, and how did we select the sample from the population? If we deliberately excluded some people in our sampling, or made it more difficult for some rather than others to be included in our sample, then the sample may not represent the population equitably—we may have a *biased* sample. Secondly, we expect that if we repeat the data collection, even under identical conditions, we will get somewhat different results. This variability, called *sampling variability*, needs to be taken into account in deciding how precisely findings from our sample reflect what is happening in the population.

We now have access to a wider range of statistical techniques than ever before. It is important that analytical methods used are appropriate to the sampling strategy, the type of data collected, and the research questions to be answered. We usually want to generalize our results to a population. The process of using samples to draw conclusions about populations is called *statistical inference*.

In this chapter, we discuss basic concepts underpinning data analysis and statistical inference. The ideas of probability theory are heavily involved in random sampling, which takes place under the assumption that a probability model governs the selection of the sample. Probability models are also involved in helping quantify uncertainty in sample estimates. We will also discuss a range of statistical techniques in common usage, outlining the underlying assumptions, and focusing on interpretation.

Basic concepts

Populations, samples, and sampling

For the purpose of discussing statistical methods, a *population* is the complete set of entities we want to consider in our enquiry. The entities may, for example, be free-living humans, hospital patients, disease vectors, communities, or health services. A *sample* is defined generally as a subset of a population. The sample may not be of interest in itself; its use is to provide information about the population, such as to estimate the incidence of malaria or to compare the risk of lung cancer among smokers and non-smokers. By taking a sample from the population instead of enumerating the entire population, we save resources and time. We may choose to spend some of these savings on achieving greater quality of measurement, or better follow-up of those we select. The price paid, however, is that we cannot make an absolute statement about the population; we have only an estimate —the sample incidence, or the excess of lung cancer in our sample of smokers.

Probability and random sampling

The solution to the concerns of obtaining an unbiased estimate and being able to quantify uncertainty entails the notion of ‘fairness’ in the sample selection process. A ‘fair’ method of sampling does not favour or discriminate against any member of the population. However, if we can quantify any ‘unfairness’, we can correct for this in the analysis, and so still obtain an unbiased estimate. For example, if males are twice as likely as females to be selected from a population that contains equal numbers of each sex, we can compile the data so that females have twice the weight. Thus,

what actually matters is that we know how likely it is that each individual in a population is selected for the sample—i.e. the *probability of selection* of each person.

We measure probability with a single number, which has particular properties, some of which are as follows:

Probabilities lie between 0 and 1 (or 0 and 100%).
If the probability of the event is 0, there is no chance of the event occurring.
If the probability of the event is 1, the event is certain to occur.
The combined probability of a complete collection of events is 1.

A process whose outcome is unpredictable and governed by rules of probability is termed *random*. If we are drawing random lots to select one person from 100 people, we can say (before sampling) that the probability of inclusion of an individual is 1 in 100, but we cannot predict exactly which individuals will be included. Other classic random processes are outcomes of coin tosses or rolls of a die. We know that in the long run, the chance or probability of a head is 0.5 or 50% on any one toss of an unbiased coin, but the outcome of any particular toss is unpredictable.

The word ‘random’ as used in statistics has a specialized meaning. It is used to describe a process whose outcome (in this case, getting selected for the sample or not) is governed by the play of chance. Random does not mean ‘haphazard’ or ‘arbitrary’.

A sample in which each person in the population has the same chance of selection is called a *simple random sample*. This can be achieved by listing all the members of the population (this list is called a *sampling frame*), applying an unbiased random process of selection, such as drawing lots or using computer-generated random numbers, and obtaining a sample of the required size. In practice, compiling a sampling frame can be difficult. More generally, a sample for which we know the probability of selection (whether the same or not) for each person in the population is called a *probability* or *random sample*.

Recommended sampling techniques usually require identifying a population as the source of our sample. Thus, to obtain a sample of 7-year-old children to estimate the prevalence of childhood asthma, we might begin by obtaining school class lists. It is important to be clear about the population for which we want to draw conclusions. Is it the population of 7-year-old school children or is it all 7-year-olds? It may only be feasible to

sample formally a restricted population (school children), but we really want to make conclusions about a wider population (all school-aged children). This wider population is sometimes referred to as the *target population*. Whether conclusions can be extrapolated to a wider population than actually sampled is then a matter of judgement.

If someone has no chance of being selected in the sample, and they are different with respect to the characteristics we are measuring, or if individuals vary in both their chances of selection and the characteristics of interest, we expect to have a biased sample. We often have no way of predicting how individuals vary in the characteristics being measured, but if we can control, and therefore know, the probability of selection, we can control the potential for bias. Sampling which does not follow these rules is termed *non-probability sampling*. Here we do not know the probability of inclusion of population units. Sometimes we cannot define the population sampled. These methods include convenience samples (people waiting in outpatient departments) or haphazard samples (‘people in the street’).

Critically, a sample is termed a random sample because of its method of selection. We cannot determine whether a sample is random by examining it, we must know the process by which it was obtained. Examining a sample for observations which are deviant in some respect or comparing its characteristics with those of a target population cannot ascertain randomness.

Thus, ‘random’ does not equal ‘representative’ (although using a random method of selection, in some sense, decreases our chances of non-representativeness). In summary, the reasons for using random sampling are to:

Enable quantification of the sampling variation using probability theory.
Ensure that a statistically unbiased estimator of the quantity of interest is obtained.

Complex sampling

Complex sampling is the term used to describe probability sampling which is not simple. A variety of methods, or their combination, may be used. *Stratified sampling* is used when the population consists of a number of subpopulations or strata which vary in the quantity of interest. We sample

randomly within each stratum separately, in order to control the stratum-specific numbers, or to take into account large variability across strata. For example, typically (but not universally) urban areas have larger populations than rural areas. For sampling such a population we might first wish to stratify by rural/urban status, to achieve predetermined numbers or sampling fractions in each region. If sampling fractions differ for each stratum, the overall sample will not be a simple random sample, because the probability of selection will vary across strata; it will, however, be a probability or random sample because we can, knowing the sampling fractions within strata, calculate the probability of selection of any unit. If we control the stratum sizes to exactly reflect those in the population we can achieve greater precision than a method which ignores strata. In designing a stratified sampling scheme, we need to be clear about our priorities—do we want to disproportionately increase the numbers in a particular stratum, or do we want to control optimally for interstrata variability?

If we select a simple random sample from a large city, individuals selected would be widely scattered and costly to reach if we have to conduct face-to-face interviews, for example. *Cluster sampling* involves selecting groups of individuals, rather than individuals themselves, to increase logistical efficiency. A random sample of people in a city could be achieved by first selecting a simple random sample of census collection districts, and including all people living within the selected districts. The disadvantage is that the sample may be artificially ‘homogeneous’; the selected people may be more alike than if we had used a simple random sample. This statistical inefficiency is measured by what is known as the *design effect*, which must be estimated in the analysis phase.

Two-stage sampling is similar to cluster sampling except that a sample of the cluster is taken instead of the whole cluster. This helps overcome the problem of ‘homogeneity’ to some extent, but creates a more complex process, as there are two sampling stages.

In some cases, the sampling fractions for selecting clusters and selecting from them are carefully manipulated so that the overall probability of each population unit being selected is the same. One such method is called *sampling proportional to size*—clusters are selected with a probability proportional to their size (larger clusters have larger chance of selection) and then a fixed number of individuals is selected randomly from each selected cluster. Another method is *proportional sampling* in which clusters are

selected with equal probability, and a fixed sampling fraction is used to select individuals from each selected cluster. Cluster sampling and two-stage sampling do not require an explicit sampling frame for the whole population. In two-stage sampling we need a list of first-stage units (e.g. census districts) and then a list within only each first-stage unit actually selected. This is an advantage, particularly if sampling poorly documented populations. Two-stage sampling can be extended to three or more stages, for example, districts, towns, households, and individuals.

Stratified, cluster, or multistage sampling strategies provide opportunities to measure entities at all levels. Thus, factors may be relevant at the village level (presence of a health centre, degree of remoteness), the household level (family income, access to piped water), or the individual level (age, sex).

Complex sampling allows individuals to have different probabilities of inclusion in a sample. It is imperative that we can calculate each person's probability of inclusion, otherwise we cannot make the necessary analytical adjustments. All information relevant to probability of inclusion must be documented in the course of the sample selection.

Complex sampling schemes require expertise and care to design and analyse. It is usually necessary to seek advice from a professional statistician. Most statistical software has appropriate analytical procedures, and these may have particular requirements in the construction of the data set.

We next consider the issue of characterizing information collected on our sample. This involves categorizations of variable types, crucial in deciding how to present or analyse data.

Describing variables

A primary distinction is made between *quantitative* and *categorical* variables, because these are analysed using different techniques. The distinction is based on the kinds of *values* a variable may take. For the purpose of statistical analysis, what matters is the type of measurement of the variables, specifically whether they are measured on a numerical scale (such as age) or in categories (male or female). Sometimes a numerical variable (e.g. blood pressure in mmHg), is subsequently categorized (hypertensive or not hypertensive), but it is important to realize that it is the final form (numerical or categorical) of the variable that matters for analysis.

Categorical variables

A categorical variable is one whose values are expressed in mutually exclusive categories (e.g. survival status, social class, sex, religion, extent of disability). These are further subdivided into *nominal* and *ordinal*. A nominal variable has values that are categories, with no implicit ordering of the categories (e.g. sex, religion). A variable with two levels only (e.g. sex) is referred to as a *binary*, or *dichotomous* variable. Categories of an *ordinal variable* have an underlying order (e.g. social class, extent of disability). Categorical variables are usually described by *frequencies* and *percentages* in each value category, and presented in tabular or graphical form, such as bar charts or pie charts. For example, a study of child mortality examined the types of birth attendant at delivery of children in the study. This can be presented in a table (Table 5.14.1), or graphically in various ways (Figure 5.14.1).

Table 5.14.1 Community-based sample of children under 5 years of age in Bohol Province, the Philippines, 1984–1986, by birth attendant at delivery

Birth attendant	Number of deliveries (*n* = 511)	Percentage of deliveries (%)
Untrained TBA	8	1.6
Trained TBA	224	43.8
Midwife	186	36.4
Nurse	3	0.6
Physician	34	6.7
Unknown	56	11.0
Total	511	100.0

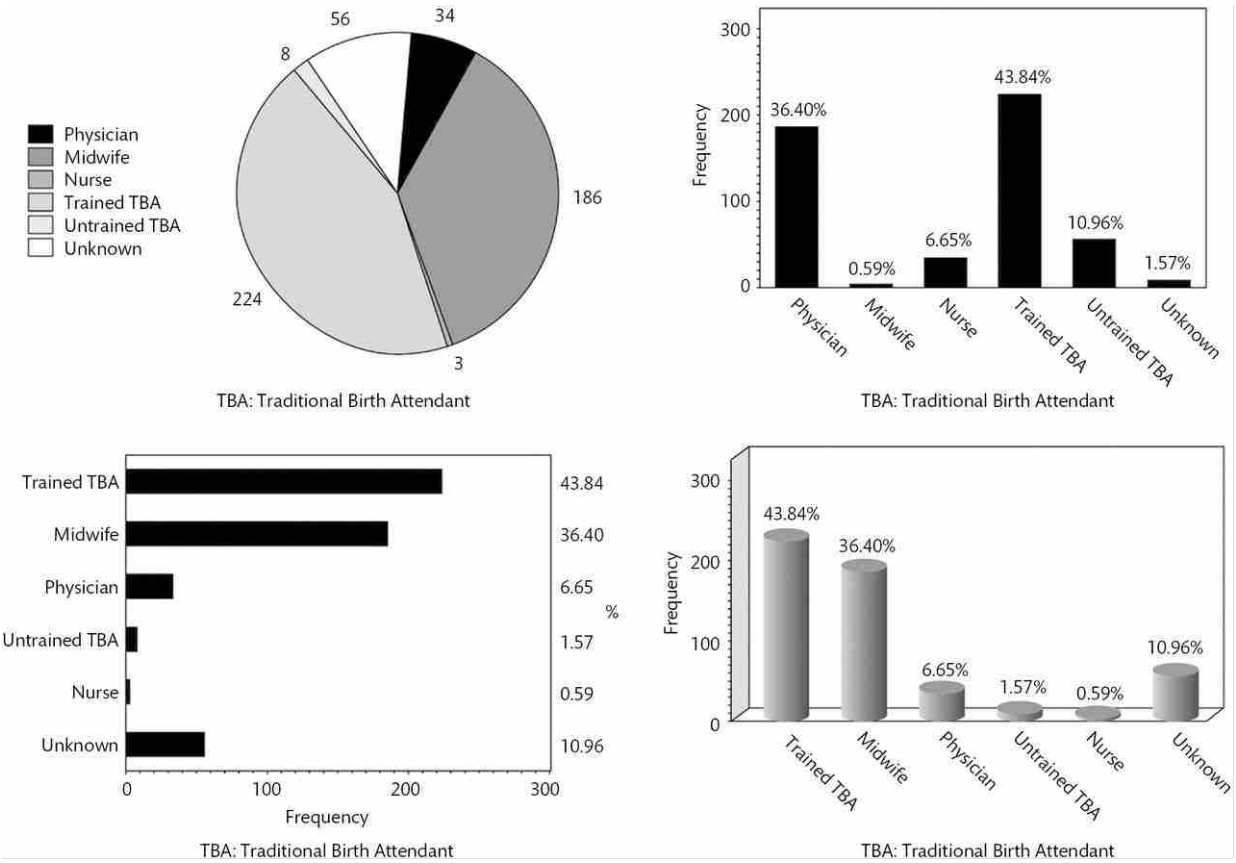

Fig. 5.14.1 Community-based sample of children under 5 years of age in Bohol Province, the Philippines, in 1984–86, by birth attendant at delivery. Alternative graphical methods of presentation. Although the choice of graphical presentation is partly a matter of taste, bar charts tend to be used for ordinal variables (as the bars can be ordered appropriately) and pie charts used for nominal variables (to de-emphasize order).

Quantitative variables

Quantitative variables express values in numerical measurement (e.g. height, age, number of births), and are further subdivided into *discrete* and *continuous* variables. A discrete variable takes only certain distinct values, usually whole numbers (e.g. number of births). A continuous variable takes all values within the observable range (e.g. age, birthweight, serum cholesterol). It is essential to specify units of measurement.

Frequency distributions

Quantitative variables are usually described, at least initially, in a frequency distribution, which tabulates, in mutually exclusive and contiguous groups, the number or percentage in each group. For example, a study documents birthweights (kg) of children born at a major obstetric hospital in Brisbane, Australia, using a sample of 500 full-term babies (gestation of at least 39 weeks). A frequency distribution portrays this (Table 5.14.2), after cut-off points for groups according to birth weight are chosen.

Choice of cut-off points for groups is to some extent arbitrary. We usually want at least eight groups, and prefer them to be evenly spaced, although this is not strictly necessary. Some recommend using $\sqrt{N}$ (square root of N) groups, where N is the sample size. We may use cut-offs defined for other purposes (e.g. using 2.5 kg as a cut-off identifies 'low' birthweight babies, as commonly defined). If we want to compare with a frequency distribution from another study, we use the same cut-off points. A frequency distribution is often graphed in a histogram (Fig. 5.14.2a). This usually requires a large number of values to provide a picture of the shape of the distribution, which may be important when we are choosing a method of analysis. Not all distributions are symmetric. A variable may have a negatively (Fig. 5.14.2b) or positively (Fig. 5.14.2c) skewed distribution, when the peak is pushed to the right or left, respectively.

Table 5.14.2 Sample of births in Brisbane, Australia, 1981, by birthweight

Birthweight (kg)	Number of babies (n = 500)	Percentage of babies (%)
2.3–2.49	6	1.2
2.5–2.69	10	2.0
2.7–2.89	19	3.8
2.9–3.09	63	12.6
3.1–3.29	71	14.2
3.3–3.49	94	18.8
3.5–3.69	78	15.6
3.7–3.89	65	13.0
3.9–4.09	41	8.2
4.1–4.29	26	5.2
4.3–4.49	20	4.0
4.5–4.69	6	1.2
4.7–4.89	1	0.2
Total	500	100.0

Measures of location

The measure most commonly used to summarize the magnitude of a quantitative variable is the *mean* (the usual arithmetic mean, or average). When some values need to be given more or less weight, a *weighted* mean may be used. When distributions are positively skewed, *geometric means* are typically used. The *median* of a variable is the middle value of its distribution; that is, half the distribution is below, and half is above, the median. The mean for the distribution of 500 birthweights given in Figure

5.14.2a is 3.49 kg, and the median is 3.47 kg; these are very similar because of the symmetry of the distribution.

When data are 'skewed', as shown in Figure 5.14.2b, c, the median is usually considered preferable to the mean (i.e. a better representative of the data), because the 'extreme' values may unduly influence the mean, whereas the median is little affected. In positively skewed data, the mean is greater than the median; in negatively skewed data, the reverse is true. The *mode* is the most frequently occurring value; a variable will have two local modes if the distribution has two peaks (this can be checked using histogram plots as in Fig. 5.14.2). The mode has few useful applications in health statistics, as well as being difficult to handle mathematically. A *quantile* is a value cutting off a specified proportion of values of a random variable. Common particular cases are tertiles (two cut-off points, dividing the distribution into three equal areas of 33.3% each), quartiles (25%), quintiles (20%), deciles (10%), and percentiles (1%). Note that the median is also the second quartile, the fifth decile, and the fiftieth percentile. An extremely useful method of graphical display of a continuous variable is the *box plot*. These compactly incorporate information about location, variability, and shape of a distribution, as well as about outliers.

Measures of variability

From a statistical viewpoint, describing the variability of a quantity is just as important as describing its average value. The most useful measures of variability depend on the difference between individual values and the mean value (deviations). If all values equal the mean (no variability at all), all deviations are zero; large deviations indicate greater variability.

One way of combining deviations in a single measure is to first square the deviations and then average the squares. Squaring is done because we are equally interested in negative deviations and positive deviations; if we averaged without squaring, negative and positive deviations would 'cancel out'. This measure is called the *variance* of the set of observations. It is 'the average squared deviation from the mean'. Because the variance is in 'square' units, a second measure is derived by taking the square root of the variance. This is the *standard deviation* (SD), and is the most commonly used measure of variability in practice. The SD for the distribution of 500 birthweights given in Figure 5.14.2a is 0.45 kg. The *range* of a variable is

defined as the difference between the largest and the smallest values. For the birthweight data in Figure 5.14.2a, the range is (from the raw data) 4.71—2.34 = 2.37 kg. The range is susceptible to extreme values and depends on the number of observations; in general, the more observations, the greater the range. In practice, reporting the smallest to the largest values (2.34 to 4.71 kg) is more useful than the range itself.

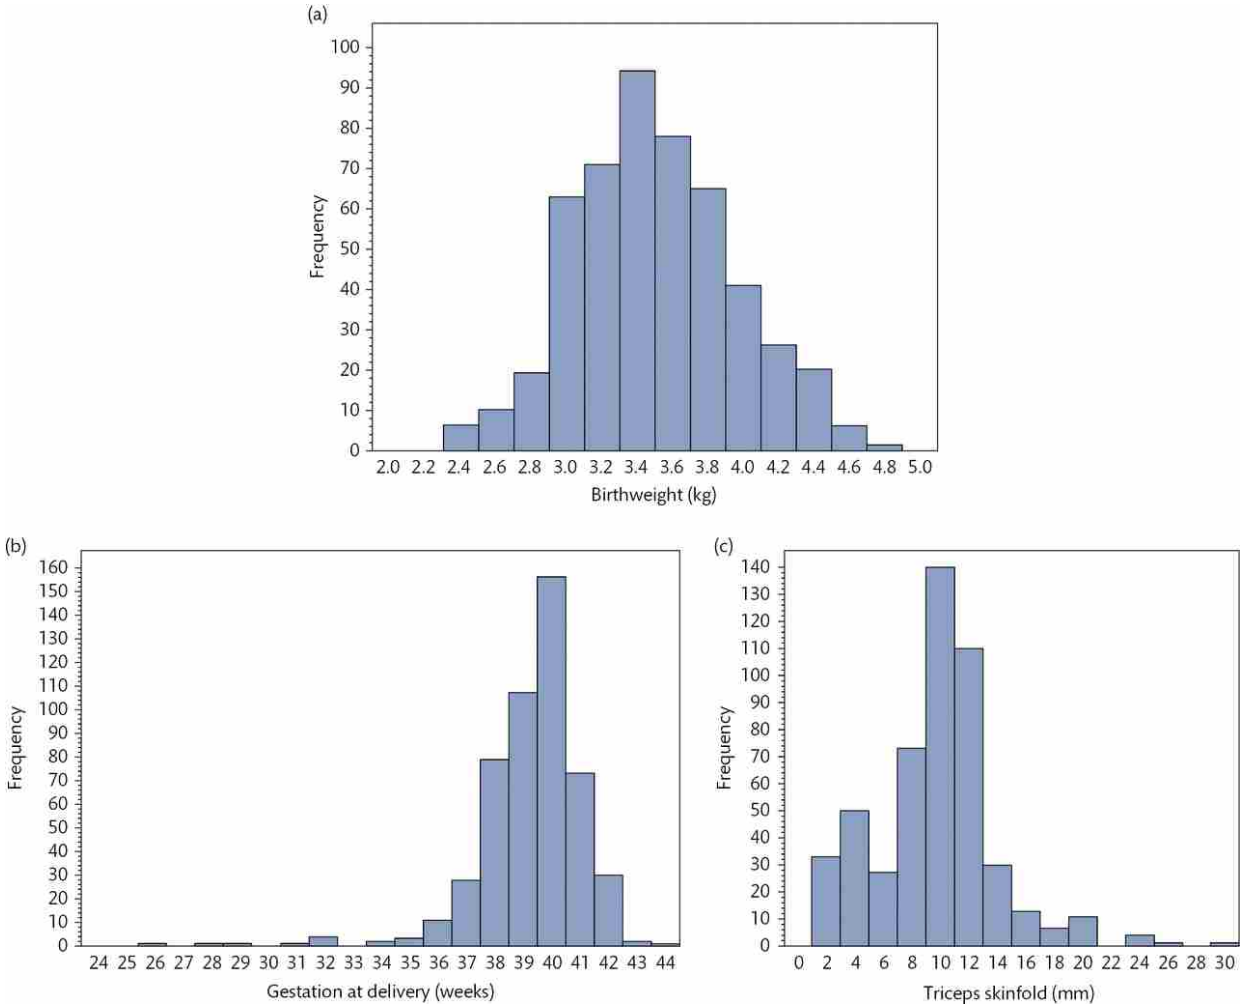

Fig. 5.14.2 Frequency distributions of characteristics of 500 babies born in Brisbane, Australia, 1981. (a) birthweight (kg), (b) gestation at delivery (weeks) for 500 babies, and (c) triceps skinfold thickness for 500 5-year-olds.

The *coefficient of variation* is the ratio of the SD to the mean, usually written as a percentage. It thus expresses variation in relation to location or

size. For the birthweight data, the coefficient of variation is 0.45 kg/3.49 kg = 0.129 or 12.9%: the SD is 12.9% of the mean birthweight.

Probability distributions

Just as a sample mean or SD (if the sample is randomly drawn) reflect the population mean or SD, so the observed distribution in the sample reflects the distribution of values in the population. In practice, it is found that certain distribution shapes re-occur. It turns out to be extremely useful to give a particular mathematical form to these characteristic shapes, which can then serve as 'models' to enable further conclusions from samples.

The normal distribution

The distribution of birthweight for a sample of 500 full-term babies born in Brisbane, Australia, followed a roughly symmetric and bell-shaped curve. The empirical observation that distributions of continuous variables often follow this shape prompted mathematicians to work on finding a mathematical or idealized representation to describe this.

The smooth curve so discovered has the mathematical formula:

$$f(X) = \frac{1}{\sqrt{2\pi}(SD)} \exp\left(-\frac{1}{2 \times (SD)^2} (X - Mean)^2 \right),$$

where 'exp' is the exponential (or antilog) function, and π ('pi') = 3.14159. *X* is the symbol given to the value of the variable in question (e.g. birthweight). Note the dependence on the mean of the population and its SD. This formula is known as the normal distribution and is a specific instance of a probability distribution; a mathematical description of the behaviour of a random variable (a variable whose values cannot be predicted with certainty). It can be thought of as an 'idealized' description of data, and can serve as a model upon which we base an analytical approach. The purpose of having an idealized model may be to 'smooth' the data or acquire some insight into the processes that underlie the generation of observations, by allowing us to test data against a given model. Once we have sample

estimates for the mean and SD, we can fit this distribution to the sample. The mean controls the location of the central peak and the SD controls the extent of variability.

Many statistical procedures depend upon assuming an underlying probability model. Checking actual observations against these predictions can provide us with insight: if the probability model 'fits', then we can use features of the model to make further inferences or predictions about the population. If the model does not 'fit', then we need to find a more appropriate one. We would not regard the normal distribution a 'good' model for all distributions, such as those shown in Figure 5.14.2b, c. Other probability distributions may be used in such instances; they may be more complex, because they incorporate additional information about the extent and type of skewness.

The usefulness of the normal model lies in the fact that its properties have been well studied. Specifically, for example, we know that approximately two-thirds of the distribution is enclosed by 1 SD either side of the mean, and approximately 95% of the distribution is enclosed by 2 SDs either side of the mean. Figure 5.14.3 shows the normal model fitted to the mean and SD of the sample of birthweight.

Within this normal model, 2 SDs either side of the mean takes us from 3.49—(2 × 0.45) kg = 2.59 kg to 3.49 + (2 × 0.45) kg = 4.39 kg. The area (or the area under the curve) between 2.59 and 4.39 kg in Figure 5.14.3 (the outer set of vertical lines) is approximately 95% of the total area.

In summary, the descriptive properties of the normal distribution are as follows:

It describes a continuous variable across the entire numerical scale, although in practice values from an assumed normal distribution will be confined to a particular range.
It is bell-shaped, and symmetrical about its mean value; that is, half of the distribution lies on either side of the mean.
It is determined completely by its mean and SD.
Limits sets by the number of SDs either side of the mean predict the proportion of the distribution enclosed by these limits—for 1 SD, the area is 68% of the distribution; for 1.96 SDs (≈2 SDs), it is 95%; and for 2.56 SDs, it is 99%. The number of SDs corresponding to different proportions is calculated from the standard normal distribution, which has zero mean and a SD of 1.

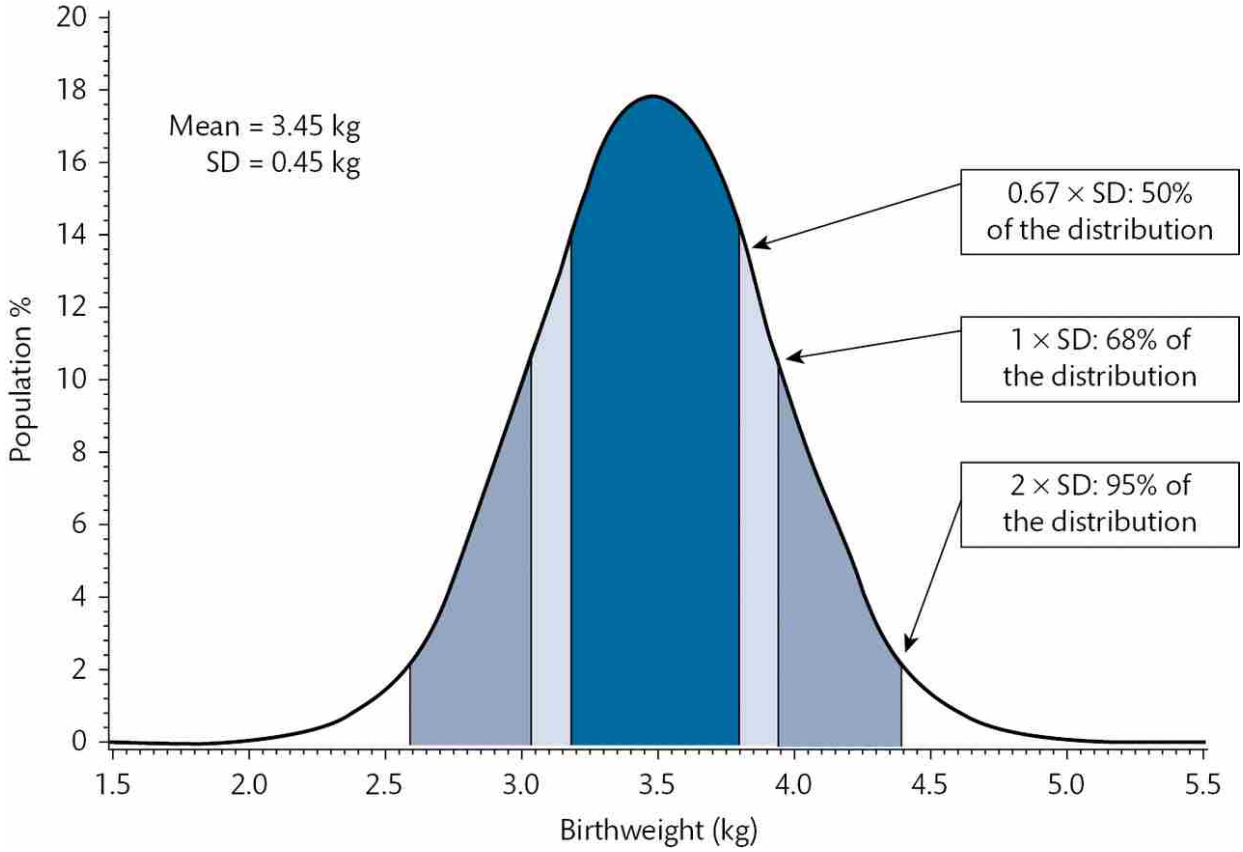

Fig. 5.14.3 A normal distribution fitted using the sample of 500 birthweights (mean = 3.49 kg, SD = 0.448 kg) showing areas enclosed by 0.67, 1, and 2 standard deviations (SDs) either side of the mean. The purpose of fitting a distribution in this way may simply be to obtain a 'smoothed' picture of a distribution. But we can use this 'smoothed' representation as a model for further calculations, such as estimating: (1) the proportion of babies whose birth weights are within a particular range or (2) the value of birth weight that cuts off a certain proportion of birth weights.

Sampling variability

The concept of sampling variability lies at the heart of what is known as *statistical inference*. Using a sample to estimate a mean or a proportion relating to a population, as opposed to examining the entire population, results in a considerable reduction in cost. This, however, results in some uncertainty about our estimate. Mathematical rules have been established which enable us to predict, within limits of probability, the sampling variability inherent in an estimation process based on random sampling.

These rules contribute to the well-known practices of estimating confidence intervals (CIs), testing hypotheses, and fitting statistical models.

Sampling distributions

The *sampling distribution* of an estimate describes the chance variability we would expect to see in the distribution of sample estimates if we were to repeat our sampling process a large number of times. In practice we only have one sample and one estimate (of the mean, for example) and so must rely on mathematical theory to tell us the properties of the sampling distribution of the mean and therefore its precision.

Consider the example of taking a random sample of births, in order to estimate mean birthweight. As random sampling favours neither high nor low birthweights (i.e. it is unbiased), we expect that any particular sample mean will be as likely to be above the mean as below it. So, the first property governing the behaviour of random sampling is:

Irrespective of sample size, the sampling distribution of a mean has the same mean as the population mean.

Next, consider the size of the sample. Given an estimate is unbiased, how close is it likely to be to the true population value (i.e. the value we would obtain if we measured everyone in the population)? Intuitively, we would expect a random sample of 1,000 members of a population to provide a 'better' or more precise estimate than a sample of 100. This results in the second property governing the behaviour of random sampling: governing the behaviour of random sampling:

The sampling distribution of a mean has variability (i.e. standard deviation) which decreases with the size of the sample.

The practical implication of (1) and (2) is that as the sample size N becomes larger, our sample estimate is more likely to be closer to the population mean.

Both properties of the sampling distribution of the mean have been mathematically demonstrated and further quantified. An important mathematical discovery related the expected SD of a sample mean to the

sample size and the SD of the variable within the population. The SD of a mean is more usually referred to as the *standard error of the mean* (SE).

The variability in the sample mean is defined by

$$\text{SD of the means Standard error of the mean} = \frac{\text{SD of the population}}{\sqrt{N}},$$

where N is the size of the sample.

This shows that the larger the sample size, the less variable are the means, and that the greater the variability in the original measurements in the population, the more variable are the means.

In a remarkable mathematical result (the Central Limit Theorem), Pierre-Simon Laplace showed, in 1810, that the sampling distribution of the mean follows a normal distribution, once N becomes large enough, even when the original distribution itself does not follow a normal distribution! This puts us in a powerful position to predict the behaviour of sampling variability.

Confidence intervals

Confidence interval for a mean

The sample mean provides us with an estimate of the unknown population mean. Using the previous theory, we now know what to expect of its sampling variability.

Using our example of birthweights, and $N = 64$, we have an expected SE of 0.07 kg. Using the assumption of a normal distribution for sample means (the Central Limit Theorem), there is a 95% chance that the error of our estimate is less than 0.14 kg (1.96 × 0.07). Another way of putting this is to say that there is a 95% chance that:

Sample mean—population mean <0.14 kg, if the sample mean is greater than the population mean; and
Population mean—sample mean <0.14 kg, if the population mean is greater than the sample mean.

Reorganizing these, with 95% probability, equivalent statements are:

Sample mean—0.14 kg < population mean, if the sample mean is greater than population mean; and
Sample mean + 0.14 kg > population mean, if the population mean is greater than the sample mean.

Combining (1) and (2), we can say, with 95% probability, that the limits (sample mean—0.14 kg, sample mean + 0.14 kg) enclose the true (unknown) population mean. This is known as the *95% CI for the mean*. We use other values (from the standard normal distribution) to obtain the CIs corresponding to different percentages. Generally:

$$\text{CI for a mean} = \text{sample mean} - k \times \text{SE},\ \text{sample mean} + k \times \text{SE}$$
$$\text{where SE} = \text{standard error of mean} = \frac{SD}{\sqrt{N}},$$

where k = 1.28, 1.645, 1.96, and 2.56 for a 80%, 90%, 95%, and 99% CI, respectively.

In expressing these results we say ‘there is a 95% probability that the interval (3,284 g, 3,516 g) contains the true mean birthweight’, *not* that ‘there is a 95% probability that the population mean lies within (3,284 g, 3,516 g)’.

In practice, we do not know the SD of the population and usually replace it with the sample SD. This introduces very little error if the sample size is 50 or more. If the sample is small, we use a different multiplier for the standard error (i.e. a different k); this multiplier is obtained from the *t*-distribution (i.e. not the standard normal distribution), available in statistical software. We need to specify another parameter called *degrees of freedom* (df), which depends on the sample size: for sample size N, df = N—1. Therefore, for N = 30, df = 29; for a 95% CI, we use k = 2.045, instead of k = 1.96.

Note that a CI combines information regarding the size (location) of the parameter, the variability of values within a population, and the sample size used to estimate the parameter. It is thus a very useful quantity to summarize sample results.

Confidence interval for a proportion

We can also obtain a CI for proportions. The concept of a CI for a mean extends to a proportion, or indeed other epidemiological measures. Let us return to the birth attendant data from the Philippines (Table 5.14.1). We estimate that 224 of the 511 babies (43.8%) were delivered by trained traditional birth attendants (TBAs). The principles underlying consideration of sampling errors for proportions are the same as for the mean. The Central Limit Theorem again assures us that, provided samples are large enough, sample proportions will have, approximately, a normal distribution.

The only different feature of the process of obtaining a CI for a proportion is the formula for the standard error of the estimate. The standard error of a proportion is

$$\text{Standard error of a proportion (SEP)} = \sqrt{\frac{p \times (1-p)}{N}},$$

where p is the sample proportion, and N is the sample size. In our example, we have $N = 511$, $p = 0.438$:

$$\text{Standard error of a proportion (SEP)} = \sqrt{\frac{0.438 \times (1-0.438)}{511}} = 0.022.$$

The formula for a CI for a proportion is then completely analogous to that for a mean. The 95% CI for the proportion of babies delivered by TBAs is then 0.438—(1.96 × 0.022), 0.438 + (1.96 × 0.022), or (0.395, 0.481). Expressing the result in percentages, an estimated 43.8% of babies are delivered by TBAs, with a 95% CI of (39.5%, 48.1%).

Basic principles and methods of comparative analysis

This section deals with some of the basic methods of analysis. Firstly, we consider situations in which we want to compare a set of mutually exclusive groups. This comparison may be on a number of different variable types, such as categorical or continuous health outcome, or the prevalence or mean of a risk factor. Secondly, we introduce models, aimed at examining associations of variables, or patterns of risk factors.

Group comparisons

Many research questions in public health involve comparing groups. This may be in the context of an experimental or intervention study, a designed analytical study such as a cohort, case– control, or cross-sectional studies. Such analyses proceed in two phases: first we describe the pattern of the data *within* each group, using methods such as those described earlier, and then we evaluate the comparisons *between* groups.

The comparison between groups may initially be descriptive, but then we usually want an evaluation of the 'significance' of the differences we see; that is, are the differences compatible with sampling variability alone, or are there 'real' differences between the groups, which might be due to biological or other effects? If the differences are not attributed to chance, are they important from a clinical or public health perspective? We also often want to determine whether differences are due to 'causal' factors, and whether these causal factors are modifiable and so provide a basis for prevention or management. The judgement of causality involves additional evidence other than statistical analysis, such as biological plausibility, magnitudes of effects, and considerations of confounding. Although statistical analysis, particularly multivariable analysis (see later), can help provide some information, the final judgement of causality is a complex one.

Some examples of research questions, how they might be framed, and the nature of the variables involved are shown in Table 5.14.3.

If a relationship is being examined, it is usually important to consider whether variables have a role (or potential role) as 'outcome', 'explanatory', or 'predictor' variables. In Table 5.14.3, birthweight, length of labour, and stage of disease are outcome variables; mother's height, number of previous births, and distance from the health centre are potentially explanatory variables ('potentially' because if it turns out there is no relationship, then one variable can hardly 'explain' the other). A variable may take on different roles in different questions; for example, number of years of schooling is an outcome variable in question 6 and an explanatory variable in question 7. So, for the purpose of classifying variables as outcome or explanatory, what matters is the orientation of the question (which event comes first?).

Analyses of relationships depend on the types of variables involved, and there may be several valid methods from which to choose.

Comparing proportions or percentages

The first step in examining the relationship between two categorical variables is usually to cross-classify them; that is, break down one variable by the values of another. This is usually displayed in a contingency table, which shows all combinations of values. Consider an example (Table 5.14.4) taken from a study of skin cancer in Queensland, Australia (Green et al. 1999).

Table 5.14.3 Some research questions that involve relationships between two variables

Question	Variable combination
1. Does **height** influence the **birthweight** of her child?	Continuous–Continuous
2. Is there an association between **length of labour** and the **number of previous births** a woman has had?	Continuous–Discrete
3. Do people present at a later **stage of disease** if they live a greater **distance from the health centre**?	Ordinal–Continuous
4. Do different **ethnic groups** have different **calcium intake**?	Nominal–Continuous
5. Does the **number of sunburns** a person has experienced predict the **number of skin cancers** they have?	Discrete–Discrete
6. Does the **number of years of schooling** a child acquires depend on his or her **birth order** in the family?	Discrete–Ordinal
7. Does the **number of years of schooling** a girl acquires influence her **paid employment status** in later life?	Discrete–Nominal
8. Do different **socioeconomic groups** present with different degrees of **disease severity**?	Ordinal–Ordinal
9. Does **diagnosis at presentation** depend on **socioeconomic group**?	Nominal–Ordinal
10. Does susceptibility to **skin cancer** depend on **skin colour**?	Nominal–Nominal

Table 5.14.4 Numbers of people with a non-melanoma skin cancer (NMSC) diagnosed on a sun-exposed site in the period 1993–2006, by skin type, as reported in 1992

	No NMSC	One NMSC lesion only	Multiple NMSC lesions	Total
Always burn	236 (69.4)	50 (14.7)	54 (15.9)	340
Burn, then tan	866 (78.8)	112 (10.2)	121 (11.1)	1,099
Tan only	148 (82.7)	16 (8.9)	15 (8.4)	179
Total	1,250 (77.3)	178 (11.0)	190 (11.7)	1,618

Figures in parentheses are percentages within each skin type.

Source: data from *The Lancet*, Volume 354, Issue 9180, Green, A. et al., Daily sunscreen application and betacarotene supplementation in prevention of basal-cell and squamous-cell carcinoma of the skin; a randomised controlled trial, pp. 72–5, Copyright © 1999 Elsevier Ltd. All rights reserved.

A contingency table should include *all* combinations of *all* categories of each variable. The overall incidence of skin cancer in the follow-up period is 22.7% (combining single and multiple lesions), but incidence is higher in those reporting a skin type that sunburns, with or without tanning (21.2% and 30.6%, respectively), than in those whose skin tans without burning (17.3%).

If we repeat the skin cancer study with another sample of 1,600 or so participants, we will obtain slightly different results, even if we follow exactly the same procedures. This is due to sampling variability: within our study population, individual people with the same characteristics will have different skin cancer outcomes. How do we take this into account in our interpretation of findings? To simplify the example, consider the comparison of the three skin types, combining single and multiple lesions. The first step is to calculate what we would expect to see if people with different skin types produced on average, the *same distribution of responses*. In other words, what would we expect to see if sampling variability was the *only* factor operating to produce variability in responses? The answer is: the same distribution of skin cancer within each skin type. The results of calculating these ‘expected’ results are shown in Table 5.14.5.

The figures in parentheses in the table are called *expected frequencies*; that is, the numbers expected if skin type is unrelated to skin cancer. Note that the marginal totals of observed and expected frequencies are the same. We have observed more skin cancer in the ‘Always burn’ group (about 27 more cases) than expected on the basis of no real difference between skin types and less in the ‘Tan only’ group (10 fewer cases). These differences relate either to:

Sampling variability alone (i.e. no additional risk of skin cancer associated with skin type).
Sampling variability *plus* an additional risk of skin cancer associated with skin type.

The statement that, in the study population, skin type is unrelated to skin cancer is called the *null hypothesis*, and is the first step in any formal evaluation of the role of chance.

The Pearson chi-squared test

The statistic called the *chi-squared test statistic*, developed by Karl Pearson, enables us to summarize the differences between observed and expected frequencies, so we can make a decision as to the significance of these. Calculations are shown in Table 5.14.6.

Table 5.14.5 Numbers of people with a non-melanoma skin cancer (NMSC) diagnosed on a sun-exposed site in the period 1993–2004, by skin type, as reported in 1992, and numbers expected (in parentheses) if the distributions of skin types are the same in each group

	No NMSC lesions	One or more NMSC lesions	Total
Always burn	236 (262.7)	104 (77.3)	340
Burn, then tan	866 (849.0)	233 (250.0)	1,099
Tan only	148 (138.3)	31 (40.7)	179
Total	1,250	368	1,618

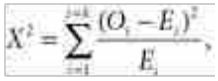
Source: data from *The Lancet*, Volume 354, Issue 9180, Green, A. et al., Daily sunscreen application and betacarotene supplementation in prevention of basal-cell and squamous-cell carcinoma of the skin; a randomised controlled trial, pp. 72–5, Copyright © 1999 Elsevier Ltd. All rights reserved.

Table 5.14.6 Calculation of the chi-square statistic for data in Table 5.14.5

	No lesions	One or more lesions
Always burn	236 262 7. ^{2} (−) = 271. 262. 7	104 77 3. ^{2} (−) = 922. 77. 3
Burn, then tan	866 849 0. ^{2} (−) = 034. 849. 0	233 250 0. ^{2} (−) = 116. 250. 0
Tan only	148 138 3. ^{2} (−) = 068. 138. 3	31 40 7. ^{2} (−) = 231. 40 7.
Sum of all (Observed Frequency − Expected Frequency)^2 Expected Frequency = 271. + 922. + 034. + 116. + 068. + 231. = 16. 42		

Source: data from *The Lancet*, Volume 354, Issue 9180, Green, A. et al., Daily sunscreen application and betacarotene supplementation in prevention of basal-cell and squamous-cell carcinoma of the skin; a randomised controlled trial, pp. 72–5, Copyright © 1999 Elsevier Ltd. All rights reserved.

The formula for the chi-squared statistic is:



where k is the number of cells in the table. The following is observed:

The smallest value of X^2 that can occur is 0, when all individual terms have their smallest value as 0 and corresponding expected and observed frequencies are exactly equal.
The value of X^2 increases as differences between observed and expected frequencies increase.
The larger the sample, the larger the value of X^2, for a given strength of association: if we double the sample size, for example, we double the calculated value of X^2.

So, the measure (X^2) increases as the observed frequencies increasingly depart from the expected frequencies. Thus small values of X^2 are consistent with (1) above, but increases in X^2 suggest that (2) is the underlying explanation.

The calculated value of X^2 is 16.42 (Table 5.14.6). But how large does X^2 need to be before we can decide in favour of (2) over (1)? Is there a cut-off point? The mathematics of this question have been solved: for any given value of X^2 we can find the probability that this value, or one larger than it, will occur if the observed differences are due to chance alone; that is, if (1) is true. The relationship between values of X^2 and the probability of such values occurring is expressed in the *chi-squared distribution*. Tables for the chi-squared distribution are available in standard textbooks, or values can be obtained from statistical software. The probabilities depend on another parameter, the df, which depends on the number of row and column categories in the contingency table. If the table has r rows and c columns, df = (r—1) × (c—1). For Table 5.14.6, there are three rows and two columns: df = (3—1) × (2—1) = 2.

The probability, referred to as the p-value, of getting X^2 = 16.42, or larger, is 0.0003. So if (1)—sampling variability—is the sole explanation for the observed treatment difference, the probability of seeing such a large value of X^2 is 0.0003, or 0.03% or 1 chance in 3,333. Because this is very small, we would feel inclined to reject (1) in favour of (2). In practice, the most common cut-off point to use in order to make this decision is p = 0.05 or 5%.

We then say that there is a *statistically significant difference* between skin types in risk of skin cancer ($p = 0.0003$). From Table 5.14.6, we see that the 'Always burn' skin type contributes by far the most to the value of X^2, so we could conclude that this category is responsible for most of the statistically significant finding.

Limitations of the Pearson chi-squared test

The use of the *Pearson chi-squared test* involves an important underlying assumption—that the observed frequencies are independent. If, for example, instead of skin type we were comparing pre- and post-intervention incidence of skin cancer within the same sample of people, the observations would not be independent, because outcomes for the same person would be expected to be related and the Pearson chi-squared test should not be used.

The chi-squared test also depends on samples being 'large enough' to be valid. For contingency tables, 'large enough' has been found to depend on the size of the expected frequencies. The rule of thumb has emerged that if around 1 in 5 (or 20%), or more, of expected frequencies are less than 5, then the test is not valid. Statistical software provides simulation or permutation tests which give an estimated *p*-value directly, which is then interpreted in the usual way.

We had decided to reject the null hypothesis based on a probability cut-off point in order to distinguish between (1) and (2). This decision might have been incorrect. It is unlikely (about 1 chance in 3,333), not impossible, that a value of $X^2 = 16.42$, or larger, could occur if (1) were true. Rejecting the null hypothesis, concluding there is a significant difference when there is not, is a *type 1 error*. The reverse error, failing to reject the null hypothesis when it is false or concluding there is no difference when there really is, is called a *type 2 error*. This error typically arises when we have a small sample size, and our data are insufficient to detect a difference.

Table 5.14.7 summarizes the four possible outcomes from a statistical test of a hypothesis, according to whether there is a real effect (e.g. a real difference) and whether the test statistic is significant (i.e. the *p*-value is small). A type 1 error is a false-positive finding and a type 2 error is a false-negative finding.

Asserting that a difference, or an association, is ‘significant’ does not mean that the association is ‘strong’ or that it is causal. A statistically significant finding means that the size of the difference or association is larger than would be likely to occur by chance alone (i.e. sampling variability alone) in the absence of any real association. These techniques can be applied to larger contingency tables, although sometimes further examination of the data may be needed to identify the nature of the differences.

Table 5.14.7 Type 1 and type 2 errors

		True effect	
Null hypothesis true	**Null hypothesis not true**		
Statistically significant effect (reject null hypothesis)	No	✓	Type 1 error (false-positive)
	Yes	Type 2 error (false-negative)	✓

The chi-squared test explores all variability in proportions in a contingency table. However, sometimes we want to examine a more specific type of association, and the chi-squared test may not be the best one to use. An example of such a situation occurs when we want to examine trends in proportions.

Suppose we regarded the skin type groups (in order) in Table 5.14.5 as indicative of an increasing inflammatory reaction to sun exposure and wanted to test a hypothesis about increasing risk of skin cancer with increasing inflammatory response (rather than just variability in risk with skin type, whatever the pattern). That is, we want to treat the variable as ordinal rather than nominal—we need a statistical test that specifically looks for a trend pattern. Various options are available, which usually involve assigning an increasing score to the categories of the ordinal variable. Tests for these will be discussed in the subsection for regression modelling of binary variables.

Comparing means

Suppose we want to examine whether a child's birthweight depends upon his or her mother's marital status. We know that the distribution of birthweight, a continuous variable, can be summarized by its mean and standard deviation. So we examine these summary measures within values of the categorical variable (marital status, a nominal variable) to see how the continuous variable varies with the categorical variable. Table 5.14.8 shows the results.

If the frequency distribution of a continuous variable is approximately normal (as it is for birthweight), then it is described fully by its mean and SD, which is why we use these measures in the example. In other cases, such as skewed distributions, we might use the median or the geometric mean as a measure of location and the interquartile range as a measure of variability, and present these instead of, or along with, the mean and standard deviation.

These results show that, compared to 'Married' women, women who have 'Never married' have slightly heavier babies (by 0.07 kg), whereas women 'Living together' and 'Other' have slightly lighter babies (by 0.19 kg and 0.17 kg, respectively). These differences seem comparatively small, but would be regarded as important differences (by comparison with other risk factors that decrease birth weight, e.g. smoking). The mean for married women is very close to the overall mean, because they make up most (363/500 = 72.6%) of the sample. We now need to make an assessment of the role of chance in producing the observed differences. We know that some variability in observed means is due to sampling error, but could sampling error be the complete explanation? The crucial question is whether the means differ more than would be expected by chance alone.

The sampling variability of a mean is assessed by its standard error of the mean (SE) which has earlier been used to derive a CI for the true mean. We can apply these techniques to the data in Table 5.14.8, examining mothers' marital status and birthweight (Table 5.14.9).

Table 5.14.8 Mean, standard deviation (SD), and range of birthweight, by marital status of mother, for a group of Brisbane babies born in 1984–1988

Marital status	*N*	Mean (kg)	SD (kg)	Minimum (kg)	Maximum (kg)
Married	363	3.57	0.42	2.33	4.85
Never married	70	3.64	0.44	2.34	5.06
Living together	53	3.38	0.42	2.27	4.18
Other	14	3.40	0.40	2.86	4.28
Total	500	3.56	0.43	2.27	5.06

Source: data from Najman, J.M. et al., Cohort profile: the Mater University of Queensland Study of Pregnancy (MUSP), *International Journal of Epidemiology*, Volume 34, Issue 5, pp. 992–7, Copyright © 2005.

Table 5.14.9 Mean birthweight (kg), standard errors (SE), and 95% confidence intervals (CI), by marital status of mother, for a sample of Brisbane babies born in 1984–1988

Marital status	*N*	Mean (kg)	SE (kg)	95% CI
Married	363	3.57	0.022	(3.53, 3.62)
Never married	70	3.64	0.052	(3.53, 3.74)
Living together	53	3.38	0.058	(3.27, 3.50)
Other	14	3.40	0.108	(3.16, 3.63)
Total	500	3.56	0.019	(3.52, 3.59)

Source: data from Najman, J.M. et al., Cohort profile: the Mater University of Queensland Study of Pregnancy (MUSP), *International Journal of Epidemiology*, Volume 34, Issue 5, pp. 992–7, Copyright © 2005.

Note the variability in the standard errors due to the variability in the sample size: the largest group (‘Married’ women) has the smallest standard error and the smallest group (‘Other’) has the largest standard error. Correspondingly, the CIs vary greatly in their widths. For ‘Married’ and ‘Never married’ mothers the CIs overlap considerably, but the ‘Married’

group has a very narrow CI, which does not overlap the ‘Living together’ category. We might feel that the difference among ‘Married’ and the ‘Never married’ could be explained by sampling variability, but that the difference between ‘Married’ and ‘Living together’ categories could not. Sometimes overlap or non-overlap of CIs is used in this way, but if we wish to make a formal statement about the difference between means then we must make a formal statistical test.

The two-sample *t*-test

The first step of a formal statistical test is to formulate a null hypothesis. In this case, the null hypothesis is that (true) mean birthweights do not vary among marital status groups. First consider the difference between birthweights of children of ‘Married’ (3.57 kg) and ‘Never married’ (3.64 kg) mothers—a difference of 0.07 kg. The next step involves assessing the role of chance in producing this observed difference if there is no difference in the population means. As before, we need to obtain the probability of getting a difference of 0.07 kg, by chance, if the null hypothesis is true. We evaluate this by first calculating a *t*-statistic. Perhaps not surprisingly, the test statistic depends on:

The size of the difference between the means.
The standard errors of the means.

Therefore:

$$t = \frac{\text{Difference between the means}}{\sqrt{\text{Sum of } (\text{SE})^2}}$$

with degrees of freedom (df) = sum of sample sizes –2.
This is called the *two-sample t-test*. The larger the difference between the two sample means, and the smaller the standard errors (or the larger the samples), the larger the value of *t*. As for the chi-squared test, once we have a calculated value and a value for the degrees of freedom, we obtain a *p*-value using statistical software.

For the comparison of birthweights of children whose mothers are ‘Married’ or ‘Never married’, we have:

$$t = \frac{3.57 - 3.64}{\sqrt{0.002^2 + 0.052^2}} = -1.24,$$

with degrees of freedom (df) = 363 + 70—2 = 431.

From statistical tables, we see that the *p*-value is > 0.10 (using df = infinity (∞)). The probability that such a difference could occur by chance is quite high. We then attribute the observed difference to sampling variability and conclude the difference is not significant.

Analysis of variance

For the example of mothers’ marital status and birthweight, we could carry out more *t*-tests, looking at the difference between other pairs of groups. However, it is considered bad practice to ‘search’ for significance in this way. A more acceptable practice is to carry out a ‘global’ test on the set of four means, to see if there is any significant variability among the means as a set, without specifying any particular pair of means. Pairwise differences may then be examined post hoc, once overall variability has been established. The technique used for this global test on a set of means is called *analysis of variance* (ANOVA). The null hypothesis is that there is no variation in the population means for all groups. Effectively, we assume all mothers, irrespective of marital status, belong to the same population, as far as their babies’ birthweights are concerned. No new conceptual issues arise in this analysis.

Again we work out a test statistic, now called an *F*-statistic. This test statistic depends on:

The variability among the means.
The standard errors of the means.

Now we have 2 df to work out: the so-called ‘numerator’ df is the number of groups minus 1 and the ‘denominator’ df is the total sample size minus the number of groups being compared.

We would usually use statistical software for ANOVA, which will also give us a *p*-value. In this case, the *F*-statistic is 14.01, with df = (3,497), and $p = 0.0029$. This is smaller than our usual cut-off point of 0.05, and we conclude that there are significant differences in birthweight among the marital status groups. These differences obviously arise from the 'Living together' and 'Other' groups.

If we had decided not to reject the null hypothesis, the matter would have ended there. When we do reject the null hypothesis, we might want to examine the pairwise differences using *t*-tests. Although opinions vary, sometimes modified versions of the *t*-test are used to take into account the multiple comparisons that might be involved in such examination. Multiple comparisons increase the overall risk of a type 1 error (i.e. finding at least statistically significant result just by chance).

Assumptions of the two-sample *t*-test and ANOVA

The two-sample *t*-test and ANOVA have important underlying assumptions. These are as follows:

If the sample is small, the mean is based on a variable with a normal distribution; if the variable does not have a normal distribution, the sample is large enough for the Central Limit Theorem to apply to the distribution of the mean.
The SDs within each group are approximately equal.
The samples are independent observations; that is, separate groups of individuals.

We have already established that the distribution of birthweight is quite close to a normal distribution, so the first assumption has been met. What about the second? Inspection of the 'SD' column in Table 5.14.8 confirms this—the SDs vary only slightly.

A statistical test, called Bartlett's test, can be used to determine whether SDs are significantly different. Some statistical software automatically carries out this test when an ANOVA is requested. Alternative tests are available in such a situation.

There are two main options for dealing with non-normal distributions: transformations and non-parametric tests.

Transformations: it is sometimes possible to transform the variable to make a normal distribution, and then carry out the *t*-test or ANOVA on the transformed variable. If a variable has a positively skewed distribution, the log transformation is sometimes used to give a more symmetric distribution, closer to the normal distribution. Many transformations are available, but there is no guarantee that any will work in any particular case. The distribution of the transformed variable needs to be examined to confirm this.

Non-parametric tests: if a transformation cannot be found, it is possible to use a non-parametric test. These do not require the first two assumptions, but still require independence between observations (the third assumption). Instead of a *t*-test, we use the Wilcoxon–Mann–Whitney test to get a *p*-value for comparing two means; instead of ANOVA, we use the Kruskal–Wallis analysis of variance to obtain a *p*-value for comparing two means.

If the assumptions are met and non-parametric tests are used, these tests will have less ability to detect differences between means; that is, they will result in larger *p*-values than the *t*-test or ANOVA and be less likely to reject the null hypothesis. Usually researchers want to make the maximal use of their data, and carry out the most sensitive tests possible, so they prefer to use tests based on the normal distribution if possible.

Repeated measurements of a quantitative variable

The questions in Table 5.14.3 are about relationships between two variables, each of which is measuring a different entity. Sometimes our question relates to whether a single variable changes over time. Suppose we are investigating the effectiveness of an intervention to improve the nutritional status of children. In this case, we might measure the nutritional status of each child within the sample of children before and after the intervention. At first sight, this looks similar to the previous case: there are two variables, nutritional status before intervention and nutritional status after intervention. But this is different because we are really observing one variable at two different times. We expect measurements taken on the same individual at two different times to be related so the measures are not independent. This relationship needs to be taken into account when the effect of a second variable (intervention) is being evaluated.

In a trial to examine the effectiveness of a dietary intervention, 17 participants had vitamin A intake (in µg) assessed at baseline and 6 months later, to see whether the dietary intervention helped increase vitamin A intake over the 6-month period (Table 5.14.10). At first sight, we might see this as a situation for a two-sample *t*-test, comparing mean vitamin A intake at baseline and at 6 months. This is not appropriate because the third assumption for the two-sample *t*-test—independence of the groups being compared—has not been met.

Table 5.14.10 Vitamin A intake levels (micrograms = µg) at baseline and 6 months post-intervention

Person	Baseline	6 months	Change (6 months–baseline)
1	120	124	4
2	122	135	13
3	126	140	14
4	131	130	–1
5	135	169	34
6	157	189	32
7	160	176	16
8	181	196	15
9	195	223	28
10	200	254	54
11	205	267	62
12	211	289	78
13	215	301	86
14	220	227	7
15	246	305	59
16	255	278	23
17	278	299	21
Mean (SD)	185.7 (49.6)	217.8 (65.4)	32.1 (26.3)

Almost all 6-month values are higher than baseline values, although some individual differences are quite small. The appropriate summary statistic to compare paired repeated measurements of a continuous variable is the *mean change* within individuals. For each participant, we subtract baseline vitamin A levels from 6-month values. The mean and SD of these individual changes are then calculated. Hence, for matched data, we finally deal with one variable (i.e. change after intervention) and not two variables. In this

example, the mean change in vitamin A levels was 32.1 µg, with a range of changes from –1 to + 86 µg and a SD of 26.3 µg. Where the distribution of the observed changes is not normal, a more valid summary would be the median.

To get a 95% CI for the mean change, we first calculate the standard error of the mean change in vitamin A intake, which is

$$\mathrm{SE(change)} = \frac{\mathrm{SD(change)}}{\sqrt{N}} = \frac{26.3}{\sqrt{17}} = 6.4\mu g.$$

The 95% CI = (mean change—1.96 × SE(mean change), mean change + 1.96 × SE(mean change)) = (19.5, 44.6).

Notice that the lower limit of this 95% CI is well above zero, so we have considerable confidence that the change is positive, at least.

We can formally test the null hypothesis that the true increase is zero by calculating a *t*-statistic, as follows:

$$t = \frac{\text{mean change}}{\mathrm{SE(change)}}$$

This is referred to as the *paired or one-sample* t-*test*, because it assumes paired measures, and we want to evaluate the significance of the change (or more generally, the difference) within the paired values. The larger the mean change, and the smaller the standard error (or the larger the sample), the larger the value of *t*.

Once *t* and its df are calculated, we obtain a *p*-value from *t*-tables or statistical software. For the paired *t*-statistic on *N* pairs, the df is *N*—1. We calculate $t = 5.02$, with 16 df, for which $p = 0.0001$. It is extremely unlikely that such a difference could occur by chance, or sampling variability, alone, with no effect attributable to the intervention. So we reject the null hypothesis and conclude that the intervention has increased dietary intake by an estimated 32.1 µg per day, with a 95% CI of (19.5 µg, 44.6 µg).

Again, this *t*-test is based on the assumption that the change in vitamin A level is normally distributed. If this assumption cannot be made, a non-parametric counterpart test can be used—the Wilcoxon signed-rank test.

Correlation and regression

We now examine similar questions, when both variables being considered are continuous. This leads to some different measures of data presentation, and different techniques for assessing the significance and size of associations.

Scatter plots

Suppose we are interested in the relationship between birthweight and maternal weight prior to pregnancy, both continuous variables. An efficient method of displaying such a relationship visually is to use a scatter plot in which each point represents a particular mother (weight)–child (birthweight) pair. Figure 5.14.4 shows that heavier mothers tend to have heavier babies. Although such a pictorial representation of the relationship is useful, we usually summarize the relationship more concisely, with a ‘coefficient of association’.

Coefficients of association

Various coefficients of association have been developed for quantitative measures, with some common properties. These include the following:

A value of zero for the coefficient means no association.
A negative value for the coefficient means that one variable increases as the other decreases.
A positive value for the coefficient means that the variables increase or decrease together.
The range of the coefficient is from –1 to +1. Attainment of –1 or +1 is said to be ‘perfect association’.

For the relationship shown in Figure 5.14.4, we would expect a measure of association to be a positive value, somewhat less than 1.

Pearson correlation coefficient

The most commonly used measure of association is the Pearson correlation coefficient (r), used to describe the linear relationship between two continuous variables. If values of both variables increase together, r will be positive. If values of one variable increase as those of the other decrease, r will be negative. In the earlier example, 'Y' is birthweight and 'X' is maternal weight, corresponding to our scatter plot in Figure 5.14.4. The correlation coefficient is estimated as +0.50. Is this a 'high' or 'strong' correlation? As a rough guide, in biostatistics, 0–0.15 is usually regarded as a 'low' correlation, 0.16–0.4 as a 'modest' correlation, 0.41–0.7 a 'moderate' correlation, and above 0.7 a 'high' correlation, although context usually matters.

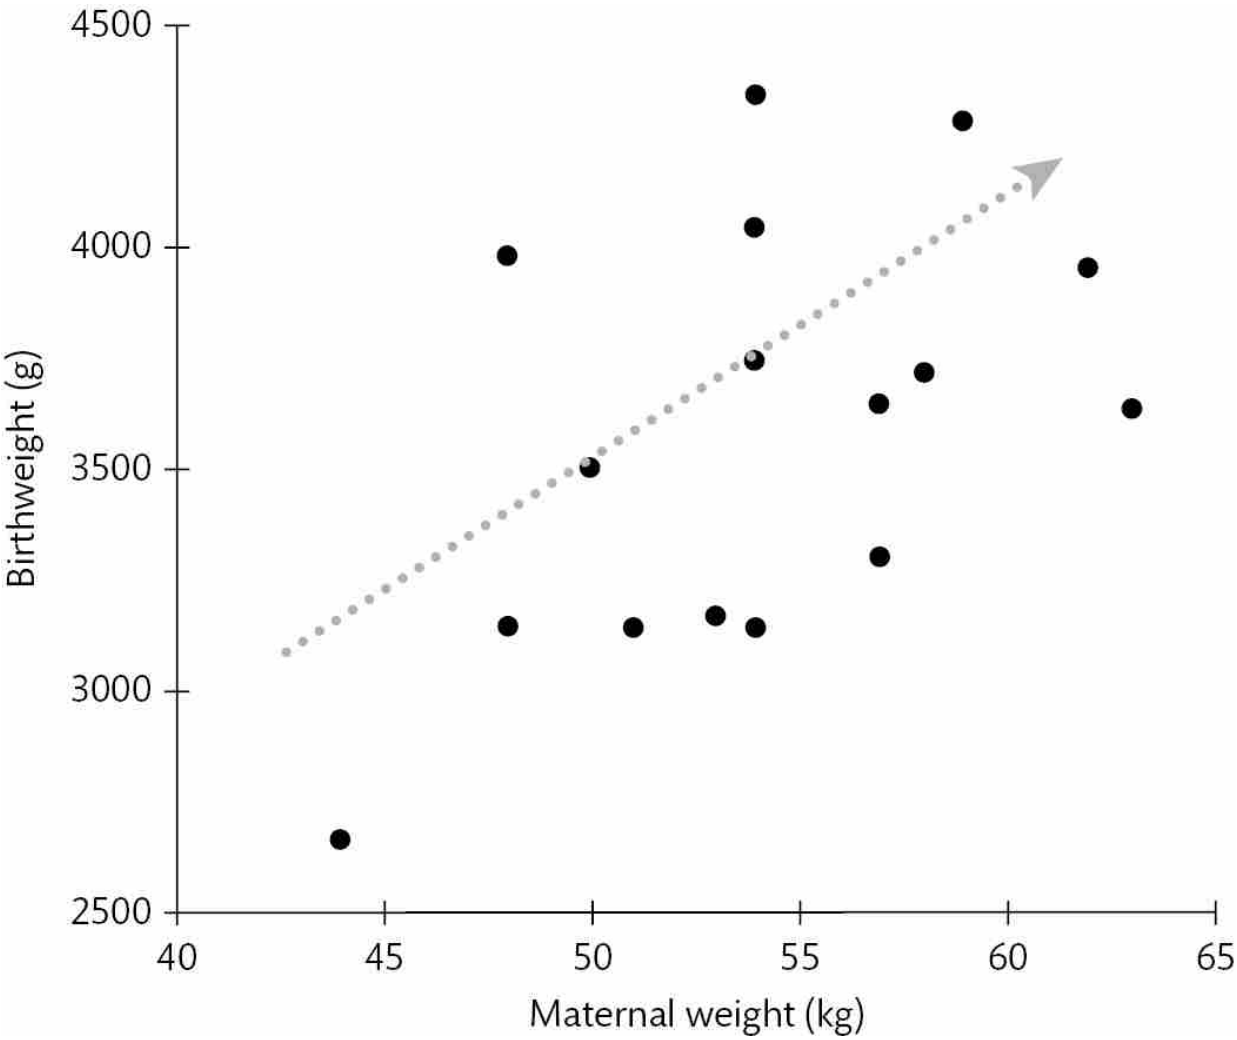


Fig. 5.14.4 Scatter plot and regression line of birthweight (g) and maternal pre-pregnancy weight (kg) fitted by least squares for a group of 16 term Brisbane babies, born in 1984–1988.

Significance of the correlation coefficient

The value of 0.5 obtained may be considered moderate in magnitude. A separate issue is that of significance. This examines the role of chance or sampling variability in observing a coefficient of this size. We need to obtain the probability that a coefficient as large as 0.5 would be observed by chance in a sample of this size if maternal weight and birthweight had no true relationship (a true correlation coefficient of 0).

In the case of the Pearson correlation coefficient, the *p*-value is obtained directly from tables or statistical software. As before, we need to calculate the df parameter which depends on the sample size *N*. In this case, df = *N*—2, or 16—2 = 14. This gives $p = 0.048$, just less than the conventional cut-off. So the correlation coefficient could be described as 'significant' or, more completely, as 'significantly different from zero'.

Types of association and correlation

Figure 5.14.5 shows various types of association and how they would be described. It is important to note that the correlation coefficient measures only linear relationships; alternatively, we might say the correlation coefficient only measures that part of the relationship which is linear. A linear relationship is one in which a straight line approximates the relationship.

Note that the lower right graph in Figure 5.14.5 would give a correlation close to zero correlation for the Pearson coefficient. The reason for this is that the data are non-linear, even though there appears to be a relationship between the two variables. Thus, the Pearson coefficient only measures strength of a linear relationship. If we wanted to estimate strength of association for a non-linear relationship, we would have to specify a particular non-linear form.

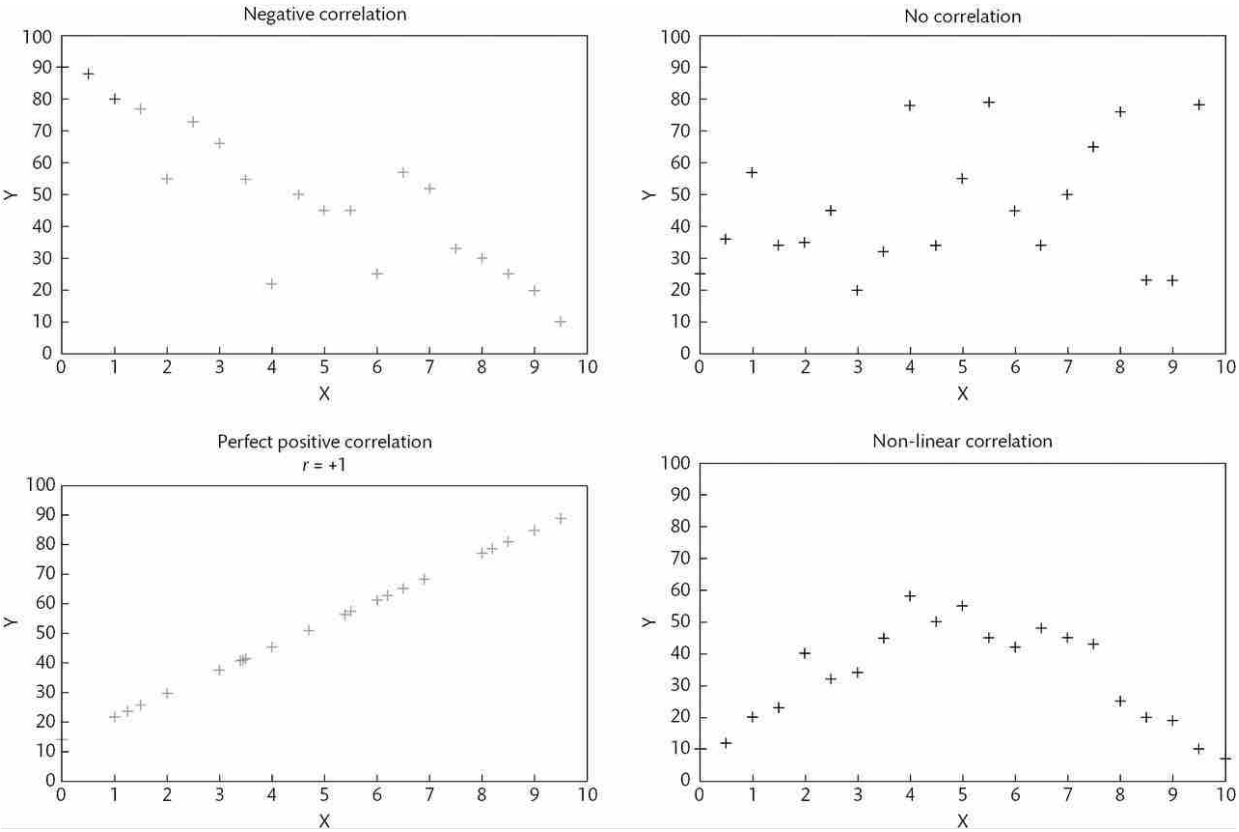

Fig. 5.14.5 Types of association.

Regression

To illustrate the regression approach to analysis, we use the data in Figure 5.14.4. We wish to 'model' the association between the two variables by fitting a straight line to the data, as follows. A linear model involving one dependent and one independent variable is expressed as:

$$Y = \alpha + \beta X + e.$$

In setting up a regression model, one variable, usually denoted Y, called the *dependent variable* (or *outcome*), is the variable to be predicted or modelled. The other variable, usually denoted X, is sometimes called the *independent variable* (or better, the *predictor* or *explanatory variable*) and is the variable used to predict or explain Y. The formula of the model assumes Y has a straight-line relationship with X. The symbols α and β represent the intercept

and the slope, respectively, of the line on a scatter plot of Y versus X. The parameter β is called the *regression coefficient*, and is a measure of how much Y changes for a unit (e.g. 1 kg of maternal weight) change in X; α is usually not of interest. The quantity e measures the 'error'—given that it is very unlikely such a simple model will describe data such as that in Figure 5.14.4, we allow for the 'error' to have a distribution. In this case, for each value of X, the errors are assumed to have a normal distribution about the predicted value $\alpha + \beta X$.

A mathematical algorithm is needed to estimate α and β—the simplest of these is the *method of least squares* which minimizes the squared differences between observed values and those predicted by the model.

For the birthweight data in Figure 5.14.4, we obtain the following model:

$$Y = 1{,}124 + 45.5X.$$

That is, birthweight increases by 45.5 g for every 1 kg of mother's weight. So mothers who differ by, say, 10 kg in their pre-pregnancy weight would expect to have babies, on average, who differ by 455 g in birthweight. Standard errors and CIs can be calculated for a regression coefficient. In this case, the 95% CI for the regression coefficient is (4.5, 86.5). Although this CI is quite wide, it excludes the value 0, which would correspond to no relationship between mother's weight and child's birthweight (a horizontal line on Figure 5.14.4).

We can also formally test for the statistical significance of the regression coefficient, using statistical software. For this example $p = 0.03$, which is small enough to conclude the relationship is significant.

The model can be used for prediction. If a pregnant woman has a pre-pregnancy weight of 50 kg, we can predict that her infant will have a birthweight of $Y = 1{,}124 + (45.5 \times 50) = 3{,}399$ g.

Assumptions of correlation and regression analyses

Correlation and regression coefficients are estimated on an assumption of a linear association. To make inferences (test hypotheses or calculate CIs), however, you need to make additional assumptions. These are as follows:

For correlation analyses, the two variables involved have joint normal distributions.
For regression analyses, the outcome (dependent variable) has a normal distribution.
For correlation and regression analyses, the samples are independent observations; that is, all pairs of observations are independent.

We have already established that the distribution of birthweight is quite close to a normal distribution, so the second assumption needed for regression analysis is met. What about the others? What do we do if the assumptions are not met? Again there are two main options: transformations and non-parametric correlation coefficients.

Transformations: transformations can be used, as described in the subsection on *t*-tests and ANOVA.
Non-parametric correlation coefficients: if a transformation cannot be found, it is possible to use a non-parametric test instead. These do not require either of the two distribution assumptions mentioned here. Instead of a Pearson correlation, we use the Kendall (τ or tau) or Spearman correlation coefficient (r_s).

The successful fitting of a straight line to the data does not establish causality. Although we predict that babies whose mothers' weights differ by 1 kg will have birthweights differing on average by 45.5 g, we cannot predict that increasing a mother's weight by 1 kg will cause an increase of 45.5 g in her child's birthweight. Observing an association between an outcome and a potential risk factor is, however, the first step in examining causality; we then have to consider possible explanations, which include chance, bias, and confounding. The results of a significance test enable us to assess the role of chance, but bias and confounding are crucial to consider. Multivariable statistical modelling is one approach to examining confounding; and is dealt with later in this chapter.

Survival data

In a cohort study, if an event or disease of interest is likely to occur in most participants, then interest centres on the actual time till the event, rather than

the occurrence of the event itself. Examples include time to death following a diagnosis of breast cancer, time to remission of disease following treatment, or time to cessation of breastfeeding, in a cohort of infants. Such data are referred to as *survival data* or *failure time data*. A person's 'survival time' is his or her time from entry in the study until the occurrence of the event. The distribution of survival times is often very skewed and may be bimodal (e.g. if significant postoperative mortality is followed by increased then gradually decreasing prospects of survival).

Survival data may be *censored* if there are participants who do not experience an event because the study ends before this occurs, are 'lost to follow-up' (because of, e.g. migration or death), experience another type of event which precludes the event of interest (e.g. death from another cause), or cease to be eligible for the study (e.g. in a study of under-5s, children are ineligible after their fifth birthday). In such instances, the person's survival time cannot be known precisely, only that it is *at least* a certain amount. *Survival analysis* enables use of all of a person's 'at-risk' time, irrespective of whether an event is experienced. An additional feature is that it allows the incidence rate to vary for the entire period of observation.

The Worcester Heart Attack Study (WHAS) examined factors associated with survival rates following acute myocardial infarction (MI) (Tonne et al. 2005). Data were collected from 1975 to 2001, on 500 MI patients' hospital admissions in the Worcester, Massachusetts Standard Metropolitan Statistical Area. Data analysis focuses on time from admission to death, or time from admission to the last-follow-up, if the patients were still alive. Of the 500 patients, 215 (43%) died within their follow-up period.

The analytical approach is to divide the follow-up time into short periods, called *risk sets*, and count events that occur within each risk set, as a fraction of all people who were in the study for that period. The latter is particularly important: people will drop out of the analysis because they have experienced the event (died) or had finished their follow-up period. These fractions are then manipulated in a process attributed to Kaplan and Meier (1958) to form a curve that shows the estimated probability of survival to that time. Results for fitting this curve to the WHAS data overall and to two subgroups (with and without complications at admission) are shown in Figure 5.14.6, with 95% CIs.

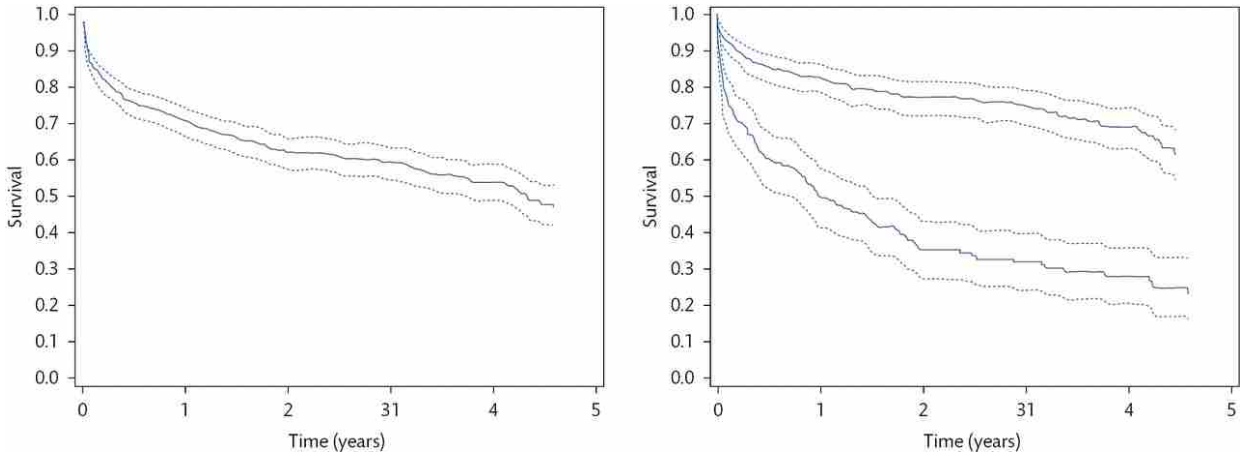

Fig. 5.14.6 Survival curves, with 95% CIs for patients with MI, overall and according to presence or absence of complications at time of admission (Worcester Heart Attack Study). Those without complications shown in the upper graph on the right.

Source: data from Tonne C, et al., Long-term survival after acute myocardial infarction is lower in more deprived neighborhoods, *Circulation*, Volume 111, pp. 3063–70, Copyright © 2005 American Heart Association, Inc. All rights reserved.

Notice that mortality is highest immediately after the initial MI, with only about 70% surviving the first year, but flattens a little at about 2 years. This analysis yields more information than simply examining mortality rates. The survival curve can also be used to estimate the median survival, the length of time corresponding to 50% survival: project from a horizontal line at survival = 0.5 to the horizontal axis to give an estimated 50% of people survive to 5 years or more (i.e. the 5-year survival is 50%). Other quantiles can similarly be estimated. Kaplan–Meier survival curves can be formally compared using the Wilcoxon or logrank tests (Martinez and Naranjo 2010; Doi and Williams 2013).

Additional comments on censoring

Whenever a participant experiences an event which precludes them from experiencing the event of interest, they are censored at that point. For example, if, in the WHAS, the event of interest is death from cardiovascular disease, then a patient who experiences death from cancer is considered censored at the time of death. We also assume that censoring is independent —that is, that people with censored observations have the same future risk as those that are not censored. This is quite a strong assumption. For example,

suppose we are examining survival of patients admitted to an intensive care unit. If follow-up ceases at discharge then, given that those discharged are more likely to have a better prognosis than those not discharged, censored observations would be likely to have a lower risk. If drop-outs differ from non-drop-outs this is also likely to lead to dependent censoring.

A specific example of this occurs in ‘competing risk’ models. In the example given earlier for death from cardiovascular disease, and censoring by death from cancer, we need to consider whether a person who dies from cancer would have the same future risk (had she/he not died from cancer) of death from cardiovascular disease. This may seem plausible. However if, in a series of patients with obesity, the event of interest is death from cardiovascular disease, death from diabetes would be a competing event, since it is likely that risks of these outcomes would be associated. In such instances it is argued that the methods described earlier would result in biased estimates of survival. The appropriate analyses are complex, essentially involving the joint analysis of the cumulative incidence of both the event of interest and any competing event(s)’ (Doi and Williams 2013).

Multivariable analysis

This section deals with the situation where we have more than one variable predicting an outcome variable. The term ‘multivariable’ is used in preference to ‘multivariate’ which is commonly also used to describe this situation. Classical statistical usage for the term ‘multivariate’ is in describing analyses which are required to predict more than one outcome variable simultaneously, such as when one has a set of items purporting to measure a common dimension, for example, depression or anxiety, or when measurement of outcomes is repeated over time. We consider various models which arise, as a consequence of different outcome variables or study designs. As we shall see, these models share a common framework, the generalized linear model, which is a generalization of the simple regression model discussed earlier; models differ only where necessary to incorporate their different assumptions. We begin with models based on the normal distribution.

Normal theory regression

Having established that birthweight and maternal weight are associated, and having estimated the regression coefficient, we might be interested in further exploring the prediction of birth weight. We could perform the same analyses on a range of other variables, such as family income, tobacco, or alcohol consumption. In each case, a regression model provides us with a measure of the size of the effect (the regression coefficient, at a 95% CI) and its statistical significance (*p*-value). In this way, we might identify a collection of predictors or 'risk factors'. It is likely that these predictors will themselves be related: consider the following example, now based on a sample of 500 births.

Regression of birthweight upon maternal pre-pregnancy weight yields:

Birthweight (g) = 2,832 + 11.3 × maternal weight (kg).
Birthweight increases by 11.3 g per kg of maternal weight.

Regression of birthweight upon number of previous pregnancies yields:

Birth weight (g) = 3,453 + 29.5 × number of previous pregnancies.
Birth weight increases by 29.5 g per previous pregnancy.

But if a woman's weight increases with increasing number of pregnancies, then these two findings might be related; for example, does birthweight increase with increasing number of pregnancies because of the increasing weight of the mother, or is the effect separate?

To examine this, we set up a multivariable linear model such as:

$$Y = \alpha + \beta_1 X_1 + \beta_2 X_2 + e,$$

where β_1 and β_2 are regression coefficients indicating the dependence of Y upon variables X_1 and X_2, X_1 being maternal weight and X_2 being the number of previous pregnancies. This model is fitted in the same way as before, to obtain:

Birth weight (g) = 2,830 + 11.0 × maternal weight (kg) + 16.9 × number of previous pregnancies.

We see that the maternal weight effect remains virtually the same, but the effect of number of previous pregnancies has about halved, and is no longer significant. To see why this has happened, we use our multivariate model to

assess the effect of a difference in maternal weight of 1 kg on birthweight. Suppose a woman A has a pre-pregnancy weight of 50 kg and one previous pregnancy. Her baby's predicted birthweight (g) is 2,830 + 11.0 × 50 (kg) + 16.9 × 1.

Suppose a second women B has a pre-pregnancy weight of 49 kg and no previous pregnancies. The latter has an effect on birth weight, so B is not comparable to A. The prediction model can make A and B comparable in terms of pregnancy history, by setting B to have one previous pregnancy. The predicted birthweight for B's baby (if she had one previous pregnancy) is 2,830 + 11.0 × 49 (kg) + 16.9 × 1.

Subtracting these two equations to obtain the difference in predicted birthweight for these two women, gives a predicted difference of 11.0 g, the regression coefficient for maternal weight in the multivariable model. Thus, the regression coefficient of 11.0 g represents the effect of an additional 1 kg of maternal weight, after controlling (or adjusting) for number of previous pregnancies.

Reciprocally, the regression coefficient for number of previous pregnancies reflects the association between birthweight and number of previous pregnancies, after adjusting for the effect of maternal weight in the multivariate model. As this effect has been much decreased to the point of non-significance, we would conclude that the significant effect we saw in the first separate analysis was due to confounding by maternal weight.

A *confounding variable* is one that is associated with both the outcome variable and a predictor variable. In summary, a multivariable regression model yields estimates of the separate or 'adjusted' relationships between the outcome variable and the predictor variables.

Essentially, no new principles emerge when this process is extended to more predictors or risk factors. We obtain a series of estimated regression coefficients, and confidence limits for the parameters, and *p*-values, each reflecting the association between the outcome and the predictor, after adjusting for all other predictors included in the fitted model.

If an outcome variable is continuous, but the normal distribution for errors does not apply, the outcome variable can sometimes be transformed, so that the normal assumption is satisfied. Typical transformations include the log or square root transform, which can correct skewness. While these are useful statistical devices, they can sometimes make results more difficult to interpret.

Logistic regression

Logistic regression is used in similar situations to normal theory regression, but where the outcome variable is binary (e.g. dead/alive, having a specific disease or not) and we want to model the risk of this outcome (death, diseased) according to certain predictors or risk factors. The difference is that we use a transformation, called the *logit* transformation, to account for the binary nature of the variable. This is seen on the left hand side of the following formula:

$$\log(p) = \log(p/(1-p)) = \alpha + \beta_1 X_1 + \beta_2 X_2 + e,$$

where log is the logarithm function to base e, p is the predicted proportion of people with the outcome of interest, given particular values of the predictor variables X_1 and X_2. Note that the left hand side is now modelling the log(odds of outcome), where odds of outcome may be estimated by the number with the outcome, divided by the number without the outcome. The error distribution on the right hand side (e) is assumed to follow a binomial distribution, which is a probability distribution describing the number of times an outcome occurs, in a set number of individuals at risk. The regression coefficients β_1 and β_2 now need to be re-interpreted in the light of the transformation. When the model is fitted to data, and the regression coefficients back-transformed by exponentiating (taking anti-logs), we obtain odds ratios for the association between the outcome and the risk factor. The odds ratio is the odds of the outcome (defined earlier) within those who have the risk factor, divided by the odds of the outcome within those who do not have the risk factor. It is a widely used measure of association between a risk factor and an outcome. An odds ratio of one indicates no association between risk factor and outcome; odds ratios of greater than one or less than one indicate an increased or decreased risk of the outcome associated with the risk factor, respectively.

As an example, suppose we are interested in examining the predictors of overweight in adolescent girls, using data on 1,823 14-year-old girls born into a cohort study (Najman et al. 2005). Of these we note that 466, or 26%, are overweight at age 14, and also that being overweight at age 14 is associated with parental weight at the child's birth. A girl was more likely to

be overweight at 14 if her mother was overweight at the start of the pregnancy (51% of daughters of overweight mothers were overweight, compared to 21% of non-overweight mothers). Calculating from first principles, the odds ratio for the association between mothers and daughters being overweight is (0.51/(1 − 0.51))/(0.21/(1 − 0.21)) = 3.9. A similar, but not quite so marked, result was noted for fathers'- weight: 39% of daughters of overweight fathers were overweight, compared to 21% of daughters of non-overweight fathers. These data are displayed in Table 5.14.11.

In addition, girls who were overweight at age 14 had a mean birthweight of 3.4 kg, compared to 3.3 kg for those who were not. We could surmise (and can conform by additional analyses) that the mother's pre-pregnant weight, the father's weight at the time of pregnancy, and the daughter's birthweight are likely to be positively associated, resulting in some confounding of their effects. In order to sort out the separate contributions of these three predictors we use a logistic regression model as follows. We would typically begin with a model which uses one risk factor at a time, then a multivariable model, or series of them which examines the effects of adjusting for other risk factors. As before, effects obtained from multivariable models are adjusted for all other variables (risk factors) in the model. When this is done for this example, we find the various effect estimates and 95% CIs as shown in Table 5.14.12.

Table 5.14.11 Association between maternal pre-pregnant overweight status and daughters' overweight status at age 14

Risk factor		*N*	Daughters overweight	Odds ratio (OR) for daughter overweight and risk factor (1 = reference category)
Mother overweight	No	1,545	324 (21%)	Reference
	Yes	278	142 (51%)	3.9
Father overweight	No	1,381	293 (21%)	Reference
	Yes	442	173 (39%)	2.4

Family and early life factors associated with changes in overweight status between ages 5 and 14 years: findings from the Mater University Study of Pregnancy and its outcomes. *International Journal of Obesity (London)*, 29(5):475–82.

Table 5.14.12 Logistic regression: predicting overweight in adolescent girls from maternal and paternal overweight status prior to pregnancy, and birthweight

Risk factor		Odds ratio (OR) for daughter overweight and risk factor (95% confidence intervals)		
Unadjusted	**Adjusted for other parental overweight**	**Adjusted for other parental weight and birthweight**		
Mother overweight	No	Reference	Reference	Reference
	Yes	3.9 (3.0–5.1)	3.5 (2.7–4.6)	3.4 (2.6–4.5)
Father overweight	No	Reference	Reference	Reference
	Yes	2.4 (1.9–3.0)	2.1 (1.6–2.6)	2.1 (1.6–2.6)
Birth weight	(kg)	1.4 (1.1–1.7)		1.2 (1.0–1.5)

Source: data from Mamun, A.A., Lawlor, D.A., O'Callaghan, M.J. et al. Family and early life factors associated with changes in overweight status between ages 5 and 14 years: findings from the Mater University Study of Pregnancy and its outcomes. *International Journal of Obesity (London)*, 29(5):475–82.

Our multivariable analyses (last two columns) show some reduction in effect estimates after adjustment, indicating that the effects of maternal and paternal overweight are largely separate effects. Adjusting for birthweight makes very little difference to the magnitude of parental effects. Notice that the effect of birthweight, as a continuous variable, is expressed differently to the categorical variables of parental overweight. The odds ratio for birthweight gives the increase in odds of the daughter being overweight at age 14, for a unit (1 kg) increase in birthweight, that is, a child who was 4 kg at birth is predicted to have 40% increase in odds of being overweight at 14, compared to a child who was 3 kg at birth. This same relative increase applies when comparing a 3.5 kg child with a 2.5 kg child. When we include continuous variables in a logistic model we assume that the relative effect, per unit change in the variable, is constant. This is an assumption that should be checked.

Poisson regression

Poisson regression (named after the French mathematician who first described a probability distribution for count data) is used when the outcome variable is a count variable (e.g. number of deaths over a period, or number of incident cases of disease). There two differences, compared to normal theory regression. The first is that we apply a log transformation to our count data, and the second is that we (usually) have to incorporate an 'offset' variable' which measures the period of time at risk, over which the events are accumulated. This model is expressed according to the following formula:

$$\log(\text{number of events}) = \alpha + \beta_1 + X_1 + \beta_2 + X_2 + \log(\text{person} - \text{time at risk}) + e$$

or, equivalently,

$$\log(\text{event rate}) = \alpha + \beta_1 X_1 + \beta_2 X_2 + e.$$

The error distribution on the right hand side (e) is assumed to follow a Poisson distribution, which is a probability distribution describing a 'count' of a number of independent events. As for logistic regression, the regression coefficients β_1 and β_2 need to be re-interpreted in the light of the log transformation. When the model is fitted to data, and the regression coefficients back-transformed by exponentiating (taking anti-logs), we obtain rate ratios for the association between the outcome and the risk factor. The rate ratio in this context is the rate of the outcome (as a person-time rate) within those who have the risk factor, divided by the rate of the outcome within those who do not have the risk factor. Again a rate ratio of one indicates no association between risk factor and outcome; rate ratios of greater than one or less than one indicate an increased or decreased risk of the outcome associated with the risk factor, respectively.

As an example, consider the results of a Poisson regression applied to examining risk factors for the occurrence of a particular form of skin cancer (squamous cell carcinoma (SCC)) in a cohort study. Because participants dropped out of the study at different stages throughout the 12-year period of follow-up, it was necessary to take account of each individual's person-time of follow-up. This leads to the offset variable described earlier. The outcome of this analysis was whether or not a participant had a new SCC lesion

detected in the follow-up period. Note that an individual only appears once in the analysis. Subsequent new SCC lesions did not contribute. This is an important assumption of Poisson regression, that is, that the outcomes are independent of each other—it is likely that SCCs will tend to cluster within individuals, and therefore subsequent events within the same individual will not be independent. An alternative model (e.g. negative-binomial regression) must be used if one wants to consider multiple events within an individual. Variables to be considered in a multivariable analysis for predicting SCC included sex, age, skin colour, history of skin cancer, and skin response to exposure to the sun. The results of this analysis are shown in Table 5.14.13.

The first column of rate ratios indicates the increase in risks associated with each risk factor (and their 95% CIs), taken one at a time. The second column of rate ratios shows the increases in risks when each risk factor is adjusted for the effects of the others, and any associations among risk factors. We see that the general tendency is for rate ratios to reduce, after adjustment for confounding. Most notably, the rate ratios (RR) associated with a previous history of skin cancer drops from 5.08 (3.55–7.20) to 2.50 (1.69–3.71) when adjusted for other risk factors; this is because factors (such as age, skin response to the sun) will be associated both with a past history and future risk of skin cancer. When these factors are taken into account, some of the effect of history of skin cancer, as a single factor is reduced. Note also that the age effect appears modest—RR = 1.06 (1.05–1.08)—but one needs to take into account that this is the increase in risk, per year of age. Over a decade of age this translates to a cumulative rate ratio of 1.84 (1.64–2.23).

Cox proportional hazards regression

The Cox proportional hazards model (Cox 1972) is a widely used method for multivariable analysis of survival data. It can be thought of as a combination of the Kaplan–Meier method which involves dividing the follow-up time into small intervals, and the Poisson regression model approach which formulates a model within each of these time periods.

Consider the WHAS data referred to in Figure 5.14.6. Suppose our follow-up time is divided into intervals determined by the time points t_1, t_2, t_3, etc. We imagine a regression model within each of these intervals (t_1, t_2)

(t_2,t_3) etc., which relates the probability of death within the interval to a risk factor, such as complications of a myocardial infarct. From such a model we can obtain an effect estimate (a relative risk of death in this case, associated with having complications) for that time interval. This relative risk would vary over time. However, we begin by making a simplifying assumption that the risk ratio (usually termed hazard ratio in this context) is constant over time—this is called the proportional hazards assumption.

We now consider a Poisson model', to cover the time period from t to t + 1, as follows (Doi and Williams 2013).

$$\log(\text{event rate at time t}) = \alpha + \beta_1 X_1 + \beta_2 X_2 + e.$$

Conceptually, this model is then fitted for each time period (with the constraint that the estimates β_1 and β_2 are, the same for each period). This occurs by a process called partial likelihood. The resultant parameter estimates the log of the hazard ratio.

Table 5.14.13 Comparison of unadjusted and multivariable Poisson regression for risk factors for SCC: rate ratios

Risk factor		Rate ratios (RR) for incidence of SCC (95% confidence intervals)	
Unadjusted	**Multivariable analysis**		
Sex	Female	Reference	Reference
	Male	1.53 (2.17–5.72)	1.39 (0.98–1.99)
Age	Years	1.08 (1.06–1.10)	1.06 (1.05–1.08)
Skin colour	Olive	Reference	Reference
	Medium	1.33 (0.52–3.40)	1.22 (0.47–3.14)
	Fair	2.11 (0.86–5.21)	1.60 (0.63–4.07)
History of skin cancer	No	Reference	Reference

	Burns, then tans	1.13 (0.59–2.20)	1.45 (0.74–2.86)
	Burns, never tans	2.33 (1.17–4.62)	2.12 (1.02–4.39)

Source: data from *The Lancet*, Volume 354, Issue 9180, Green, A. et al., Daily sunscreen application and betacarotene supplementation in prevention of basal-cell and squamous-cell carcinoma of the skin; a randomised controlled trial, pp. 72–5, Copyright © 1999 Elsevier Ltd. All rights reserved.

The usual form of the model expresses the ‘intercept’ as a log of a ‘baseline hazard’, this being the predicted death rate for the reference category of the predictor variable:

$$\log(\text{event rate at time } t) = \log(\text{event rate at time } t \text{ for reference categories for } X_1 \text{ and } X_2) + \beta_1 X_1 + \beta_2 X_2 + e.$$

Thus the hazard ratios β_1 and β_2 give the multipliers of the baseline hazard associated with being in particular risk groups. You can see that the hazard

ratios ‘multiply’, since the aforementioned model, after exponentiating both sides becomes:

$$\text{Event rate at time t} = \text{event rate at time t for reference categories for } X_1 \text{ and } X_2 \times \beta_1 X_1 \times \beta_2 X_2.$$

When we fit a Cox model to the WHAS data, using the predictors of patient’s sex, age (years), and presence of complications, we find the following, as shown in Table 5.14.14.

The ‘unadjusted’ hazard ratios represent separate models, one at a time. The multivariable analysis gives hazard ratios which are mutually adjusted for other variables in the model. Thus we see the sex effect reduces when age and complications are taken into account. The magnitude of the complications effect reduces but remains quite strong.

The proportional hazards assumption and time-dependent variables

As noted earlier, the formulation of the aforementioned model assumes a constant hazard ratio. We can formally test this assumption and alter the model to accommodate some variation in the hazard ratio. We can also include time-dependent risk factors. For example if we want to include alcohol intake as a risk factor, we could include alcohol intake measured at baseline (time constant) or at any point in time, when it might change (time-dependent). While the process for doing this is a little complicated, no new concepts emerge in terms of interpreting results.

Variations and extensions to other probability models

Logistic regression has been extended to the situation where one has a categorical outcome with more than two outcomes. This is known as a multinomial (as opposed to a binomial) model and leads to *multinomial regression*. A standard multinomial model will require more than just a single odds ratio parameter associated with each risk factor level, since now there are more outcome levels to deal with. For example, suppose an

outcome variable has three levels (no disease, moderate-level severity disease, severe disease), and we are evaluating a binary risk factor (history of tobacco use, no history). A multinomial model will involve an odds ratio quantifying the increased risk associated with smoking for moderate-level severity disease, and another quantifying the increased risk for severe disease. If the outcome variable is an ordinal variable (such as in the current example), then the multinomial model can be simplified by assuming that the odds ratios associated with moving from no disease to moderate-level severity disease, and from moderate disease to severe disease are the same. This is referred to as *cumulative logit regression* or *ordinal regression*. The assumption of a common odds ratio is called a proportional odds assumption and should be checked for validity as it is quite a strong assumption. It is sometimes considered that a disadvantage of logistic regression is that it results in odds ratios, which are often not appropriate measures of relative risks, particularly in dealing with outcomes which occur commonly. *Log-binomial regression* has been proposed to deal with this situation, since it assumes a binomial distribution of errors (as does logistic regression) but the use of a log rather than logit distribution results in estimated effects which are interpreted as risk ratios. However, fitting these models can sometimes be technically problematic.

Table 5.14.14 Cox regression for mortality after a myocardial infarct by patient age at MI, sex, and presence/absence of congestive heart failure (CHF) complications

Risk factor		Hazard ratios (RR) for death (95% confidence intervals)	
Unadjusted	**Multivariable analysis**		
Sex	Female	Reference	Reference
	Male	1.46 (1.12–1.92)	0.86 (0.65–1.13)
Age	Years	1.07 (1.06–1.08)	1.06 (1.05–1.08)
Complications	No	Reference	Reference
	Yes	3.31 (2.53–4.34)	2.41 (1.82–3.19)

Source: data from Tonne, C., Schwartz, J., Mittleman, M., Melly, S., Suh, H., and Goldberg, R. (2005). Long-term survival after acute myocardial infarction is lower in more deprived neighborhoods. *Circulation*, 111, 3063–70.

As mentioned earlier, Poisson regression assumes that the outcomes of interest are independent. There are many instances when this is not the case. In the SCC example given earlier, individuals will probably have a propensity to develop SCC which is not fully explained by the risk factors we include in a model, leading to a failure of the assumption of independence. In modelling the occurrence of episodes of an infectious disease, this will also be a problem—while we can 'explain' some of the aggregation of episodes within individuals by our predictor variables (nutritional status, environmental exposure, etc.), we are unlikely to explain this completely, as unmeasured and unknown factors will affect the risk of an episode. One of the most common alternatives to use is *negative-binomial regression* which posits a somewhat more complex mechanism for development of an episode, that is that each individual has a particular propensity for the outcome (e.g. a skin cancer), and that given this propensity, an individual's number of episodes will have a Poisson distribution. Once this more complex process is taken into account, the results of a negative-binomial distribution are very similar to those of a Poisson distribution, that is, one obtains RR for episodes of the outcome of interest. Other alternatives are also used, which include *zero-inflated*

regression models. These are based on models such as the Poisson or negative-binomial but particularly assume that there are more values of zero counts (numbers of episodes) than would be predicted by those models. This would be appropriate in the case of a vector-borne disease, for example, where the population may include a large subpopulation who have no exposure to the relevant vector, and a smaller subpopulation who have varying, but non-zero, exposure.

Study designs which have a hierarchical nature often use *random effect regression* models. These may involve different types of probability models, but have the defining feature that they include factors (covariables) which are considered themselves to have distributions. For example, one may design a study to examine the relationship between air pollution and child health. A number of sites are chosen which are close to air pollution monitoring stations, and a sample of schools is selected within a defined radius of the monitoring sites. Children are chosen from each school and their lung function measured. In this case a regression model with lung function as the outcome would be appropriate, and the primary risk factor would be the air pollution level, with perhaps other covariables (socioeconomic status, age, sex, etc.) also used in a multivariable model. However, variation among schools needs also to be taken into account. Given that we had taken a sample of schools, we would regard this effect as random, in the sense that we want to regard the study schools as representative of all schools. This contrasts with the more usual ‘fixed’ effects, such as for smoking status where we have levels of non-smoking or smoking and there is no sense in which we have a sample of levels of smoking. A consequence of a random effects regression model is that we can allow for effects (such as the mean lung function or the regression coefficient linking lung function and air pollution) to vary by school. Our model than examines the variability of these effects and estimates a mean across schools. Thus one has within-school effects and between-school effects.

The multivariable models so far considered have the common property that they either consider individual records to be independent, or, as in the negative-binomial or the random effects model, incorporate non-independence into the probability model itself. Non-independences occur in many study designs. These include repeated measures designs, hierarchical designs, or spatial designs. Regression models applied to such designs

incorporate a non-independence correlation structure which allows the correlations between measures within the same individuals over time, or within the same subpopulation, or the same spatial unit, to be estimated and taken into account. Depending on the software used, a variety of options is available for this structure, such as a constant correlation, an exponentially decaying correlation over time or space, and others. Complex designs are often fitted using the method of *generalized estimating equations* (GEEs), which is an extremely flexible approach to fitting models, and has an added advantage of coping somewhat better with missing data than classical fitting approaches.

Generalized additive regression models (GAMs) have been used particularly to explore non-linearity in effects. A simple regression model assumes, for example, that the relationship between a continuous outcome variable (birthweight) and a predictor (maternal weight) is linear—the increase in birthweight per unit of maternal weight is constant over the range of maternal weight. This is a strong assumption and will often need to be explored. A GAM is constructed in a very similar fashion to a generalized linear model except that one may specify a predictor as a collection of curvilinear functions fitted over various subranges of the predictor variable. The complexity of the non-linearity may be specified. This is a very sensitive and flexible approach to exploring curvilinearity of effects, or in the case of a confounding variable which has non-linear effects, ensuring minimal residual confounding.

Summary

Modern statistics and software offer a wide array of approaches to statistical analyses. The key to appropriate and efficient analysis lies in clarity around the study design and the questions to be answered, thorough preliminary analyses of the data available and selection of the appropriate techniques to be used, and a critical approach to presentation and interpretation of results. Common errors include applying techniques that are not appropriate to variable types or their distributions, ignoring design features (such as repeated or hierarchical sampling), and misinterpretation of computer output. Unfortunately, the availability of statistical software that can perform sophisticated analyses is likely to make these errors more frequent, rather

than the opposite. There is little substitute for consulting a qualified statistician, particularly with complex study designs.

Measuring the health of populations

The Global Burden of Disease study methods

Theo Vos, Christopher J.L. Murray and Alan D. Lopez

Introduction to measuring the health of populations

Over the last two decades, the global health landscape has undergone rapid transformation. People around the world are living longer than ever before, and populations are getting older. Many countries have made remarkable progress in preventing child deaths. As a result, disease burden is increasingly defined by disability as opposed to being dominated by premature mortality. The leading causes of death and disability are shifting from communicable diseases in children to non-communicable diseases in adults. These global trends differ across regions. Notably, in sub-Saharan Africa, communicable, maternal, and newborn diseases and nutritional deficiencies continue to dominate. While low- and middle-income countries are tackling this 'unfinished agenda' of largely poverty-related diseases, increasingly they also need to prepare their health services for a growing burden of non-communicable diseases and injuries, which some have called the 'double burden' or 'triple burden' (Bradshaw et al. 2003; Marshall 2004; Boutayeb 2006). In high-income countries, health budgets are steadily increasing relative to gross domestic product due to ageing of the population, an ever-expanding array of medical technologies, and greater demands of consumers for healthcare services (Lorenzoni et al. 2014; Richardson 2014; Keehan et al. 2015). For governments and other healthcare providers to be able to respond to these challenges, high-quality comparable data on the size and trends in mortality and morbidity are essential. The word 'comparable' is of paramount importance. Commercial and professional interests often lead to implausible claims of the number of deaths or cases affected by a

particular disease. The only way to deal with these exaggerated claims is to make a comprehensive assessment of the health of each population by ensuring that all deaths by cause add up to the total number of deaths and a similar rigour is applied to classifying cases of disease. The successive iterations of the Global Burden of Disease study (GBD—a full list of abbreviations is given in Table 5.15.2) (Murray et al. 1996; Mathers et al. 2008; Murray et al. 2012) are the only global effort to estimate health loss across the age spectrum and for all diseases and injuries. After the initial GBD assessment for 1990, updates until 2008 largely continued to use the same methods, with piecemeal improvements. In 2007, the Bill & Melinda Gates Foundation funded the Global Burden of Diseases, Injuries, and Risk Factors Study 2010 (GBD 2010), which endeavoured to rethink methods and assumptions underlying population health measurement while making use of the vastly improved health data and computational resources. GBD 2013, GBD 2015, and GBD 2016 are updates of the GBD 2010 study. Going forward, every year all estimates are updated to reflect the time period from 1990 to the most recent complete calendar year: GBD 2017 is due for release in October of 2018.

About GBD

The GBD approach is a systematic, scientific effort to quantify the comparative magnitude of health loss due to diseases, injuries, and risk factors by age, sex, and geography for specific points in time (Table 5.15.1). Since GBD 2010, every GBD update has been published in a series of papers in *The Lancet*. The information is made available as a global public good that will be useful for informing the design of health systems and the creation of public health policy. GBD 2016 estimated premature death and disability from 333 diseases and injuries, 2,982 sequelae (direct consequences of disease and injury), and 84 risk factors for 23 age groups and both sexes for the years 1990 through to 2016. The study produced many billion estimates of health outcomes.

Table 5.15.1 Number of diseases and injuries, risk factors, sequelae, age groups, sexes, geographical locations, and years of estimation for successive iterations of the Global Burden of Disease study

	1990	2000–04	2010	2013	2015	2016
Diseases and injuries	107	136	291	306	315	333
Risk factors	10	25	67	79	79	84
Sequelae	483	500+	1,160	2,337	2,619	2,982
Age groups	5	8	20	20	20	23
Sexes	2	2	2	2	2	2
Geographical locations	8	211	215	295	590	774
Years of estimation	1	1	21	24	26	27

The Institute for Health Metrics and Evaluation (IHME) at the University of Washington in Seattle has acted as the coordinating centre for the GBD study since 2007. GBD 2010 was a collaborative effort among 488 researchers from 50 countries and 303 institutions, while GBD 2016 involved the work of 2,518 researchers from 133 countries and three territories. The collaboration strengthens both the data-gathering effort and the quantitative analysis by bringing together some of the foremost minds from a wide range of disciplines. The annual updates ensure that the international community can have access to high-quality estimates in the timeliest fashion. Through sound measurement, it provides the foundational evidence that will lead to improved population health. Abbreviations are shown in Table 5.15.2.

Table 5.15.2 Abbreviations

CODEm	Cause of death ensemble model
DALY	Disability-adjusted life year
DFLE	Disability-free life expectancy
DW	Disability weight
GBD	Global Burden of Disease
HALE	Health-adjusted life expectancy or healthy life expectancy
ICD	International Classification of Diseases and Related Health Problems
IHME	Institute for Health Metrics and Evaluation
5q0	Probability of dying before fifth birthday
45q15	Probability of dying between 15th and 60th birthdays
UNAIDS	Joint United Nations Programme on HIV/AIDS
VA	Verbal autopsy
WHO	World Health Organization
YLD	Years lived with disability
YLL	Years of life lost

Value choices and population health metrics

Several metrics that combine mortality and morbidity are in use. They all have in common that health loss or health gain is measured in units of time. There are two classes of population health measures: health expectancies and health gap measures. Health expectancies extend the concept of life expectancy, a composite measure of age-specific mortality rates in a given year in a population, and adjust years in a life table for loss of health from non-fatal conditions. Demographers calculate life expectancy in a life table by applying the currently prevailing mortality rates in a population to a hypothetical birth cohort. In each row of the life table deaths and survivors of the birth cohort are tracked at successive age groups until a top age category (e.g. 80+ or 100+) in which everyone is assumed to die. In each age

group the average number of years lived is calculated and the sum of years lived over all ages divided by the initial size of the assumed birth cohort is the average life expectancy. A common interpretation of life expectancy is ‘the average number of years a child born today can expect to live’. Of course, this interpretation only holds if the currently prevailing mortality rates at each age would continue to apply for the total life span of the birth cohort. In reality, mortality rates are changing considerably over time. As mortality rates are declining at almost all ages in most countries, the true life expectancy in a population is higher than the figures that are frequently used in health statistics. However, it is a popular and frequently used statistic because it is an easy way to summarize in one number a lot of detailed information on mortality rates by age and because users have an intuitive understanding of how to interpret a life expectancy measure (even if that interpretation is not quite right).

Health expectancies are an adaptation of life expectancy taking into account that not all years of remaining life expectancy are lived in good health. The coarsest version of health expectancy is disability-free life expectancy (DFLE), which classifies disability in a dichotomous way: those above the threshold contribute no time to DFLE and those below contribute a full year to the measure (Murray et al. 2002). Health-adjusted life expectancy (HALE), also sometimes referred to as healthy life expectancy, grades the severity of disability across several categories or the full spectrum and adjusts time lived at each age in a life table by the severity-weighted prevalence of disability. The attraction of health expectancies is that they capture health of a population in a single number and that the concept is relatively easy to explain to policymakers. Its main uses are ranking lists by country or subpopulations within a country, and tracking of change over time for the same population. The downside of health expectancies is that it is not easy to attribute a population’s health to underlying diseases, injuries, or risks.

The disability-adjusted life year (DALY) is a health gap measure that was created to allow measurement of a population’s health with the ability to express the contribution of diseases, injuries, and risks as a proportion of the total burden of disease. It is called a health gap measure as it quantifies loss of health from mortality and morbidity in a population against a stated ideal that ‘everyone should live until a ripe old age, free of disease’. A number of social value choices are incorporated into the DALY, all of which were

reconsidered by a panel of ethicists and philosophers for GBD 2010 (Murray et al. 2012).

The first inevitable choice in constructing a health gap measure concerns the choice of the standard for length of life. In earlier versions of GBD, a standard life table was chosen that mirrored life expectancy of Japanese women in the early 1990s. This was Coale and Demeny's West level 26 female model life table with a life expectancy at birth of 82.5 years (Coale and Demeny 1966). A choice was made to set a slightly lower standard for men, postulating a biological difference in life expectancy between men and women. As there was no male model life table in the Coale and Demeny series that came close to the chosen female life table, the West level 25 female model life table with life expectancy at birth of 80 years was chosen for men. Use of a standard life table essentially is a weighting for age at death: infant deaths are considered equivalent to a loss of the number of years of life expectancy at birth; a death at age 20 is equivalent to the loss of the remaining standard life expectancy at that age. It also follows that even deaths at the oldest age groups still account for some years of life lost. The panel of ethicists and philosophers advised that there was no clear rationale for a difference between males and females and that it would be fitting to update the standard to achievable levels of life expectancy in 2010. A choice was made to create a new standard life table consisting of the lowest observed mortality rates in any age group in any population greater than 5 million. The standard life table used in GBD 2016 has a life expectancy at birth of 86.6 years. The full list of life expectancy at each age from the standard life table can be found in the web appendix to one of the GBD 2016 papers published in *The Lancet* (Naghavi et al. 2017).

A second choice is whether to apply the same standard life table to all populations and over time. From a principle of wishing to compare 'like with like' and for the sake of making meaningful comparisons of changes in health status of populations over time, GBD uses a single model life table to measure years of life lost, regardless of whether the death occurred in a population currently experiencing high or low mortality rates.

A third choice that has to be made in a summary measure like the DALY is how to value health loss from non-fatal conditions relative to the loss of health from deaths. The previous two choices determined how counts of death are translated into a number of years of life lost. To translate non-fatal health loss in a population into a comparable time measure of 'lost healthy

years', a severity weighting for each disease or consequence of disease and injury is needed. The original GBD study in the 1990s derived these 'disability weights' (DWs) from a panel of international health experts who valued 22 tracer conditions with person trade-off methods. Subsequently, they were asked to interpolate all remaining health states by indicating a distribution across seven classes of severity after binning the valuations for the 22 tracer conditions (Murray et al. 1996). DWs ranged from a low of 0.005 for mild anaemia and a high of 0.85 for a number of severe congenital anomalies. Since then, national burden of disease studies (Melse et al. 2000; Begg et al. 2008) have continued to use these DWs but supplemented them with a new set of DWs developed for the Dutch burden of disease study (Stouthard et al. 2000), as well as a number of ad hoc derivations of DWs for new conditions. As this had led to a lack of consistency between DWs, and because there had been criticism of depending on the values of a small panel of health experts, for GBD 2010 population surveys were conducted in Peru, Indonesia, Bangladesh, Tanzania, and the United States, as well as an open-access Internet survey. More than 30,000 respondents took part from 167 countries. For GBD 2013, four more surveys were conducted in Italy, Sweden, Hungary, and the Netherlands using the same survey design, which doubled the available data from the previous surveys. To minimize the cognitive burden, a simplified method of pairwise comparisons was adopted. Each time, a respondent was asked to decide, between random pairs of health states, 'who is the healthier?' The health states were described in short lay descriptions capturing the essential domains of loss of function in fewer than 35 words, as pilot testing indicated this was the maximum of information respondents were able to absorb. Valuations were obtained for a parsimonious set of 235 health states covering all sequelae of diseases and injuries. In addition, respondents to the Internet survey were asked to answer a small number of population health equivalence questions to anchor the values from the pairwise comparison on a 0–1 scale, where 0 represents no health loss and 1 represents health loss equivalent to being dead. All DWs were estimated with an uncertainty interval. The least severe DW, of 0.003, was for mild vision loss, while the worst DW, of 0.770, was given to the acute, psychotic phase of schizophrenia. Further methods and details of all lay descriptions and DWs can be found in Salomon et al. (2015).

Two other choices that had been used in previous GBD studies, discounting, and age-weighting, were rejected by the panel of ethicists and

philosophers. Both these choices had been subject to criticism in the academic literature (Anand and Hanson 1997; Tsuchiya 2001; Arnesen and Kapiriri 2004) but also were difficult to explain to policymakers. With discounting a future stream of lost health, greatest value is given to loss of health in the year of interest while years into the future get valued less and less. Previous GBD studies used an instantaneous discount rate of 3%, which meant that a female infant death with a standard life expectancy of 82.5 years would translate into 30.5 years of life lost. Age-weighting was a further complication incorporated into the DALY of previous GBD studies. The age-weighting function intended to give less value to health loss at young and older ages and greater value to health loss in young adults, arguing that the latter have a social duty to look after the young and the old.

A further general choice is whether to generate estimates of non-fatal health loss from incident or prevalent cases. Previous GBD studies used an incidence approach, arguing that it fits better with the measurement of lost years from deaths and that it would suit policymaking about prevention, as the future stream of health lost in an incident case of disease reflects the potential health gain from prevention (Murray et al. 1996). However, it was difficult to explain to policymakers that the burden of disease in a particular year was not reflecting the health loss from current cases of disease. The most important consideration to adopt a prevalence approach to non-fatal health loss measurement in GBD 2010 was that it would have been computationally nigh impossible to correct for comorbidity with an incidence approach, as it would have to deal with a large combination of lost health streams of different durations. A corollary of choosing a prevalence approach is also that by definition you cannot apply discounting, but that was a decision already made.

This was a long introduction about the metrics used in burden of disease and how key assumptions have changed over time. It is important to point out that any change in these value choices means using a different metric that is no longer comparable to another. For that reason, in each cycle of GBD estimates are explicitly re-estimated for the whole time period from 1990 to the most recent year in order to avoid anyone making comparisons with the previous GBD estimates. A list of key terms is found in Box 5.15.1.

Estimation principles

The GBD cause list is a set of mutually exclusive and collectively exhaustive categories. The 333 causes included in GBD 2016 were chosen based on considerations of their relevance to global health policymaking and/or the size of their expected contribution to mortality and/or morbidity burden. At the beginning of each GBD cycle, decisions are made about new additions to cause and risk factor lists by the GBD Scientific Council consisting of prominent members from the collaboration and senior faculty at IHME.

Box 5.15.1 Key terms

Years of life lost (YLLs): years of life lost due to premature mortality.

Years lived with disability (YLDs): years of life lived with any short-term or long-term health loss.

Disability-adjusted life years (DALYs): the sum of YLLs and YLDs. DALYs are also defined as years of healthy life lost.

Healthy life expectancy, or health-adjusted life expectancy (HALE): the number of years that a person at a given age can expect to live in good health if current rates of mortality and disability would remain constant.

Sequelae: consequences of diseases and injuries.

Health states: groupings of sequelae that reflect key differences in symptoms and functioning.

Disability weight: number on a scale from 0 to 1 that represents the severity of health loss associated with a health state.

Uncertainty interval: a range of values that is likely to include the correct estimate of health loss for a given cause.

All quantities of interest are estimated arguing that an uncertain estimate even when data are sparse or not available is preferable to no estimate. No estimate can be interpreted to mean no burden from that condition.

To convey to users the strength of the evidence for each quantity, uncertainty distributions for each quantity are reported in various metrics of uncertainty such as 95% uncertainty intervals.

An important component of the analytical work on GBD is to ensure that the set of results are internally consistent. The sum of cause-specific mortality must equal all-cause mortality: ‘you only die once’. Deaths are assigned following International Classification of Diseases and Related Health Problems (ICD) rules on underlying cause. The sum of cause-specific estimates of impairments such as blindness and anaemia must equal estimates of all-cause blindness and anaemia. For non-fatal disease

outcomes, incidence, prevalence, remission, and duration must be internally consistent.

Burden of disease estimation should be seen as an iterative process. New data and methodological innovation will lead to revision of estimates. Revisions should re-estimate the entire time series so that results are always available over time using consistent data and methods.

Data synthesis

The emphasis in the GBD is on systematically identifying all published and unpublished data sources. Published literature is a good source for some conditions such as epilepsy. For many others, national data systems such as vital registration, hospital discharges, national surveys, and surveillance data are equally important sources. By starting with the universe of all measurements, we can avoid publication or selection bias where different groups pick and choose between data sources.

Making use of all available data requires careful consideration of non-sampling error due to variation in case definition, diagnostic technology, study design, training of data collectors, recall periods (1 month, 12 months, lifetime), etc. For example, review of diabetes prevalence studies found 18 different case definitions in use, and review of myocardial infarction data showed marked differences in rates using heart-related serum creatine kinase fraction or troponin tests. Across studies or measurements, sampling error is a much smaller contributor to observed variance than these sources of non-sampling error. The GBD approach is to identify and correct for bias.

Key areas in cause of death data concern mapping across variants of the ICD, redistribution of intermediate causes (such as sepsis and heart failure) and ill-defined or ‘garbage’ codes (such as unspecified cancer or senility), and validity of verbal autopsy (VA) diagnoses (attribution of cause of death based on interviews with relatives of a deceased). For epidemiological data, statistical methods are used to quantify the relationship between different types of measurement such as variations in case definitions, diagnostic technologies, or recall periods. Setting a ‘desired’ reference measurement definition allows adjustments of all available data (‘crosswalks’) into comparable units, definitions, or categories. Where possible, uncertainty in these mappings is propagated into the uncertainty interval for the measurement. Some measurements may have to be excluded because they

cannot be made comparable to the rest of the measurements or have fundamental problems of validity. For instance, measures of lifetime prevalence were rejected as invalid measures of disease occurrence due to recall bias. A few exceptions to this rule were made for conditions where exclusion of such estimates would leave little other information for making estimates.

After adjusting the data into comparable units, appropriate statistical methods are used that are designed to handle both sampling and non-sampling error. Covariates are added to the models, and we use statistical methods to borrow strength across time or geography to improve predictions where data are sparse. All estimates in GBD are generated with 1,000 draws reflecting uncertainty from sampling error, non-sampling error, methods of correcting data, and where possible, model specification. Ideally, the validity of the data synthesis approach is determined using out-of-sample predictive validity. This has been fully implemented for mortality and causes of death but not for the synthesis of data on disease sequelae. Computational limitations and sparse data have so far limited the extent to which formal out-of-sample predictive validity can be evaluated for disease sequelae.

The analytical steps of GBD

The GBD approach contains 22 distinct components, as outlined in Figure 5.15.1. The components of GBD are interconnected. For example, when new data are incorporated into the age-specific mortality rates analysis (components 2 and 3), other dependent components must also be updated, such as rescaling deaths for each cause (component 9), healthy life expectancy, or HALE (component 17), years of life lost (YLL) (component 18a), and estimation of YLLs attributable to each risk factor (component 22a). A brief description of these key components follows. More detailed descriptions of each component are included in published articles (Gakidou et al. 2017; Hay et al. 2017; Naghavi et al. 2017; Vos et al. 2017; Wang et al. 2017).

Covariates

Where data are sparse, extensive use is made of a database of covariates. The more than 200 covariates cover socioeconomic factors (e.g. gross

domestic product), demography (e.g. population density, total fertility rate), behaviours (e.g. mean consumption of alcohol, tobacco, and a range of foods), and health system characteristics (vaccination coverage or a composite measure of health systems access). Essential is that values are available for all populations and years of analysis. The information largely comes from international databases, national censuses, surveys, and risk estimates generated by GBD (e.g. the prevalence of obesity or stunting). Where information is missing for a time period or particular population, imputation techniques are used to fill in the gaps.

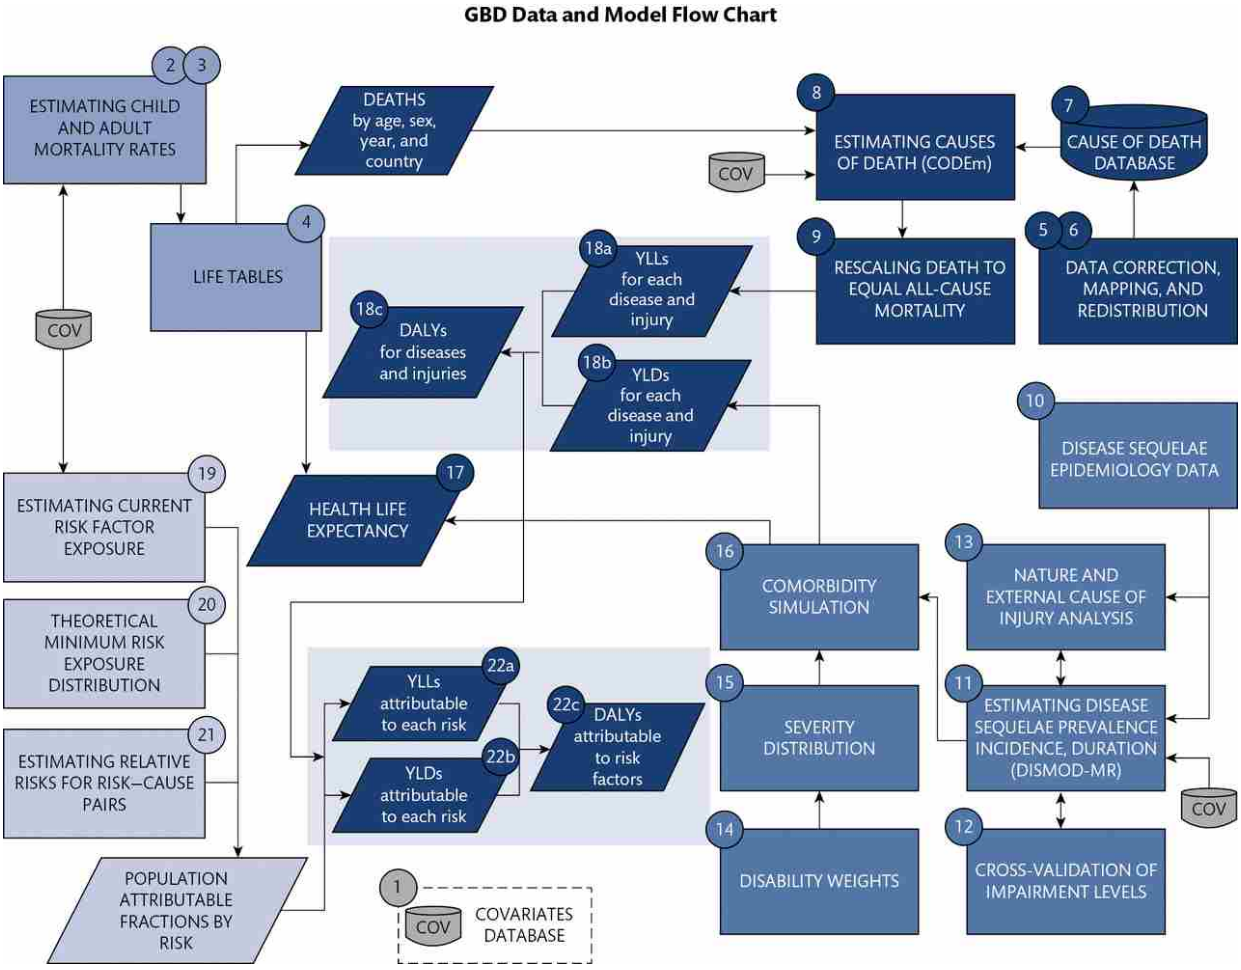

Fig. 5.15.1 The 22 components of the Global Burden of Disease study.

Estimating mortality in children under 5

Sources of under-5 mortality data include vital and sample registration systems as well as surveys and censuses that ask mothers about live births and deaths of their children. All available data are processed to address biases and estimate the probability of death between ages 0 and 5 ($_5q_0$) using Gaussian process regression.

Estimating adult mortality

Sources of adult mortality include vital and sample registration systems as well as surveys and censuses that ask about deaths among siblings. Similar methods to those for childhood deaths are used to estimate the probability of dying between ages 15 and 60 ($_{45}q_{15}$).

Life tables

The estimates of $_5q_0$ and $_{45}q_{15}$ are entered into a model life table system to determine age-specific mortality rates by sex for each country between 1970 and the most recent year of estimation with life expectancy at birth estimates and counts of death by age, sex, country, and year as outputs.

Cause of death data sources

Information on causes of death comes primarily from vital registration systems and VA studies. VA is a means of ascertaining the cause of death in populations with incomplete vital registration systems. With a structured questionnaire, interviewers ask relatives about the signs and symptoms of a recently deceased individual. Validation studies suggest that VA performs reasonably well for many causes of death (Lozano et al. 2011). For selected causes, additional sources such as police records for homicides and road traffic accidents, surveillance systems for maternal mortality, and cancer registries provide further information.

Data correction, mapping, and redistributions

A first task to make cause of death data comparable is the mapping across various revisions and national variants of the ICD. Algorithms have also been developed to deal with the problem of ill-defined coding in vital

registration and VA data where deaths are assigned to unknown causes, intermediate causes, or immediate causes of death rather than the underlying cause of death. For comparisons between countries and over time it is undesirable to have varying numbers of deaths in such 'garbage' code categories. The GBD approach is to reassign such deaths to more specific causes. The allocation of these garbage codes across target causes is done on the basis of published scientific literature, expert judgement, or statistical analysis. In some cases, deaths in garbage codes are reassigned proportionately across all causes. Full details can be found in the web appendix to the GBD paper on causes of death (Naghavi et al. 2017).

Cause of death database

The GBD 2010 cause of death database contains 2,798 site-years of vital registration data from 130 countries and 486 site-years of VA data across 66 countries, of which 10% were nationally representative. For the estimation of mortality from cancer, 2,715 site-years of cancer registry incidence data across 93 countries were included. From registries that also track cancer mortality, mortality-to-incidence ratios were derived. The log of the mortality-to-incidence ratios for each type of cancer was modelled using a statistical model that borrows information over time and between countries with guidance from a covariate on level of development as measured by an indicator combining a country's gross domestic product (GDP), education level, and fertility rate. The ratios were then applied to the incidence figures and the resulting cancer death estimates added to the cause of death database. Multiple demographic and health surveys, other surveys, and censuses provided data on the fraction of deaths in the reproductive age groups that are pregnancy-related. Sibling history data from 1,609 survey years covering 61 countries were identified. Another eight countries had nationally representative maternal mortality surveillance systems.

Estimating causes of death

GBD 2010 used a new statistical approach, named CODEm (Cause of Death Ensemble model), to determine the number of deaths from each cause by age, sex, country, and year. Ensemble modelling was made famous by the recipients of the Netflix Prize, BellKor's Pragmatic Chaos, in 2009, who

engineered the best algorithm to predict how much a person would like a film, taking into account their past movie preferences.

The basis of CODEm is that the analyst takes no firm position on what the best statistical method and choice of predictive covariates are but rather tests a large range of plausible statistical models and determines which single model or combination of models performs best. Four families of statistical models are used: mixed effects linear and spatiotemporal Gaussian process regression models of either the log of the death rate or the logit of the cause fraction. These four families of statistical models are run with multiple combinations of covariates. Based on published studies, plausible relationships between covariates and each cause are identified and tested. All models where the sign on the coefficient for a covariate is in the direction expected based on the literature and the coefficient is statistically significant are retained.

Next, the performance of single models and blends of various models, so-called ensembles, is evaluated using out-of-sample predictive validity tests. This is done by running the models on 70% of the data and comparing predictions for the remaining data withheld from the model-building exercise with the actual observed data. Tests of out-of-sample performance include the root-mean-squared error of the log of the cause-specific death rate, the direction of the trend in the prediction compared to the data, and the validity of the 95% uncertainty interval. The best-performing model or ensemble is selected on the basis of out-of-sample predictive validity.

Typically for each cause of death, several hundred single models are run and ensembles created of five to 20 best-performing individual models, but for some causes almost 100 models contribute to the final ensemble.

CODEm was not used for a number of conditions, including infectious diseases such as HIV/AIDS, measles, whooping cough, congenital syphilis, and malaria in sub-Saharan Africa, which are known to be subject to considerable misclassification bias in cause of death registrations. Instead, natural history models are created based on incidence or prevalence, and case-fatality rates. Estimates of HIV/AIDS deaths are modelled using software programs developed by UNAIDS and adapted for use in GBD. Information on deaths due to conflict, natural disasters, and epidemics from international databases is used to incorporate sudden peaks in mortality from these causes.

Rescaling deaths to equal all-cause mortality

The number of deaths from all causes in a sex, age, country, and year category are scaled to ensure their sum equals the total number of deaths estimated in the GBD demographic analysis of steps 2 to 4.

Systematic review of the epidemiology of disease sequelae

A large effort in GBD is dedicated to the systematic review of published and unpublished data on prevalence, incidence, remission, mortality risk, and duration. In GBD 2016, non-fatal estimates were made for 328 diseases and injuries and their 2,498 sequelae. The systematic reviews are supplemented with analyses of household survey data, antenatal clinic surveillance, reportable disease notifications, disease registries, hospital admissions data, outpatient visit data, medical claims data, population-based cancer registries, active screening data, and other administrative data. As with data on causes of death, a considerable effort goes into documenting and correcting for factors that influence the quality and comparability of all data points, such as different case definitions, diagnostic technologies, and sampling strategies (Vos et al. 2017).

Estimating disease sequelae prevalence by Bayesian meta-regression

For the task of developing estimates for disease prevalence by age, sex, year, and country, a Bayesian meta-regression tool was specifically developed for GBD: DisMod-MR. This tool is designed to process data presented with a wide variety of age intervals; to predict values for countries and regions with sparse data; to correct data from studies with different case definitions, diagnostic technology, or sampling strategies; and to ensure internal consistency between related epidemiological parameters such as incidence, prevalence, excess mortality, and duration. DisMod-MR estimates a log-normal model for all epidemiological data. The model includes the option to select covariates that predict variation in true rates and to correct for study characteristics that are a source of measurement bias. It estimates random effects for seven super-regions, 21 regions, and 195 countries and territories. It uses differential equations governing the relationship between the parameters of incidence, remission, mortality, prevalence, and duration to

enforce consistency. More detail is provided elsewhere on the development and application of DisMod-MR (Vos et al. 2012; Flaxman et al. 2015).

Cross-validation of impairment levels

There are no data sources we can use to set all-cause disability in a population similar to the all-cause mortality rates from demographic data sources that determine the 'envelope' of deaths. However, there are a number of conditions for which there are data collections of the overall prevalence in a population. In GBD we call these impairments. In GBD 2016 this was the case for vision loss, hearing loss, anaemia, infertility, heart failure, intellectual disability, epileptic seizures, pelvic inflammatory disease, and Guillain-Barré syndrome. In these cases, the quality and extent of data on the overall impairment level were considered stronger than the disease-specific estimates of the same impairments.

External cause and nature of injury analysis

Injuries are classified in the cause list according to the external cause such as a road injury, animal bite, or interpersonal violence, whereas the disability from injury is determined by the nature of injury such as brain trauma, hip fracture, or spinal cord lesion. The injury analysis is carried out in six steps. First, household survey, hospital discharge, and emergency department data were analysed using DisMod-MR to generate estimates of incidence for each external cause by age, sex, country, and year. Survey data included recall of injuries that led to hospital admission and other levels of medical attention. The meta-regression includes a covariate for whether an individual was admitted to hospital or not, which is used to generate predictions both for injury warranting hospital admission and injury warranting outpatient care. Second, multinomial regression models were used to analyse hospital data from 28 countries that have dual coding of discharges by external cause and nature of injury after ICD-9 and ICD-10. This produces matrices of external codes and nature of injury categories by age and sex, for high-income and low/middle-income countries and separately for injuries that were treated in emergency departments and those that led to admission. Third, for each nature of injury the prevalence of short-term disability is estimated from incidence and estimates of duration for major causes of injury from a follow-

up study in the Netherlands and supplemented with expert advice from trauma surgeons for the remaining causes. Fourth, the probability of individuals developing long-term disability is estimated in a re-analysis of follow-up data from seven studies in the United States, the Netherlands, and China that documented outcomes of injuries after one year. Fifth, DisMod-MR is used again to estimate the prevalence of individuals in the population who have disability from a previous injury. Prevalence of long-term disability is estimated from incidence assuming zero remission and, for spinal cord lesion, more severe traumatic brain injury, extensive burns, and hip fractures, a relative risk of death compared with the general population-based on follow-up studies of people with such long-term disabilities. For long-term outcomes with a different disability weight for a treated and untreated case, we estimate access to effective treatment on a scale ranging from 20% in the least developed countries to full access in high-income countries. This concerns mainly spinal cord injury and amputations, where access to a functional wheelchair or a prosthesis substantially alters the health loss from those disabling outcomes. In the last step, the years lived with disability (YLD) due to prevalent cases of long-term injury were attributed back to external causes in proportion with the contributions of these causes to every type of injury.

Disability weights

Disability weights used since GBD 2010 have already been discussed in the earlier section on value choices.

Severity distributions

For many diseases, the sequelae of the disease are linked to more than one health state (often classified as mild, moderate, and severe) including stroke, anxiety, major depressive disorder, dementia, and asthma. DWs across these severity levels are measured in population surveys for individuals without comorbidity. Therefore, estimates of the distribution of severity need to be controlled for comorbidity, otherwise the severity distribution would be systematically biased toward more severe symptoms. For example, if individuals with stroke are also likely to have diabetes and kidney disease,

the reported distribution of functional health status would be shifted toward the more severe end.

For some diseases for which data are available for the distribution of severity by age, sex, and region, we pooled proportions in each health state using DisMod-MR or simple meta-analysis methods. Data for severity distributions are often scarcer and of poorer quality than data for prevalence of disorders. Because of the heterogeneity of the available evidence for disease severity, disease-specific reviews had to be supplemented with an analysis of three high-income country data sources which combined a range of diagnostic information and health status data. These sources allowed the assessment of the severity distributions, taking into account comorbidity. With the general lack of comparable data on severity of diseases, it is difficult to account for the differential access over time and by location to treatments that can affect severity. This is clearly an area where new data collection is warranted and in the future may be facilitated by analyses of linked datasets of health encounter data with diagnostic information and health surveys with general health status measures.

Comorbidity simulation

In past GBD studies, YLDs were estimated for each disease and sequela and then simply added, implicitly assuming that disability from different conditions is additive. At the level of an individual this can lead to a person with several severe sequelae having a combined level of DWs exceeding one, that is, being worse than dead. The 2003 Australian Burden of Disease study (Begg et al. 2008) introduced a method to simulate hypothetical populations with a correction for comorbidity using a multiplicative rather than additive function to combine DWs. A similar approach was adopted for GBD 2010 and later iterations.

For each age, sex, country, and year, we use a Monte Carlo simulation of 40,000 individuals to estimate the cooccurrence of sequelae using the prevalence data with uncertainty intervals as probabilities. In simulated individuals with two or more sequelae a combined DW is calculated with a multiplicative function and then parsed back proportionately to each comorbid sequela. The mean reduction across all individuals with a particular sequela is taken as the comorbidity correction.

Tests on real data from the US Medical Expenditure Panel Surveys (Agency for Healthcare Research and Quality 2000) suggest that this multiplicative model is appropriate and accounts for the larger component of comorbidity corrections as long as these are estimated separately for each age and sex category. For several GBD iterations we have had the intention to also take dependent comorbidity (e.g. the common combinations of e.g. diabetes and heart disease or alcohol dependence and anxiety or depression) into account but have been held back by prohibitively long computation times. We are hoping to resolve this by optimizing the simulation code.

Healthy life expectancy

The life tables developed in component 4 for each country and the output of the comorbidity simulations were combined to estimate healthy life expectancy for 195 countries and territories as well as over 500 subnational locations for which GBD 2016 made estimates. Healthy life expectancy is a single summary metric of population health that is not affected by population age structure. It can be thought of as equivalent to the expectation of life at birth in full health given the currently observed age-specific death rates and severity-weighted prevalence of disease and injury sequelae.

Calculation of YLDs, YLLs, and DALYs

YLLs are simply the multiplication of the deaths by cause, age, sex, country, and year with the relevant value from the standard life table for the age at death. YLDs are the product of prevalence of a sequela and the comorbidity-corrected DW for the health state assigned to the sequela. DALYs are the simple addition of YLLs and YLDs. Each quantity in GBD is estimated with uncertainty by generating 1,000 draws. A thousand values of each summary measure are computed by taking the first draw for each quantity, then the second draw and so on until 1,000 estimates are calculated. Thus, the correlation across age and over time for causes of death and prevalence is retained.

Estimating risk factor exposure

In GBD, risk factors are chosen based on their likely importance to disease burden or policy; availability of sufficient data and methods to enable estimation of exposure distributions by country; sufficient evidence for causal effect and to estimate outcome-specific effect sizes; and evidence to support generalizability of effect sizes to populations other than those included in epidemiological studies.

Analogous to the same principles used for work on disease sequelae, a database of published and unpublished sources on the prevalence of exposure was created. For some risks, innovative sources such as satellite imagery for ambient air pollution by particulate matter are used.

Theoretical minimum risk factor level

The tradition in risk factor epidemiology is to assess attributable burden by estimating a counterfactual scenario where exposure to a risk factor in the past is set to a counterfactual distribution. Attributable deaths, YLLs, YLDs, or DALYs are then the difference between observed burden of disease and the counterfactual scenario. Following the framework for comparative risk assessment (Murray and Lopez 1999), counterfactuals are set to the lowest risk level that has been observed or is theoretically possible—the theoretical minimum risk exposure level.

Estimating relative risks for risk factor–disease pairs

For each risk–disease pair, relative risks for specific disease outcomes are taken from published meta-analyses or updated meta-analyses that have been undertaken as part of GBD. Standardized approaches to the attenuation of relative risks with age for cardiovascular disease outcomes are included. Uncertainty in the relative risks for each risk–disease pair by age and sex is propagated into the final estimates. Full details on the risk factor estimation are provided in Gakidou et al. (2017).

Estimating deaths, YLDs, YLLs, and DALYs attributable to risk factors

Risk factor burden is assessed using the distributions of burden for each disease associated with a risk factor. Uncertainty from the prevalence of

exposure, relative risks, and, where appropriate, the theoretical minimum risk exposure level, are all propagated into the final risk factor uncertainty. Final uncertainty reflects both the uncertainty for an age-sex group from the process of disease and injury estimation and the uncertainty in the population attributable fractions. We assume that uncertainty in the population attributable fractions is uncorrelated with uncertainty in disease and injury burden. For the computation of clusters of risk factors (e.g. diet, or environmental and occupational risks), we have assumed that the combined effects of risk factors are multiplicative. Where the impact of one risk is mediated through one or more risks, we derive mediation factors from cohort studies that provide relative risk estimates with and without controlling for these risks that lie in the pathway to a disease outcome. Aggregate estimates of groups of risks take into account the known mediation factors.

Exploring GBD results

The GBD is considered a 'public good'. To guide policymakers, researchers, students, and interested individuals through the large amount of results, IHME has created innovative data visualization tools to explore health trends for different countries and regions. The visualization tools allow people to view GBD estimates through hundreds of different dimensions. To explore the IHME website to use the GBD data visualization tools, visit https://vizhub.healthdata.org.

The *Mortality* and *Causes of Death* visualizations show the results, data inputs, and data transformations of all mortality estimates. *GBD Compare* shows results of deaths, YLLs, YLDs, and DALYs by diseases and risk factors. The main view is a 'tree map', which is basically a square pie chart showing the proportional distribution of the overall burden by underlying causes. Additional views can be selected showing a map of the world, rankings, time plots, or age plots. Each can interactively be explored by country, age, sex, year, cause, or risk factor. Data are available as counts, rates, and proportions of total. Rates can be shown by age for all ages combined and age-standardized to the GBD standard population (Naghavi et al. 2015). The former is most useful to explore the amount of disease burden health systems need to address. The latter helps to understand the underlying epidemiological trends, that is, after taking out population growth and ageing

as drivers of differences in burden estimates. The arrow diagram allows the user to compare ranking lists for countries and world regions between years. Cause patterns is the view of choice to compare country results with any grouping of other countries. It can also be used to explore age patterns. The heatmap is a different method of showing rankings of diseases or risk factors between countries and regions of choice. Top ranking causes are coloured in deep red and successively shaded in lighter hues that change to yellow, green, and blue further down the ranking. This tool quickly shows areas of progress or concern in a particular country in comparison to others. The *Life Expectancy & Probability of Death* tool graphs these two summary measures of mortality and how they have changed over time for each country. Input data sources and detailed results from GBD can be explored and downloaded at the http://ghdx.healthdata.org/gbd-2016/data-input-sources and http://ghdx.healthdata.org/gbd-results-tool sites.

Key GBD results

A comparison of the top 20 causes of DALYs in the world between 1990 and 2016 shows a shift from communicable, maternal, neonatal, and nutritional disorders (dark blue) to non-communicable diseases (blue) and injuries (light blue) (Fig. 5.15.2). Ischaemic heart disease has become the leading cause in 2016, displacing lower respiratory infections and diarrheal diseases which led the rankings in 1990. Among the major infectious diseases, only HIV/AIDS increased in rank and size, but the peak of HIV/AIDS DALYs occurred in 2005, after which the widespread use of antiretrovirals made death and YLL rates drop, though with a consequent rise of YLDs in the survivors. The growing importance of disability contributing to the burden of disease globally is illustrated by the prominent and rising positions of low back pain, migraine, and major depressive disorder, each responsible for large numbers of YLDs but no mortality (Fig. 5.15.2).

The column on the right of Figure 5.15.2 shows the proportion change in DALYs (with a 95% uncertainty interval) between 1990 and 2016. The change is due to a combination of population increase, ageing of the world's populations, and change in the epidemiological trends. Figure 5.15.3 shows the same top-20 ranking of DALYs but based on age-standardized rates. In this figure the column on the right reflects the change in epidemiological rates over time, having removed the demographic drivers of changes in the

numbers of DALYs. Apart from a shift in the ranks of some conditions, the greater difference is in the proportion change column. For instance, the increase in DALYs from ischaemic heart disease of 46.8% was entirely due to demographic changes, while the epidemiological rates actually dropped by 23.4%, as seen in Figure 5.15.3. In contrast, for diabetes, DALY counts, and age-standardized rates increased by 108.3% and 14.9%, respectively. Both measures have their own use. Changes in the volume of disease (as in Fig. 5.16.2) inform policymakers about health service planning. The epidemiological changes tell us something about the impact of prevention and cure on the occurrence of disease.

The shift from communicable diseases largely affecting children to non-communicable disease in adults is further illustrated by the change over time in the ranking order of the main risk factors (Fig. 5.15.4). While child and maternal malnutrition has remained at the top of the ranking list, its size reduced by 55.7%. Dietary risks, high systolic blood pressure, high fasting plasma glucose, and high body mass index increased in rank as well as in size over the 1990 to 2016 estimation period. The small increase in burden from smoking by 5% globally masks an increase in low- and middle-income countries being compensated by a decreasing burden from smoking in high-income countries.

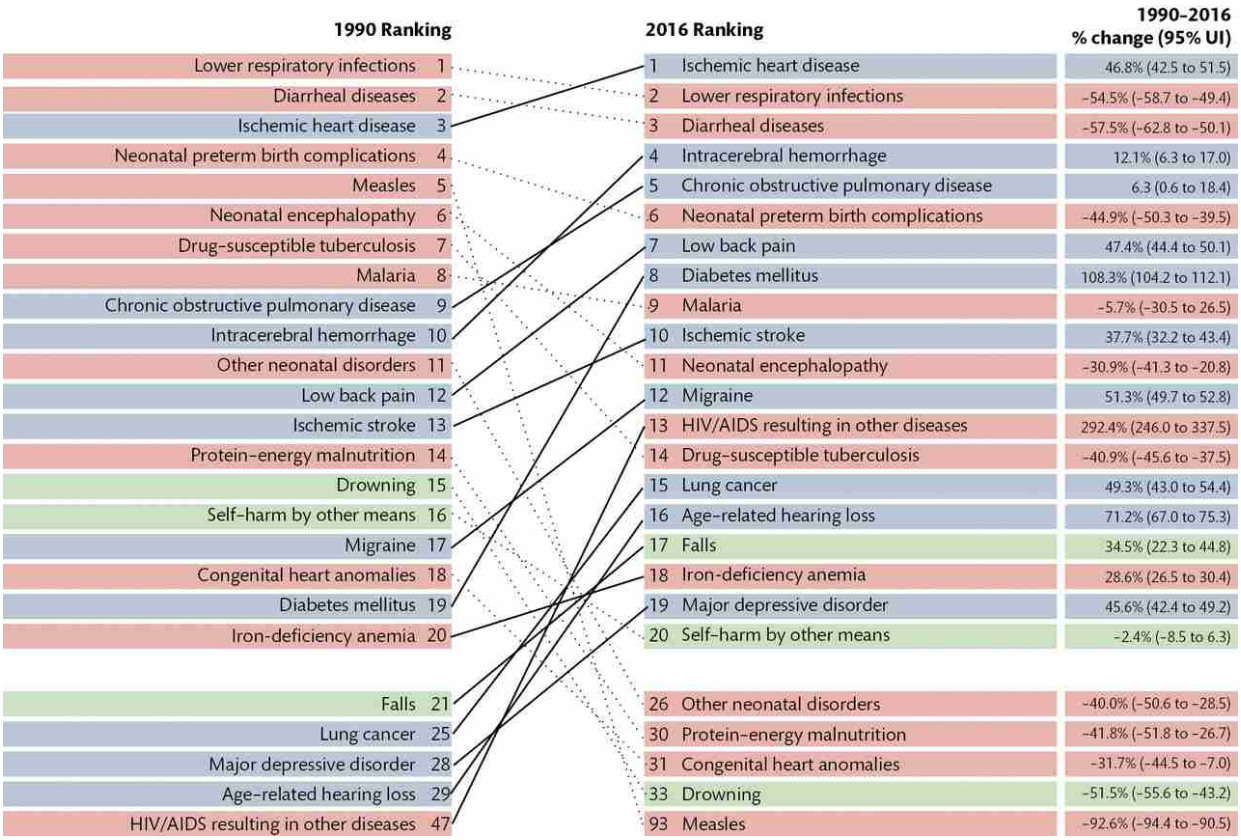

Fig. 5.15.2 Global top-20 ranking of diseases and injuries in DALYs, 1990 and 2016.

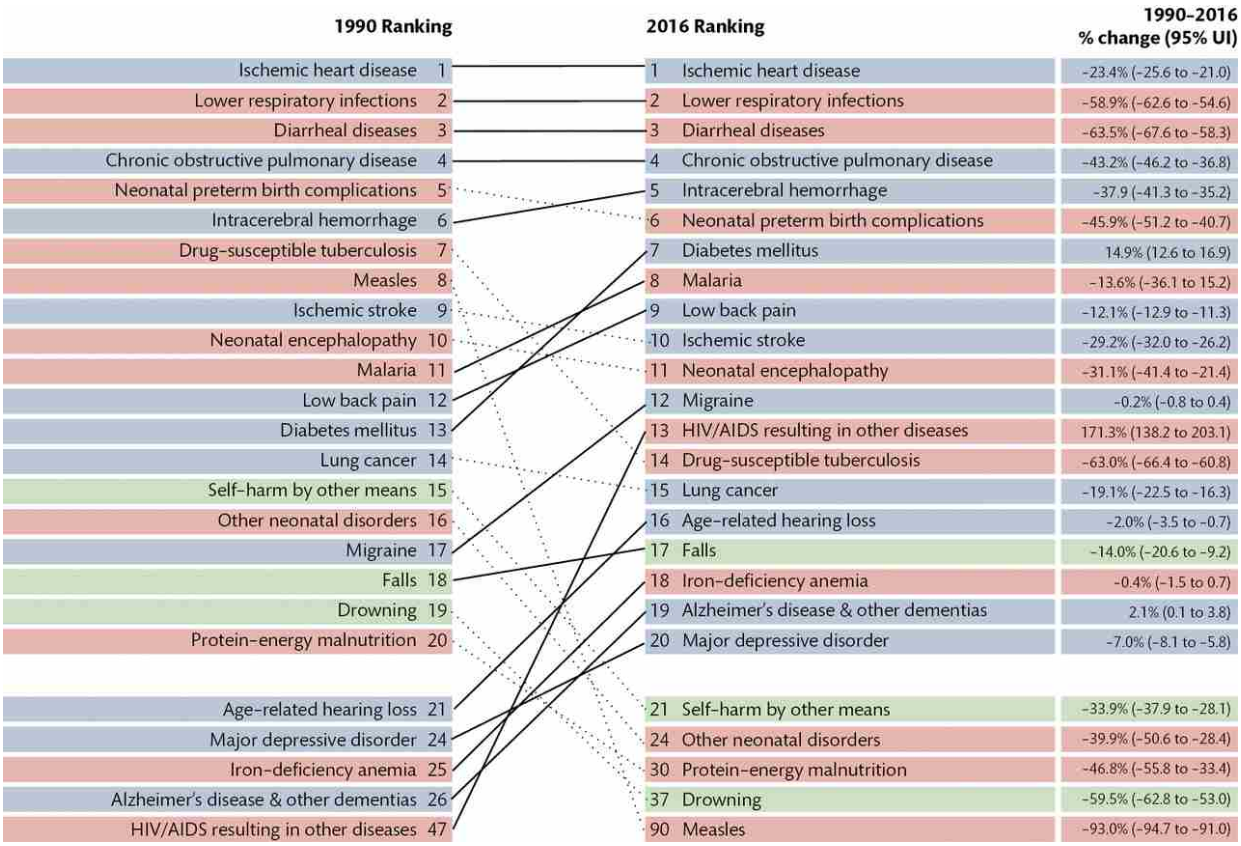

Fig. 5.15.3 Global top-20 ranking of diseases and injuries in age-standardized DALY rates, 1990 and 2016.

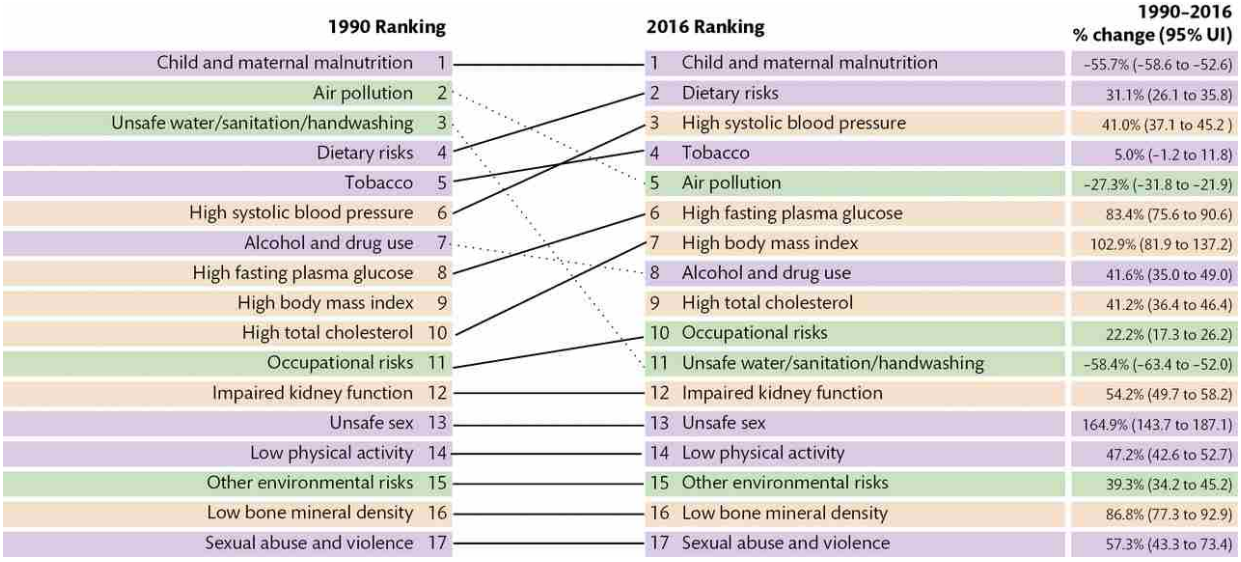

Fig. 5.15.4 Global top-20 ranking of risk factors in DALYs, 1990 and 2016.

The future of GBD

GBD is updated annually. The intention is to continue expanding the network of collaborators and strengthen ties between country researchers, ministries of health, the World Health Organization, and IHME to improve national estimates and to undertake subnational burden of disease studies. Through such partnerships, IHME is helping governments and donors gain insights into localized health trends to inform planning and policymaking. Local epidemiological assessment is crucial for informing local priorities.

The future of GBD is to continue to refine the spatial resolution of estimates, making use of disease mapping techniques developed for malaria ('The Malaria Atlas Project' n.d.). Forecasts of GBD estimates to 2040 will soon become available, first for a baseline scenario, to be followed by analyses of the health impacts of areas of major policy concern, e.g. different levels of global warming, spread of antimicrobial resistance, or the introduction of new vaccines for major infectious diseases.

IHME is also committed to building capacity for GBD analysis in countries around the world, and conducts a variety of training workshops. Information on training can be found at http://www.healthdata.org/gbd/training.

Mathematical models of transmission and control of infectious agents

Alex Welte and Cari van Schalkwyk

Introduction

Indeed, the ‘heavy lifting’ of healthcare is in the care of patients, the development and distribution of vaccines, drugs and devices, and the conception and implementation of sensible systems and policies. However, in recent decades, spectacular increases in the availability of computational capacity have paved the way for mathematical modelling to play an ever-increasing role in many aspects of public health, by supporting formal analyses at various scales of the processes involved.

The core ideas of mathematical modelling are beautiful, powerful, and simple. However, it can seem like a dark art to outsiders, distracted by the details or daunted by the considerable training and experience that appears to be required for attaining confidence, intuition, and proficiency.

By its nature, mathematics is a broad framework, and the natural maturation of mathematical modelling lies in abstraction and generalization. Under this large and growing umbrella there is room for many mathematical ideas, approaches, and techniques. For biomedical research in general, and public health in particular, most mathematical analysis and modelling takes the form of ‘statistical’ modelling of some kind.

In statistics, the key point is usually to understand how details of data are driven by ‘randomness’, and how, despite the randomness, when there is ‘sufficient’ data, we can learn a great deal about the underlying situations and events from which our data are generated. These ‘statistical’ methods of biomedical and public health research are the underlying mathematics that brings us such things as ‘confidence intervals’ for estimates, ‘p-values’ that express the consistency of a hypothesis with data, ‘correlation coefficients’,

and so on. This health-applied statistical field, usually called biostatistics, is a major industry, and some familiarity with its key concepts is a prerequisite for reading about public health research at any depth beyond the most superficial. While we presume that the reader has some basic statistical knowledge, we will not lean heavily on this assumption.

This chapter explores a particular kind of ‘modelling’—and it is not the common (bio)statistical kind. We focus on what we would call ‘dynamical’ modelling (as opposed to ‘statistical’ modelling, see Table 5.16.1.). This essentially entails the reduction, to mathematics, of key facts and principles inherent in the ‘processes’ or ‘mechanisms’ in an epidemiological situation. We can then manipulate these mathematical constructs, in search of insights that, while ultimately implied in the model construction, are not superficially apparent from our primary data and our intuition.

Table 5.16.1 Basic features and uses of ‘statistical’ and ‘dynamical’ models

Statistical Models	Dynamical Models

• Account for random error and bias in data to find correlations that may imply causality
• Support assessment of relationships
• Assume independence of individuals (sometimes independence within clusters)
• Typical questions:
  ◦ Is HIV status positively associated with the risk of TB infection?
  ◦ Are insecticide-treated bed nets (ITNs) or indoor residual spraying (IRS) more effective for controlling malaria?
	• Systems approach—explicitly model (hypothetically ‘declare’) specific mechanisms, to explore their interactions
	• Encapsulate particular relationships between parts of the system
	• Explicitly focus on interdependence of individuals
	• Typical questions:
	  ◦ Based on increased TB risk due to HIV, how should we expect the TB notification rate to vary with HIV prevalence?
	  ◦ How do we expect the age distribution of malaria incidence to change after implementing ITNs or IRS?

Of course, it’s not just surveys and clinical trial measurements that involve randomness. Many processes that are fundamental to epidemiology are ultimately subject to some randomness. Decapitation in an industrial accident is sure to lead to death, but even being infected with Ebola virus does not have an entirely predictable outcome. There are many levels of

randomness that inevitably creep into any description of a complex situation involving biology and society. Typically, given a fully (as far as possible) specified situation and set of rules, outcomes (like infections) vary (in number), by chance, around some ‘average’, ‘mean’, or ‘expected’ value.

Our focus, however, is on capturing and understanding the average/expected behaviour of an infectious epidemic, given some specific assumptions about the rules that govern its behaviour. This allows us to use methods of quantitative investigation that are not fundamentally dominated or complicated by randomness.

Infections such as HIV, tuberculosis (TB), malaria, measles, dengue, zika, cholera, Ebola, etc. persist as major causes of ill health, psychosocial stress, and premature death—not to mention economic strain and impediments to development more broadly. Among the many details which are specific to each infectious agent and outbreak, an important recurring theme, in the analysis of infection moving through a population, is that there is more going on than just a collection of individuals who happen to share a ‘risk profile’ or ‘environment’. There is a fundamental difference between the risk of heart disease, driven by genetic and lifestyle factors, and the risk of tuberculosis, which depends heavily on how many TB infected people one comes into contact with. This dynamical interaction between people who have acquired, and those who are susceptible to, an infection, is the heart and soul of infectious disease epidemiology. Using mathematics to model this process provides a powerful way of elucidating concepts that can help us understand aspects of disease dynamics that would otherwise be difficult to approach intuitively.

Aside from helping us better understand subtle collective effects, there is another fundamental aspect of the unique power of mathematical modelling: direct observation, and the application of formal experimental techniques, can only take us so far in the context of studying people, illness, care, and social systems. Ideally, scientists prefer to watch a system again and again, varying one ‘thing’ at a time (temperature, voltage, force, infectiousness, etc.) to elucidate the impact various factors have on the behaviour and/or state of a system—whether this be a solid material, a liquid solution hosting chemical reactions, or a gas trapped in an airtight container. When we want to understand a very much more complex system, comprised of many components, such as a society grappling with diseases, it’s almost too obvious to bear spelling out that we cannot just perform arbitrary

experiments. Even if it were ethically/morally defensible, it would simply not be possible to learn enough, sufficiently quickly, and at feasible cost, to provide meaningful actionable insights.

For example, we may wonder:

> *Do we need to vaccinate everyone to prevent measles outbreaks, or is some incomplete, approximately quantifiable, level of coverage sufficient to provide 'herd immunity' by restricting the transmission network so that even those who are not vaccinated will be highly unlikely to encounter infectious individuals, i.e. that a single case will not plausibly lead to a wider outbreak?*

This question cuts to the heart of 'collective' effects in infectious spread, and it clearly cannot be answered by

isolating numerous communities with various well-defined interaction/activity networks
subjecting them to different (precisely measured) levels of vaccine coverage
introducing a case of measles into each isolated community
noting how big the outbreaks tend to be as a function of the vaccination coverage and social network structure

One would have to do it all many times, to explore the many permutations of factors. Even worse, because there is inherent randomness in disease transmission in the real world, one would actually need to probe the *average* behaviours of any particular combinations of factors (as well as other statistical/distributional properties, such as, for instance, the worst 5% of outcomes).

What else can we do, then, to explore such questions, which are forever and fundamentally beyond the scope of controlled experiments? This is where models come into their own. Glossing, for now, over pretty much all the *details*, but not, we hope, all the important *concepts* (which we will also revisit more thoroughly), we can summarize a model-based investigation of the measles question as:

building a *model world* in which we declare specific hypothetical rules about measles transmission—based on biological and health systems insights.
(**Model world** construction is best done by a multidisciplinary team.)
capturing the *states* and *rules* of the model world in precise mathematical statements/equations/computer code
(*i.e. building a* ***mathematical model***
, using particular techniques.)
calibrating/fitting the model to *data* from past measles outbreaks with varying levels of vaccine uptake, including, crucially, no vaccine.
(***Calibration***
is a process that engages heavily with biostatistics.)
running *scenarios* from various *initial conditions* defined by factors like which (or simply *how many*) population members are initially infected/infectious; and, critically, the vaccine coverage.
(*This is sometimes known as '*
driving
' the model.)
Exploring trends in the *realizations* of the simulated epidemics by noting how various indicators of epidemic trajectory/severity/duration depend on the simulated policies (*i.e. conduct an actual* ***investigation.***)

A model-based investigation, then, leverages our current insights, beliefs, data sets, perhaps in conjunction with some interesting 'what if' scenarios, and turns these into their downstream implications (sometimes referred to as 'predictions', causing unnecessary confusion). Some inferences are obvious, like '*Increasing vaccine coverage reduces the size of outbreaks*'. Some may be striking discoveries, like '*essentially complete outbreak suppression can be achieved at less than complete vaccine coverage*'.

The fundamentals of modelling

The recurring central problem facing all attempts to describe the natural world, including the world of human endeavours, is this:

> *How do we describe a particular part of the world, about which we have specific questions, without being drawn into attempting to describe so much of it that we drown in details and complexity?*

This is the recurring challenge, whether we are trying to make sense of basic physical concepts like gravity, or trying to understand why some parents decline to have their children given readily available vaccinations. Mathematical modelling is a powerful tool which can help us to make key aspects of this process explicit and clear, and to be disciplined and consistent in our investigations.

Stepping one step further back: our current goal is to help the reader improve their mental model of *the modelling process itself*, without getting too far into philosophical asides. To this end, we will rely heavily on a modelling framework which, as far as we know, is the brainchild of Tony Starfield. We will call it the '*real-world, model-world, model'* paradigm (Starfield et al. 1990). We would also like to tip our hat to the somewhat older heuristics toolbox contained in the classic *How to Solve It* by George Polya (Polya 1945). Polya's ambition was far broader than our current focus on models of infectious agents, but for anyone intending to wrestle with formal problem construction and solution, it is extremely valuable, and hence paraphrased in Box 5.16.1. Starfield acknowledged Polya's groundwork by choosing the title 'How to Model it' for his own excellent and entertaining guide to, in his words: 'modelling in the computer era' (Starfield et al. 1990).

Box 5.16.1 Polya's 'How to Solve It' heuristic

- **Understand the problem.** Restate the problem in your own words (possibly to someone else); Consider whether you have enough information; Draw a picture.
- **Devise a plan.** Solve a simpler problem (the simplest possible, we recommend); eliminate possibilities; guess (and check); look for patterns; Be creative!
- **Carry out the plan that you have chosen.** At first, persist with your plan some through initial setbacks; If it really does not work, make another plan.
- **Review/extend.** Look back at what you have done—what worked and what didn't; Learn from this to help you solve future problems.

Source: data from Polya, G. (1945) *How To Solve It*. Princeton University Press.

Particularly striking in Starfield's exposition (Box 5.16.2), and the main point which we would like to help make more mainstream, is the habit of taking seriously the middle ground between the external *real world* and *mathematical details*, what he calls the '*model world*'. We have found this

device to be extraordinarily useful, not just pedagogically, but also as a modelling insiders' heuristic that tangibly supports the planning and execution of model-based investigations.

Box 5.16.2 Starfield's three realms

Real world: The world we live in: inordinately complex, only partly knowable, not under our direct control.

Model world: Rules and 'degrees of freedom' are arbitrarily declared and fully known. We also have the power to declare the model world to be in any (internally consistent) particular state, without considering how such a state might have been attained.

Model: Mathematical constructs and computer code that capture aspects of a model world—its states and rules. Models are intended to be manipulated and explored (analysed) to help understand the model world, and by extension, aspects of the real world.

Source: data from Starfield, A. M., Smith, K. A. and Bleloch, A. L. (1990) *How to model it: Problem solving for the computer age*. McGraw-Hill.

The model world

Before any mathematical equations or lines of computer code are written, there is usually some considerable, if not always explicit, mental construction of some simplified analogue of reality—a '*model world*'! In a model world which we create, the possibilities are constrained, the fundamental rules are asserted rather than discovered, and we can press rewind, change the starting point (or even the rules), and let time run again, as often as we want. This is essentially what we always do, at least implicitly, when conceiving of any object, system, or principle.

When a bridge is designed, it does not matter exactly how many turns will be applied to each bolt—what matters is the basic structure and sufficiency of all beams and joins—although the final bridge will manifest countless minute details. All gadgets are manufactured to 'tolerances' which, while acknowledging the impossibility of producing an exact incarnation of a blueprint, provide guidance on the scale of acceptable deviation. When we say the word 'house' we have access to substantial shared meaning with all speakers of English, without having to spell out anything else, because we all carry around with us the *concept*; in other words, a *model*, of a house.

The point of this lengthy conceptual preamble is that the first, **and most important**, step in *practical mathematical modelling* does not require any

substantial detailed knowledge of *the formal subject of mathematical modelling*. It is an *inherently* interdisciplinary process, and one to which professional modellers are but one of several crucial contributing groups. The more this idea becomes accepted, the better will be the models that are implemented, and the better will be the interpretation of modelling investigations into real world action—a process lately popularly known as knowledge translation. What we are calling Starfield's 'three-realms' 'model of modelling', then, emphasizes that before we write down equations, or generate computer code to run simulations, we need to spell out, preferably in plain English (or another natural language) and simple diagrams, which hypothetical world(s) we wish to explore. We are free to create as many new model worlds as we like. One of the most important rules of thumb in model world construction is to start as simply as possible. In other words, start by constructing the simplest model world in which anything resembling your actual question can actually be asked, even/especially if this version of your question is so simple that you can answer it.

For example, if we wish to model the spread of seasonal influenza, we may want to explore a model world characterized by the following characteristics:

People infected with flu virus become infectious immediately, and remain infectious for precisely 7 days.
Any pair of individuals, regardless of infection status, have some given probability per day of coming into contact with each other in a manner that would cause transmission if one of them is infected and the other not.
Once people cease to be infectious after 7 days, they cannot be infected again.
No one dies during the timeframes under consideration (3 months of flu season).

This relatively simple to grasp, if obviously simplistic, set of rules specifies a fully-fledged 'model world': a realm in which we know precisely what the rules are—because we declared them!

The model world is further unlike the real world in that we get to choose, arbitrarily, in what state the population is at some point in time—without regard to questions about how we got there. For example, we can 'start' with one individual who is infected with flu, living among 1,000 who are not, and have never been; and we can do this without having to ask, much less

explain, where this one person came from, or how he/she became infected with flu. Then we can ‘let four months pass’ under the rules specified earlier, and we can investigate how the world unfolds. We can ‘dilute’ the transmission process by declaring that some proportion of the individuals begin the flu season with immunity from a vaccine they took before the outbreak, and we can consider different population sizes and numbers of cases specified in the ‘initial conditions’ from which our ‘model scenarios’ start.

To generate analysable scenarios, we usually need to go beyond conversational thought experiments. Of course, if we make a simple enough model world, we can immediately tell what will happen. Consider that aliens have landed in an isolated town of 100 people, and they exercise the arbitrary power to seize one person every day for their amusement and nourishment. It does not require mathematical skill to conclude that in at most 100 days, the town will be devoid of living people; somewhat earlier if our model world allows for other causes of death, or successful escape—but we have the power to rule these out, if we wish.

Alternatively, perhaps the aliens need a day to recharge their stun gun. They aim at one juicy looking human early in the morning, but, alas for the aliens, the stun gun bullets are flaky and half of them misfire. Then we can no longer be sure that one person dies per day—but every day, there is half a chance of someone dying.

Consider yet another possibility: each alien needs to eat one person each day to survive (the food on board having rotted rapidly after exposure to earth’s bacteria after landing). In fact, if the aliens aren’t doing so well themselves in the face of earthling microbes, then we would need to keep track of the number of aliens who are healthy enough to hunt, if we wish to be able to specify the number of human deaths.

The point of this cartoonish example is to show that full specification of model world rules can take many forms, but, if done carefully, often leads to simple mathematical ideas. In the three examples of aliens hunting for humans, we have human deaths occurring, respectively:

at a steady rate of one per day;
randomly, but, on average, once every other day;
at a rate determined by the current number of healthy aliens.

A key determinant of the satisfactoriness of a story, especially in the realm of science fiction, or fantasy, is no doubt whether the model world created by the author seems internally coherent, and whether the particular storyline (scenario) plays itself out in a manner that is consistent with various explicit and implicit rules we have discerned. Even children want to know whether and how it makes sense that Lord Voldemort was apparently killed by his own death spell, in the final climax of Harry Potter and the Deathly Hallows. Fortunately, the internet provides parents with detailed analyses of the nature of wands, and wand 'allegiance' or 'ownership'. Armed with this knowledge, parents can reassure their children that it's not a case of 'it's complicated', or just some arbitrarily slapped together plot holes. The natural ability of people of all ages to discuss, critique, and savour stories is ample testament to the universal capacity of the human mind to build, upload, analyse and critique model worlds by wielding substantial sophistication, insistence on internal consistency, and intuition.

And just as the naturalistic learning and investigations of children are similar to, but not the same as, formal scientific inquiry, so creating and exploring model worlds in words, pictures, and thought, is intimately related to, if not quite the same as, quantitatively generating 'scenarios' through mathematical devices such as algebra and computer simulation.

Historical overview of disease modelling

Perhaps the first application of dynamical mathematical modelling in public health was carried out in 1760 by Daniel Bernoulli to understand the efficacy of inoculating people with smallpox to prevent their developing the disease later. Bernoulli used what we would now call an 'SR model' (of susceptible and removed elements) to elucidate the variations in the size of susceptible and removed subpopulations over time (Bernoulli 1760; Dietz and Heesterbeek 2002; Bacaër 2010). Bernoulli concluded that, while inoculation carried some risk, it could substantially increase life expectancy, not only by trading the risks and benefits for individuals but (crucially) also by reducing overall transmission in the population.

More than one hundred years after Bernoulli's seminal work, Ronald Ross showed that malaria infects people through the bites of mosquitoes (Ross 1895, 1899), and for this discovery he was awarded the Nobel Prize for Physiology or Medicine in 1902. In fact, Ross may have been a better

mathematician than he was an entomologist. He developed one of the first mathematical models of disease transmission based on differential equations, to support his claim, in the face of considerable scepticism, that malaria could be eradicated by reducing the mosquito population to below a critical level, without the need to eradicate the mosquito population entirely.

The notion that there are critical thresholds on dynamical parameters, below which disease transmission cannot persist, is perhaps the central point of mathematical models of the spread of infectious agents. This is most famously embodied in the concept of R_0, the basic reproduction number, defined next.

Another crucial example of such a 'tipping point', which can only be understood through the collective dynamics of a population, is the attainment of 'herd immunity' at partial coverage of an imperfect vaccine. Even if there are still infected and susceptible individuals in a population, if transmission is not efficient enough to replace cases as quickly as they are naturally removed, then prevalence and incidence are doomed to decline—ultimately to zero (see online appendix for more details).

Ross's model, published in the second edition of his book The Prevention of Malaria (Ross 1910, 1923), became the basis for subsequent modelling of vector-borne infections. He concluded, as also crucially cited in Bacaër (2010):

> As a matter of fact all epidemiology, concerned as it is with the variation of disease from time to time or from place to place, must be considered mathematically, however many variables are implicated, if it is to be considered scientifically at all. To say that a disease depends upon certain factors is not to say much, until we can also form an estimate as to how largely each factor influences the whole result. And the mathematical method of treatment is really nothing but the application of careful reasoning to the problems at issue.

In the late 1920s and 1930s, William Kermack and Anderson McKendrick introduced continuous time epidemic models that incorporated stochastic (random) elements of infection and recovery (McKendrick 1926; Kermack and McKendrick 1927; Harvey 1943; Bacaër 2010). They showed how to include age, or time since infection, as continuous variables, and how to generalize models to deal with time-dependent infectiousness and recovery rates. Together with Hamer, Soper, and Ross (Hamer 1906; Ross 1923; Soper 1929), they laid the early foundations for modern mathematical modelling in epidemiology. Crucially, they realized that epidemics are driven by the rate of contact between susceptible and infectious individuals.

Because the simplest models do not distinguish between individuals, all uninfected people are equally likely to be infected and the probability that a susceptible person is infected is simply proportional to the number (or proportion) of people who are already infected. This so-called principle of mass action, first formulated to model the rates of chemical reactions, now found applications in infectious disease epidemiology. It simply captures the idea of two (sub) populations being so perfectly mixed that the 'contact rate' is proportional to each (sub) population size (or proportion) individually.

When considering the control of transmissible diseases, the single most important concept is the basic reproduction number, conventionally written as R_0 and most commonly thought of as the number of secondary cases produced by a single primary case introduced into an otherwise entirely uninfected population. The roots of this concept can be traced through the work of Alfred Lotka, Ronald Ross, and others, but its first modern application in epidemiology was by George Macdonald (Lotka 1923; Ross 1923; Macdonald 1957), in constructing population models of the spread of malaria. The concept was extended and developed by Dietz (Dietz 1980) and by Anderson and May and their various colleagues and coworkers. The collaboration of Anderson and May culminated in their definitive book *Infectious Diseases of Humans: Dynamics and Control* (Anderson and May 1991).

The number of publications applying mathematical models to answer questions regarding infectious diseases has increased dramatically in the last two or three decades, due largely to the unprecedented growth in computational power. Models are increasingly relied upon to inform public health policy and funding decisions, examples of which will be discussed later in this chapter.

Key concepts for modelling infectious disease are outlined in Box 5.16.3.

Box 5.16.3 Basic concepts crucial to the modelling of infectious agents

(See online appendix for a more detailed treatment)

- **Basic reproduction number**: number of new cases directly produced by one case in a purely susceptible population.
- **Disease duration**: length of time individuals spend in an infected state.
- **(Disease) mortality**: rate of death (usually probability per year).
- **Equilibrium**: a scenario in which the state of the model world is unchanged by time.
- **Herd immunity**: collective ability of a population to resist or extinguish an outbreak, despite containing susceptible individuals.
- **Incidence**: rate of occurrence of infections.
- **Prevalence**: proportion of a population affected by a condition at a point in time.
- **Model scenario**: 'model world' history with fully specified initial conditions and rules.
- **Parameter**: a variable which expresses a rule—a model *input*.
- **State variable**: a variable capturing a model *output*.

Types of model worlds, or mathematical models

In this section we give conceptual definitions of, and brief remarks on, some of the most important model-world/model 'types' encountered in disease modelling. The list is far from a systematic review, and avoids overanalysis of grey areas. The categories are cross cutting. For example, compartmental models may be deterministic or stochastic, and they may be discrete or continuous, in any combination.

Static vs. dynamic models: In *static* models, the rules affecting individuals are fixed. For example, the incidence of infection is given a predetermined value, and no interaction between individuals is considered. In *dynamic* models, the rule defining parameters may explicitly be varied over time, and the time-dependent prevalence of an infection may be allowed to play a role in transmission of the infection. Static models, commonly used in cost-effectiveness analyses, can track individual life trajectories involving costs and benefits of health system interactions, within a context that is declared by fiat. Here *static* doesn't mean that nothing happens in the model world. Rather, the term indicates that we are ignoring the emergent impact (feedback) of factors like health system interventions, or prevalence of disease, on the overall context in which individuals will find themselves. In a *dynamical* model world, such feedback is considered. For example, an intervention may change infectious pressure in some non-trivial way as time passes. This can be crucial to sensibly modelling long-term costs and benefits. A *static* model can estimate long-term costs for individuals who received the vaccine or not, but it cannot account for herd

immunity—i.e. the indirect protection individuals obtain by interacting with immune individuals.

Compartmental vs. individual-based models: In a *compartmental* model, population members move between compartments or health states according to rates determined by parameter values that are defined at an aggregate level. Within each compartment, all members are equal in every detail, and indeed utterly lose their individual identity. When noting *how many* population members flow out of a compartment, during a given period, there is no way we can even sensibly ask such questions as *which* population members they are, or how long they have been in the compartment they are leaving. An *individual-based* model (also known as a *microsimulation* model or *agent-based* model) explicitly keeps track of individuals' particular states, and, in principle, their individually tailored tendency to experience events. Infection, relationship formation or dissolution, death, and so on, are simulated as occurring to *particular* individuals. A key feature of this approach is that it allows for extensive, complex, and not-consciously-predetermined heterogeneity between individuals, whereas compartmental models must explicitly enumerate all possible states in which population members may be found. Both of *compartmental* and *individual-based* types of models can be either *dynamic* or *static*.

Deterministic vs. stochastic models: In *stochastic* models, there is intrinsic randomness in the occurrence of events. The key epidemiological processes, such as transmission of infection, are governed by *probabilities*, or *probabilities per unit time* (or time step). These probabilities are of course not just an expression of vagueness. They capture, or, depending on your point of view, emerge from, specific dynamical rules. In *deterministic* models, the future is entirely *determined* by the choice of a combination of 'initial conditions' and 'dynamical rules'. Usually, when we construct a *deterministic* model world, we are actually thinking of capturing some aspects of real world dynamical processes that are at least in part *stochastic*. Then we usually interpret the outputs of a *deterministic* model to be *average numbers of events* (like infection or death), or *average sizes of population groups* (like people requiring long-term HIV treatment) that are *expected* (rather than strictly *determined*) in a model world where the dynamics are ultimately *stochastic*.

Population-level vs. *in vivo* models. Models of biological processes within an individual, from the life cycles of cells and infectious agents to

pharmacokinetic and pharmacodynamic processes, are often referred to as *in vivo* models. In contrast, population-level models focus on a higher level/scale of aggregation. Usually this point is not explicitly noted, as most epidemiological models disregard complex biological details. However, it is useful to be aware that there are interesting questions at both scales, and the fundamental modelling process is very similar, and even leads to similar structures and processes, like healthy and infected subpopulations, cycles of death and reproduction, transmission of infection status through contacts and environmental exposures, etc.

Discrete models vs. continuous models. In discrete models, features, such as time itself, or other quantities expressing the state of the model world, jump in discrete steps. For example, individual level models always have whole numbers of people. In continuous models features vary continuously, being able, in principle, to take any value in some sensible range. We can run a continuous model until 0.4 people are left alive. It is not at all unusual for a single model to simultaneously conceive of some aspects continuously and others discretely—for example, discrete jumps in population states occurring against a continuous timeline and continuously varying risk factors.

Fundamental models

This section aims to capture the essence of dynamical modelling by demonstrating, in considerable detail, including conceptual digressions, some very simple models. We hope to show that modelling is really not something strange or difficult, accessible only to a closed circle of initiates or specialists.

Useful epidemiological models can be complex, and many models appearing in the literature are, we would argue, unnecessarily complex. ‘Occam’s razor’ is the tried and tested philosophical heuristic that encourages us to cut away unnecessary details and assumptions in our search for explanations, and it applies with great consistency in formal modelling. We noted earlier that one should always *start* with the simplest possible model worlds in which we can see any trace of the issues we are exploring—and we would now add that indeed one should also stay as simple as possible at all times. The examples next are particularly stripped down—so much so that one could be forgiven for wondering whether they are to be taken

seriously, or whether they really illustrate real contemporary disease modelling. In fact, they fully illustrate a conceptual framework for approaching population dynamic models, and, in particular, disease transmission models.

We trust readers can recall some advanced high school mathematics. Familiarity with basic calculus will greatly help. Even readers with no prior modelling experience, but a willingness to take the plunge, notepad in hand, should be able to follow most, if not all, of the details of these examples, and should find here a foundation for a deeper reading of the modelling literature.

‘Exponential’ growth or decline

The notion of ‘exponential growth’ (or decline) is one of the most important recurring themes in all dynamical modelling—from the pure sciences like physics and engineering, to highly applied social sciences like population dynamics. Exponential growth has little to do with the popular notion that something has grown ‘exponentially’, which often simply means that something has grown ‘enormously’ (explosively?).

Technically, exponential growth simply means that some quantity is changing (growing or shrinking) at a rate *proportional to how large it currently is*, with both the size and the growth continuously adjusting to maintain this relationship, at least for a while, if not indefinitely.

Exponential growth can lead to surprisingly rapid growth in some cases, but it can also be very slow. A simple savings account that attracts a measly few percent interest per year, in a society where inflation runs in the double digits, will experience face value exponential growth in the monthly balance statements, but leave us with (exponentially) less and less purchasing power over time.

Let’s consider a question of the most fundamental kind in population dynamics:

> **Question 1:** *Given a population of 1 million individuals, with individual mortality (m) of one percent (0.01) per year, how many will (are expected to) be alive after 10 years?*

Following our noses, we now build a model world in which this question can be explored. It involves nothing more than spelling out what the rules are:

There are neither births nor migrations in or out of the population.
Each member of the population faces a predetermined fixed probability, *m*, of death each year.

And just like that, our model world has been created. The assertion that we begin with 1 million individuals is not so much a dynamical rule, as a statement about *initial conditions*. To go beyond the purely conceptual, so that we can calculate something useful using the tools of mathematics, we now consider whether there is some subtlety in how we think about time.

Thinking of time as passing in discrete steps

One view on time passing is to accept that either the model world itself, or the mathematics we are using to describe it, is somehow vague on exactly when people die, and that it is only the number of deaths in each year, or alternatively, the population size at the beginning/end of each year that is well-defined.

Another way of spelling things out in gory detail is to come up with a quite contrived (even if absurdly comical) ‘dynamical process’:

At the beginning of each year, 1% of people are handed death notices, requiring them to report to the Grim Reaper at the end of the year.
Just after the deaths all occur just at the stroke of midnight on New Year’s Eve, a new round of death notices is handed out to the survivors.

We can even ponder the possible arcane details of how the Grim Reaper’s administration works. For example:

Perhaps the death scheduler in chief does some rounding off, to the nearest whole number, when deciding, explicitly, according to a formula, how many death notices to issue each year, based on how many people are currently alive.
Perhaps people are required to roll a one hundred sided die, which has one side with a 0, and 99 sides with a 1. A death is scheduled for every person who rolls a zero.
Perhaps there really aren't well-defined individuals here—just an annually revised declaration of the number of individuals. And perhaps we don't much care whether this is a whole number. Then we can simply schedule $(0.01)N$ deaths, even if N is not a multiple of 100. For example, if there are 250 people at the beginning of a year, we will let 2.5 people die that year, without worrying that this is not possible in the real world. In fact, one could argue that 2.5 deaths are not even possible in our model world. The fractional population members could be said to be a trick to create a simple mathematical approximation to what happens in our model world.

The last of these three, even though it is in some sense the weirdest, departing even from our real world experience of people being counted in whole numbers, is actually the most simple, analytically. Allowing for non-whole numbers of individuals is an important and widely recurring device. It allows the stated individual-level risk or *probability of death* to be directly manifested, within each time step, as the actually realized population proportion which dies. This is the crux of focusing on 'dynamical principles', which are well-defined, rather than 'actual realizations' of a dynamical rule, which are usually subject to some sort element of randomness in the real world. This hints at a recurring theme. We can often buy a lot of analytical efficiency, not to mention simplicity and clarity, with just a little bit of abstraction, just a bit of appropriate slippage between either:

the real world and a model world, or
(and this is a point of view not often spelled out) a model world and a set of equations which purports to capture aspects of the model world.

The abstraction from real to model world has at least two distinguishable aspects:

In order to get off the ground, we need some simplification and spelling out of the basic rules that embody what the investigation is about, such as births, deaths, and infection.
There is additionally often a need to decide on some very mundane details, which may at first appear irrelevant, or extraneous to the main question. Everything that can happen in the model world needs to be spelled out with sufficient specificity for the mathematics to be able to enter the discussion, and possibly, as a bonus, for the analysis not to be overly complicated.

It is well understood among scientists, engineers, etc. that there is much value in drawing semi schematic diagrams (suggestive of key aspects of reality) to help visualize complex biological systems like cells or organs. These pictures are usually called cartoons, which is by no means a disparaging term. It's just another example of the process building a model world to support a conversation where there are in principle many complications that we cannot possibly consider in detail. Similarly, it is absolutely normal for modellers to make up superficially silly sounding explanations for how things are decided, coordinated, implemented, and tracked, in model worlds. We enthusiastically encourage an unrestrained approach to making up model world rules, and visualizations to support thinking about all the required details.

Having made quite a meal of the construction of this most simple model world, we are ready to assign actual mathematical relations to what is happening. We introduce the state variable, which is just the population size (N), and which we need to evaluate at discrete values of time, namely 1, 2, 3, … (years in our example, but it could be any unit of time such as days, weeks, months, even hours, and so forth). Letting N_t denote the population after t years, we can now finally proceed to build equations.

The flipside of the declaration about the *proportion of deaths*, m, per year, is that $(1–m)$ is the *proportion which survives* each year. Hence we have the following expressions for the population at later times, in terms of the population at the start:

$$N_1 = (1-m)N_0$$

$$N_2 = (1-m)N_1 = (1-m)(1-m)N_0,$$

and so forth. These lead us naturally to identifying a general expression governing the population dynamic. Given the population at an arbitrary time *t*, we can write the population 1 year later:

$$N_{t+1} = (1-m)N_t.$$

This kind of relation is called a *difference equation*. It tells us something about a function, intended to be evaluated/interpreted at particular steps—in this case, *N*, should be a whole number, interpreted as time measured in years. More specifically, this particular difference equation tells us how the function is related to itself when it is evaluated at two values separated by one time step. Even more specifically, increasing the 'independent variable' (time) by one (interpreted as the passing of one step of time, i.e. one year) causes the function *N* to change by a given multiplicative factor—which we happen to express as (1–*m*).

Difference equations are a widely applicable way of capturing a range of idealized (model world) dynamical rules, like:

Each year, the staff complement of a rapidly growing company doubles.
Each month, my bank adds to my account 0.5% of the average value I have maintained in my account during that month.
Each month, the amount of money under my mattress increases by exactly the $100 I put there on payday.
After I reach age 65: every month, my retirement fund will be affected by two components of change: a decrease by a fixed pay out to me (my pension) and an increment of 0.5% of the value of the fund the moment before the pension pay out.

Most people are somewhat familiar with 'algebraic equations'. A 'linear' equation can be solved for a unique value of *x* that satisfied $Ax + B = 0$, for some given values of A and B (the answer is $x = -B/A$). A quadratic equation ($AX^2 + Bx + C = 0$) can be solved for potentially two values, and so on. Difference equations are not used to solve for *particular values* of *x* in this sense. The '*solutions*' of difference equations are fully specified

functions N_t, which, in order to be solutions, have to obey the difference equation for at least a specified *range of values* of the step variable—in our case, all positive whole (natural) numbers. It can be very challenging to solve such equations, but in this case (Equation 1), it is not difficult to figure out that the population after *t* years is given, completely generally, by

$$N_t = (1-m)^t N_0.$$

Even without any substantial mathematical analysis, we should expect that, as the number of years grows indefinitely large (tends to infinity), the population in Question 1 becomes indefinitely small (tends to zero). This is reflected in key features of the model formulae:

the population size after *t* steps (years) is the original population size, multiplied by *t* copies (or *t* th power) of the factor (1–*m*), and
(1–*m*) is positive but less than one.

An often wielded algebraic/analytical concept is that powers of any positive number less than one can be made as close to zero as we want, by taking a high enough power.

The very particular property that in each time step the population:

shrinks by a factor

or, put differently:

sheds a number of members in proportion to how large the population was at the beginning of that time step

is known as the *exponential decline* of the population. Of course, we can also turn it around and define exponential growth as increasing by a certain *factor* in each time step.

According to the discrete time analysis, then, the concrete answer to Question 1 is given, to the nearest whole number, by:

$$N_{10} = (1-0.01)^{10} \cdot 10^6 = 0.9910 \cdot 10^6 = 904,384.$$

Figure 5.16.1 shows the decline of a population over successive years. The annual mortality has been increased substantially, relative to our preceding example, in order to show the effect more starkly in a small number of steps.

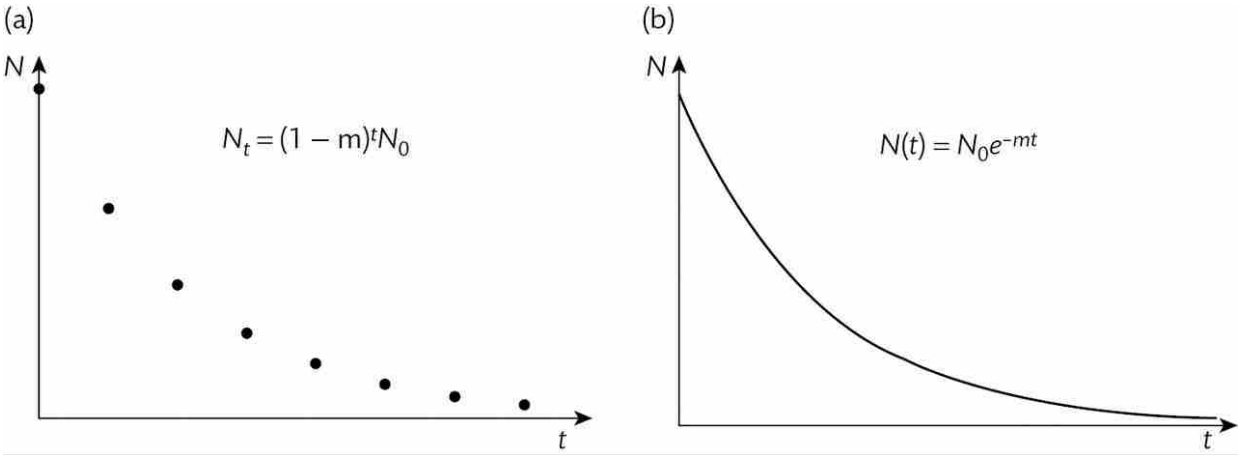

Fig. 5.16.1 Exponential decline (of a model world 'population'), observed (a) in regular time steps, and (b) continuously.

Thinking of time as passing continuously

With time, *t*, now allowed to take any value, not just whole numbers, we want to find a fully specified function of time, *N*(*t*)which expresses, for any (positive) real number *t*, the population size at time *t*. The crucial conceptual leap here is to construct a slightly different kind of model world, still inspired by the same underlying question (the 'Question 1' referred to previously) but a world that fundamentally deals with time continuously. Just as we discovered some details that needed to be spelled out in the discrete time model world, here we are left with choices about the representation of the population itself. Firstly: should the population be allowed to vary continuously, or should the population jump in steps of one, at appropriate times?

As before, we will allow no births or migration to take place in the *continuous time* model world. Before we confront the problem of tracking and updating the population size, we need to adapt the stated mortality dynamic as being a constant *mortality rate m*. In discussing what this means, and how, ultimately, to incorporate the idea into a *mathematical model*, we

will use the language of calculus, but develop the argument intuitively rather than formally.

The recurring elementary task, in specifying the behaviour of a continuous time model world, is to consider what happens to the system when time t advances by a very ('infinitesimally') small increment, usually called *dt* (time intervals which are not necessarily infinitesimal are usually called Δt). The deceptively simple Figure 5.16.2, which does little more than remind us to think about a short time interval, *dt*, is such a useful crutch, that we in all seriousness recommend it be drawn whenever continuous models are being developed.

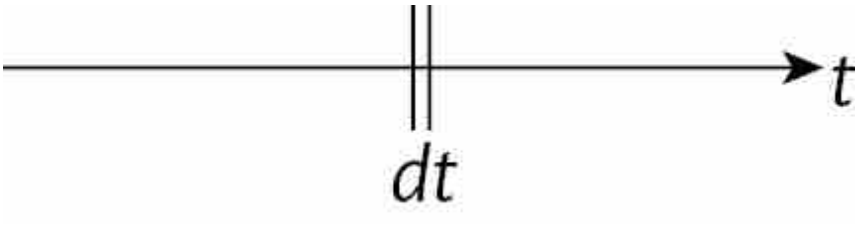

Fig. 5.16.2 The fundamental diagram of dynamical modelling in continuous time. Attention is drawn to what happens during an extremely small ('infinitesimal') interval of time, of duration *dt*. In such a small interval of time, there may be some discernible, and describable, tiny ('infinitesimal') changes in our model world, but they will not, during this interval of infinitesimal duration, feed back into any *changes in how the model world behaves*. This is a fundamental technique of modelling—and thus we are able to derive *differential equations*, whose solution(s), which we obtain by the tools of calculus, will describe how the model world behaves over time.

In the real world, if we were to consider ever smaller time windows, it would become more and more likely that no notable events occur in these time windows. Indeed, the very idea of a time increment, or window, of size *dt*, is of one that is small beyond all measurement and practical meaning. Nevertheless, it turns out to be perfectly sensible to say that the (very small/infinitesimal) probability *dP* of having an event occur, subject to a rate *m*, is just the rate itself, times the (infitesimal) size of the proposed interval, i.e.

$$dP = m^* dt,$$

This could be seen as a fundamental *definition* of a rate, and in the minds of many modellers, it is seen just like that.

While this is a bit abstract at first blush, it has a simplicity, and some analytical advantages, that is not as nicely manifest when accumulating events over real-sized time steps. When we want to know how many people die in a year, all sorts of complications arise. What if different times of year bring intrinsically different hazards? Or what if any of several non-lethal events (like disease acquisition), which can happen in complex ways during the year, then in turn bring with them the risk of complications and death? It can be very difficult to just write down a rule summarizing what all can all happen in a year. In fact—figuring out what can happen in a year is probably the research question, or a crucial non-trivial subquestion. We can hardly expect to get far with a method for solving this problem if that method starts by writing down the solution.

In a sufficiently small time step, however, it becomes much simpler. A key simplifying concept is that there can be no variation in rates during the interval *dt*. This is the nature of infinitesimal intervals—their most important property for modelling purposes. Events may happen within infinitesimal intervals, but these events cannot provide feedback to the rules of the game quickly enough to change the rules during the very interval under consideration.

It is in principle quite possible to construct a model world in which time passes continuously, and individuals die at well-defined points in (values of) time. These points in time can be ‘chosen according to’ (technically, ‘generated by’) a suitably well-defined (but not necessarily constant) *mortality rate*. We will, however, allow the population to be decreased by a continuous ‘flow’ of deaths, which is often much simpler—much like the non-whole number populations sizes we proposed in the discrete time formulation. This is usually done via a rule which forces the model world to track, at all times, the ‘average’ behaviour of a related model world with discrete jumps in population counts. For many investigations, this doesn’t imply any important loss of information or insight, and these models of continuously varying population sizes are indeed a mainstay of scenario models. They allow us to bring to bear, in a very direct and efficient way, powerful ideas and theorems of calculus, which make it possible to uncover detailed and robust analytical insights, and efficiently generate precise and

informative numerical/graphical representations of very complex dynamical processes.

We want to take the step from:

Modelling probabilities of events, to
Modelling a continuous flow that captures the expected accumulation of events.

In a *continuous time continuous-population-size* model world, there is always something happening—populations are flowing into each other smoothly in some way. The way to turn out ideas about probabilities into population flows is as follows:

Retain the idea that every member of some population (potentially itself a subpopulation of some wider group that we are also explicitly tracking) is, by virtue of their presence in the particular population, subject to an *event rate m*.
Hence retain the idea that each population member has an infinitesimal probability, *dP*, of experiencing the relevant event, in a time slice *dt*, with $dP = m * dt$.
Crucially, *declare* that the (infinitesimal) *proportion* of population members which experience the event in the time slice *dt*, is precisely equal to the (infinitesimal) per-individual probability *dP* which we just defined as our dynamical rule in the stochastic view. This is where we build in the rule that what happens at all times is the expected/mean behaviour of a cousin model world where events are truly stochastic and fluctuations are allowed.
Conclude that the number of population members which experience the event in a time slice *dt* is given by $dN = * dP$.

In an infinitesimal time slice *dt*, then, there will be an infinitesimal reduction in the population, due to an infinitesimal number of deaths. All the processes can now be thought of as continuous flows, just as we usually think of the flow of water as proceeding with infinite smoothness, even though we know that in the real world, there are a trillion trillion water molecules tumbling around in a small glass. It’s seldom important to know any details of how those molecules are bumping into each other.

So we have come as far as noting that, between time *t* and time $t + dt$, there will be

$$dP = dPN = mN(t)dt$$

deaths. This is more usually written as:

$$\frac{dN}{dt} = -mN.$$

Which is achieved simply by:

dividing both sides of the equation by *dt*
inserting an explicit minus signs to capture that deaths lead to a *reduction* in the population *N*.

The meaning of *dN/dt*, known as a 'derivative', is, by analogy with the concept of *gradient* or *slope*, an expression for the rate of change of *N*, with the passage of time, *t*. This equation can be solved (technically, 'integrated') by standard methods developed in any calculus course, to yield an expression for the population $N_t$after time *t*:

$$N(t) = N(0)e^{-mt},$$

The symbol *e* denotes the 'base of the natural logarithm', a number (approximately 2.718) which, for analytical convenience, is very much *the* preferred base through which to define powers. Setting

$$m = 0.01, \text{and}$$

$$t = 10,$$

we can calculate the answer to Question 1 given by the continuous model, as follows, rounded to the nearest whole number:

$$N(10) = 10^6 e^{-10 \cdot 0.01} = 904,837.$$

This differs slightly (by about 1 part in 2,000) from the answer given by the discrete model in Equation 2, and the respective solutions will diverge further, as the time passes. This somewhat fine but conceptually interesting point is not an error *per se* in either method, or a sign of some fundamental incompatibility of approaches, and certainly not a reason for concern about the formal manipulations we have performed. In fact, it simply reflects our slightly casual correspondence between the notion of (cumulative) *annual risk of death*, and (instantaneous) *probability per unit time of death* (with time measured in years). This detail is explored a little more in the online appendix to this chapter, along with other fundamental modelling concepts.

The value of m in Equation 3 in the continuous time model is the intrinsic *risk per unit time*. When we change our minds about the unit of time in which we want to work (days versus years, for example) then rates change their values accordingly. A rate defined *per year* does not take the same value as that same rate, defined *per day* (just like a length measured in centimetres does not assume the same value as the same physical length measured in inches). By choosing suitably different units, the value of a rate parameter can take any rate at all—as close to zero as we want, or as large as we want. However, the cumulative probability of an event occurring in a *particular period, T*, like one year for example, is an actual specific number between zero and one. If we now want to work in days, we should also update the question to ask what is the probability of the event occurring in 365 days, and the answer should be the same as the probability in one year. In practice, the cumulative probability of a common epidemiological event of interest actually happening to a particular individual, during an actual year of waiting, is a small number—like a few per cent. In this case, the instantaneously defined probability per year of the event happens to be a very similar number—and so subtle the difference is frequently not apparent.

A theorem of calculus translates *rates* (which are measured in a way that is sensitive to our choice of time units) into well-defined *probabilities* of events occurring in a particular physically meaningful period T (the value of which depends on the choice of units):

$$R(T) = e^{-mT}.$$

Using the corresponding value for $1–R(t)$, the probability of surviving for t years, in place of $(1–m)$ in Equation 1, we can make the *discrete time model*

solution correspond *exactly* to the *continuous time model solution* in Equation 4. All we need to do is slightly adjust the values of *m* to account for the fact that they mean something slightly different in the two cases. Now the only difference between the discrete time *mathematical model* and the continuous time *mathematical model* lies in the fact that we did not intended to evaluate the discrete time model for non-whole-numbered values of *t*—the formulae are in fact identical!

The models we have just constructed also apply to a susceptible population being infected at a constant rate, which might then be called 'force of infection', 'incidence', or 'hazard rate'. Similar problems may be framed in many other contexts, modelled by essentially the same equations: an infected/infectious population disappearing due to a constant rate of recovery, the mass of water remaining in a towel drying on a clothes line, the temperature (relative to room-temperature) of a cooling cup of coffee, the decaying mass of a radioactive substance. Exponential growth and decay are the fundamental recurring theme of population models, as has been pointed out extensively by Lev Ginzburg and Mark Colyvan in their book (Ginzburg and Colyvan 2004).

Know your model world building blocks

It is not necessary here to explore in detail how continuous and discrete time models differ or correspond in more complex cases, but the following remarks may be helpful.

Continuous time models, though they may be daunting to people who are not comfortable with calculus, are in fact usually mathematically much simpler than discrete time models.
The rules which apply over an ‘infinitesimally’ small period of time, *dt*, do not need to be updated over this period of time, because the system itself accrues irrelevantly small (infinitesimal) changes in this interval. This is the key simplification offered by thinking in infinitesimal steps.
Hence, without much technical effort, we can usually solve for the state of the system at the end of an infinitesimal time step, relative to a specified initial state, by simply translating the rules of our model world from words into algebra.
Thus we derive ‘differential equations’.
Then, if we want to know how the system changes over a substantial period of time, we invoke the tools of calculus to ‘solve’ the differential equations.
‘Solutions’ to differential equations are not values of populations at particular times, in the sense that ‘values’ are ‘solutions’ to the more familiar ‘algebraic’ equations. Solutions to differential equations are ‘functions’. This means they are fully specified formal relations between population states and time, which, to be valid solutions to differential equations, provide the values/sizes of population variables at infinitely many points in time, spanning some period over which the rules, captured in the differential equations, apply.
Solutions of differential equations capture internally consistent ‘histories’ of model worlds in particular scenarios.

Discrete time step models may require either extra technical sophistication, or additional assumptions of convenience, in order for the fundamental time-step relations to be written down.

These relations are called ‘difference equations’, and their solutions too are mathematical functions (of time).
For functions to be solutions to difference equations, they are only required to correspond to model world states at certain discrete times.
Sometimes these discrete time steps need to be taken seriously, so that it may not be sensible to simply read off the system state at non-whole-number times.
For instance, it may be possible to build a year-on-year model of an insect population, which accounts for the net result of a brief breeding season with many births and deaths, but does not attempt, nor claim, to describe the intermediate states when many eggs, larvae, and pupae are being formed and eliminated.
Similarly, seasonal models of human disease may not be intended to model the details of brief outbreaks, but merely account for net impact of typical outbreaks in terms of mortality, morbidity, vaccines used, accumulated immunity, and so forth.

Often, indeed usually, neither differential nor difference equations can be neatly solved with explicit formulae. Then it becomes necessary to use computational means to provide numerical approximations, graphical representations, and the like. These numerical methods form a mature and robust field of knowledge in their own right, and can deal routinely with most epidemiologically interesting models, so it is not necessarily a big deal if we cannot analytically solve the central equations in a model-based investigation. Of course, it is always useful to have analytical solutions, if they can be found.

For extensive in-depth investigations, challenges may arise with computational power and run-times required. Exploring many alternative scenarios in an attempt to ‘fit’ models to data, and exploring the sensitivity of outcomes to inputs and assumptions, may involve many millions of complex calculations, and demand quite sophisticated use of data management technology and computer clusters.

To avoid proliferation of analytical threads and details, the remaining examples in this section will be demonstrated with the continuous formulation, chosen for its conceptual clarity and pedagogic value. The development of intuition about the applicability of calculus is a powerful problem solving capacity. Now let’s return to our simple population dynamics.

Question 2. *What will happen to the population of Question 1, with a death rate of 1% per year, if there is immigration of individuals at an average rate of 200 per year?*

We assume a constant per capita mortality rate m (a probability per unit time of death) as before, and now, in addition, add a constant immigration rate b (a number of people coming in per unit time). In other words, in a small time increment *dt*, the change in population is given by:

$$dN = dbt - mNdt.$$

Hence the derivative (rate of change) is given by:

$$\frac{dN}{dt} = b - mN(t).$$

This 'differential equation' can be solved, by relatively elementary methods of calculus, to yield:

$$N(t) = \frac{b}{m} + \left(N(0) - \frac{b}{m}\right)e^{-mt}.$$

Note that the second term of the solution has the previously discussed 'exponential decline' structure. Whatever value is taken for the initial population $N(0)$, this second term fades after a large period of time, so that, as time t tends to infinity, the population size tends to a constant equilibrium value, namely b/m which in our case is 200,000.

The key point is that this is the eventual state of the system *no matter what the (positive) initial value* $N(0)$ *was* (see Fig. 5.16.3). A corollary to this is that, for our particular original population size to be maintained, an average influx of 1,000 individuals per year would be required, since then $N_E = b/m = 1{,}000/0.001 = 1{,}000{,}000$. Indeed, Equation 5 shows directly, without passing through the formalities of obtaining a solution, that the rate of change of the population will be zero when $N = b/m$. We need just ask what it takes to have $dN/dt = 0$, bearing in mind that $dN/dt = b–mN$. This idea of exploring the behaviour of dynamical (difference, or differential) equations in their own right, without directly constructing and manipulating

potentially complicated ‘solutions’, is a normal, and very informative part of the investigation of the properties of model worlds.

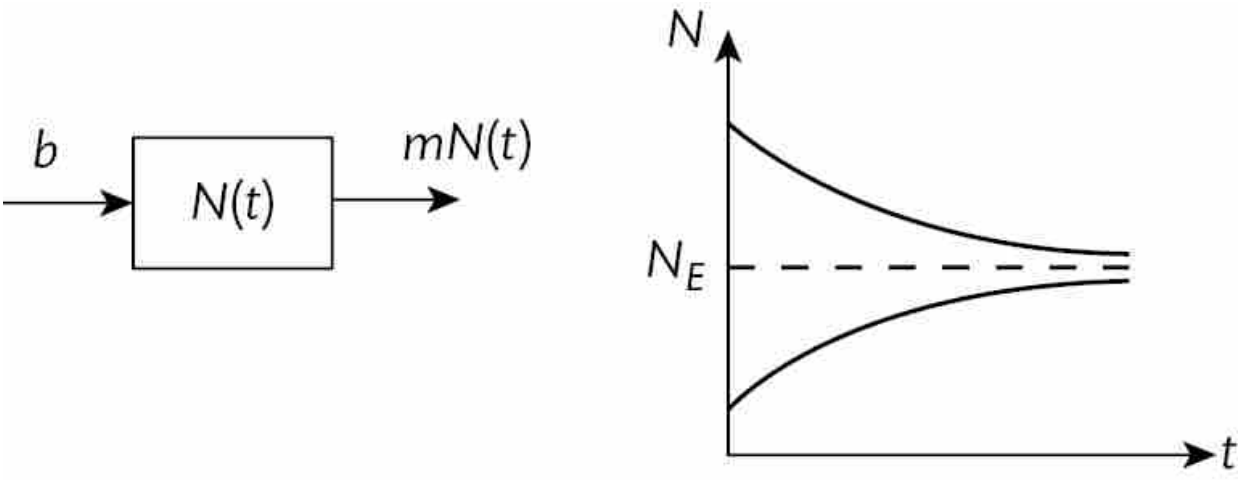

Fig. 5.16.3 Stable equilibrium of a model world population subject to a constant death *rate*, i.e. probability of death per unit time, given by *m*, and being replenished with a steady inflow of *b* new members per unit time. No matter what the initial population, the model world rules eventually drive the population size ever closer to the intrinsic equilibrium value $N_E = b/m$.

The volume of water in a vertical-sided tank can be used as a helpful concrete mental image for this model world. It also makes for a cheap and informative physical demonstration. Consider water in a tank, filled to some level above a small outlet, from which we declare (because we can do that, in our model world) that the *rate of flow* is proportional to the *pressure* at the outlet. Pressure in a simple liquid is just proportional to depth, and the height of the water level above the outlet is proportional to the volume$V(t)$ of water which stands above the outlet (see Fig. 5.16.4).

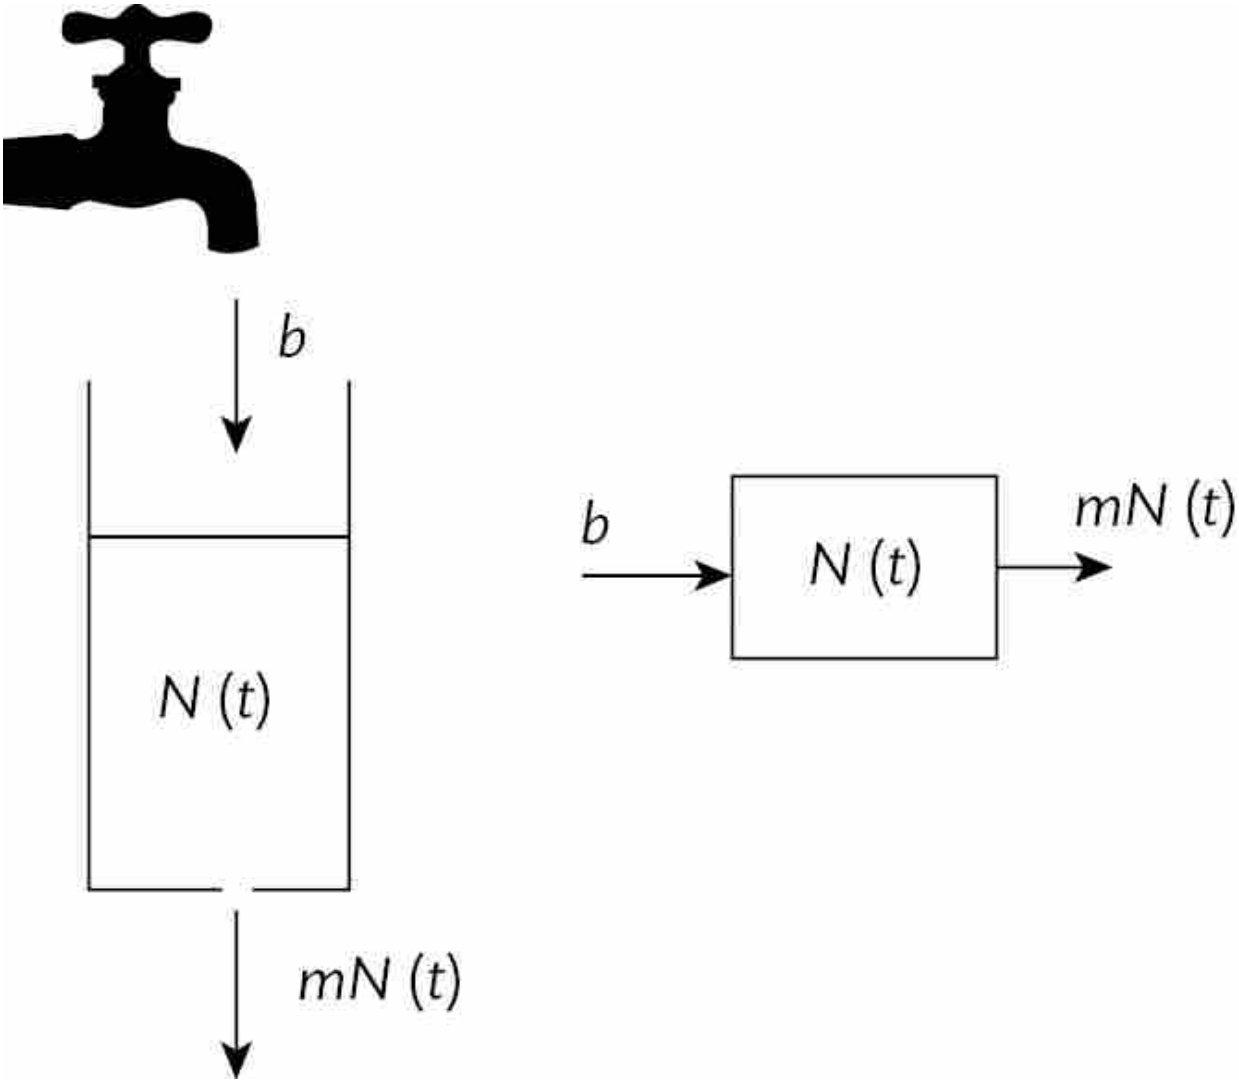

Fig. 5.16.4 Cartoon *Punctured water-tank* and schematic *flow diagram* representation of model world population $N(t)$ with constant inflow b and ('linearly') variable outflow $mN(t)$.

If the tap feeding into the tank is shut off, water will just run out of the tank through the hole on the side, at a rate that is always proportional to the height of the (ever declining) water level above the hole. In other words, the level will *exponentially decay* down to the level of the hole. If the tap produces a steady stream of water, the level in the tank will approach an equilibrium value at which the outflow (which depends on the water level) matches the inflow (which is fixed). In principle, the tank may overflow if the hypothetical equilibrium water level is higher than the top of the tank, but if we want to, we can make our model world tank automatically be big enough.

This inflow–outflow process can be applied to the population of red blood cells in a human body. Bone marrow normally produces a roughly steady supply of about $2 * 10^6$ cells per second, or $1{,}728 * 10^8$ per day, while a nearly constant *proportion* of cells die daily. If we assume the body maintains an equilibrium population of about $2 * 10^{13}$ (20 trillion!) red blood cells at any moment, that mortality rate can easily be calculated from our model. (It's really worth trying it out—the 'real world' answer can be looked up readily enough online)

Question 3. *What will happen to the population of Question 1, with a per capita death rate of 0.01 per year, if there is no immigration, but a constant per capita birth rate of 0.04?*

Once more, we assume a constant per capita mortality rate (probability per unit time of death) *m*. The new part is in the interpretation of fertility. Most naively, we would say that the probability of any population member giving birth to an offspring in any infinitesimal time, *dt*, is given by:

$$dP_b = bdt.$$

This is pretty much all we can mean by constant fertility rate, and it is a rather crude model of fertility. Clearly our model world does not know about the different roles of men and women in reproduction, and there is also no concept of pregnancy or fertility variations within and between individuals. Nevertheless, the fertility rate b can be chosen to produce some reasonable dynamics. Certainly, a nuanced discussion of fertility, and other demographic processes like changing age structure of a country over time, cannot be supported by models lacking explicit age structure, but these kinds of complications are mainly about proliferation of detail, not mainly about new concepts. The conceptually important step is to translate the probability of birth, per population member, into the actually realized (infinitesimal) number of births (*dB*) in the generic infinitesimal time slice *dt*:

$$dB = bNdt.$$

Considering also the mortality, the net change in population, during *dt*, is given by:

$$dN = bNdt - mNdt,$$

hence the derivative (rate of change) is given by:

$$\frac{dN}{dt} = (b-m)N.$$

This can be solved to give:

$$N(t) = N(0)e^{(b-m)t}.$$

In Question 3 we proposed values of m = 0.01, b = 0.04. The model world manifests an exponential population *increase* when $m < b$, a *constant* population when $m = b$, and exponential *decline* when $m > b$ (see Fig. 5.16.5). Exponential growth or decline is also called 'geometric' increase or decline (but less frequently, these days). When there is exponential growth, it is easy to show that there is a fixed 'population doubling time', and in the case of exponential decline there is a fixed population 'halving-time', sometimes called the 'half-life'.

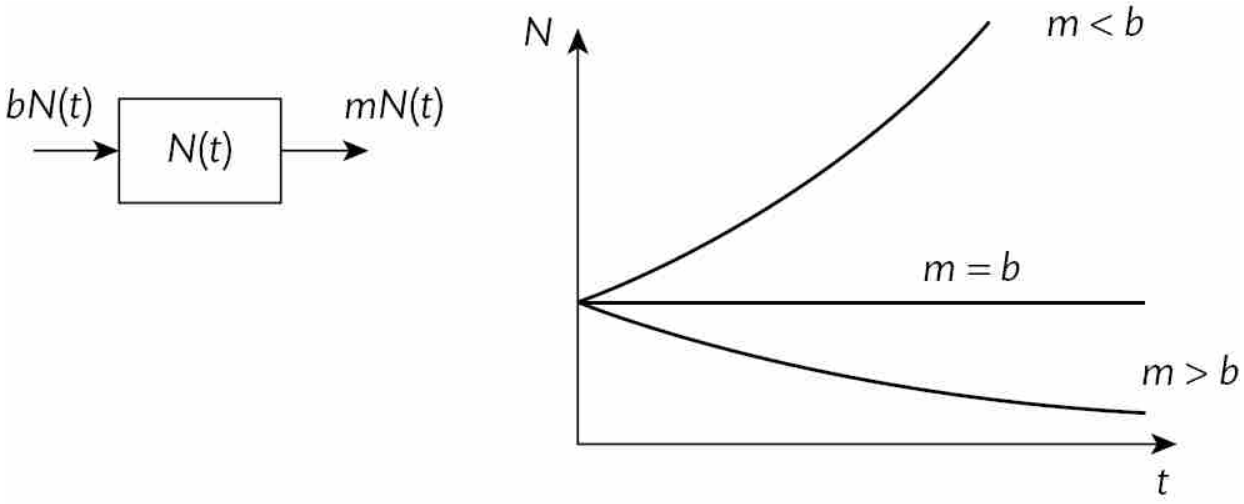

Fig. 5.16.5 Exponential growth (m < b), decline (m > b), and equilibrium/maintenance (m = b) arising from competing replenishment and attrition, both of which proceed in direct ('linear') proportion to the instantaneous population size.

That populations, even under much less simplistic assumptions, tend to increase ‘geometrically’ was first observed and studied by the great mathematician Euler in the mid-eighteenth century (Euler 1748), before being more famously explored by Thomas Malthus (Malthus 1798). Although exact exponential relations such as those presented here arise only under the idealized conditions in model worlds, their conceptual importance and wide applicability can hardly be overstated. With a technically small but far-reaching mathematical twist, exponential functions also form the basis of much modelling in pure science and engineering, including the study of oscillations and waves.

Susceptible–infectious compartmental models

The introduction of multiple health or disease states into our model worlds is naturally crucial to modelling disease transmission and progression. We will also need to expand our options for thinking about rates. Thus far, the populations in our example models have been allowed to:

grow by fixed in- or out-flows (immigration or cell generation), or
experience growth or decline processes scaled in proportion to the instantaneous population size (our fertility and mortality models).

Next, we consider the most basic model of *actual disease transmission*, previously noted as utilizing *the principle of mass action*. Thus, the number of new infections occurring in a time window of duration *dt* is proportional to the number of infection-susceptible individuals, and, importantly, also proportional to the number of infectious individuals. To be proportional to two things at the same time requires being proportional to the product of the two.

This means we need to choose a value for the constant of proportionality, relating the product of infectious and susceptible individuals to the rate of occurrence of new infections. This parameter can be understood to capture both:

the *probability per unit time* of any one member of one group coming into contact with any one member of the other, and
the *ordinary probability* (not *per unit time*) of such a contact leading to transmission of infection.

If the rate of interaction is twice, in model world A, what it is in model world B, but the probability of successful transmission, given an interaction, is half, in world A, what it is in world B, then emergent value for the final model transmission rate is the same in the model equations for A and the model equations for B.

So we have another interesting and useful aspect of introducing figurative daylight between the 'model world' discussion and 'mathematical model' analysis: we can be explicit about details in model worlds which do not directly manifest in the model equations, and we can see how some views of models (and data) cannot distinguish one dynamical rule (model world) from another. This has important consequences for interpretation of, and inferences intended to be based on, models. If we only think about equations, we will necessarily leave aspects of model worlds undetermined. This is not a problem *per se*, but it is good to be able to keep track of one's mental images, assumptions, etc. and to know which rules and principles are manifesting; where, when and how, in our *model worlds* and *mathematical equations*.

Question 4. *How can we describe the prevalence of gonorrhoea in a closed sexually active population?*

Let $S(t)$ and **I(t)** denote the numbers of susceptible and infectious people at time t. We can build a model world based on the following rules:

Individuals mix randomly, any pair of them coming together with the same probability (per unit time) as any other pair.
People become infectious as soon as they are infected.
They recover at a constant per capita rate r per day, at which point they immediately become susceptible again.

In a small period of time, dt, the increments in numbers of susceptible and infectious individuals are:

$$dS = -KI(t)S(t)dt + rI(t)dt$$

$$dI = KI(t)S(t)dt + rI(t)dt,$$

where K is the mass action proportionality constant. Seen from the point of view of an individual, this indicates that the probability of infection, in a small time slice dt around the time t, is given by (see also Fig. 5.16.6).

$$dP = KI(t)dt$$

Which can also be stated as the 'incidence' of infections, among susceptible individuals. This is an important measure of the intrinsic risk associated with an infectious disease epidemic.

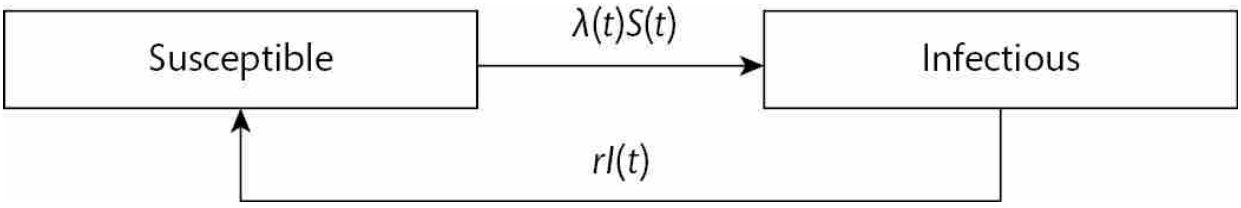

Fig. 5.16.6 Flow diagram of a basic transmission and recovery model. Individuals move from the *susceptible* class to the *infected* (and *infectious*) class with an incidence λ(t) that is explicitly allowed to vary dynamically, in order to capture potentially complex rules for contacts with individuals in the *infectious* class. Infected individuals move back to the susceptible state by recovering with a (constant) probability per unit time r. Equation 6 captures the dynamics for a simple gonorrhoea model by modelling contact according to the principle of mass action (i.e. perfectly random mixing).

Another important measure of infectious risk is what is usually called the basic reproductive number, usually denoted R_0. This is essentially to be understood as the number of new cases that would be produced *by a single infectious person* who is introduced into a large population of people susceptible to infection. The key point is that we are only counting persons *infected by* this artificially introduced infectious individual (sometimes called the *index case*), and not those infected, in turn, by others who acquire the infection over the course of the epidemic. Calculating R_0 for complex model worlds can be a painful exercise in rearranging the model equations, but the important points to understand are:

If the index case is not expected to infect at least one additional individual before either recovering or dying, or somehow ceasing to be infectious, then there is no prospect of sustained spread for the infection.
If the index case is expected to infect numerous individuals, then there will be, in a deterministic model world, at least a period over which the number of infectious cases increases.

Depending on the rules for transmission, there will be some dynamical feedback as the infection spreads, reducing the number of still-susceptible cases. Unless there is a mechanism to replenish the susceptible population, this group will eventually decline to the point that the infected individuals, even if there are many of them, simply don't have enough potential contacts with susceptible individuals to sustain spread. In this case the epidemic 'burns out' without infecting everyone.

Epidemic model equations can be subjected to some considerable instructive detailed analysis beyond our immediate scope. Hethcote and Yorke (Hethcote and Yorke 1984) noted that their model has prevalence declining to zero for plausible estimates of the average partner change rate, the transmission probability per partnership, and the duration of infection.

Indeed, as just noted, model worlds involving infections for which survival or cure confers immunity, or for which infection is incurable, generically manifest epidemics that die out (potentially after rising to a peak) unless there is a sufficient source of new susceptible individuals. In our gonorrhoea model world, the cured individuals recover to be susceptible again, so, in principle, an endemic equilibrium might have been produced, though at apparently infeasible values for certain rates. As it was, the model led to a conundrum in the context of data on gonorrhoea as it could not reasonably explain the low, stable equilibrium prevalence in the United States in the 1980s.

Question 5. *In what kind of model world can we maintain an observed low endemic prevalence of gonorrhoea in a closed sexually active population?*

Hethcote and Yorke (1984) went on to build a further model (Fig. 5.16.7) in which they divided the sexually active population into two groups: low activity (the majority) and high activity—2% of the population with higher partner change rate. They showed that with plausible estimates of the

relevant parameters they could convincingly model the low gonorrhoea prevalence shown by the data.

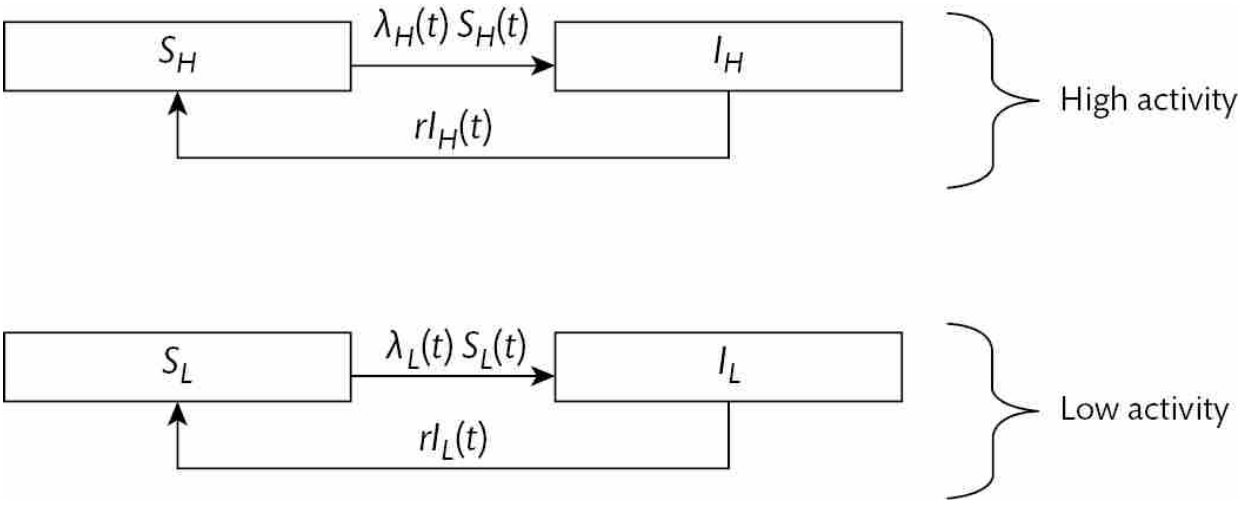

Fig. 5.16.7 Flow diagram of a transmission model with simple contact heterogeneity. The population is divided into a high- and low-activity (contact rate) class. Within each, individuals move from the susceptible class to the infected class with the applicable activity-level-specific incidence λH(t) or λL(t). They move in the opposite direction through a common (and constant) recovery rate *r*.

It is very common that simple first models of systems sensibly capture initial insights and data, but fail to reproduce crucial features which are known to arise in the real system. It is also very typical that one seeks to address this by identifying some important further refinement of population classes. This will require thinking about estimates of subpopulation sizes, and details of contact and mixing rules. The work of Cooke, Hethcote, Nold and Yorke (Cooke and Yorke 1973; Yorke et al. 1978; Hethcote et al. 1982; Hethcote and Yorke 1984) highlighted the importance of incorporating in modelling both risk-heterogeneity, and also of accounting for the class of asymptomatic individuals. The implications of their work helped to inform US control policy for sexually transmitted infections in the 1980s.

Our somewhat dry technical examples have only considered:

Single populations experiencing in- and out-flows.
Simple structured populations with susceptible and infected classes, and high or low contact tendencies.

Other key population structures which may be important to consider are:

Sex/Gender
Age
Location
Relationship status
Finely resolved disease states such as exposed but clinically healthy and uninfectious, or
Detailed viral and immunological markers
Treatment access and utilization

Putting to one side the list of potential complications, we want to return to our opening remarks for this section. Model building and interpretation, while deserving care and attention, and benefiting from technical skill and experience, should not be seen as obscure activities left to the obscure practices of a secret society.

Example applications

Modelling can help us to understand the natural history of the infections or diseases that we are studying. Before we start to build models to explain these different time trends, it is essential to learn more about the biology of the disease and think of other data that is crucial in understanding the unfolding of disease incidence, such as treatment and vaccine availability and coverage.

Historically important infectious diseases

Figure 5.16.8 shows the number of reported cases for each of four diseases in England and Wales between 1930 and 2000 (Public Health England n.d.). Before we can begin to make models to explain these different trends, we need a better understanding of the biology and control of the individual diseases.

Diphtheria is a bacterial upper respiratory tract infection spread through contact with saliva. A vaccine has been available since the 1920s, yet the number of cases in the United Kingdom remained very high at around 60,000 per year between 1930 and 1940. Only when mass childhood

immunization was introduced in 1940 did the number of cases consistently drop to effective elimination in 1950.

Measles is highly contagious and almost everyone who come into contact with aerosols from infected people will get the disease. Survival of an infection ensures lifelong immunity and so does vaccination, which has been available since the late 1960s. In Figure 5.16.8 it is clear that England and Wales, almost without fail, experienced a measles outbreak every second year prior to vaccination. Why would this be? Since measles is an immunizing disease, a large outbreak can only occur once the pool of susceptible people has been sufficiently replenished. This implies that the birth rate in England and Wales was such that measles outbreaks occurred every second year. We can use a mathematical model to show that the interepidemic period would be longer for lower birth rates and vice versa.

Pertussis, or whooping cough, is a highly contagious bacterial upper respiratory tract infection and those infected may cough for up to three months. Outcomes of treatment with antibiotics are poor. Before the introduction of a vaccine in the 1950s, incidence of whooping cough was very high at around 100,000 cases per year. Numbers of cases fell dramatically until unfounded beliefs that the vaccine causes brain damage led to reductions in coverage to a low of 30% in 1978. Major epidemics followed soon after and coverage gradually increased and has remained at around 90% since the 1990s. The whooping cough vaccine is ideally given in three doses to infants and one booster dose in young children due to waning immunity.

Polio is in a race with Guinea worm disease to be the second human disease, after smallpox, to be eradicated from the world. According to the World Health Organization (WHO), only 33 cases of polio are estimated to have occurred worldwide in 2018. This viral disease is highly contagious and spreads through the oral-faecal route. The rapid rise in reported cases in the United Kingdom in 1947 remains unexplained to this day. One theory suggests that improvements in water and sanitation lead to an increase in the age of infection and adolescents are much more likely to develop severe symptoms than infants. However, age distribution of cases did not change from before to after the large outbreak. The second theory suggests that a strain of the polio virus previously not endemic to the United Kingdom caused the large outbreak, but no data are available on the circulating strains prior to the outbreak to confirm this theory (Agerholm 1953). Mass

vaccination with an inactivated vaccine from 1956 and then a live, oral vaccine from 1962 lead to rapid decline in notified polio cases and the last case of wild virus polio infection in the United Kingdom occurred in 1984.

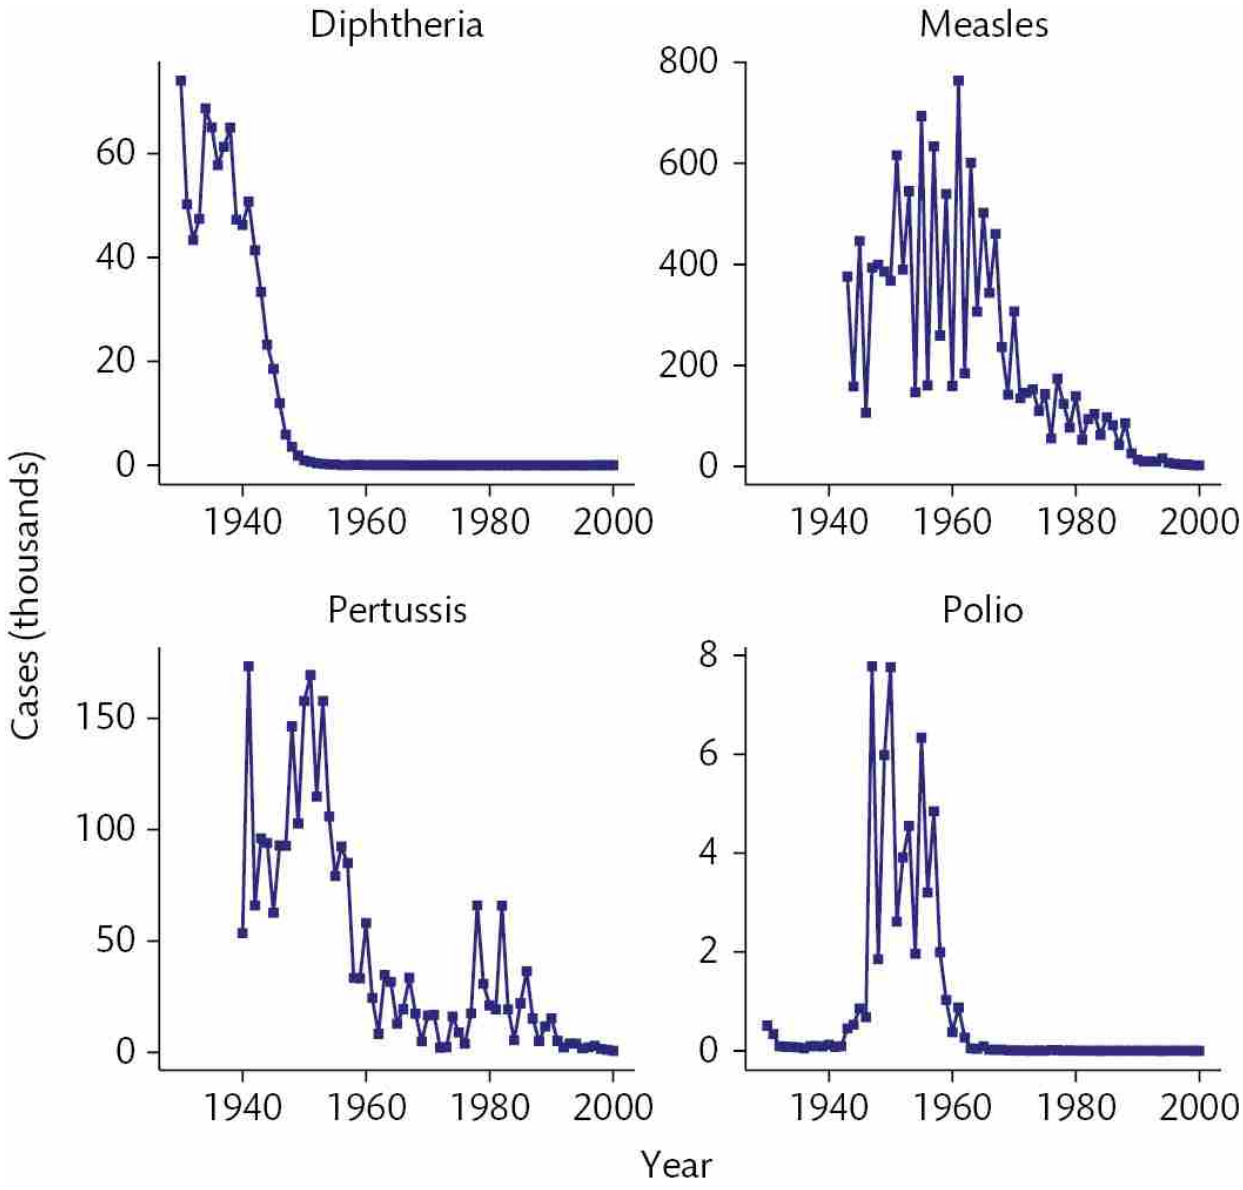

Fig. 5.16.8 Disease incidence trends in England and Wales for diphtheria, measles, pertussis, and polio, from 1930 to 2000. The data points indicate the recorded annual number of cases *in multiples of one thousand*.

Modelling can help us to understand the time trends of these four diseases and help inform decisions that policymakers need to make. All four of these

diseases are preventable through vaccination. We can collect data on the coverage of vaccination over time and develop a mathematical model to see if the increase in coverage (and decrease in the case of whooping cough) sufficiently explains the trends in prevalence over time. Then we can use the model to see whether different vaccination strategies would have had similar impact. For example, would vaccination of targeted age groups have had similar impact on diphtheria and polio prevalence as mass vaccination? What impact would changes in vaccine schedule have on whooping cough prevalence?

Application Laundry list

The following applications demonstrate examples of mathematical modelling in the context of public health:

Encapsulating the quantifiable essence of a complex situation in a simple framework which can then be used to make estimates. Dual infection or co-infection is a good example—infection with human papillomavirus (HPV) is more likely to persist in HIV infected individuals, which may increase incidence of cervical cancer.

Translating descriptions of behaviour at one scale (e.g. individual-level epidemiology of a disease) into descriptions at another scale (e.g. population dynamics). The HPV vaccines used in most public health settings protect against the two oncogenic HPV types that can be found in 70% of cervical cancer cases—will this lead to a 70% reduction in population-level cervical cancer incidence in the long term?

Enabling extrapolation, with quantified uncertainty, from data measured over a relatively short term, to a projection of what is likely to happen in the long-term. HPV vaccines have been available since 2007 and observed efficacy is good—so far. By setting rules in our model world about long-term efficacy, we estimate impact on cervical cancer incidence, a disease that can take decades to develop from initial HPV infection.

Synthesizing data from different fields into a single framework, thus enabling checks on consistency. In modelling the impact of an HPV vaccine on cervical cancer incidence, in a setting with high HIV prevalence, we need clinical information concerning the rates of progression/regression of cervical disease; we need epidemiological data concerning time trends in HIV, HPV, and cervical disease; we need data on cancer screening and vaccination coverage; and we need economic data if we are to assess the cost-effectiveness of new cancer prevention strategies.

Providing clear guidelines for new data collection strategies when trying to answer specific questions where critical features are missing from existing data. This may include identifying what type of data, how much data, and at what temporal and spatial resolution it should be collected, within financial and operational constraints.

Identifying the factors that sustain the spread of infection within a population and estimating the relative importance of various factors/parameters, thus informing control and prevention programmes. In the case of HIV, factors include sexual behaviour, the use of condoms, the extent of ‘intergenerational’ sex, and age at sexual debut. Modellers might seek, for example, to compare the effects on HIV

transmission of sexual heterogeneity, concurrency, and different mixing patterns.

Making predictions over time of the probable dynamics of prevalence, incidence, and infection-related mortality, under different interventions and comparing the impacts and synergies of different combinations of interventions.

Identifying threats to the success of an existing intervention. A model can be used to show that the scale-up of HPV vaccination may have a less than desired effect on cervical cancer incidence, if coverage of screening is not maintained for several more years.

Maximizing cost-effectiveness of interventions, hence enabling optimization of use of resources to combat an infection. Models can assist in evaluating the economics of different control strategies, and can help to decide whether programmes should re-allocate funding in response to the new data or scientific breakthroughs. Providing the new 9-valent HPV vaccine plus HPV DNA testing may be more expensive in the short term, but may reduce cancer rates, and very expensive cancer treatment, more drastically in longer term than vaccination with 2-valent vaccine and cytology based screening.

Concluding remarks

The role of models is to formalize our understanding of, or hypotheses about, data and processes, so that we can tap into powerful tools developed by mathematicians over many years. This allows us to restate our thoughts about systems in an orderly fashion, demonstrating details of their internal workings, in the context of tough political and technical questions about investment in, and management of, public health systems.

We hope readers of this chapter will take away the following key messages:

The conceptual heart of modelling is the construction of interesting 'model worlds'—realms in which we declare how things work, in order to explore dynamics that, in the real world, are too complex to track in detail, or are not amenable do direct experimental control that might teach us what we are looking to learn.

Building model worlds is not a specialist activity to be performed only by technical modellers. Anyone who has a vested interest in a question can contribute to model world construction and exploration.

There are some technical details that must be faced in producing and manipulating mathematical equations of various kinds, which capture the processes we have built in to our model worlds. While this is indeed a specialist activity, there are a number of recurring themes, and even non-specialists can achieve quite a high level of familiarity with important modelling concepts.

ACKNOWLEDGEMENTS

The authors owe a particularly big thanks to Gavin Hitchcock and Brian Williams, who coauthored the previous edition of this chapter together with Alex Welte, and then declared that they were happy for the present authors to adopt, revise, and arbitrarily recycle as they saw fit. GH additionally provided many useful comments on the new version. While we have made deep and extensive changes, relative to the previous edition of the *Oxford Textbook of Global Public Health*, this chapter is in many ways recognizable as a revision of that original work.

Online appendix: key modelling concepts

Here we variously recap and expand on the key modelling concepts of Box 5.16.3, illustrating them by default with reference to HIV. Further elucidations of these concepts may be found in many modelling texts (see, for example, 'Further reading').

Basic reproduction number R_0

This very important concept is somewhat more subtle than usually noted, but there is a valid heuristic: the total number of secondary cases that arise (or are expected to arise, on average) from direct infection by one primary case introduced into a (very large) completely susceptible population.

Disease duration

The length of time for which people have a disease, infection, or medical condition before they are treated, cured, or die. For example, without treatment, people will live with HIV for about 10 years, on average.

(Disease) mortality

The proportion of (infected) people that die per unit of time, for instance within a year. Since HIV-positive people live for about 10 years without treatment, the mortality rate is about 10% per year, averaged over the course of disease.

Epidemic growth rate

The rate at which the prevalence of infection rises at the start of an epidemic. For example, the prevalence of HIV initially grew at a rate of 60% per year

in South Africa.

Equilibrium

A scenario in which the state of the model world is unchanged by the passing of time. This is a subtle concept, and may refer to a scenario in which it is implicit that individuals are entering and leaving various population groups, but in such a way that the total numbers in each group (the ‘state variables’ which define the population) are unchanging. This requirement of ‘detailed balance’ between processes moving individuals into and out of population groups can only be precisely realized in a model world.

It may appear strange or contrived to have finely adjusted all dynamical rules and state variables to achieve such a seemingly delicate balance. The key point to note here is that equilibrium can readily and naturally emerge dynamically from the system over time, even if it was not originally evident. Although real-world systems rarely display anything close to true equilibrium, the concept is very important—and not just for the purposes of formal analysis of mathematical models. Practically, the ideal of equilibrium is a useful concept that enhances insight, for example in understanding where trends, under current conditions, are in principle headed. For example, are we essentially on the way to disease elimination, or apparently doomed to high endemic persistence.

Herd immunity

As indicated throughout this chapter, the heart and soul of dynamical modelling is the consistent propagation, through time, of rates of occurrence of epidemiological events. Crucially, these rates need to be consistently adapted as the state of the population changes from the application of the rules. The feedback loops which this implies are often characterized by critical ‘tipping points’ such as embodied in R_0. One of the most important insights that comes from this kind of analysis is that it is not necessary to protect (e.g. through vaccination) every individual of a population, in order to achieve the elimination of an otherwise endemic infection. Thus ‘herd immunity’ is the collective ability to clear an existing, or resist an invading, epidemic even when some individuals are fully susceptible.

Incidence

This can be thought of as the richly informative cousin of prevalence, and warrants a lengthier discussion because the understanding and estimation of incidence, and its susceptibility to intervention, is ultimately the central technical problem of all modelling of infectious agents. There are several valid ways to define incidence, but ultimately they all refer to the notion of the number of new cases that occur within a given population and period of time. This is sometimes stated as a raw number of cases per time window, such as 1,000 cases of severe influenza needing handling at a major hospital within a month. However, a more 'intrinsic' notion of incidence captures *risk per unit time* experienced in an exposed population. This risk is often expressed as the proportion of a susceptible group who are, or would be expected to become, infected in a period of time. When modellers and statisticians speak of event rates, in general, what they mean is the probability per unit time of an event occurring, clearly stated as referring either to an individual or to some population.

A subtlety is that, even when we express incidence in *probability per year*, for example, this is not entirely the same as the probability of an infection *actually occurring within a year*. Firstly, risk can vary over time, but this changing *instantaneous* risk can still be expressed in units of probability per year. Secondly, even if the risk is constant, any particular rate (probability per unit time) can be expressed in as large, or as small, a numerical value as one wants, by choosing different units of measurement of time. This is just like noting that an object's length can be made as large or small a number as we like, by choosing different units in which to measure length. However, the probability of an event actually occurring saturates at a value of one, which is the limit of certainty of occurrence. This is true no matter how high the rate (probability per unit time) or how long the window of time for which we wait. For hazards of no more than a few per cent, such as the annual probability of HIV acquisition in high-risk settings, the incidence as an instantaneously conceived probability per year, and the probability of infection during the course of a year, are numerically similar enough that they can be regarded as the same thing—especially when we consider the imprecision with which they can be estimated. On the other hand, a flu outbreak which brings an infection risk of 20% per week, sustained for 4 weeks, will affect about 59% (not 80%) of individuals—that is, $1—(0.08)^4$, or one minus the probability of escaping infection for 4

weeks. To press the point: a flu outbreak which brings an infection risk of 30% per week, sustained for 4 weeks, clearly cannot affect 120% of the population! It will affect about 76%.

There is no simple general relationship between prevalence and incidence—a source of much inconvenience and technical pain for epidemiologists. It is simpler at *equilibrium*: if an epidemic of HIV reaches a 'steady state' so that all rates, and the resultant prevalence, are constant, then the number of new infections each year will be equal to the number of deaths. Thus the incidence, expressed in units of events per unit time per total population (as opposed to per susceptible individual) is equal to the ratio of prevalence to duration (with a consistent set of units to measure time). Hence a 'stable' HIV epidemic (without effective treatment—see '(Disease) mortality', earlier) has a value of incidence (expressed as infection risk per year) of about one-tenth of prevalence. In reality, there is no equilibrium, and incidence and prevalence vary in complex ways as functions of both calendar time and age.

Model scenario

Mathematical models, in the basic abstract sense, capture rules about processes in a model world, a world which *by definition* functions according to *rules* captured in certain mathematical statements. This however leaves (wide) open the question of *what actually hap*pens in this model world, as the rules by themselves do not spell out a 'starting point' or 'initial condition' from which the system is then driven by the clearly stated rules. For example, we may have captured rules about the transmission of HIV, but when applied to a population in which there is at some point no infected individual, these rules will not lead to the spontaneous appearance of an outbreak. When populations have structure, such as heterogeneity in age, gender, and various other 'risk factors', these also need to be specified at some initial time, in order for the rules to be applied to a concrete 'realization' of the model world. This fully specified realization of a possible history of a model world, in which rules as well as initial conditions are spelled out, is often called a 'scenario'. A scenario may also involve arbitrary 'midstride' impositions of rule changes, such as the initiation of a vaccination or treatment campaign at some point in time. In epidemiology, such 'interventions' by human agency are usually treated as arbitrary

changes to the model ‘rules’, rather than as events which unfold according to some complex higher level sociological rules—as this level of emergent behaviour is almost impossible to build into a model world. Model world rules are usually best kept as close as possible to rules of nature that can plausibly be modelled.

Parameter

Any variable in a model which captures a *rule* about the model behaviour, such as the rate of recovery from infection, the probability that a ‘contact’ leads to ‘transmission’, and so forth. (See also ‘State variable’).

Prevalence

The proportion of a population or group who are currently suffering from a disease, infection, or medical condition. For example, in South Africa about 10% of adults are infected with HIV.

State variable

Any variable in a model which captures the state of the system, such as the number of living individuals, the number of people in a particular risk category, and so forth. (See also ‘Parameter’).

Note that mathematically there may sometimes be no way to distinguish state variables from parameters in a model equation. The distinction is conceptual, and usually straightforward: parameters are usually model inputs, and state variables are usually model outputs.

Public health surveillance

Nguyen Tran Hien, James W. Buehler, and Ann Marie Kimball

Introduction to public health surveillance

Public health surveillance provides the epidemiological foundation for modern public health practice. The ongoing monitoring of disease or health trends within populations informs what public health actions are taken and reflects whether those actions are effective. Surveillance may involve monitoring of diseases and other health-related conditions as well as their antecedents, characteristics, and consequences. Surveillance can guide the local response to individual cases of disease or more broadly inform public health programmes and policies. A key function of surveillance is to identify circumstances that merit further public health scrutiny, such as groups or locations that are disproportionately affected or changes in disease occurrence or severity. Person, place, and time are the key epidemiological attributes of disease distribution in populations, and knowledge of these attributes afforded by surveillance allows targeting of public health programmes. General principles that underlie the practice of surveillance are essentially the same for all countries, regardless of economic development. Defining surveillance objectives depends on programme goals and on what information is needed, who needs it, and how it will be used. Desirable but potentially competing attributes of surveillance include completeness, timeliness, representativeness, high predictive value, acceptability, flexibility, simplicity, and low cost. Public health surveillance is conducted in many ways, depending on the nature of the health event under surveillance, the nature of healthcare and information infrastructures, the population involved, resources available, and information needs. The widespread and expanding use of the internet, electronic media, communication technologies, and mobile computing have enabled

innovations in public health surveillance that reach far beyond traditional methods. Surveillance systems should be periodically assessed to determine whether information needs are being fulfilled and whether the resources are being used effectively. Although surveillance methods were originally developed as part of efforts to control infectious diseases, basic concepts of surveillance have been applied to all areas of public health.

In many resource-poor countries, challenges to meeting needs for population health information are heightened and include potential tensions between the perspectives of external funders and in-country officials, between the interests of those responsible for disease-specific 'categorical' programmes and those interested in strengthening general surveillance infrastructures, and between advocates for using limited resources to strengthen information capacities versus those who would focus spending to address urgent service needs. At the same time, recent innovations hold promise for improving surveillance in resource-poor settings, where precedents in developed countries that can impede innovation are absent or less established.

Definition of surveillance

People who are responsible for protecting and promoting the health of populations need ongoing, timely, and reliable information about the health of the populations they serve. The term 'surveillance' encompasses the multiple processes that public health agencies employ to meet this need for information. Surveillance can include information about specific diseases, health risks, or more general indicators of overall population health. As an integral part of public health practice, surveillance is an ongoing, systematic process of information collection, analysis, interpretation, visualization, dissemination, and connection to public health programmes (Thacker and Berkelman 1988). Surveillance systems are organized networks of people and activities dedicated to managing and maintaining surveillance for specific conditions. Surveillance systems can operate at various levels within countries, from local to national, or on a global scale.

In 1963, Langmuir established the modern concept of surveillance as 'the continued watchfulness over the distribution and trends of incidence through the systematic collection, consolidation, and evaluation of morbidity and mortality reports and other relevant data' together with timely and regular

dissemination to those who ‘need to know’ (Langmuir 1963). In 1968, the twenty-first World Health Assembly described surveillance as the systematic collection and use of epidemiological information for the planning, implementation, and assessment of disease control; in short, surveillance implied ‘information for action’ (WHO 1968). Over time, the scope and methods of surveillance have been adapted to meet the information needs of public health programmes that address a broad spectrum of infectious and non-infectious diseases and acute and chronic conditions. For brevity, the term ‘diseases’ or ‘conditions’ will be used as shorthand throughout this chapter for diseases, injuries, risk factors, and other health-related events that are the focus of public health programmes and surveillance systems.

Surveillance can include monitoring of the incidence, prevalence, antecedents (such as behavioural risks or hazardous exposures), characteristics, and outcomes of disease and other health conditions of public health importance. According to the US Centers for Disease Control and Prevention (CDC), a ‘public health surveillance system is useful if it contributes to the prevention and control of adverse health-related events and can be useful in contributing to [public health programme] performance measures, including health indicators that are used in needs assessments and accountability systems’ (CDC 2001). Surveillance should begin when there exists, or is likely to exist, a public health problem that merits attention, and it should be discontinued or revamped when the information it yields is no longer needed or useful. Surveillance systems can operate at various levels within countries, from local to national, or on a global scale.

The International Health Regulations (IHR) of 2005 provide a legal and practical framework among all World Health Organization (WHO) member countries to protect against the international spread of disease. The IHR require that all countries can detect, assess, report, and respond to public health threats that have the potential to spread across borders. So the IHR call for strengthening of national capacity for surveillance and control of public health events of national and international concerns (WHO 2016).

Establishing a surveillance system

Establishing a surveillance system requires a statement of objectives, definition of the disease or condition under surveillance, and implementation of procedures for collecting information (or obtaining information from

existing sources), managing, analysing, visualizing, interpreting, and disseminating the information. In addition, as the number of surveillance systems increases, attention should be given to whether there are multiple systems collecting information within a population and, if so, whether these systems collect common data elements and adhere to shared information standards. This is important to allow for information sharing across systems, to minimize duplication of effort, and to simplify the work of those who are asked to report to these systems. Attention should also be given to whether surveillance for a particular condition can be done similarly in different locations, increasing the likelihood that comparison of disease incidence or prevalence across multiple localities or countries is meaningful.

Surveillance systems are information loops, or cycles, that involve healthcare providers, public health agencies, and the public in a process of information collection, analysis and interpretation, and feedback. The cycle begins when events of public health concern occur and is completed when information about these events is made available and applied in public health programmes. This may involve multiple levels that should be specified in developing a surveillance system, ranging from the anticipated local response to individuals with cases of disease to the use of information aggregated from multiple localities to inform national policies. The delivery of information to constituents and policymakers (Langmuir 1963) is essential to the completion of the surveillance cycle. To the extent that surveillance data can be released without compromising privacy or confidentiality, they should be placed in the public domain to allow full use and benefits, with appropriate documentation.

Weaknesses in any part of the information chain can affect the entire surveillance process, and potential constraints should be anticipated. For example, when surveillance draws upon information arising from the use healthcare services, surveillance will be affected by the availability and quality of those services, including laboratory and other diagnostic services (Berkelman et al. 1994) and by the accuracy with which diagnoses are recorded or coded. No information resource is perfect, and establishing surveillance requires consideration of options, each with strengths and limitations, for how surveillance should be conducted at each step in the surveillance cycle. Having data that are complete and without error is desirable, but the effort required to obtain such data in a timely manner may not be feasible or sustainable.

Objectives of surveillance

Goal of public health surveillance is to provide information that can be used for health action by public health personnel, government leaders, and the public to guide public health policy and programmes (Smith et al. 2013). Surveillance is essential for monitoring events that might jeopardize the health of a population so that appropriate prevention and control measures can be implemented in a timely manner. An effective surveillance system includes the following: collection, reporting, and consolidation of data; routine analysis and interpretation of data; feed-forward of surveillance data to decision makers; feedback of surveillance data to those providing the data and other interested parties; detection, evaluation, and response to unusual patterns in the data and quality assurance (PAHO WHO 2014).

The objectives of surveillance systems will be shaped by the public health programmes they serve. For example, a programme to eradicate an infectious disease requires intensive surveillance in the later stages of the campaign that emphasizes identification of all people with the disease (Hinman and Hopkins 1998).

The purpose of surveillance is to meet the needs of public health programmes for information about the health of the populations they serve. The following are purposes of public health surveillance:

To define public health priorities.
To characterize disease patterns by time, place, person, and disease characteristics.
To detect epidemics, health problems.
To monitor changes, measure trends of diseases, and health-related events.
To suggest hypotheses for further investigation.
To estimate magnitude and scope of health problems.
To guide and evaluate prevention and control programmes, including assessment of effectiveness and/or adverse consequences.

Taken together, population-level measures of time, place, person, and disease characteristics can lead to an understanding of the impact of various diseases and insights into individual and social determinants of their occurrence. Surveillance might lead to hypotheses that can be tested in more definitive investigations and can identify individuals who could be enrolled

in further epidemiological studies. In some instances, surveillance alone can provide compelling evidence of the impact of prevention programmes, such as the sharp decline in the incidence of a vaccine-preventable disease coincident with the widespread use of a new vaccine (Seward et al. 2002). In other situations, surveillance can contribute to evaluating the impact of interventions, but more detailed investigations are necessary to explain trends that are shaped by multiple factors. Low incidence or prevalence does not necessarily mean that certain diseases do not deserve public health attention, including continuation of surveillance, since this might reflect the impact of successful prevention efforts that must be sustained in order to prevent re-emergence. Information on disease trends gained through surveillance, when combined with other information, can also be used to predict future disease trends. For example, with the ageing of the 'baby boom' population in countries such as the United States, projections of disease prevalence in the elderly, such as the anticipated prevalence and cost of dementia (Hurd et al. 2013), are garnering increased attention.

Surveillance for a disease or other health problem should have clear objectives. These objectives should include a clear description of how data that are collected, consolidated, and analysed for surveillance will be used to prevent or control the disease. When establishing the objectives of surveillance, several issues should be considered, including: health-related event and case definition; population under surveillance; data sources and data collection approach; planned uses of the surveillance data; legal authority and frequency of data collection; organization of the surveillance; integration with other surveillance and health information systems; data processing, analysis and management; information dissemination methods and ethical issues (CDC 2012c).

An important use of surveillance is to help set public health priorities. In addition to recent measures of incidence or prevalence, other factors that can shape priority setting include likely future trends, the potential for public health or other interventions to have an impact, severity, disparities and attendant social justice concerns, and public interest. To the extent that surveillance data are used in priority setting, deliberations may give rise to concerns about surveillance methods, how surveillance data are queried and analysed, and the accuracy of estimates of disease impact. For example, even though mortality monitoring is the oldest form of surveillance and remains important in assessing the impact of different diseases (Thacker 2010),

different agencies using mortality data may arrive at different conclusions, depending on the use of overall mortality measures, age-specific measures, or approaches that seek to integrate measures of mortality and wellness. Table 5.17.1 provides two estimates of the number of deaths (in millions) for leading causes of death globally in 2010, one from the Institute for Health Metrics and Evaluation (IHME) and another from the WHO (Liu et al. 2000). Such estimates from different organizations rarely line up, and disparities in estimates can cause consternation among donors and national governments seeking to prioritize interventions.

Table 5.17.1 Estimates of the global number of deaths, by cause, 2010, Institute of Health Metrics and Evaluation (IHME) and World Health Organization (WHO)

	IHME	WHO
Cause of death	Deaths (millions) (95% CI)	Deaths (millions) (95% CI)
Pneumonia/lower respiratory infections	0.847 (0.736–0.981)	1.396 (1.189–1.642)
Diarrhoeal diseases	0.666 (0.544–0.763)	0.801 (0.555–1.182)
Malaria	0.676 (0.445–1.002)	0.564 (0.432–0.709)
HIV/AIDS	0.126 (0.105–0.150)	0.159 (0.131–0.185)
Neonatal sepsis or meningitis	0.514 (0.318–0.841)	0.573 (0.388–0.789)
Total deaths in children <5 years of age	6.841 (6.439–7.302)	7.622 (no CI is given)

CI, confidence interval.

Efforts to estimate the impact of different diseases can be done periodically as data and the resources to analyse them become available, but this approach does not lend itself to frequent and ongoing monitoring where disease patterns are shifting because: (1) data quality is highly variable from different surveys or settings and often repurposed from its original collection

goal; (2) cross-sectional survey information typically becomes available 1–2 years after surveys are completed; (3) estimates for very remote and information-poor geographic locations are often based on imputed data from neighbouring localities, and little ‘ground truthing’ is done to verify imputed data; and (4) assignment of causes of death, especially when based on verbal autopsies, is plagued with potential misclassification.

Health problems under surveillance

It is necessary to decide exactly what disease or health problem will be under surveillance. Surveillance may frequently be conducted for any of several points along a spectrum, ranging from exposure to an adverse outcome. It is important to consider which manifestations or stages of a disease should be under surveillance. For example, manifestations of ischaemic heart disease include angina pectoris, acute myocardial infarction, and (sudden) death, and precursors may include hypertension or behavioural risk factors such as tobacco use, unhealthy dietary habits, or lack of exercise. Criteria developed for selecting and prioritizing health problems for surveillance are described as following (CDC 2012b):

Public health importance of the problem: incidence, prevalence, severity, sequel, disabilities, mortality caused by the problem, socioeconomic impact, communicability, potential for an outbreak, public perception and concern, and international requirements.
Ability to prevent, control, or treat the health problem: preventability, control measures, and treatment.
Capacity of health system to implement control measures for the health problem: speed of response, economics, availability of resources, and what surveillance of this event requires.

Target population

The population under surveillance may be defined on the basis of where people live, work, attend school, consume water or food, or use healthcare services. Alternatively, the population may be defined on the basis of where health events occur. For example, surveillance of traffic injuries aimed at identifying roadway hazards could include all injuries that occur in a target community, regardless of whether affected people live in that community. In

some cases, target populations for public health surveillance may be animals. For example, animal surveillance systems for West Nile virus and avian influenza have been developed, recognizing that these pathogens of concern to human health also infect animals and may alert public health authorities of potential transmission to humans.

Questions addressed by surveillance can be summarized using epidemiological measures of disease characteristics (what), person (who), place (where), and time (when):

Disease characteristics: what are the characteristics of disease, such as the clinical or laboratory manifestations, severity, and outcomes? For example, understanding the prevalence of the sensitivity or resistance of infectious agents to antimicrobial drugs is critical to informing healthcare and public health responses, and monitoring the prevalence of different microbe strains can be important for understanding the spread of different infectious or for vaccine development. Global influenza surveillance is used to anticipate which strains of influenza virus will be most prevalent during upcoming influenza seasons and to develop annual influenza vaccines (Cox et al. 1994). Differences in the spectrum or severity of disease among affected people might pinpoint differences among groups in genetic susceptibility, the co-occurrence of other illnesses, or access to healthcare.

Person: who is affected? Understanding the characteristics and commonalities of affected people, such as their age, gender, occupation, race, ethnicity, habits, customs, or social or economic status, provides further insights into potential exposures or behaviours that can affect the risk of disease. Combined with information about the characteristics of the population at large, as from census data or population surveys, surveillance can provide critical insights into variations in the rates of disease among different groups. For example, in 1981, shortly after the disease later named acquired immunodeficiency syndrome (AIDS) was recognized and before the aetiological agent (human immunodeficiency virus (HIV)) was identified, by describing the sexual, blood-related, or perinatal exposures of affected people, surveillance combined with early epidemiological investigations helped to determine the infectious nature of the disease, identify probable modes of transmission, inform early prevention recommendations, and calm fears about the potential for widespread transmission through casual contact with affected people (Jaffe et al. 1983).

Place: where is disease occurring or not occurring? Understanding geographic variations in incidence or prevalence can inform where investigations and interventions should be directed and can provide important clues to environmental, occupational, water- or food-borne, behavioural, or other risk factors. Alternatively, geographic variations might reflect differences in detection of disease resulting from variations in the availability, quality, or use of public health or healthcare services.

Time: are disease trends upwards, downwards, or stable? Do downward trends coincide with interventions, such as the introduction of a vaccine,

treatment, or prevention programme? Do upturns coincide with aggravating situations? Changes in trends might reflect the underlying health of populations or they might reflect changes in how surveillance is conducted or changes in medical or public concern about particular conditions. A key purpose of surveillance is to recognize changes in trends that might herald the onset of an outbreak or epidemic, prompting investigations to confirm the observed upturn in disease and, if so, identify the likely cause and guide interventions.

Case definition

The case definition is fundamental to any surveillance system because it is the formal declaration of what is to be monitored. The case definition is primarily a criterion for determining who or what is to be counted but can also serve other objectives, such as providing a guide to clinicians for diagnoses. Where feasible, consistent use of case definitions across geographical areas permits comparison of disease rates. The case definition should be sufficiently inclusive (sensitive) to identify people who require public health attention or to monitor trends reliably but sufficiently exclusive (specific) for surveillance to have adequate predictive value.

Case definitions must be crafted so that they can be applied in a given surveillance context, reflecting the level of expertise of those who report and collect surveillance data and the extent of information that is likely to be available. Surveillance case definitions may also be layered to include those with possible, suspected, presumptive, or confirmed diagnoses, depending on the urgency of need to respond to certain diseases before diagnoses are definitively established. '*Possible*' is classification of cases is based on clinical criteria. '*Probable*' is classification of cases is based on clinical criteria, epidemiological link, and presumptive laboratory criteria. '*Confirmed*' is classification of cases is based on laboratory confirmation. For infectious diseases, confirmation of the diagnosis typically requires a positive laboratory test. But, if laboratory testing is not routinely available, syndromic criteria might be sufficient to guide treatments and to monitor disease trends. For example, in the United States, surveillance criteria for sexually transmitted infections (STIs) such as gonorrhoea or syphilis, incorporate both clinical and laboratory criteria (CDC 2011), reflecting the routine availability of diagnostic testing. However, in many countries,

routine access to such tests is not available, and syndrome-based criteria have been developed to treat and monitor conditions such as urethritis or cervical infection, based on prior assessments that included laboratory testing and informed presumptions regarding likely diagnoses and effective treatments (WHO 2003).

Types of surveillance

There are two approaches to categorize types of surveillance: by the format and by the content of data collection.

Types of surveillance by forms of data collection

Passive and active surveillance: A passive surveillance 'relies on the physicians, laboratory or hospital staff or other relevant sources to take the initiative to report data to the health department'. A key data quality concern of passive surveillance systems is external completeness. *An active surveillance* system is a system that is 'based on the public health officials' initiative to contact the physicians, laboratory or hospital staff or other relevant sources to report data'. Active surveillance typically generates high-quality data (high levels of completeness, validity, and timeliness) through a direct link with data providers. Active surveillance relies on a prompt response from public health professionals, who will usually monitor replies and can respond to low response rates in order to improve external completeness. Completeness for key variables, and thus better representativeness, will be achieved if distribution and composition of data providers are carefully chosen. Data comparability will be improved if data are collected through a common surveillance protocol. The main disadvantages of active surveillance are the substantial resources needed and the subsequent need to focus on high-priority diseases and questions that justify the additional expense.

Compulsory versus voluntary: Surveillance systems rely on processes and individuals. Countries use different approaches to elicit surveillance data from their sources. Some systems make data submission mandatory or quasi mandatory (either by law, professional edict, policy, or guidance), whereas others rely on a voluntary approach. A legal or professional obligation to

report may lead to greater external completeness and may increase timeliness but is unlikely to have an impact on representativeness or validity.

Comprehensive versus sentinel: Comprehensive surveillance systems include reports of cases of infectious diseases that occur within the whole population of the geographical area covered by the surveillance system (national, regional). Sentinel systems rely on notifications from a selected group of physicians, hospitals, laboratories, and other institutions. In the case of sentinel systems, representativeness is often established as part of the system-design process. The choice between sentinel and comprehensive systems is based on surveillance objectives, characteristics of the disease, and the availability of resources (ECDC 2014).

Types of surveillance by content of data collection

Following WHO WPRO, there are two main types of surveillance—event-based and indicator-based (WHO WPRO 2008b). Although the functions differ, these systems are both essential components of a national surveillance system and should complement each other.

Indicator-based surveillance is routine reporting of disease cases including notifiable disease surveillance system, sentinel surveillance, and laboratory surveillance. Reports are from healthcare facilities weekly and monthly. Indicator-based surveillance involves the routine collection of standardized information to establish historical trends and baselines to which the current situation can be compared. Data collection and analysis is very structured and specific to the disease or syndrome being monitored. Public health responses are triggered when pre-defined threshold activity levels are surpassed.

Event-based surveillance is rapid detection, reporting, confirmation, and assessment of public health events, including clusters of disease and rumours of unexpected deaths. Reports are intermediate commonly. Event-based surveillance involves rapidly detecting events that potentially pose a high risk to public health. These systems are designed to detect rare and new events, such as high-impact outbreaks or emerging and unknown diseases, at a very early stage when the event is geographically localized and involves a relatively small number of people, so that rapid assessments and responses can be made to contain or mitigate the situation. In order to accomplish this, event-based systems use broader and more sensitive definitions and flexible

reporting structures than indicator-based systems. Event-based surveillance complements indicator-based surveillance. both systems should be seen as essential components of a single national surveillance system.

Integrated diseases surveillance (IDS): To improve responses to emerging and re-emerging events, African Region has developed an integrated diseases surveillance (IDS) in the advocated for countries to establish community-based surveillance systems since 2001. Community-based surveillance (CBS) is an active process of community participation in detecting, reporting, responding to, and monitoring health events in the community. Community representatives and health workers were to be used as contact persons for the purpose of surveillance. Main activities of IDS are including (WHO Regional Office for Africa 2014):

Use standard case definitions to identify priority diseases, conditions, and events.
Report suspected cases, conditions, and events to the next level of the health system.
Investigate and confirm suspected cases, outbreaks, and events.
Analyse and interpret data collected.
Prepare to respond to outbreaks and other public health events.
Coordinate and mobilize resources to respond appropriately.
Provide feedback within and across levels of the health system.
Monitor and evaluate the system and component activities.
Conduct operational research to inform better practices and processes.

Methods for data collection

A number of methods are used to collect the majority of health-related data for surveillance. These methods can be further characterized by the approach used to obtain information from the sources described previously. Depending on the situation, these methods might be used to obtain information about a sample of a population or events or about all members of the population or all occurrences of a specific event (e.g. birth or death). Careful consideration of the objectives of surveillance and a thorough understanding of the advantages and disadvantages of different sources and methods for gathering data are critical in deciding what data are needed for surveillance and the most appropriate sources and methods for obtaining it.

Sources of data

Typical sources of data for surveillance are as following (CDC 2012c):

Individual persons
Healthcare providers, facilities, and records: physician offices, hospitals, outpatient departments, emergency departments, inpatient settings
Laboratories
Environmental conditions: air, water, animal vectors
Administrative actions
Financial transactions: sales of goods and services, taxation
Legal actions
Laws and regulations

Vital statistics

In countries with well-established vital event registration systems, monitoring trends for various causes of death is a long-standing part of surveillance for life-threatening conditions. Despite the well-recognized limitations in how causes of death are classified on death certificates, monitoring cause-specific mortality trends overall and by age, gender, and geographic location provides a useful, broad-brush picture of the impact and trends for multiple conditions.

There is frequently a lengthy interval between death and collection and analysis of death certificates, which may make such vital statistics less useful for surveillance purposes when more current data are needed. However, summary vital data can be rapidly collected. For example, weekly reporting of deaths from 122 cities to the CDC has been integral to the surveillance of influenza epidemics in the United States (Fig. 5.17.1), providing an indication of the timing and severity of annual seasonal influenza relative to historical norms (Choi and Thacker 1981; CDC 2009).

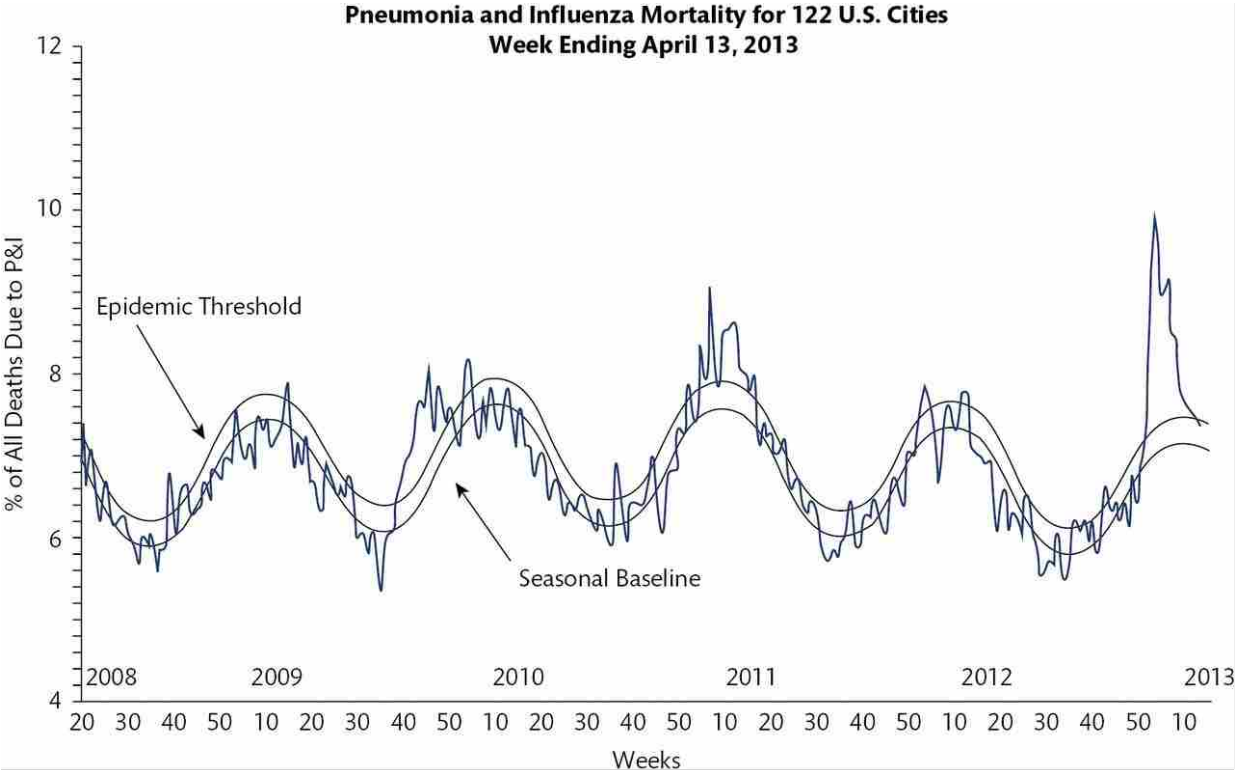

Fig. 5.17.1 Percentage of deaths attributed to pneumonia and influenza (P&I) reported by the 122 Cities Mortality Reporting System, by week and year—United States, 2008–2013.

Reproduced from *FluView, 2013–2014 Influenza Season Week 3 ending January 18, 2014*, Pneumonia and Influenza (P&I) Mortality Surveillance, available from http://www.cdc.gov/flu/weekly/#S2.

Medical examiner and coroner reports

For more detailed descriptions of the circumstances surrounding deaths (including autopsy reports, toxicology studies, and police reports), medical examiner and coroner records may be useful. These reports are typically representative of unexpected or medically unattended deaths or deaths caused by intentional and unintentional injuries and have been used for surveillance of such conditions as heatwave-related mortality and alcohol-related injuries. Systematic necropsy examinations have also been useful in ascertaining the contribution of tuberculosis to mortality of HIV-infected individuals in West Africa. Antibody determinations performed on post-mortem medical examiner samples may be useful for estimating population prevalence of infectious diseases (e.g. dengue) (Rigau-Perez et al. 2006).

Syndromic surveillance

A growing number of public health agencies have been prompted by concerns about the threat of bioterrorism to invest in automated ‘syndromic surveillance’ to detect epidemics more quickly than possible using traditional approaches (CDC 2004; Mandl et al. 2004). This involves monitoring trends in healthcare use for relatively non-specific syndromes (e.g. febrile respiratory illness or gastrointestinal symptoms) or other manifestations of illness (e.g. medication purchases, work, or school absenteeism) that may be apparent and can be monitored before diagnoses are established. Because these systems emphasize timeliness of the entire surveillance process, often enabling tracking of events within a day or less of their occurrence, they generally rely on data from electronic health information systems. These systems use automated methods to harvest electronically stored data, apply statistical tools to detect aberrant trends, and develop visual displays of geospatial disease trends. Despite this emphasis on automation, these systems still require human judgement to interpret reports and determine what level of further assessment or response is warranted when statistical alerts are generated.

Notification

Notifiable disease reporting is the approach traditionally used by public health programmes, based on laws or regulations that require reporting of selected diseases or conditions to public health departments. People or institutions responsible for reporting often include doctors, other healthcare providers, coroners, and medical examiners, laboratories, clinics, and hospitals. With the emergence of large, often commercial, laboratories that serve multiple providers across relatively large geographic areas, public health agencies are increasingly emphasizing laboratory-based reporting. This approach increases the timeliness and completeness of case reporting for diseases that require a laboratory test to diagnose. Because clinical information that accompanies specimens submitted to laboratories is often limited, however, follow-up with the providers who order laboratory tests or with patients themselves is often needed to complete case reporting (Ackers et al. 2000).

The overall completeness of notifiable disease surveillance depends on a succession of events: affected people must be sufficiently ill to seek healthcare, diagnostic tests are performed (which might not occur if patients are treated empirically), and positive results are reported. This approach may

be relatively passive, meaning that public health staff do not reach out to healthcare providers to encourage reporting, or more active, meaning that public health staff may contact or visit providers to prompt reporting or assist in the reporting process. In general, more active approaches to surveillance will result in more complete and timely reporting. For example, in the late 1970s, a relatively large shigellosis outbreak in Washington, District of Columbia, United States, was not recognized by the health department's surveillance system because fewer than a third of outbreak-associated cases had been reported as required. A review of the surveillance system found that surveillance was not only incomplete but also not representative because reporting varied considerably among different facilities. In hindsight, adherence to reporting requirements lagged because the health department had taken a very passive approach and had done little to inform and remind local healthcare providers of their reporting requirements (Kimball et al. 1980).

Completeness of reporting may be affected for multiple other reasons: if patients and doctors seek to conceal the occurrence of diseases that carry a social stigma, if healthcare providers are unaware of regulations, or if interest in particular diseases is limited. Even if reporting is incomplete, temporal trends and geographic patterns can be determined as long as the proportion of cases detected remains consistent over time and across geographical areas. Conversely, lack of representativeness and heterogeneity of reporting further limit the usefulness of incomplete data (Lowndes and Fenton 2004).

Example: notifiable disease surveillance in China

The China Infectious Disease Automated-alert and Response System (CIDARS) is an extension of the nationwide electronic system for notifiable disease reporting that was initiated in 2004 following the severe acute respiratory system (SARS) outbreak. The system focuses on 39 infectious diseases or syndromes that clinicians are required to report to the Ministry of Health. CIDARS added a formal process for analysis and follow-up that specified statistical thresholds for prompting alerts, based on the number of cases relative to historical precedents or temporal–spatial clustering; procedures for notifying responsible local officials via mobile telephone when those thresholds were exceeded within a locality; responsibility for preliminary assessments and, if indicated, more definitive field

investigations; and responsibility for documenting and reporting the results of those assessments and investigations. In an initial evaluation of CIDARS conducted in a sample of ten provinces, for nine relatively rare but potentially severe infections, 308 alerts were identified during a 2-year period in 2008–2010, of which 69 (22%) merited a field investigation, leading to detection of nine cholera outbreaks. For other more common but less severe diseases, there were more than 100,000 statistical alerts, of which 1.4% were deemed to merit further attention, leading to detection of 167 disease outbreaks (Yan et al. 2012).

Healthcare providers networks

Networks of healthcare providers have been organized for several decades, primarily to gather information on selected health events. Most have been organized by practising doctors on a voluntary basis; in many European countries, these networks have formed firm relationships with both public health authorities and academic centres. The strengths of sentinel provider systems include the commitment of the participants, the possibility of collecting longitudinal data, the flexibility to address a changing set of conditions, and the potential to conduct focused studies of the incidence, prevalence, care, or outcomes of various conditions, typically in primary care settings (Fleming et al. 2003). The main limitation of this type of system is that the population served by participating doctors may not be representative of the population.

Disease registries

Registries are comprehensive longitudinal listings of people with particular conditions. They often include detailed information about diagnostic classification, treatment, and outcome. Registries were initially established primarily for epidemiological research on individual diseases or conditions to develop aetiological hypotheses and to identify cases for further research (Weddell 1973). Registries have also been used to ensure the provision of appropriate care and to evaluate changing patterns of medical care; unlike other disease information systems, they cut across the different levels of severity of illness and may provide information over time about individual people. Registries can also be valuable for monitoring disease incidence and distribution. To focus on selected diseases or conditions, registries often

develop a constituency that promotes participation and reporting. Most registries rely on numerous sources of data for case detection including, but not limited to, hospitals, laboratories, and death records; few registries rely primarily on doctor notification.

Example: birth defects. Surveillance for birth defects was first initiated in response to the thalidomide tragedy in the late 1950s and early 1960s; registries were established to provide reliable baseline rates for specific birth defects and to detect increases in the prevalence of birth defects as a means to identifying human teratogens. The CDC has conducted birth defects surveillance in metropolitan Atlanta, Georgia, United States, since 1967 by using multiple sources of ascertainment of all serious birth defects observed in stillborn and liveborn infants and recognized by signs and symptoms apparent in the first year of life (Correa-Villasenor et al. 2003).

The International Clearinghouse for Birth Defects Surveillance and Research consists of 40 registries globally (Botto et al. 2006). The International Clearinghouse conducts a spectrum of surveillance activities that includes monitoring of selected conditions, and the exchange of information about birth defects clusters under investigation, findings of unpublished studies, and rumours about the occurrence of birth defects. Clearinghouse participants work at the intersection of surveillance and research in their assessment of the potential teratogenicity of first-trimester use of medications.

Laboratory surveillance

Laboratory surveillance may be conducted as part of a notifiable diseases system, sentinel surveillance system, or other system. In addition to supporting routine case reporting, laboratory-based surveillance can allow for the use of molecular epidemiological tools, more detailed evaluation of microbe strains or types, and monitoring of drug sensitivity. The use of molecular tools to enhance surveillance of pathogens is growing in many countries to facilitate outbreak detection, especially in situations where disease is associated with widely distributed food products, where the number of cases of illness due to a particular infection is insufficient to prompt attention, but where epidemiological linkage of geographically disparate cases allows detection of distinctive outbreak-associated pathogen strains. In the United States, PulseNet is a network of public health

laboratories that performs DNA ‘fingerprinting’ on bacteria that may be food-borne (Swaminathan et al. 2001). The network permits rapid comparison of these ‘fingerprint’ patterns through an electronic database and has detected multiple outbreaks that likely would have been otherwise unrecognized. For example, in 2008–2009, PulseNet detected and enabled tracking of an outbreak of salmonellosis associated with contaminated peanut butter with over 500 cases of illness detected in 43 states (CDC 2009). Molecular methods are also increasingly applied in surveillance of the HIV epidemic. For example, surveillance systems in Canada (Jayaraman et al. 2006) routinely characterize newly diagnosed HIV infections with respect to the HIV subtype.

Sentinel surveillance

Sentinel surveillance is the most efficient way to collect high-quality data in a timely way. It is typically carried out with indicator-based surveillance and involves systematically collecting data on a routine basis from a limited number of surveillance sites. Data collected in a well-designed sentinel system can be used to signal trends, identify outbreaks, and monitor the burden of disease in a community, providing a rapid, economical alternative to other surveillance methods. Because sentinel surveillance is conducted only in selected locations, however, it may not be as effective for detecting rare diseases or diseases that occur outside the catchment areas of the sentinel sites. Ideally, the sites are chosen to be representative of the population so that the information gathered can be applied to the population as a whole. For example, the spectrum of influenza infections varies widely in terms of severity and various indicator-based systems are used to monitor these syndromes. Specifically, sentinel influenza-like illness (ILI) surveillance is focused on mild manifestations of influenza in the outpatient setting while sentinel severe acute respiratory infection (SARI) surveillance is used to monitor persons with more severe illness who have been admitted to a hospital for their respiratory illness. Selecting sentinel SARI surveillance sites should consider following issues: representativeness of the population of interest (climate zones, demographic, and socioeconomic characteristics); feasibility and sustainability (staff and leadership motivation; mechanisms for collection, storage, and transport of clinical specimens; high-quality diagnostic laboratory, ability to reliably manage and report surveillance data; long-term funding); disease burden (population-

based incidence, healthcare seeking rates); and availability of reliable numerator and denominator data (PAHO 2014). Influenza surveillance is often multifaceted and includes measures of morbidity (e.g. office or hospital emergency department visits for 'influenza-like illness' or hospitalizations among people with laboratory-confirmed influenza), mortality (e.g. deaths attributed to 'pneumonia and influenza'), and laboratory-based indicators (e.g. viral isolates from participating laboratories where virus type, alignment with vaccine strains, or sensitivity to antiviral medications can be tested) (CDC 2012a).

Population health surveys

A survey is an investigation that uses a 'structured and systematic gathering of information' from a sample of 'a population of interest to describe the population in quantitative terms'. The majority of surveys gather information from a representative sample of a population so that the results of the survey can be generalized to the entire population. Behavioural data can be collected from samples of the population at large, from populations at particular risk for the health condition of interest, and from populations affected by the health condition of interest (Davy 2006). When conducted in person, objective measures of health can also be obtained, such as measurements of height, weight, blood pressure, or collection of specimens for laboratory testing. Population-wide household surveys, such as the National Health Interview Survey in the United States (CDC 2013b) or the General Household Survey in England and Wales (Twigg 1999), have provided information on personal health practices such as alcohol use and smoking, disabilities, and doctor encounters.

In countries where most residents have telephones, telephone interviews have the advantage of lower cost per interview, allowing for wider geographic coverage and more local estimation of the prevalence of various health indicators. For example, in the United States, all states conduct the Behavioural Risk Factor Surveillance System (BRFSS) to monitor a spectrum of health-related behaviours at the state, and in many instances local level. The BRFSS, like all telephone-based surveys, has had to adapt to the declining use of landline telephones and the increasing use of mobile telephones, trends that have varied among demographic groups within the population (CDC 2013c).

Inclusion of behavioural measures has been advocated by the WHO for HIV and STI surveillance programmes. Increasingly, demographic and health surveys are conducted to include both behavioural and biological measures, and to use sampling methods that provide representative data on a population level (Kenya Central Bureau of Statistics et al. 2004).

Surveys of populations at special risk may also play an important role in guiding public health response. Such systems may be relatively simple, in the form of episodic surveys of convenience samples (e.g. episodic convenience samples of men who have sex with men attending gay bars in Scotland) (Williamson et al. 2006) or may be formalized as ongoing surveillance systems. Such surveys can provide data on levels of risk behaviours, on adoption of desired preventive behaviours, and on exposure to public health prevention messages.

Healthcare information systems

Surveillance systems often depend on existing health data collection systems. These systems may be either integral to surveillance or serve as an adjunct to surveillance for specific diseases or conditions. Examples include use of hospital discharge databases and insurance claims data. The advantage of this approach is that it involves use of information systems that have been previously established for other purposes and can be tapped for surveillance applications for relatively little additional expense. In addition, these information systems often represent very large numbers of people. The main limitation is that diagnoses may be inaccurately or variably recorded or coded. A growing number of healthcare providers are using electronic health records to foster automated exchange of information from patients' medical records. From the public health perspective, these 'health information exchanges' provide a focal point for obtaining surveillance information within communities and for providing feedback to clinicians (Public Health Informatics Institute 2005).

Second generation surveillance

Second generation surveillance systems do not propose any new methods of data collection. Rather, they focus existing methods on appropriate populations and subpopulations, and combine them in ways that have the greatest explanatory power. For HIV surveillance, it means making best use

of other sources of information, communicable disease surveillance, reproductive health surveys, etc. to increase understanding of the HIV epidemic and the behaviours that spread it. These are most useful in reducing the spread of HIV and in providing care for those affected. Second generation surveillance systems include biological surveillance (sentinel serosurveillance in defined subpopulations, regular HIV screening of subpopulations, HIV screening of specimens); behavioural surveillance (repeat cross-sectional surveys in the general population and in defined subpopulations); and other sources of information (HIV and AIDS case surveillance, death registration, STI, and tuberculosis (TB) surveillance (UNAIDS/WHO 2000).

Internet-based approaches to surveillance

The widespread use of the internet and electronic media has led to innovations in population health monitoring that reach far beyond traditional surveillance methods. In 1994, the International Society for Infectious Diseases launched the Program for Monitoring Emerging Diseases (ProMed), which allowed individuals to post reports and updates on disease events on a public-access internet site, with a moderator assuring the professionalism of the website. Information posted on ProMed includes alerts, reports of epidemics, and local observer reports, with over 30,000 subscribers worldwide (Madoff and Woodall 2005). For example, the earliest public notice of the outbreak later known as SARS was in the form of a query posted on ProMed in early 2003 by a physician who learned from an acquaintance of widespread severe respiratory illness in Guangzhou, China. This report and other updates to ProMed alerted the global public health community to this epidemic and played a key role in charting its course of spread to multiple countries (Yu and Madoff 2004).

The Global Public Health Intelligence Network (GPHIN) is managed by the Public Health Agency of Canada and is geared to providing early warning for potential threats to public health worldwide. GPHIN uses an ongoing, automated process to monitor online media reports in six languages worldwide for early indicators of events such as disease outbreaks, natural disasters, food or water contamination, potential biological or chemical terrorism, and other threats. GPHIN operates 24 hours a day, 7 days a week in ‘near real time’. Access to GPHIN is limited to agencies determined to have a legitimate public health mandate, as determined by the WHO and

Health Canada (Public Health Agency of Canada 2013). The Google.org Flu Trends monitors trends in internet searches using terms that have been observed to correlate with influenza activity. While this approach yields trends that parallel other indicators of ILI, its public health application is yet to be determined (Valdivia et al. 2010).

The growing use of the internet, including use of mobile phones that provide mobile internet access, is enabling a form of public 'participatory epidemiology' or 'crowd sourcing' where interested members of the public or members of online communities interested in specific health problems are encouraged to post reports of illness or disease outbreaks. The application of such utilities and services is an area of ongoing development and evaluation (Freifeld et al. 2010).

Use of big data for surveillance

Today, use of big data has been shown to improve precision in selected disciplines of public health. Big data is an extremely large volume of structured, semi-structured and unstructured data sets that may be analysed computationally to reveal patterns, trends, and associations, especially relating to human behaviour and interactions. Such voluminous data can come from myriad different sources, such as business transaction systems, customer databases, medical records, internet clickstream logs, mobile applications, social networks, the collected results of scientific experiments, machine-generated data, and real-time data sensors used in internet of things environments. Disease surveillance using big data has shown efficacy in air pollution, antibiotic resistance, cholera, dengue, drowning, drug safety, electromagnetic field exposure, influenza A H1N1, Lyme disease, monitoring food intake, whooping. Effective signal detection often leads to attempts to predict future signals. Predicting public health risk leads to a chance to implement preventive interventions (Dolley 2018).

Data collection instruments

The desire to collect detailed information must be tempered by the need to limit data collection to information that can be reliably and consistently collected and used over the long term. Forms, questionnaires, or other data collection instruments that are too extensive will not be welcomed by those on whom the surveillance system must depend. While computerized systems

may permit more detailed data collection, collecting large volumes of data may exceed the capacity of public health agencies to make effective use of those data. Standards for exchanging electronic health information are critical as healthcare information systems and public health surveillance systems become increasingly automated. In the United States, the Health Information Technology for Economic and Clinical Health (HITECH) Act in 2009 provides incentives for healthcare providers to adopt electronic health records and requires that doctors and hospitals use their electronic health record systems to report quality-of-care measures to government-sponsored healthcare insurance programmes for the elderly and poor and immunization service and certain disease data to state and local public health programmes, using national information standards (HealthIT.gov 2013).

Analysis and management of surveillance data

Data analysis

Uses of surveillance data begin with descriptive analyses according to the basic epidemiological parameters of time, place, and person, including the use of standard tests for statistical significance. Typically, public health surveillance data are completed, summarized, and reported over specified time intervals (days, weeks, months, or years) and for specific geopolitical jurisdictions (cities, counties, states, provinces, nations, etc.). Incidence or prevalence rates can be calculated using various population denominators, typically census data, and comparisons of rates over time or across geographic areas should be adjusted using standard methods to account for differences in population characteristics, such as differences in the age distribution of populations. The use of maps or graphics is common to illuminate differences in disease incidence or prevalence by time, place, or personal characteristics such as age or gender.

Analyses of trends are generally designed to determine whether current or recent levels of disease differ from levels that would be expected based on historical precedent, which may be defined over a period of years to days, depending on the availability of historical data and the epidemiology of different diseases or conditions. Detection of epidemics or evaluation of suspected epidemics is a key function of surveillance. Nonetheless, many epidemics are first recognized by astute healthcare providers who observe an

increase in disease occurrence, instead of being detected by surveillance systems, because the cycle of surveillance has not had time to detect an upturn. Even in such instances, however, surveillance can be useful to help assess whether recently observed cases of disease exceed expected levels. Surveillance is most likely to provide the initial recognition of potential epidemics in situations where cases are occurring over a sufficiently large geographic area or time period so that the increase would not be apparent to individual practitioners.

The key to discerning whether observed trends are in excess of expected trends is excluding the possibility of random variations or 'noise' in observed disease levels. One approach to resolving this dilemma is to employ various techniques to 'smooth' the data, especially for graphic displays of temporal trends (Devine and Parrish 1998), including the use of moving averages or the aggregation of data points into longer but still relevant time intervals (by week instead of by day or by month instead of by week). A spectrum of advanced analytic techniques for evaluating trends in surveillance data has evolved to model various types of historical trends, such as seasonal variations or long-term secular trends, to estimate predicted or expected levels of disease based on those trends, and to determine whether observed levels are statistically different from expected levels (Brookmeyer and Stroup 2003). The use of geographic information systems extends the traditional use of maps to display surveillance data by allowing for analyses that allow geospatial assessment of disease and locations of risk exposures or preventive or therapeutic services (Waller and Gotway 2004). Recognition of clusters of disease is common but often difficult to distinguish from random variation, giving rise to various statistical techniques to detect and characterize clusters (Kulldorff 1997). The increasing automation of the surveillance process, especially for systems of syndromic surveillance that track daily trends in disease and seek to detect changes in disease trends quickly, has spawned the development of statistical methods and computer software algorithms for automatic trend aberration detection, including techniques that are derived from cluster detection and industrial quality control methods (Burkom 2007).

Regardless of whether analyses involve straightforward descriptive statistics or advance modelling techniques, any analyses of surveillance data must take into account potential limitations of the data, including variations in their completeness, representativeness, timeliness, or data quality over

time or among different locations. Data quality reflects features and characteristics that ensure data are accurate and complete and that they convey the intended meaning. It refers to individual records and to data system. Data of high-quality improve the intended use in operations, decision-making, and planning. These are some of the data quality issues which might be encountered, including: poorly completed forms; under-reporting, over-reporting, and duplicate reporting; unsystematic data collection and untruthful reporting; inconsistent reporting formats/forms; inconsistent reporting periods, and calculation errors.

Aggregation of data

Surveillance data may be in the form of individual patient records or aggregate counts and tabulations. In some instances, there may be a need at the local level to maintain records on individual people to direct follow-up services but for regional or national reports to be in the form of aggregate counts. Individual-level data permit more flexibility of analysis than aggregate data. This can be useful when routine analyses raise questions that require more detailed analyses.

Linkage of surveillance data to other information sources

Given the complexity of establishing new data and information systems, there is increasing interest in the combination of existing databases for surveillance purposes. This allows the combination of information about individual case-patients from multiple sources. For example, linkage of birth certificates (which include the birth weight and information on other infant or maternal characteristics) and death certificates (which include information on the age and cause of death) allows determination of neonatal or post-neonatal deaths rates for infants in different birth weight or gestational age groups (Buehler et al. 2000). Linkage of HIV and tuberculosis records enables surveillance for the co-occurrence of these two infections (Ahmed et al. 2007).

Techniques involved in data linkage are based on comparing records from different information systems, assessing the likelihood that records from two different sources represent the same individual, and combining the data for those individuals whose records match (Clark 2004). In using linked record systems, assessments should be done to determine what proportion of linked

records do not actually represent the same individual and, conversely, what proportion of records should have been but were not correctly linked.

Data management

Critical to the ongoing nature of surveillance is the management of surveillance data, including the maintenance of historical data and procedures for incorporating new information into surveillance databases. Surveillance data often need to be updated. Information that was initially missing may become available; follow-up investigations may yield supplemental information; people initially classified as meeting or not meeting a case definition may be reclassified; errors may be identified and corrected; and duplicate case reports may be recognized and culled. One approach to handling these and other changes is to maintain both provisional and final records. Measures such as physical and technical protection for keeping surveillance data in confidentiality should be implemented.

Data reporting

The flow of information

All countries have laws or regulations that require the reporting of certain diseases by healthcare providers to a government agency. Regulations specify not only who must report and the list of diseases to report, but also how to report, how promptly, etc. In most jurisdictions, reporting is required from primary care provider, clinic, hospital, and/or sometimes the laboratory to local health agency, usually the district or subdistrict. The local health agency is usually responsible for case investigation and action as necessary. The local health agency forwards the report or numbers up to the up next governmental level (province or state or equivalent intermediate level), who then compile the data and forward the reports or numbers to national level-Ministry of Health (MOH). The MOH reports a few conditions required by IHR to the WHO. In turn, both WHO and most national MOHs produce reports or bulletins that get back to the lower levels.

Surveillance may rely on data acquired explicitly for surveillance purposes or on secondary uses of data obtained from existing information sources. Regardless, there is a flow of information throughout the surveillance process, which should be planned. For surveillance systems that

depend on reporting individual cases of disease or tabulations of disease counts, people responsible for reporting may be all or selected healthcare providers in a defined area, including laboratories. Reporters may also be asked to collect specimens needed by public health agencies for laboratory confirmation or characterization of specific diseases or exposures.

Surveillance systems collect and provide data on a regular basis, ranging from daily to annually or, in some instances, every few years when surveillance depends on information from surveys that are conducted intermittently. This periodicity should be specified. For surveillance of a given disease or condition, acceptable intervals between the occurrence of events of interest and the eventual availability of reports from surveillance systems will depend on the nature of the targeted condition and how data are needed and used to inform public health actions.

For the reporting, the '*zero reporting*' method should be used. It means that a 0 (zero) on the reporting form should be recorded when no cases of an immediately reportable disease have been diagnosed during the week. Submitting a zero for each immediately reportable disease when no cases were detected during the week tells the staff at the next level that a complete report has been filed.

Data transmission

The mode of data transmission will depend on both the need for timeliness and availability of resources. While reliance on postage of paper forms or facsimile transmission continues, there is growing use of telecommunications and the internet to transmit surveillance information. In places where internet access remains limited, the use of hand-held mobile devices and mobile telephones for data collection and transmission is growing. In 2012, the World Bank estimated that three-quarters of the world's population have access to a mobile telephone, providing a relatively inexpensive and widely available technology to improve access to health information and public health surveillance (World Bank 1993, 2012).

Dissemination of surveillance information

Communication of surveillance data is an essential step in the surveillance chain. Appropriate feedback must be given to those providing the data, such

as analyses that allow them to compare their experience to that of the community at large and other reports that enable them to see the value of the information resource to which they contributed. When appropriate, people or institutions providing the data should be credited for their contributions and acknowledged. Public health professionals, policymakers, or others who may be responsible for taking action or setting the direction of public health programmes in response to surveillance data must receive the information that they need from the surveillance system on a timely basis and in an appropriate format for their use. In addition, these data should be available as widely as possible to all who may be interested in analysis and interpretation of these data. Websites are increasingly used to disseminate surveillance data as with the US CDC's *Morbidity and Mortality Weekly Report* (http://www.cdc.gov/MMWR), the WHO's *Weekly Epidemiological Record* (http://www.who.int/wer), and the European *Eurosurveillance* (http://www.eurosurveillance.org/).

The data must be provided on a regular basis, with the frequency of surveillance reports commensurate with the nature of the surveillance system, the characteristics of the disease under surveillance, and information needs. To improve the timeliness of surveillance data, provisional or preliminary data may be released, with appropriate caveats, in advance of completion of more definitive reports.

The format for dissemination varies with the target audience; a creative design will help to make the information stand apart from other documents and receive greater attention. Most policymakers and clinicians would prefer to see the data interpreted using graphics that provide a quick visual image that highlights key observations, accompanied by an abbreviated summary text. The important role that graphs and maps can play in visually decoding large quantities of data has been clearly demonstrated, with graphic displays giving the reader an understanding of large and complex datasets not conveyed easily in other ways (Tukey 1977; Tufte 1983). In contrast, many epidemiologists and other scientists will find access to more detailed data to be most useful.

Evaluation of surveillance systems

Surveillance systems should be periodically evaluated to ensure that important public health problems are under surveillance, that the information

provided is useful, and that resources dedicated to surveillance are being used wisely. Such evaluations may include a mix of quantitative and qualitative assessments (CDC 2001, 2004; Silk and Berkelman 2005; Buehler et al. 2009). Evaluation may also be considered in a broader strategy of continuous quality assurance (Krause 2006). Reflecting the steps that are taken in establishing a surveillance system, an evaluation of a surveillance system should include a review of its objectives, a detailed description of its operation, an assessment of its performance using the surveillance attributes as a guide, and recommendations.

Samuel describes the main the attributes used to evaluate a surveillance system as the following:

Acceptability: Willingness of persons and organizations to participate in the surveillance system.
Cost-effectiveness: Relationship between the expected outcomes and the costs of surveillance to achieve these outcomes. Surveillance system costs include direct costs (personnel and material resources), indirect costs (resulting from preparedness and response to surveillance findings), and prevention benefits or costs from a societal perspective (e.g. effects of the information generated on decision making and population health).
Data quality: Completeness and validity of data in the surveillance system.
Flexibility: Ability of the surveillance system or its processes to adapt with little additional time or resources to changing epidemiology, information needs, technologies, or clinical practices.
Predictive value positive (PVP): Proportion of cases reported to the system that actually have the health condition under surveillance. For event-based surveillance, PVP represents the probability that a detected outbreak is of public health significance and requires response.
Representativeness: Ability of the system to accurately describe the occurrence of a health condition under surveillance over time and its distribution in the population by place and person.
Security: Processes and methodologies to keep surveillance data and information confidential, available, and accurate.
Sensitivity: Sensitivity of a surveillance system to (a) case detection (proportion of individuals who have the condition of interest), (b) outbreak detection (probability that the surveillance system will detect a significant increase in a health condition in time or space), and (c) case definition (ability of the case definition criteria to accurately represent the health condition of interest and classify the cases to which it is applied).
Simplicity: Structure and ease of operation of the system across the surveillance process cycle from data collection to use. Systems should be as simple as possible while still meeting their objectives.
Stability: Ability to collect, manage, and provide data without failure (reliability) and to be operational when needed (availability).
Standards use: Use of data exchange, messaging, or other information technology standards by a surveillance system that enhances the ability of the system and its software applications to communicate, exchange data, and use the information that has been exchanged.

Timeliness: Time between any two steps in the surveillance process. Steps in the surveillance process will vary by system. The relative importance of timeliness of surveillance process intervals varies by surveillance objective and health event under surveillance (Groseclose and Buckeridge 2017).

The attributes of public health surveillance systems are related to one another; strengthening one system attribute could adversely affect another attribute of a higher priority. Some attributes are more important for selected surveillance purposes and health outcomes than others. A recent systematic review of 99 articles examining animal and human health surveillance system evaluations identified 23 different attributes of surveillance systems (Drewe et al. 2012). Almost one-half of the evaluations assessed only one or two attributes; the attributes assessed most frequently were sensitivity, timeliness, and data quality. The investigators noted with some concern that surveillance objectives for the system being evaluated were often not stated, and therefore the rationale for assessing the selected attributes was not always evident.

Recommendations about the present state and future potential of surveillance system should be made based on conclusions. The conclusions should state whether surveillance is meeting its objectives and whether it is operating efficiently. Recommendations should be realistic, feasible, and clearly explained. Feedback to health facilities and stakeholders is important. Prioritizing plans and developing a timetable for surveillance improvements might be helpful (CDC 2012c).

Organizational structure

Surveillance systems require an organizational structure that defines the roles and responsibilities of participants in all stages of the surveillance cycle, including participants at different levels of government (local, state, regional, national, or international). This includes articulation of procedures for alerting those responsible for prevention and control activities when surveillance data identify situations that merit further attention, such as an upturn in observed disease incidence that might herald the onset of an outbreak.

Ethical issues in public health surveillance

As surveillance does not fall under the research, however, it may create some challenges on ethical issues. For surveillance, people have experienced legal, social, physical, and psychological harm after the public disclosure of health data. The collection of population-level health data can lead to mandatory quarantines, isolation of groups and individuals, and seizure of property. There is potential for intrusions of privacy and discrimination. Data that associate high HIV rates with particular communities, for example, can lead to stigmatization of members of those communities.

Surveillance, when conducted ethically, is the foundation for programmes to promote human well-being at the population level. It can contribute to reducing inequalities. WHO has developed guidelines on ethical issues in public health surveillance. This document can assist everyone involved in public health surveillance, including officials in government agencies, health workers, NGOs, and the private sector. The guidelines cover (i) the broad responsibility to undertake surveillance and subject it to ethical scrutiny; (ii) the obligation to ensure appropriate protection and rights; and (iii) considerations in making decisions about how to communicate and share surveillance data (WHO 2017). Ethical guidelines for surveillance address following topics: developing effective mechanisms for ethical surveillance dissemination; ensuring data are secure and collected only for legitimate health purposes; identifying and minimizing potential harms before surveillance; assisting countries' lack of adequate resources to undertake surveillance on their own; respecting values and concerns of communities in surveillance; communicating results of surveillance to relevant target audiences; ensuring that identifiable data are appropriately secured; and sharing data with all parties involved and other nations and international health agencies.

Public health surveillance in under-resourced countries: special considerations

General principles that underlie the practice of surveillance are essentially the same for all countries. These include the steps of system design and the principle of collecting and using information for action. Of interest, the revised IHR, which were adopted by the WHO in May 2005 and came into force in June 2007, provide a powerful mandate to strengthen surveillance

systems globally (Baker and Fidler 2006). However, information and other surveillance resources vary widely among countries.

Tracking disease trends, particularly infectious diseases, has been the main reason surveillance systems have been initiated in under-resourced countries. Surveillance data are also needed to establish rational public health priorities and to evaluate the impact of large-scale prevention and treatment programmes, such as those established for malaria, tuberculosis, and HIV/AIDS. Many infectious diseases and other conditions of public health import occur in settings with only rudimentary healthcare and few laboratory resources. With large-scale treatment programmes underway, the need for an adequate laboratory infrastructure has become even more critical, to assure that the treatment is appropriate, that diagnoses are accurate, that microbes are not becoming resistant to therapies, or that viral or bacterial strains represented in vaccines are not being replaced by other strains. Lack of definitive diagnoses may hinder surveillance and response efforts as well as resulting in inappropriate therapy and adverse consequences, such as increases in drug resistance.

The success of surveillance depends on having sufficient resources, the simplicity of reporting procedures, personal rapport among people in the network, regular feedback, and the visibility of actions taken in response to case reports or analyses of surveillance data. For example, programmes to eradicate polio make extensive use of surveillance to monitor progress and focus efforts towards reaching their goals. A major accomplishment of the polio eradication programme has been to develop an integrated global virological surveillance network to track the genetic profile and transmission patterns of circulating polio viruses (Pallansch and Sandhu 2006). Eradication programmes must rely on such highly targeted surveillance, which becomes more important (and expensive) as eradication of the target disease approaches.

In many under-resourced countries, the absence of an effective vital event registration systems for births and deaths shapes how surveillance is conducted. Use of the verbal autopsy, based on interviews to determine the cause of death, may assist in following mortality patterns in places without routine death registration (Kumar et al. 2006). The sensitivity of this approach in classifying causes of death may be lower for acute febrile conditions such as malaria, than for maternal deaths, injuries, tuberculosis, and AIDS. In addition, different techniques in conducting verbal autopsies

may result in different sensitivities of classifications for specific conditions (Setel et al. 2006). A potentially simple and rapid alternative to such mortality surveillance is to monitor severe morbidity through periodic surveys of hospitals for the number of admissions attributed to particular conditions. Again, the success of such surveys is largely dependent on the accuracy of diagnoses.

Other sources of health information may include UNICEF, WHO, international conferences, non-governmental organizations, and population laboratories (e.g. the International Centre for Diarrhoeal Disease Research, Bangladesh). Although some health problems are similar in many under-resourced settings, relying on data from other countries or districts can often create major problems when there are large geographical differences in the incidence of specific conditions.

The design of surveillance systems must consider the security and safety of surveillance staff, geography and accessibility, population dispersion and mobility, type of health system, and literacy. Problems (more common but not unique to under-resourced countries) may include limited personnel available for public health, coincident operation of multiple surveillance systems within a target population, lack of laboratory capacity, and infrastructure and communications constraints (e.g. lack of equipment, supplies, or electrical power).

Solutions to address the lack of personnel for public health and prevention have included voluntary systems (using community health workers, traditional birth attendants, or village volunteers). More familiar solutions are public health training programmes designed to meet human resource gaps. Concerns about the cost-effectiveness of short-term training have resulted in establishing long-term programmes to build capacity within countries. Applied field epidemiology training programmes have been applauded for boosting the number of trained personnel (Cardenas et al. 2002).

Concurrently, the increase in availability of computers to analyse and transmit surveillance data and the decrease in the cost of such technology offer increased opportunities for surveillance. Epi Info™ is a freely available computer program designed to assist public health data management and analysis (CDC 2013a); this tool has been used successfully in both well-resourced and under-resourced countries, and is available in multiple languages. Epi Info™ and other information systems should be seen as tools

to be used to provide data to policymakers and others to inform decisions that will improve health. The use of mobile phones and hand-held devices is proving useful in many areas. By leveraging the availability of mobile telephone networks and international telecommunication systems, few additional resources are needed to provide for collection of information and for two-way exchange of information needed for response.

Conclusion

Public health surveillance is a continued watchfulness over health-related problems through systematic collection, consolidation, and evaluation of relevant data. Public health surveillance has historically galvanized and guided prevention and control programmes for infectious diseases, ranging from smallpox eradication, immunization campaigns to prevent childhood diseases, programmes to prevent HIV infection and AIDS, and responses to emergent diseases such as SARS or pandemic influenza. Surveillance has also taken on increased visibility and importance in evaluating and guiding prevention and control efforts for a broad spectrum of non-infectious diseases and conditions. Surveillance provides a stimulus to keep prevention and control activities moving in the right direction, guiding the response to individual cases as well as public policy.

Effective public health interventions depend upon a continuing and reliable source of information; resources should be allocated for the maintenance of the surveillance systems and for their regular evaluation. The data must be timely and representative of the population; they must be analysed and interpreted with feedback to the reporters and disseminated as widely as possible, including to those formulating and implementing public health policy. Allocation of resources devoted to surveillance for the purpose of informing prevention and control activities must be balanced with resources needed to implement those activities.

Life course epidemiology and analysis

Elizabeth Rose Mayeda, Alexandra M. Binder, and Lindsay C. Kobayashi

Introduction

Life course epidemiology primarily aims to understand disease aetiology, with the goal of identifying effective strategies to promote population health and health equity. Successful interventions must be delivered at the right time in a person's life, and life course epidemiology focuses on evaluating how exposures at different periods of life may have different effects on subsequent health outcomes. The integration of a life course approach to epidemiologic research is central for identifying effective policies and population-level interventions to promote population health and health equity. In this chapter, we summarize conceptual models in life course epidemiology, discuss causal inference, biological mechanisms, and areas of innovation in life course epidemiology, and we close with future directions in life course epidemiology.

Conceptual models in life course epidemiology

Life course epidemiologic research is guided by conceptual models developed by Kuh and Ben-Schlomo that describe how the timing of exposure to a risk or protective factor influences health later in the lifespan (Ben-Shlomo and Kuh 2002; Kuh et al. 2003; Ben-Shlomo et al. 2016). We illustrate major conceptual models here with directed acyclic graphs (DAGs). We distinguish between models, all of which assume there is at least some effect of exposure on health: the immediate risk model, the trajectory, or chains of risk model, the critical and sensitive periods models, and the cumulative risk model.

In the *immediate risk model*, the exposure has an immediate effect on health; after the exposure is removed, the risk of the health outcome starts to decline (Fig. 5.18.1a). Examples of the immediate risk model include household firearm ownership and suicide rates among youth and adults (Siegel and Rothman 2016; Knopov et al. 2019), use of benzodiazepines and risk of falls among older adults (Díaz-Gutiérrez et al. 2017), and the effects of shift work and night work on workplace accidents and car accidents following night work shifts (Kecklund and Axelsson 2016).

In the *trajectory model* (also called 'chains of risk model'), the exposure trajectory is 'sticky': exposure at each life course period sets the stage for exposure at the next life course period. The initial insult does not directly harm health later in life, but the first exposure leads to subsequent exposures that directly affect health. Figure 5.18.1b illustrates an immediate risk and trajectory model, where the exposure in childhood and early adulthood do not directly influence midlife health, but exposure in childhood influences exposure in early adulthood, which in turn influences exposure in midlife. An example of the trajectory model would be if health behaviours established in childhood influence adult health only via influencing health behaviour patterns in adulthood.

In the *cumulative risk model*, each exposure period has an independent effect on health (Fig. 5.18.1c). This can occur with or without a trajectory model, where the exposure is 'sticky'. Note that Figure 5.18.1c displays a cumulative risk with trajectory model, as exposure at each life course period has an independent effect on the health outcome as well as exposure at the subsequent life course period. For example, socioeconomic position tends to be 'sticky' across the life course, and indicators of socioeconomic position at each life stage (e.g. early life, mid life, later life) may also have independent effects on health outcomes in later life. Using data from the US Health and Retirement Study, Marden et al. observed results consistent with the cumulative risk model for indicators of socioeconomic position at three life periods in relation to later-life memory function and decline (Marden et al. 2017). Testing the cumulative risk model can pose some challenges to causal inference, as illustrated in their study: confounders of any mid- or later-life exposure that arise from early-life exposure may also mediate effects of early-life exposure on the health outcome (often referred to as 'time-dependent confounder-mediators'), and statistical adjustment for these variables could bias estimated effects of the exposure on the outcome. This

challenge can be addressed by strategies such as inverse probability weighting to block the confounding effect of the confounder-mediator variable on the mid- or later-life exposure, without blocking its mediating effect on the early-life exposure to outcome relationship (Robins et al. 2000; McCulloch 2015).

In practice, the terms ‘sensitive period’ and ‘critical period’ are often used interchangeably, but they are conceptually distinct. We use the same DAG to illustrate both models (Fig. 5.18.1d). In the *sensitive period model*, an exposure during a specific life course period has a particularly strong influence on certain aspects of health. During other periods, the exposure has a weaker impact on health. For example, the Moving to Opportunity (MTO) for Fair Housing Demonstration Program was a randomized trial in the United States in the 1990s that randomly assigned families living in high-poverty public housing projects to receive subsidized housing vouchers to move to lower-poverty neighbourhoods (Leventhal and Brooks-Gunn 2003). Chetty et al. (2016) examined the impact of moving to a lower-poverty neighbourhood on children’s long-term outcomes using tax records and found that moving to a lower-poverty neighbourhood at younger ages, particularly before age 13 years, increased college attendance and earnings in adulthood, and reduced single parenthood rates. These findings suggested that childhood is a sensitive period for the impact of neighbourhood and long-term outcomes. Another randomized controlled trial that was influential in identifying sensitive early childhood periods for cognitive and behavioural development is the Bucharest Early Intervention Project in Bucharest, Romania. Beginning in the year 2000, this study randomized infants and toddlers living in institutions who were abandoned at or soon after birth to move to foster care (treatment) or to remain in institutional care (control) (Zeanah et al. 2003; Nelson et al. 2007; Black et al. 2017). Other examples of evidence for childhood and adolescence as sensitive periods includes studies of age at arrival and later-life health outcomes among immigrants to the United States (Roshania et al. 2008; Osypuk et al. 2015a).

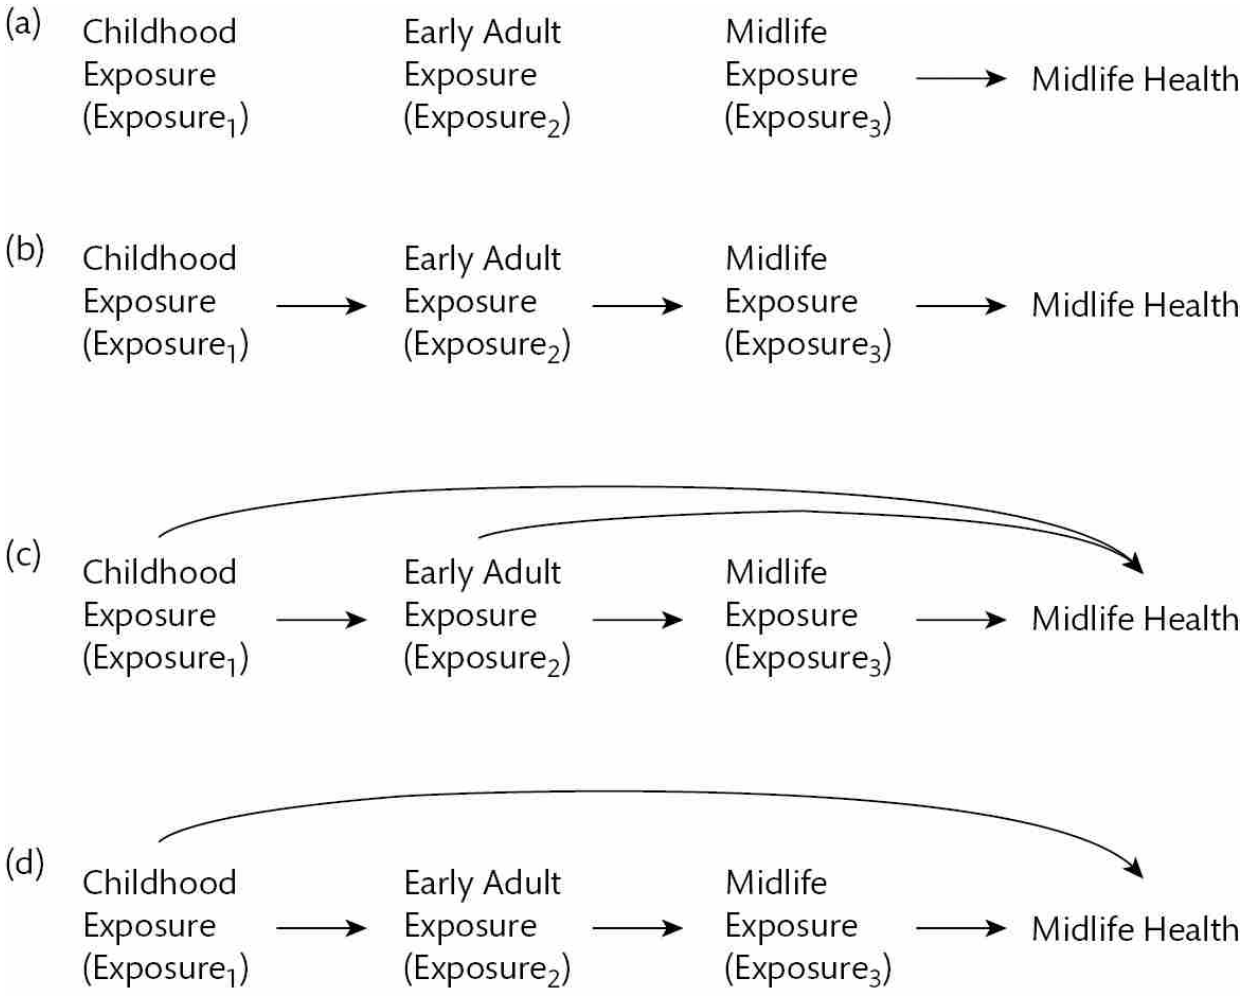

Fig. 5.18.1 Life course models: (a) Immediate risk model; (b) Immediate risk and trajectory model; (c) Cumulative risk and trajectory model; (d) Childhood critical/sensitive period and trajectory model.

An essential aspect to defining a sensitive period is distinguishing it from the induction period. The induction period refers to the time between exposure and the initiation of the disease process. To disentangle these mechanisms, investigators must consider time since exposure separate from the life course milestones that are hypothesized to define the sensitive period. This may be difficult if study recruitment is defined by the postulated sensitive window. It is also important to bear in mind that the induction period may impact the degree to which a sensitive window can be detected in a specific study. As an example, consider a hypothetical investigation of the association between gestational hypertension and cardiovascular disease (CVD) among the subset of parous women in a large established cohort. We will assume the investigators found that gestational hypertension during first

pregnancy was associated with modestly elevated risk of CVD in the 10-years following that pregnancy, but a substantially elevated risk of CVD in the 40-year incidence of CVD. These results would suggest that the induction period for the influence of gestational hypertension on CVD is, on average, longer than 10-years. However, these results do not reveal whether the association between hypertension and CVD is stronger when hypertension occurs during pregnancy versus hypertension during other life course periods. The association between hypertensive disorders of pregnancy, such as preeclampsia, and subsequent CVD has been well-replicated across observational studies (Garovic et al. 2010; Tooher et al. 2017; Ying et al. 2018). One theory behind this relationship is that hypertensive disorders of pregnancy may be an early indicator of a reduced capacity to accommodate cardiometabolic stress (Sattar and Greer 2002). Correspondingly, women with hypertensive disorders of pregnancy have a much higher risk of future hypertension (Tooher et al. 2017; Ying et al. 2018). Regardless of whether gestational hypertension has a stronger association with CVD incidence than hypertension during other periods of the life course, it does characterize a high-risk subgroup of women who could potentially benefit from early CVD prevention and screening efforts.

The *critical period model* is a more stringent form of the sensitive period model that assumes that an exposure has a specific impact on disease aetiology during a discrete life course period. Outside of that timeframe, the exposure has little to no impact on that facet of the disease process. Classically, critical exposure windows have been suggested to overlap with periods of developmental plasticity, such as during gestation, early childhood, puberty, and adolescence. For this reason, this model has often been considered synonymous with the concept of ‘developmental programming’ and the Developmental Origins of Health and Disease hypothesis (Barker 1995; Barker 2012), which is discussed later in the chapter. A recent example of the critical period model is a study in California that documented a harmful association between prenatal exposure to ambient fine particulate matter exposure and risk of preterm birth, results which highlighted specific gestational periods of vulnerability in mid and late gestation (Sheridan et al. 2019).

An important nuance to the critical period model is that a particular exposure can influence distinct aspects of the disease process during different life course periods. This is exemplified in the association between

body size and breast cancer risk, which differs across life course periods. Prior to menopause, women with an adult body mass index (BMI) classified as overweight or obese have a modestly decreased risk of breast cancer incidence compared to those with a BMI in the normal weight range (van den Brandt et al. 2000; Reeves et al. 2007). In contrast, after menopause, women with a BMI in the overweight or obese range have a modestly increased risk of breast cancer incidence relative to those with a BMI in the normal weight range (van den Brandt et al. 2000; Reeves et al. 2007). Distinct from the associations observed earlier, greater body fatness during adolescence is associated with decreased risk of both pre- and postmenopausal breast cancer, independently of adult BMI (Baer et al. 2005; Bardia et al. 2008; Baer et al. 2010).

Identification of the appropriate life course model for a given research question should be grounded in theory and relevant prior literature. If the researcher believes there is theoretical motivation that more than one life course model may be appropriate for their research question, alternative life course models can be evaluated empirically. In practice, it can sometimes be challenging to differentiate between the effects of age of onset of an exposure (reflecting a sensitive period model) and duration of exposure (reflecting a cumulative risk model) unless an analytic strategy is adopted to evaluate the extent to which the data are consistent with these two alternative models. For example, multiple studies have reported a harmful association between hypertension in midlife and later-life cognitive health (Kivipelto et al. 2001; Whitmer et al. 2005; Knopman et al. 2009; Debette et al. 2011). Power et al. (2013) evaluated whether the association between hypertension in midlife and later-life cognitive function reflected age at onset (sensitive period model) or duration of exposure (cumulative risk model) in the Normative Aging Study, a cohort study of men living in the greater Boston area. The authors found that age at onset of hypertension was not associated with cognition independent of duration, providing support for the cumulative risk model for the association between hypertension and later-life cognitive health (Power et al. 2013).

What are the goals of life course epidemiology?

Research questions in analytic epidemiology can be broken down into two broad categories: predictive research questions and causal research

questions. Life course epidemiology can include both research focused on predictive questions (e.g. does birth weight predict attained height in adulthood?) and research focused on causal questions (e.g. does exposure to maternal cigarette smoking *in utero* influence behavioural and cognitive outcomes in children?). Most research questions in life course epidemiology studies aim to draw causal inferences from the data, and throughout the rest of the chapter, we assume causal inference is the goal. The goal of drawing causal inferences in life course research is to identify the determinants of states of disease and health, in order to provide evidence towards identification of effective strategies to intervene and promote population health and health equity. Researchers should keep their research goal in mind when specifying research questions, designing studies and selecting analytic tools, and considering the strengths and limitations of their approach.

For example, a life course perspective can be taken when trying to identify effective strategies to prevent Alzheimer's disease and related dementias, a major public health challenge (Brookmeyer et al. 2007; Hebert et al. 2013). Clinical onset of dementia typically occurs in later life, but mounting evidence suggests that dementia-related brain pathology begins developing many years—likely decades—prior to clinical onset (Alzheimer's Association 2019). This conceptualization of the disease process suggests the optimal time to intervene to prevent development of dementia-related pathology is in early or mid life. Alternatively, if the researcher aims to identify factors that contribute to resilience to cognitive decline in the presence of dementia-related pathology, they may consider how exposures at different points in the life course may help buffer against the functional consequences of dementia-related pathology to prevent or delay cognitive decline and the onset of cognitive impairment.

Causal inference in life course epidemiology

Distinguishing between alternative conceptual models is important because these models have implications for designing interventions and prioritizing resources. Under all but the 'immediate risk' model, intervening to change exposure in childhood would provide the greatest benefit to improve adult health outcomes. Under the cumulative risk model, it is not possible in adulthood to completely remediate the consequences of childhood exposures. Under the critical or sensitive childhood period models,

intervening to improve exposure in adulthood has no effect on adult health. Causal inferences about life course exposures, especially when disentangling alternative conceptual models, are often challenging. More details about inference in epidemiology can be found in Chapter 5.14.

An essential, but frequently overlooked step in conducting meaningful research is to clearly define the research question. The counterfactual contrast of interest and appropriate methods to estimate the counterfactual contrast depends on the research question. This critical first step of causal inference was clearly articulated by Kaufman and Hernán (2012): 'No method is so sophisticated that it can relieve the investigator of the obligation to provide a well-formulated causal question in the first place.' Once the research question is clearly defined, major threats to internal validity in life course epidemiology include confounding, collider-stratification bias, measurement error, and reverse causation.

Bias arising from confounding from unmeasured (or poorly measured) common causes of the exposure and outcome of interest is a major concern in observational epidemiology (Fig. 5.18.2a). Clearly specifying the assumed causal structure relevant to the research question of interest using DAGs can help guide researchers towards identifying and controlling for potential confounders in a given study. Time-dependent confounder-mediators (introduced under the cumulative risk model description earlier in the chapter) are of special relevance in life course epidemiology.

Collider-stratification bias arises from conditioning on a common outcome of the exposure and the outcome of interest and related causal structures (Fig. 5.18.2b) (Hernán et al. 2004). In life course epidemiology, a special case of collider-stratification bias, called 'survival bias', can arise from conditioning on survival when the exposure of interest and the outcome of interest are correlated with survival. Survival bias is potentially relevant across the life course, as it is relevant to studies estimating the effects of prenatal exposures on health after birth (Liew et al. 2015) as well as research estimating effects of life course exposures on later-life health (Mayeda et al. 2018a; Mayeda et al. 2018b).

Reverse causation refers to when an exposure-outcome association arises from the outcome of interest influencing the exposure of interest (instead of vice versa) (Fig. 5.18.2c). The aetiology of many chronic diseases may begin years before onset of clinical disease. Often, the latency period (i.e. subclinical period following exposure) is unknown. As a result, it can be

difficult to rule out reverse causation as a potential explanation for an observed exposure-outcome association or identify the relevant life course period in which to intervene on the exposure to prevent disease. For example, reverse causation is an important concern for research on determinants of Alzheimer's disease and related dementias because of the long latency period (Singh-Manoux et al. 2017; Singh-Manoux et al. 2018).

Measurement error, including error in measurement of exposures, outcomes, confounders, and mediations, present a major challenge in life course epidemiology (Fig. 5.18.2d). Clearly defining the construct of interest is an important first step in identifying an appropriate measure of the construct. Inadequate measurement can result in conceptual inadequacy (i.e. the researcher asks a vaguely defined question and, as a result, the study yields a meaningless answer). Inadequate measurement can also result in missing data because research participants do not know how to answer or will decline to answer the interview items. If interview items are worded in such a way that most participants provide the same response regardless of their true level of the construct being measured, the study measures will have poor variability. Inadequate measurement can also result in poor validity and reliability (i.e. the measurements do not align with the underlying construct the researcher aims to measure or the study measure measures the underlying construct with a high degree of error). Given that life course epidemiology often seeks to estimate effects of exposures or requires control for potential confounders that precede the study period, measurement error is a major concern in life course epidemiology. Validation studies are a useful tool to validate study measures and to provide data to support useful quantitative bias analysis (Osypuk et al. 2015b; Niesner et al. 2013; Lash and Olshan 2016; Hinkle et al. 2017; Luke et al. 2018).

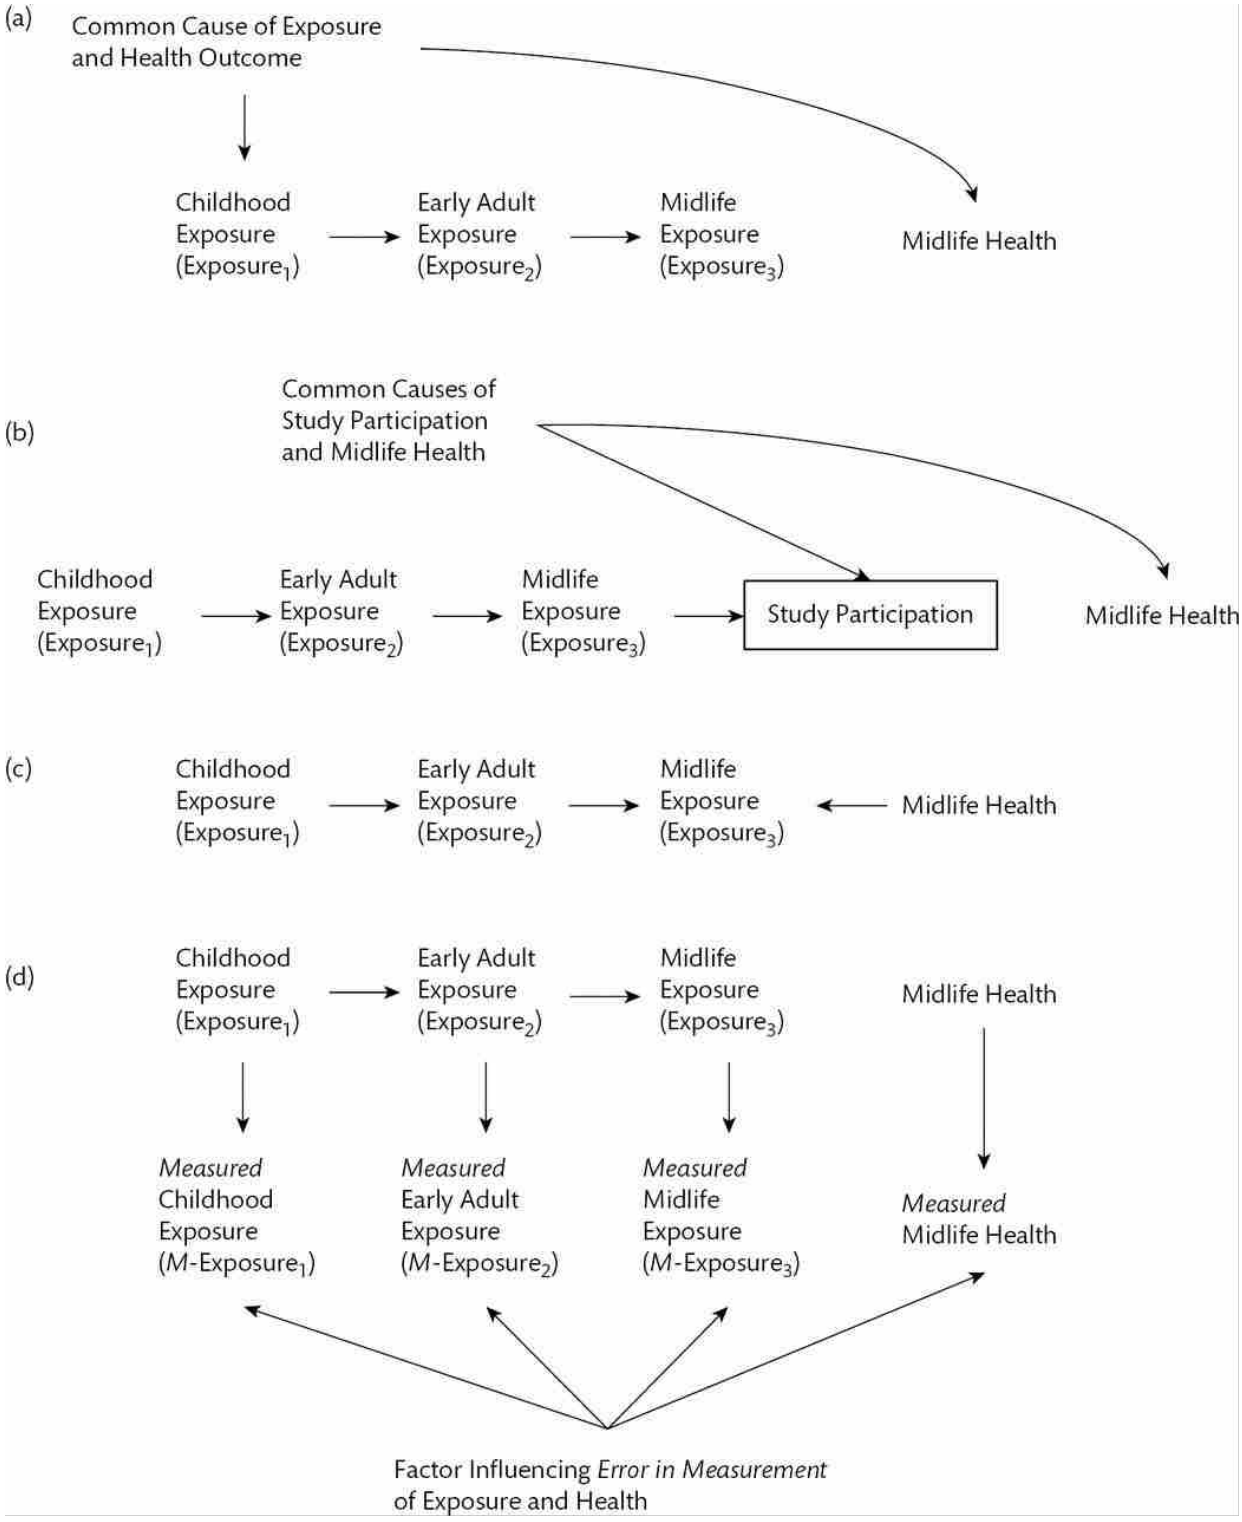

Fig. 5.18.2 Examples of sources of bias in life course epidemiology studies. Note that in all examples, there is no effect of the exposure of interest at any life course period on midlife health, but confounding, collider-stratification bias, reverse causation, or measurement error induce a spurious association between the exposure of interest and outcome of interest: (a) confounding: a common

cause of exposure the health outcome confounds the association between the exposure of interest and the health outcome of interest; (b) collider-stratification bias: the exposure of interest and determinants of the health outcome of interest both influence study participation; (c) reverse causation: the health outcome of interest influences the exposure of interest; (d) measurement error: error in measurement of the exposure of interest and health outcome of interest are correlated.

In addition to threats to internal validity, generalizability (extending study results from the analytic sample to the target population of inference) is also an important challenge, as the target population of inference almost always differs from the study sample in life course research (Lesko et al. 2017; Westreich et al. 2017; Stuart et al. 2018). A researcher may aim to generalize results to a larger target population with different distributions of socioeconomic and health characteristics than their study sample. For example, a researcher may wish to generalize results from a US-based multisite cohort study established in 2010 to the general US population in 2010. It may also be of interest to generalize results across time periods, for example, generalizing results from a national cohort study in the United Kingdom conducted in 1960 to the United Kingdom general population in 2020. For social exposures, there is potential for the correspondence between measures and constructs to differ across time and place. For example, Hayward and Gorman's influential paper 'the long arm of childhood' found that early-life social factors were powerful predictors of mortality in mid- to late-life in US men born in the early twentieth century (Hayward and Gorman 2004). One early-life social factor that was associated with elevated mortality in adulthood was having a 'mother working outside the home', which was likely a marker of early-life socioeconomic adversity in the early twentieth century, rather than representing the 'effect' of having a mother who worked outside the home. Markers of socioeconomic status are not necessarily constant across place and time, which should be considered in life course epidemiology.

Methods for drawing causal inferences using observational data are essential in life course epidemiology, and common tools such as DAGs clearly represent the challenges. DAGs are a widely used tool in epidemiology for visually encoding assumptions about causal relations among the exposure, outcomes, and covariates (Glymour 2017). DAGs can be particularly helpful in distinguishing between covariates that represent potential confounders (i.e. variables that represent common causes of the effect of exposure on the outcome) and covariates represent potential mediators (i.e. variables that are on the causal pathway of interest). Clearly

differentiating between potential confounders and mediators helps researchers plan analytic strategies accordingly. Often, several life course models may seem plausible for a given research question, but different life course models have inconsistent empirical predictions, so empirical research results based on analyses with clearly articulated assumptions can provide evidence on which is most plausible for each outcome in a given target population.

A major study design challenge in life course epidemiology is that the length of follow-up required to collect information across the human lifespan or in the case of research across successive generations, multiple human lifespans. As a result, many life course studies that use data from cohorts established in mid-to-later life but wish to examine early-life exposures must rely on retrospective collection of exposures. For example, a researcher may wish to estimate the effects of childhood exposures on health in late life in a given target population using a cohort where study participants were enrolled at ages 65 years and older. In this case, measurement error in the exposure is a major concern, as the researchers may need to rely on retrospective reporting of early-life experiences that occurred many decades prior to the time of the study. Additionally, researchers would be estimating the effects of early-life exposures on the late-life health outcomes among the people who survived to late-life. If the exposure influences survival, collider-stratification bias may arise from conditioning on survival to late life (Mayeda et al. 2018a; Mayeda et al. 2018b).

Biological mechanisms in life course epidemiology

Understanding the biological mechanisms driving the association between life course exposures and later-life health can inform the development of successful interventions to promote population health and health equity. In this section, we discuss several areas of active research advances on the biological mechanisms in life course epidemiology.

Embodiment

Embodiment refers to the processes through which our bodies physically incorporate aspects of the material and social world in which we live throughout the life course (Krieger 2005). These exposures ultimately manifest as states of health or disease; they ‘get under the skin’ to affect

human physiological systems and influence risks of health outcomes (Marmot and Wilkinson 2001). Embodiment is a core concept of the ecosocial theory of disease distribution, an influential epidemiologic theory that explicitly frames how social experiences become biologically embedded (Krieger 2005; Krieger 2011). Ecosocial theory posits that there are multiple, non-mutually exclusive pathways of embodiment that occur across spatial and temporal scales to shape the distribution of health and disease outcomes in a population (Krieger 2011). The concept of embodiment has explicitly informed some hypotheses in social epidemiologic research, such as the role of historical trauma in physical health outcomes among American Indians and Alaska Natives, the causes of US racial disparities in CVD, and gender differences in autism spectrum disorder (Gravlee 2009; Walters et al. 2011; Cheslack-Postava and Jordan-Young 2012). Many life course and social epidemiologic studies implicitly use the construct of embodiment by assuming that material and social exposures have biological effects on human bodies that result in health and disease outcomes. Embodiment inherently takes a life course perspective, as it refers to how material and social conditions across the life course lead to biological processes that ultimately result in population patterns of health and disease.

Developmental Origins of Disease hypothesis

The Developmental Origins of Disease hypothesis posits that the prenatal and early postnatal environments shape health and disease throughout the life course (Barker 1995; Barker 2012). A key theory underlying this hypothesis is that the developing body adapts to the prenatal and early postnatal environment to maximize use of available resources and minimize harm from exogenous insults. This developmental programming can persist through cell divisions to shape adult phenotypes and how the body responds to the environment across the life course. In a seminal paper in life course epidemiology, Barker reported that foetal undernutrition in middle to late gestation, which leads to disproportionate foetal growth, programmes later coronary heart disease risk (Barker 1995). Findings from research studies following people exposed to the Dutch Hunger Winter of 1944–1945 further highlighted the negative health implications of prenatal nutrient deprivation (Painter et al. 2005). A severe food shortage caused during the German occupation of the Netherlands created a tragic natural experiment of the effect of prenatal exposure to famine and health throughout the life course

(Painter et al. 2005). Among a number of adverse health impacts, offspring that were exposed to the famine during early gestation had normal birth weights, but an increased risk of obesity during adulthood (Ravelli et al. 1999). A more recent extension of the Developmental Origins of Disease hypothesis extends beyond one individual's lifespan to include intergenerational transmission of risk of life course health and disease (Barker 2012).

Epigenetic modifications

Epigenetic modifications are frequently proposed to contribute to the delayed or enduring effects of exposures on chronic disease outcomes (e.g. sensitive or critical periods). Epigenetics refers to stable, mitotically heritable regulation of gene expression that is not due to changes in the DNA sequence (Berger et al. 2009). Epigenetic modifications, such as DNA methylation, non-coding RNA, and histone modifications, can influence gene expression pre-transcriptionally (e.g. by altering DNA accessibility and chromatin structure) and/or post-transcriptionally (e.g. by targeting specific transcripts for degradation). The public health interest in the epigenetic programming of chronic disease is driven by three general characteristics of these modifications: their role in shaping development, their supposed temporal stability, and their responsiveness to environmental cues. Together, these characteristics promote the hypothesis that epigenetic modifications mediate the influence of exposures during critical periods of development on adult health. Studies of families exposed to the Dutch Hunger Winter, described earlier, generated some of the first evidence that prenatal famine exposure could have a lasting influence on epigenetic patterns (Heijmans et al. 2008; Tobi et al. 2009). Compared to unexposed same-sex siblings, individuals exposed to famine periconceptionally had lower DNA methylation within the imprinting control region of the insulin-like growth factor II *(IGF2)* gene in whole blood collected six decades later (Heijmans et al. 2008). IGF2 plays an essential role regulating gestational growth and development, and deviation from normal expression patterns is associated with major health implications (Bergman et al. 2013).

There are several complications to establishing the role of epigenetic patterns in disease aetiology (Michels et al. 2013). Many of the determinants of epigenetic patterns are still being identified, making observation studies integrating epigenetic analysis particularly susceptible to unmeasured

confounding. Like any biomarker study, effect estimates can be greatly impacted by batch effects, which can arise due to a number of factors, including variability in sample collection, processing, storage, and technical artefacts in the biomarker assay. All somatic cells in the body are genetically similar, but the epigenome differs by cell type (Roadmap Epigenomics Consortium et al. 2015), making these studies particularly sensitive to the choice of tissue assayed (Jaffe and Irizarry 2014). Generally, an exposure is assumed to influence disease risk by modifying gene regulation in a particular 'target' tissue. For example, we might expect that ambient air pollution impacts the incidence of respiratory disease by modifying gene regulation in lung tissue. If it is not feasible to assay epigenetic patterns within the target tissue, it may not be possible to capture the contribution of epigenetic modifications to the disease mechanism. In most established cohorts, often the only biospecimen collected is whole blood, which is still a heterogeneous mixture of cell types. An essential preliminary question for researchers seeking to integrate epigenetic analysis into their study questions is whether they will be able to assay the hypothesized target tissue or a surrogate tissue that captures shared variation with the target tissue. If the answer is no, and the goal is to understand the disease aetiology, the study might not be worth pursuing. However, if the intent is to identify a non-causal biomarker of exposure or subclinical disease, the study may have merit.

Epigenetic epidemiology is a young field, and many other challenges in the conduct of these studies are logistical (e.g. cost of assaying genome-wide epigenetic variation, statistical methods for integrating multiple types of epigenetic modifications into the analysis) and will evolve with time. In spite of these challenges, the capacity of epigenetic epidemiology to provide insight into the lasting effects of exposures on health motivates the continued expansion of the field. An area of growing interest and debate is whether exposures during an individual's lifetime can exert intergenerational or transgenerational effects on offspring through epigenetic mechanisms. Transgenerational inheritance refers to the transmission of acquired traits to offspring (Walker et al. 2018). In contrast, intergenerational effects occur when multiple generations are directly exposed during critical windows of susceptibility. For example, maternal grandmother's exposures during pregnancy (F0), could exert intergenerational effects on the traits of the developing foetus (F1; child) and the germline of that foetus (F2;

grandchild). One illustration of these intergenerational associations observed in prospectively collected Swedish nationwide registries is the increased risk of asthma among children whose grandmothers smoked cigarettes during pregnancy, controlling for maternal smoking behaviours (Bråbäck et al., 2018; Lodge et al. 2018). Transgenerational inheritance is difficult to prove because it requires at least three generations away from gestating female exposure, and two from either non-gestating female or male exposure to prove it is not a direct intergenerational effect of the exposure (Heard and Martienssen 2014; van Otterdijk and Michels 2016). To date, the degree to which epigenetic information can be conveyed across generations is still unclear in humans (Heard and Martienssen 2014; Perez and Lehner 2019).

Biological age

Most research in life course epidemiology considers chronological age as a measure of the ageing process, but developing accurate measures of biological age is an active area of research. Biological ageing has been conceptualized as acquired changes to cell function, based on extensive epidemiologic and experimental evidence that gene regulation is sensitive to exposures across the life course. There are several postulated measures of biological ageing that are shown to predict health outcomes independently of chronological age, including telomere length (Müezzinler et al. 2013). More recently, researchers have started to use specific variations in DNA methylation to estimate ‘epigenetic age’, which has been consistently associated with mortality and age-related diseases across cohorts, independent of chronological age (Horvath and Raj 2018). These ‘epigenetic clocks’ have been shown to be responsive to changes in environmental exposures, health-related factors, and social and behavioural factors (Horvath et al. 2014; Quach et al. 2017; Nwanaji-Enwerem et al. 2017). While current biological ageing markers require further validation, they could represent a major advance in life course epidemiology by allowing investigation of life course determinants of discrepancies between chronological age and biological age.

Biomarkers in life course epidemiology

An important consideration in life course epidemiology utilizing biomarkers is whether the life course period represented by biomarkers aligns with the

life course period the researcher aims to measure for their research question. For example, if researchers are interested in estimating health effects of lead exposure in adults and wish to identify an appropriate biomarker of lead exposure, they must first consider the lead measure most representative of their lead exposure of interest. For example, researchers might be interested in the acute health effects of recent lead exposure or they might be more interested in the health effects of cumulative lead exposure over decades. Selection of the optimal biomarker of lead exposure for a given research question should be guided by the life course exposure the authors seek to measure to address their research question. Circulating blood lead levels capture recent external lead exposure and lead that has been mobilized from tissue stores, primarily from bone tissue (Hu et al. 2007). Mobilization of lead from bone stores is particularly relevant during life course periods of high bone resorption (i.e. pregnancy and ageing) (Hu et al. 2007). Repeated measures of blood lead levels over time can be used as a proxy for cumulative exposure to lead over the time period for which blood lead levels were measured, but such repeated measures are rarely available, with the exception of some occupational cohort studies (Hu et al. 2007). Bone lead levels measured in the tibia or patella bones are considered an indicator of cumulative dose of lead over decades (Hu et al. 2007), with lead levels measured in the tibia considered to represent a longer time period of exposure than patella bone lead (Wilker et al. 2011; Power et al. 2014).

Often, researchers aim to evaluate the long-term influence of exposures during life course periods that occurred prior to the study period. An example of researchers taking advantage of sensitive periods to improve measurement is research on the effects of childhood net nutrition on later-life health outcomes. Net nutrition is determined by the net of nutritional intake and diarrheal or other diseases that affect the intake and absorption of nutrients (Perkins et al. 2016). This is an exposure that may have implications for adult health, particularly in low-income settings where poor early-life nutrition is common in the population. However, childhood nutrition cannot be measured directly in a cohort study that begins after adolescence. A solution that life course epidemiologists have taken is to use adult height as a biomarker to investigate the later-life health outcomes associated with cumulative net nutrition during growth periods in childhood. In early life, net nutrition cumulatively influences height during two growth periods that determine adult height: from conception to approximately two

years of age, and during early adolescence (Perkins et al. 2016). A range of studies using adult height as a marker of net nutrition during sensitive growth periods in childhood have shown inverse associations between adult height and health outcomes such as CVD, stroke, later-life cognitive function, and Alzheimer's disease and related dementias, as well as suicide and all-cause mortality (Magnusson et al. 2005; Schnaider Beeri et al. 2005; Lee et al. 2009; Nüesch et al. 2016; Kobayashi et al. 2019). An important methodological point is that, in studies with older populations, measurements of height may need to account for ageing-related shrinkage, although some research has indicated that statistical adjustment for age in regression modelling is often sufficient to account for shrinkage (Fernihough and McGovern 2015). These studies, whether explicitly or implicitly, use the sensitive life course model because they use adult height as a biomarker of cumulative net nutrition during sensitive growth periods in childhood growth periods. This approach allows for the investigation of an early-life exposure that otherwise could not be investigated in studies of adult health.

Areas of methodological innovation in life course epidemiology research

Causal inference methods

Life course epidemiology largely relies on observational studies. To provide the best evidence for understanding life course mechanisms influencing health and disease, causal inference methods provide useful tools for ameliorating potential sources of bias in life course epidemiology. The adoption of causal approaches to mediation analysis and effect decomposition (Vanderweele 2015) are potential boons for life course epidemiology, although uptake in many areas has been slow. As illustrated in the life course epidemiology models, causal mediation analysis is central to hypothesis testing in life course epidemiology.

Natural experiments are a useful causal inference tool to minimize threats to causal inference in traditional observational studies. Natural experiments mimic randomized controlled trials in that the mechanism determining each person's exposure is independent of their set of potential outcomes, but unlike a randomized controlled trial, treatment assignment is outside the control of researchers (Glymour et al. 2017). More detail about natural experiments and associated methods can be found in Chapter 5.10.

An example of ground-breaking work in life course epidemiology using a natural experiment is research on the health effects of exposure to the Dutch Hunger Winter of 1944–1945 (introduced earlier in the chapter). One of the most famous findings from this natural experiment link prenatal nutritional deficiency to risk of schizophrenia: the birth cohort conceived at the height of the famine had higher risk of schizophrenia up to midlife (Susser and Lin 1992; Susser et al. 1996). These findings were replicated in research on the Chinese Great Leap Forward famine of 1959–1961 (St Clair et al. 2005). A more recent natural experiment example includes a natural experiment in California, where researchers compared preterm births among mothers who lived near coal and oil power plants before and after eight power plants in California closed between 2001 and 2011 (Casey et al. 2018). They found that power plant retirements were associated with a decrease in the proportion of preterm births (<37 weeks' gestation) among mothers living nearby. For example, for mothers living within 5 km of the power plants, there was an estimated reduction in preterm birth from 7.0% to 5.1% (Casey et al. 2018).

An underutilized tool in life course epidemiology is the use of negative controls to evaluate potential bias in study findings by reproducing the original study with a 'negative control' exposure (or outcome) which cannot be causally associated with the original outcome (or exposure), but which is likely to involve the same sources of systematic bias (Lipsitch et al. 2010; Flanders et al. 2011; Arnold et al. 2016). A popular application of negative controls has been to assess bias due to unmeasured or uncontrolled confounding, although the method has been applied to assess the potential for recall bias, diagnostic bias, and selection bias (Suissa and Ernst 2005; Zaadstra et al. 2008; Ivers et al. 2015; Freedman et al. 2016; Matthay et al. 2017; Cohen et al. 2019; Liew et al. 2019; Hamer et al. 2019). Negative control studies can use negative controls for either the exposure variable or the outcome variable of interest. Here, we will discuss negative controls with respect to negative control outcome studies, although the same principles will apply to negative control exposure studies. In the case of a negative control outcome, it is assumed that the exposure does not have a causal effect on the negative control outcome. When used for the detection of bias due to unmeasured confounding, a key assumption of the method is that the negative control outcome (N) and the original outcome of interest (Y) share the same confounding structure with respect to the exposure of interest (A).

With confounders collectively referred to as U, this is referred to as the A-Y and A-N associations being ‘U-comparable’. When U-comparability or approximate U-comparability holds and measurement error in N is negligible (Lipsitch et al. 2010; Sanderson et al. 2018), any observed association between A and N indicates the presence of confounding bias in the A-Y association.

An applied example is the use of negative control outcomes by Hamer et al. (2019) to assess the potential of confounding bias in the association between physical activity and CVD mortality. A large body of observational evidence has indicated protective effects of moderate-to-vigorous intensity physical activity (MVPA) on CVD mortality, yet this association is subject to unmeasured confounding and is difficult to test using randomized controlled trials due to the long follow-up required to ascertain mortality as an outcome. Hence, Hamer et al. used data on 104,851 participants followed for an average of 9.4 (standard deviation: 4.5) years from the Health Survey for England and the Scottish Health Survey to determine whether unmeasured confounding could at least partially account for the observed association between MVPA and CVD mortality, using accidental death as a negative control outcome. In this example, the authors hypothesized no causal association between MVPA and accidental death, excluding specific causes of accidental death that could be related to physical activity (Hamer et al. 2019). They empirically confirmed the assumption of U-comparability by examining the confounding structures of the MVPA-accidental death (A-N) and the MVPA-CVD mortality (A-Y) relationships. After reproducing the analysis of the MVPA-CVD mortality relationship using accidental death as the outcome, the authors observed point estimates in the protective direction for both associations, although the MVPA-accidental death association was substantially weaker than the MVPA-CVD mortality association (hazard ratio = 0.85; 95% confidence interval: 0.54 to 1.38, and hazard ratio = 0.58; 95% CI: 0.49 to 0.68, respectively) (Hamer et al. 2019). After sensitivity analyses including the evaluation of dose-response relationships and alternative negative controls, the authors concluded that the effects of MVPA on CVD mortality are likely to be causal given the consistency and biological plausibility of the association and its robustness to negative control outcomes, but that the true effects are likely of smaller magnitude than previously reported in observational studies.

Other applications of the negative control method for other types of systematic bias involve variations on the method described earlier for the detection of uncontrolled confounding. The potential magnitude of recall bias can be empirically assessed using negative control exposure variables, by including 'probe' questions in research questionnaires about exposures that cannot be causally associated with the outcomes under study, but would be subject to the same degree of recall bias as the exposures of interest (Zaadstra et al. 2008; Lipsitch et al. 2010). Family studies that swap exposures or outcomes between family members are a special case of negative control studies to detect unmeasured confounding, because they allow for the specific identification of confounding by shared genetic or familial environmental factors (Cohen et al. 2019). Negative controls can also be used to assess diagnostic bias, such as in the paradoxical inverse and bidirectional association between diagnoses of cancer and Alzheimer's dementia, which has been consistently observed in the epidemiological literature (Driver et al. 2012; Driver 2014; Schmidt et al. 2017; Yarchoan et al. 2017). Using US Medicare claims linked to National Cancer Institute Surveillance, Epidemiology, and End Results (SEER) data, Freedman et al. observed that new cancer cases were less likely than cancer-free controls to have a history of Alzheimer's dementia, and that they were also less likely than controls to have a prior injury in an automobile accident, with almost identical point estimates (Freedman et al. 2016). Since an automobile accident injury is highly unlikely to cause cancer, the authors concluded that diagnostic bias may explain their findings, whereby cancer is detected less often among patients with a history of unrelated medical conditions (Freedman et al. 2016).

Life course epidemiology lends itself well to the use of negative controls because life course study designs often necessitate including long follow-up periods, the use of self-reported information on exposures that occurred long before the study started, and the mostly observational nature of life course studies all introduce strong potential for various biases. However, there are few true life course epidemiologic studies that have incorporated negative control methods to detect bias and improve causal inference. Increased use of negative control methods by investigators would help strengthen the evidence base for key research questions in life course epidemiology.

Finally, it is important to remember that no study is without limitations, and the triangulation of evidence across diverse study designs with different

strengths, limitations, and potential sources of bias is crucial for strengthening causal inference in life course epidemiology (Lawlor et al. 2016; Vandenbroucke et al. 2016). Ultimately, causal thinking and the thoughtful application of methods to strengthen causal inference within studies and across bodies of literature will help identify the life course determinants of health and disease in order to inform development of effective policies and programmes to promote population health and health equity.

Monte Carlo simulation studies in life course epidemiology

Monte Carlo simulation studies can be used to evaluate the plausibility of hypotheses in life course epidemiology that are difficult to investigate using empirical data. Conducting a simulation study can be conceptualized as conducting an experiment on a computer. After clearly defining the research question the simulation study is designed to evaluate, the first step in conducting a simulation study is for the researcher to express the causal structure of the data-generating process they wish to simulate as a DAG. The second step is to specify the data-generating rules corresponding with the DAG. Since the researcher is generating the data, they are generating the causal effect of the exposure on the outcome (β) in the simulated world of the study. The third step is to generate the data according to the specified rules using a statistical software package (e.g. R, Stata, SAS). The fourth step is to estimate the exposure-outcome association in the simulated data (β). The fifth step is to quantify the magnitude of bias by comparing the estimated exposure-outcome association with the causal effect in the simulated world (versus β). The final step is to run multiple (e.g. 1,000) iterations of sample generation to obtain stable estimates of the effect estimate in the simulated world, and then compare the average effect estimate and other metrics of distribution of the effect estimate (Burton et al. 2006; Morris et al. 2019). This process can then be repeated, varying the causal structure and parameterizations.

An example of the application of Monte Carlo simulations to evaluate the plausibility of explanations for empirical observations in life course epidemiology is a simulation study to evaluate the extent to which selective survival can plausibly explain the age attenuation of Black-White inequalities in stroke incidence in the United States: in midlife, Black Americans have substantially higher stroke incidence than White Americans,

but this inequality disappears by age 85 years (Giles et al. 1995; Kissela et al. 2004; Kleindorfer et al. 2006; Howard et al. 2011). Although the age attenuation of racial inequalities in stroke has been well-documented, the reason for this observation is difficult to evaluate in empirical data. From a public health perspective, it is relevant to understand the explanation for the observed age patterning of racial inequalities in stroke incidence. One possible explanation is that the observed age trends reflect true age heterogeneity in racial disparities in stroke incidence, due to the elimination of the social disadvantage that drives racial disparities in stroke incidence in midlife. This explanation would be most consistent with the immediate risk model for the effects of racism on stroke incidence. An alternative explanation is that the age attenuation of racial inequalities in stroke reflects selective survival: there are major racial disparities in life expectancy in the United States, and, as a result, Black Americans who survive to older ages may represent a more selected, healthier population than White Americans who survive to old age, which could result in lower stroke incidence rates in Black versus White Americans who survive to old age. Notably, the selective survival explanation does not imply the elimination of health disparities at older ages. Using Monte Carlo simulations guided by real data for mortality and stroke incidence, Mayeda et al. (2018a) demonstrated that the observed age attenuation of racial inequalities in stroke incidence could plausibly be explained by selective survival. More broadly, the results of this simulation study demonstrated that selective survival has the potential to obscure social disparities in health.

Sequence analysis to characterize complex life course exposure patterns

Sequence analysis is a promising method to simultaneously incorporate the order, timing, and duration of life course exposures into a single measure. Sequence analysis can be applied to multielement categorical data repeated over time, such as employment history data. Sequence analysis was originally developed by biologists to identify homology between DNA sequences. The sequence of DNA elements on a chromosome can be thought of as analogous to the sequence of life history events over time, an observation that led to the adoption of sequence analysis by sociologists in the 1980s (Abbott and Tsay 2000). The method has gone through waves of popularity, criticism, and methodological development in sociology, where it has been used to characterize a range of sequenced data, including the onset

of social welfare policies by countries, historical patterns of lynching rates in the southern United States, and daily time-use data (Abbott and Tsay 2000).

The most popular application of sequence analysis in life course epidemiology has been for employment history data (Sabbath et al. 2015; Kobayashi and Feldman 2019). Employment is a complex state that people transition into and out of over time on multiple dimensions, such as on weekly hours worked, job type, job skill level, and various forms of non-employment. When combined with life transitions such as childbirth, caregiving, illness, or retirement, sequence analysis for employment history data can provide rich insights into prototypical population trajectories of employment and life histories that may have consequences for a range of health outcomes. Sabbath and colleagues (2015) used sequence analysis to characterize exposure to work–family demands in women from ages 16 to 50 in relation to subsequent mortality risk, observing the lowest mortality rates in married women who stayed home briefly with children before re-entering the paid workforce, intermediate mortality rates in single working mothers and married non-working mothers, and the highest mortality rates for single non-working mothers (Sabbath et al. 2015). Within each of these groups, sequence analysis identified prototypical periods and durations of time that were spent with and without children and in and out of work, allowing a comprehensive exposure assessment that would not be readily possible using manual methods of classification.

Sequence analysis is a two-step data reduction technique that consists of an optimal matching analysis followed by a cluster analysis (Aisenbrey and Fasang 2010). The goal of optimal matching is to minimize the 'cost' required to transform the sequences of any two given individuals to match one another. Cost assignments must be informed by theory and prior hypotheses about the relationships under study, and have been the subject of much debate in the sociological literature (Wu 2000; Aisenbrey and Fasang 2010; Halpin 2010). After distances are calculated, the second step of sequence analysis is a cluster analysis using the matrix of optimal matching distances to distil the extremely large number of potential sequences into a handful of clusters of similar sequences.

In a causal framework, sequence data have the potential to be poorly defined exposures because they consist of multiple heterogeneous elements that have been reduced into a single entity. If theory permits that a given life course exposure trajectory identified using sequence analysis is a single

entity that can be intervened upon, rather than a series of stochastically generated events, then the exposure may be well-defined. A further issue is that control for confounding may quickly become problematic, as the possibility arises of within-sequence confounder-mediators that cannot easily be controlled for. Although it has potential limitations, sequence analysis presents a promising and underutilized approach to simultaneously characterize the aspects of timing, dose, duration, and order of complex life history exposures in life course epidemiology.

Future directions in life course epidemiology

To date, the vast majority of life course research has been conducted in the United States and Western Europe. Examining life course determinants of health in low- and middle-income countries is critical for identifying risk and protective factors for health throughout the life course in countries with rapidly growing older adult populations (Tollman et al. 2016). Research in novel contexts has the potential to expand understanding of the life course determinants of health for people in countries around the world. Until recently, there have been very few data sources to support such research. Over the past decade, new International Partner Studies of the US Health and Retirement Study have been established in several low- and middle-income countries including China, Costa Rica, Mexico, Indonesia, India, and South Africa (https://g2aging.org/). While many of these studies are currently limited to baseline data or two waves of data, their harmonized design will allow for cross-national comparisons of the life course drivers of population health outcomes, especially as longitudinal follow-up continues. For example, studies such as the Longitudinal Study of Aging in India (LASI) and the Health and Aging in Africa: A Longitudinal Study of an INDEPTH Community in South Africa (HAALSI) (Lee et al. 2014; Gómez-Olivé et al. 2018) will provide evidence on ageing outcomes in older populations with limited formal education and low literacy, who grew up under different social, political, cultural, and economic conditions than those in the United States and Western Europe, where most life course evidence to date has been from. These data will be crucial for enhancing evidence on the life course drivers of population health from a global perspective, and for allowing the triangulation of evidence across diverse populations.

Birth cohort studies, such as the British birth cohort studies established in 1946, 1958, 1970, and 2000 (Elliott and Shepherd 2006; Power and Elliott 2006; Wadsworth et al. 2006; Connelly and Platt 2014) are valuable resources for life course epidemiology, but take many years to mature. An efficient and creative strategy for life course epidemiology is to develop a follow-up study of a cohort studied earlier in the life course. For example, the Project Talent Aging Study is a follow-up study of Project Talent, a national study that surveyed over 400,000 high school students in 1960 who were followed longitudinally through 1974 (https://www.projecttalent.org/). Project Talent Aging Study researchers are re-contacting Project Talent participants for a study focused on cognitive ageing. This study has the potential to help researchers understand early-life factors that influence risk of Alzheimer's disease and related dementias in later life.

In addition to expanding epidemiologic research with a life course perspective to include people with diverse life experiences, new areas of development include life course research extending beyond one human lifespan to include intergenerational and transgenerational life course research, as well as the application of innovative methods. Including people with diverse life experiences and the thoughtful application of innovative tools in epidemiologic studies with a life course perspective has the potential to expand understanding of life course determinants of health and ultimately guide social, public health, and medical policies and programmes to promote population health and health equity.

Sociology and psychology in public health

Stella R. Quah

Introduction to sociology and psychology in public health

The disciplines of sociology and psychology differ in interesting ways but they also have common links both conceptually and methodologically. They differ in overall scope: psychology typically focuses on the individual while sociology examines the individual's social action (agency) and the community's sociocultural, economic, political, and physical context (structure) within which they live, interact, work, and play. One important similarity between sociology and psychology is that both disciplines have a dedicated subfield for the study of health and illness. These subfields are, respectively, health sociology (also known as medical sociology) and health psychology. Thus, in line with the objective of this volume, the focus of this chapter is on the contributions to public health by health sociology and health psychology, the two subfields most relevant to public health.

Just as health sociology and health psychology have common links, today both disciplines share two essential notions with public health. The first shared notion is the global impact of individuals' actions. This impact is demonstrated in many types of health-related behaviour. One of the most evident examples is the case of infectious diseases. An infectious disease may begin with one individual but, if left unchecked, it can affect entire continents. This principle was highlighted by a British physician, Southwood Smith, in the nineteenth century. Smith (1866) was alerting the health authorities on the need to investigate and control infectious diseases. By the twenty-first century, sociology and psychology have accumulated a wealth of research on the impact of individual and collective social behaviour on health to show that Southwood Smith's notion applies also to

people's behaviour and social conditions associated with non-infectious diseases and, indeed, to all health-related phenomena.

The second shared notion is the importance of trust in interpersonal relations and in the nurturing of the community' cooperation for collective action. This notion is actively scrutinized in sociology and psychology (e.g. Stevenson et al. 2014; Poulin and Haase 2015; Pletzer et al. 2018; Do Nascimiento-Bezerra and Souza-Feitosa 2018; Yost-Dubrow and Dunham 2018). Health sociology examines trust critically in interpersonal and community settings. An example at the interpersonal settings is the physician's imperative of earning the patient's trust in clinical encounters. The community setting is illustrated by the public health authorities' duty to gain the population's trust as the basic step towards the active involvement and collaboration of communities in health promotion and disease prevention and treatment, including the prevention and control of epidemics (Quah 2007a, 2007b). Research findings supporting the importance of building trust are gradually permeating public health (e.g. Adams et al. 2017; Benjaminy et al. 2018; Callis et al. 2018; Datta 2018; Ellenberg et al. 2018; Kim 2018; Nuriddin et al. 2018; Raven et al. 2018).

These two notions—the global impact of individuals' actions and the importance of trust—exemplify the current collaboration of public health, health sociology, and health psychology, as I elaborate in the pages that follow. The discussion is presented in four sections: Sociology and public health; psychology and public health; the contribution of both disciplines to public health training; and conclusion. The sections on sociology and psychology cover the same three themes: the highlights of their respective theoretical contributions; the main methodological approaches that are relevant to public health; and a succinct summary of areas of research that illustrate the contributions of health sociology and health psychology to the field of public health. The list of references documents the arguments made in the text and serves as further reading on the historical as well as most current information on what health sociology and health psychology offer to public health researchers and practitioners.

Sociology in public health

The sociological analysis of health and illness can be traced back to the beginnings of sociology as an area of systematic knowledge in the late 1800s. Sociology's pioneers in Europe investigated the influence of cultural, socioeconomic, and political conditions in the community on individuals' social action. Two of the pioneers were Emile Durkheim (1858–1917) in France and Max Weber (1864–1920) in Germany. In the midst of the development of sociological theorizing, while sociology pioneers were examining the nature and dynamics of society and social action, the spread of infectious diseases was exerting a heavy toll in Europe. The damage caused by epidemics alerted some British and European medical authorities to the possible connection of three phenomena hitherto seen as unrelated by medical experts: social conditions in the community, social behaviour, and public health. Among the first physicians to presume that connection existed were Virchow and Billings. A notable German pathologist, Rudolf Virchow (1812–1902), seen as 'a dominant figure in German medicine' (Shryock 1974, p. 202) was perhaps the first medical scientist who considered medicine as a social science (Elling and Sokołoska 1978, p. 14). John Shaw Billings, an American surgeon and the first publisher of the *Index Medicus*, wrote on the link between 'hygiene and sociology' around 1879 (Shyrock 1974, pp. 182–3; Cockerham 2010, p. 2). In a 1894 article on the social factors of illness another physician, Charles McIntyre, used for the first time the term 'medical sociology' (Cockerham 2010, p. 2). Along the same line of thought, public health practitioners recognized very early the importance of sociology and psychology to public health research and practice (Roney 1960).

The initial phase of health sociology was rooted in research by sociologists working in medical academic settings and in public health or biomedical clinical settings (Elling and Sokołoska 1978). Health sociology research and publications paved the way to the inclusion of health sociology courses in the medical curriculum at American and British universities after the Second World War (Elling and Sokołoska 1978; Cockerham 2010, pp. 2–3), as I explain later. Some of the signposts of the formalization of health sociology as a subdiscipline of sociology are the establishment of the Medical Sociology Section of the American Sociological Association in 1959; the Research Committee on Medical Sociology of the International Sociological Association in 1963[1]; and the Medical Sociology Research Network in the British Sociological Association in 1969 (Reid 1976). From

its early years, health sociology has focused on all aspects of health and illness adeptly classified into two general dimensions by Robert Strauss: 'sociology *of* medicine' comprising the analysis of 'the organizational structure, role relationships, value systems, rituals, and functions of medicine as a system of behavior'; and 'sociology *in* medicine' dedicated to the analysis of the disease process, health-related behaviour, and the sociocultural, political and socioeconomic determinants of health and illness in the community (Strauss 1957, p. 203).

Research publications in health sociology include journal articles and books. Among the most important domain-specific international refereed journals are the *Journal of Health and Social Behaviour* (JHSB), the dedicated health sociology journal of the American Sociological Association; *Social Science & Medicine* (SSM); *Sociology of Health and Illness*; and *Health Sociology Review*, the journal of the Health Sociology Section of the Australian Sociological Association. There are several textbooks in health sociology, one of the most established is Cockerham's (2017), already in its 14th edition. Among serial books is the *New Blackwell Companion to Medical Sociology* (with editions published in 2001, 2005, and 2010) and the *Handbook of Medical Sociology* (HMS). The first edition of the HMS was published in 1963 and it discussed 'the *potential* of the sociological enterprise for understanding the etiology, diagnosis, and treatment of diseases; the ways health care is provided and funded; the societal and communal commitment to the support of health activities; and, indeed, the very definitions of health and illness'. Looking back at the first three editions of 1963, 1972, and 1979, the editors of the fourth edition wrote that, 'the promise of medical sociology [is now] replaced by hard evidence as to its utility' (Freeman and Levine 1989, p. 1). These authors correctly pointed out that health sociology uses the full range of sociological theories and methodologies (1989, p. 7).

In concert with the increase in research and publications by the 1980s, medical sociologists were also 'actively involved in public health programs, and … accredited schools of public health in the United States were required to provide formal training in the social and behavioral sciences' (Coreil and Dyer 2017, p. 600) and there were calls to increase health sociology input in the training of public health practitioners not only in the United States (Gordon and McFarlane 1996) but also in Canada (Massé and Moloughney 2011) and elsewhere. I return to this issue later.

Sociological theories and public health

Historically, the twin theoretical roots of sociology are philosophy and science as they developed in the seventeenth and eighteenth centuries in Europe with the writings of thinkers such as Charles Montesquieu (1689–1755) and Jean Jacques Rousseau (1712–1778) on social forces, power, and social facts; Emmanuel Kant (1724–1804) on the systematic analysis of cause and effect; and Henri de Saint-Simon (1760–1825) about industry, the need for social reforms, and the scientific study of society and social life. Philosophers such as René Descartes (1596–1650), Thomas Hobbes (1588–1679), and John Locke (1632–1704) aimed at 'grand, general, and very abstract systems of ideas that made rational sense', but other thinkers were more concerned with testing those ideas against their 'real world' experiences or more specifically, 'to combine empirical research with reason' following the path of science (Ritzer 1992, pp. 6–11). The latter trend 'led to the application of the scientific method to social issues' seeking to identify possible laws governing social behaviour just as Newtonian physics demonstrated that physical laws rule the physical world (Ritzer 1992, pp. 10–11). This embryonic tension and subsequent symbiosis between the two approaches—a purely theoretical outlook vis-à-vis the imperative to test assumptions empirically—remain at the core of sociology as a field of knowledge today.

Sociology grew from those early ideas into a distinct discipline in the context of wide-ranging social change. Two founding fathers of the discipline were born at the time of the Industrial Revolution and the rise of capitalism in the nineteenth century. The first was the French thinker August Comte (1798–1857) who contributed his treatise on a new discipline that he labelled 'Sociology' and envisaged it as the systematic analysis of society following the model of physics. The second pioneer thinker was Comte's compatriot Emile Durkheim (1858–1917), who promoted the symbiosis of theory and empirical research. Durkheim paid particular attention to, on the one hand, the study of disorder, conflict, and its consequences in society; and on the other hand, to the importance of social facts for the study and planning of social reform to reduce social disorder. Durkheim 'legitimized sociology in France' (Ritzer 1992 p. 17). Durkheim's treatise on the systematic analysis of social facts and his study of social factors associated with suicide are seminal works in sociology.

Two of Durkheim's most influential books are *Suicide* (1897/1951) demonstrating the link between individual behaviour and society's socioeconomic conditions; and *The Rules of Sociological Method* (1895/1964). Durkheim's emphasis on both sociological theory and empirical research paved the way for today's evidence-based research. His conceptual contribution on the notions of 'the socially *normal* and *abnormal*' set the path for 'twentieth century medical sociology' along 'the enlightenment inspired *normal/pathological* bifurcation in medicine' (Thomas 2012, p. 216).

Two other pioneers in sociology were German: Georg Simmel (1858–1918) and Max Weber (1864–1920). Simmel and Weber were cofounders of the German Sociological Society. Simmel's key contribution is his notion of reciprocity and uncertainty in social interaction (Gerhardt 1989, p. 17). Max Weber's theory of social action, authority systems, and bureaucratization, are among many other seminal contributions in his large body of work, and form part of the foundation of contemporary sociology (Ritzer 1992, pp. 25–9). Among Weber's contributions is his ground-breaking theory of social action and social systems (1921/1968), a classical theory in sociology. In health sociology, Weber's conceptual contributions are applied to a wide range of studies including, for example, the analysis of the bureaucratization of healthcare systems and organizations (Fox 1989; Germov 2005), the analysis of power and authority of the medical profession (Starr 1982; Freidson 1988); and the impact of life chances and lifestyle on health-related behaviour (Cockerham 2010).

The body of theory in Sociology has grown exponentially over the past century. Sociological theories may be classified into two types: general theories that address all human behaviour and have 'universal' applicability; and 'middle-range' theories that have limited applicability. The most relevant general theories for the sociological analysis of health and illness are: structural-functional theory, symbolic interactionism, conflict theory, and phenomenology/ethnomethodology. Given the space constraints of this chapter, only the general theories are discussed.

The structural-functional theory (now neo-functionalism) is the contribution of American sociologist Talcott Parsons (1937). This theory addresses societies as social systems and proposes that all components of society whether they are individuals, groups, communities, nations, or global organizations, have functions—both manifest and latent—for their

maintenance and growth. The dominant trend in social organizations, groups, and social interactions is the maintenance of balance or equilibrium. Consequently, conflict is considered dysfunctional to the development of organizations and social relationships, and dysfunctions need to be rectified or balanced through normative values and the correction of unanticipated consequences of action (Ritzer 1992). Parsons (1937) approached the analysis of health-related phenomena from the perspective of structural-functionalist systems theory, offering two 'models of illness': the 'deviance' model and the 'sick-role' or 'capacity' model, both of which incorporate the micro- and macro-levels of the social structure. The 'deviance' model presents illness as a state of dependency for the person affected whereby therapy is expected but seen as a social control system and the physician as an agent of social control. The 'capacity' model proposes that illness is a breakdown of normality leading to the individual's total or partial incapacity to perform normal social roles, and brings the person into the 'sick-role'. The sick-role is a social position with different rights and obligations within the social structure that includes the doctor-patient interaction and the doctor's role with specific rights and obligations (Parsons 1937; Gerhardt 1989, pp. 1–67).

The second influential general theory is symbolic interactionism. It proposes that the individual's subjective perception of the situation through meanings and symbols has a significant impact on his/her behaviour. In contrast to structural-functionalism that is predominantly associated with one theorist—Talcott Parsons—symbolic interactionism represents the conceptual contributions of several theorists and offers two models of illness: the 'labelling' model and the 'negotiation' or 'crisis' model. The labelling model proposes that illness may be socially defined or labelled through a process of normative evaluation. Correspondingly, the negotiation model proposes that patients have control over their illness through negotiation: diagnoses and treatments by the medical profession may be negotiated and treatment involves the patient's active participation (Gerhardt 1989, pp. 73–173). Some analysts consider symbolic interactionism as playing an important part in current health sociology through qualitative methodological designs such as participant observation (Cockerham and Scambler 2010, p. 8).

Conflict theory is the third general sociological theory of relevance for public health. One of the earliest perspectives in conflict theory was the

Marxist postulation that social conditions of deprivation and exploitation lead to illness (Gerhardt 1989, pp. 254–5). More abstractly, conflict theory proposes that the potential for conflict is a normal component of social relationships, thus, negotiation and bargaining are key elements of social interaction. When applied to health phenomena, conflict theory offers two models, the 'loss' or 'stress' model and the 'domination-deprivation' model. The 'loss' or 'stress' model proposes that there is a strong connection between stress and illness; the loss of required social support increases the likelihood of illness; and vulnerability to illness is unequally distributed in society. The body of sociological research on the stress-illness connection was initiated in the 1950s and continues growing today (Pearlin 1989; Thois 2010). The 'domination-deprivation' model argues that the medical profession occupies a dominant position in society by virtue of its expertise vis-à-vis the patient's position of dependence given the patient's lack of specialized knowledge. The domination-deprivation model is also applied to the analysis of social inequality and socioeconomic deprivation in society (Gerhardt 1989, pp. 249–348). Besides providing the conceptual basis for critical and feminist perspectives, conflict theory as a school of thought has been particularly influential in the analysis of health policy: 'one of conflict theory's most important assets for medical sociology [is] the capacity to explain the politics associated with health reform' (Cockerham and Scambler 2010, pp. 10).

A fourth theoretical position is that of phenomenology/ethnomethodology which proposes, as Ritzer (1992, p. 388) summarizes it, that 'people are the product of the very society they create'. This phenomenology model regards illness as belonging to 'a broad category of disturbing occurrences … which breach the taken-for-granted peace of everyday routines' (Gerhardt 1989, p. 190). Compared to the other theories, and particularly, to the abundance of empirical research generated by the other three conceptual orientations—structural-functionalism, symbolic interactionism, and conflict theory—the phenomenology/ethnomethodology school of thought has contributed relatively less to empirical research in health sociology (Cockerham and Scambler 2010).

Sociological research relevant to public health

At the most abstract level, there are two distinctive contributions of health sociology to the study of health and illness in general and public health in particular. The first contribution is the systematic examination of the link between individual and community and 'the social organizational factors that shape the behaviour of groups' (Thorlindsson 2011, p. 21). The second main contribution is 'that health care systems are organizations … embedded within larger institutions, which have been shaped by historical precedents and operate within a specific cultural context' (Quadagno 2010). Health sociology research relevant to public health can be found within the framework of these two key contributions. The most significant social aspects that exemplify the link between individuals and groups in the context of public health are cultural and social class influences on health-related behaviour of individuals and communities; lifestyles; and the creation and transformation of healthcare systems. Cultural values rooted in ethnic and religious ethos together with social class differences shape people's beliefs and attitudes on health and illness and their lifestyles. Healthcare systems originate, develop, and change as part of the interplay of socioeconomic, cultural, and political factors. Let us discuss each of these aspects—culture, social class, lifestyle, and health systems—in more detail.

Culture and public health

Culture is a key term that refers to values and beliefs emanating from one's ethnic and/or religious ethos, typically transmitted across generations as part of the community's identity or 'design for living'. The impact of the physical environment on people's health has been historically recognized. Today we know that the socioeconomic environment is also a crucial factor in the risk of infectious and chronic illness (Armelagos and Harper 2010; Charmaz and Rosenfeld 2010; Baum 2016; WHO 2018). The impact of culture on public health is manifold and it is manifested in at least three main ways: health behaviour, that is, what people do regarding health risks; health attitudes and beliefs, that is, how people feel and think about health and illness; and people's perceptions of and responses to health authorities' public health guidelines and recommendations (Fox 1989; Quah 2007a, 2007b, 2010; Brown et al. 2012; WHO 2018). Perhaps the best example of this threefold impact is the influence of cultural and/or religious norms and

traditions on people's food preparation and diet. Irrespective of what public health authorities advise on food consumption (Harvey 2017, p. 204), ethnic, and/or religious groups differ in this regard as they tend to follow their traditionally sanctioned diet, such as vegetarian cuisine, avoidance of pork, the use of animal fat or refined vegetable oils in food preparation, or the avoidance of fried food at all; preferred beverages; and level of sugar consumption, among other aspects (Cockerham 2010b, pp. 29–32; Idler 2010; Seow 2017, pp. 314–15).

Cultural norms and traditions also guide people's preference for some types of health services over others. For example, cultural healing traditions such as traditional Chinese medicine and Ayurveda represent, respectively, essential aspects of Chinese and Indian cultures and thus the population's preference for and use of these therapeutic practices must be taken into consideration in public health policy (Quah 2003, 2008; Etkin et al. 2017).

Yet another contribution of health sociology research on the impact of culture on public health and the wider healthcare system is the analysis of the provision of healthcare from two perspectives: the micro-cosmos of clinician-patient interaction, and its permutation into the macro-cosmos of the interaction of health authorities with communities and groups. Two examples suffice. It has been found that social stereotypes held by practitioners (whether clinicians or public health practitioners) distort their decisions and interactions with their subjects of care. Clinicians' subjective perceptions of cultural or socioeconomic differences might lead them to link 'certain diagnoses to certain patients' (Smith et al. 2012, p. 162). Similarly, social perceptions of the community held by public health officials might unwittingly influence their public health approaches (e.g. Callis et al. 2018; Nuriddin et al. 2018). These examples also illustrate a related phenomenon: the impact of 'medical constructs', that is, when a physical or mental condition is defined by the health authorities 'as a *disease*' while the same condition is considered normal by the community or at least not a condition that requires medical attention. When this clash of the expert versus lay interpretations occur, the official classification 'has consequences for the social legitimacy of the symptoms, access to treatment, and costs to the health care system' (Conrad and Barker 2010; Rosich and Hankin 2010, p. S4). One illustration of this problem from the field of epidemic prevention is the opposition to mandatory culling of poultry or livestock by some farming communities who fail to appreciate

the connection between disease and the destruction of what for them are healthy farm animals and their families' source of livelihood (Quah 2007a).

Lifestyle and health

Health sociology research provides evidence of another significance influence—related to but distinct from culture—on what people do about health risks: their lifestyle. Cockerham (2010, p. 159) defines health lifestyles as 'collective patterns of health-related behavior based on choices from options available to people according to their life chances'. Life chances is a concept proposed by Max Weber (1968) to represent choices, that is, opportunities and constraints imposed on individuals by their relative position in society. People's lifestyle shapes their patterns of leisure and physical activity: some people have no time for leisure; others are sedentary or engaged in extreme sports; some frequent gyms as networking and thus do regular exercise; others are regularly involved in alcohol drinking, cigarette smoking, and/or hard drugs consumption. Likewise, a person's lifestyle is associated with the risk of serious injuries and the likelihood of contracting infectious diseases. Consequently, it is not surprising to find persistent differences in morbidity and mortality across ethnic groups that are basically of social rather than biological or genetic origin (Krieger 1987; Link and Phelan 1995; Williams and Sternthal 2010; Whyte et al. 2017). Considering that lifestyles vary for men and women particularly in Asia, gender differences are clearly discernible in morbidity and mortality figures (Quah 2011). The importance of culture for public health policy and practice is becoming better recognized and has led some analysts to recommend that public health practitioners be equipped with 'cultural competence' (Perez and Luquis 2008; Waters et al. 2017).

A person's lifestyle is shared and reinforced by his/her social network. Health sociology research demonstrates the active link between social relationships—also known as social ties—on the one hand, and health behaviours and outcomes on the other (Umberson and Montez 2010). Social ties and social networks significantly influenced health-related behaviour leading to obesity, cigarette smoking, 'recreational' drug use, and alcohol consumption, among other risk behaviours (Cockerham 2010a; Jones et al. 2011). However, while the most visible influence of social networks on health is negative, membership in social networks plays a positive role in

well-being and healthy longevity (Lund et al. 2000; Nyqvist et al. 2013). Social networks can also be mobilized in public health policy for the promotion of healthy habits and health risk-avoidance in the community (Mechanic and Tanner 2007; Umberson and Montez 2010; Brown et al. 2011).

The impact of lifestyle on health and illness is also analysed from the life course perspective, a conceptual approach that examines the changes experienced by individuals along their process of physical and socio-psychological maturation and experiences. An increasing body of evidence-based sociological research demonstrate important differences in the exposure to health risks across the life course of different ethnic groups and social classes (see, for example, Brown et al. 2012).

Social class, social stratification, and public health

Social class, a fundamental sociological construct, depicts the relative position of an individual in the social hierarchical system of prestige in his/her society (Weber 1968). In sociological research, a person's social class—socioeconomic status or SES—is ascertained by means of a composite index of three or more indicators, the most common of which are personal income level, years of formal education completed, and occupational prestige.[2] The resultant SES scores may be used as a continuous scale (usually standardized scores ranging from 0 to 100) or as a set of discrete categories based on the arithmetic mean and standard deviation. The simplest presentation of SES scores is a three-level description of lower class, middle class, and upper class. However, quantitative and continuous SES scores are preferred in sociological studies of class differences and patterns of stratification in society (Bendix and Lipset 1966; Nam and Powers 1983; Phelan et al. 2010).

The nearly universal phenomenon of social class differences influencing the person's access to and utilization of healthcare services is supported by sociological research findings: the higher a person's social class, the greater his/her access to healthcare services (Lahelma 2010; Rosich and Hankin 2010; Brown, et al. 2011; Quah and Cockerham 2017). A country's socioeconomic conditions lead to 'persistent health inequalities among social groups' (Rosich and Hankin 2010), inequalities which normally are 'deeply rooted in society' (Phelan et al. 2010). Research findings indicate

that social class reinforces the influence of lifestyle on health behaviour. However, under certain conditions, social class—mostly due to the influence of education and occupation—may have a stronger impact than cultural beliefs and norms on health behaviour, on access to health services, and on a person's exposure to occupational hazards. Indeed, workers have differential exposure to dangerous repetitive tasks, risk of industrial accidents, and environmental pollution, among other health risks embedded in the nature of the job. Consequently, sociologists examine the health impact of each SES component separately: occupational prestige, income level, and educational level as well as the strength of SES as a predictor of health behaviour.

The influence of social class on health status, health behaviour, access to, and use of health services, is one of the earliest and most examined social influences on health. Summarizing the advances of health sociology in the study of social class and health in the last 50 years, Phelan et al. (2010, p. S29) report that their data support 'the theory of fundamental causes'. This theory states that social class 'influences multiple disease outcomes … through multiple risk factors'; impacts 'access to resources that can be used to avoid risks or minimize the consequences of disease once it occurs'; and that those influences tend to persist over time. Their research findings support the theory and have implications for public health policy that are different from results in studies applying 'an individually oriented risk-factor approach'. Thus, these authors recommend that social class-induced health inequalities 'can be reduced by instituting health interventions that automatically benefit individuals irrespective of their own resources or behaviors' (Phelan et al. 2010, p. S37). Research on the social determinants of health and illness—scrutinizing social, economic, cultural, and ideological factors—continues in earnest (e.g. Pearlin 1989; Link and Phelan 1995; Kawachi et al. 1999; Lund et al. 2000; Mechanic and Tanner 2007; Phelan et al. 2010; Williams and Sternthal 2010; Doyal 2014; Baum 2016; Quah and Cockerham 2017; Marmot 2018).

Taken together, the related phenomena represented by the person's lifestyle, life course, and social class, point to the need to focus on families in the investigation of health promotion as well as disease risks. Typically, in addition to genetic background, family members share some main lifestyle features such as diet, recreation patterns, and the physical neighbourhood. Moreover, some disease vectors (e.g. fleas, mosquitos,

mice) settle in family homes. Thus, it is not surprising to find crucial differences in health risks exposure between, for example, individuals living in rural and urban communities and between people living in rich and poor neighbourhoods. With this in mind, Valberg and colleagues (2018 p. 1) discuss the use of 'family relative risk' (FRR) as 'a continuous risk model' for the public health assessment of families at risk at the community level.

Two additional contributions of the sociological study of occupations and professions that increase our understanding of health and illness in society are the analysis of occupational hazards and the role of the medical profession. On the one hand, the comparative analysis of health outcomes, disease prevalence and disease incidence across the wide spectrum of occupations in society consistently reveals clear variations derived mainly from the nature of work performed and occupational hazards (e.g. Christ et al. 2012; NASEM 2018). On the other hand, sociologists also examine the biomedical profession and traditional healing occupations in terms of their relative prestige, their training, internal composition and dynamics, and their impact on the health of populations (e.g. Starr 1982; Friedson 1988; Quah 2003, 2008). Research findings indicate that the ideal trust-based and confidential doctor-patient relationship is corporatized today as the medical profession is overwhelmed by 'the healthcare industry' dominated by employers' 'guidelines, pre-authorization, centralization and financial awards for increased output' (Starr 1982; Freidson 1988; Timmermans and Oh 2010; Vanderminden and Potter 2010, pp. 356–7).

Healthcare systems and public health

In addition to the analysis of the impact of culture and social class on public health, another illustration of the contributions of health sociology is the study of the nature, dynamics, and evolution of healthcare systems at the national and transnational level. When sociologists study healthcare systems they include the approaches taken by nation-states towards the creation, organization, distribution, and management of their healthcare resources. Thus, health policy and healthcare reform are integral parts of this type of studies. Some cross-national and comparative research findings on healthcare systems suggest that in many countries today 'too much priority has been given to hospital care at the expense of the development of primary care, community care and public health' (Stevens 2010, p. 435).

One of several aspects of healthcare systems that have received increased attention by medical sociologists in the past decade is the analysis of flaws in health systems that distort the link between cost and utilization of health services, thus the urgency of healthcare reform (Mechanic and McAlpine 2010). One sector of the healthcare system that has a significant input in healthcare costs is the role of stakeholders such as the pharmaceutical industry in the promotion of medicalization, particularly through the use of market opportunities and marketing methods to sell their products (Rosich and Hankin 2010, pp. S4–5).

Another illustration of health sociology analyses of health systems is the area of health services research. There is a vast literature of studies documenting the influence of social class and ethnic differences on unequal access to and utilization of health services. Three types of studies illustrate this research area. The first type of studies show that unequal access to healthcare services is preserved by institutions and policies that constrain and enable 'the actions of health services organizations, health care providers, and consumers' (Wright and Perry 2010, p. S109). Those studies of multiple dysfunctions of health systems challenge international policy makers and are the subject of social policy interventions based on social science research such as the Disease Control Priorities Project jointly conducted by the World Health Organization, the US National Institutes of Health and the World Bank (Laxminarayan et al. 2006). The second type of health systems research studies is the comparative analysis of health financing approaches and systems in terms of their suitability to the socioeconomic needs and demographic characteristics of the population. One example of this type of research is the study of insurance plans by Zaslavsky and Epstein (2005). The third type of study represent the direct input of medical sociologists on public policy; one recent example is the analysis of changes in state regulations on the collection and access to health relevant population data for research purposes (Hynes 2011).

In addition to the relevance of the analysis of culture, lifestyle, social class, and social systems for public health, health sociology also examines the interaction of these and other factors in the analysis of disease incidence and prevalence in the community. For example, Anderson et al. (2011, p. 390) found that 'social, cultural, and biological issues should all be considered in the assessment of differences in breast cancer survival'. Brown et al. (2011, p. 941) discuss the relevance of social factors in the

diagnosis and management of obesity, diabetes, and asthma. A wealth of studies on the social factors of disease is found in health sociology journals mentioned earlier such as *JHSB*, *SSM*, and *Sociology of Health and Illness* and numerous other international refereed journals on health research.

Sociological research methods and public health

Health sociology applies the full range of sociological approaches and methodological tools to the study of socioeconomic, cultural, and demographic characteristics of populations and individuals that impact their health (Rosich and Hankin 2010; Smith et al. 2012; Baum 2016). Indeed, referring to the analysis of epidemics and health behaviour in general, Hedges et al. (2002) argue that 'social science knowledge in theory and methodology has guided public health research for several decades'. One illustration of this influence is the application of sociological approaches to the analysis of income inequality and health in most of the articles compiled in the book on that topic by Kawachi et al. (1999).

The fundamental position of sociology in general, and health sociology in particular, regarding scientific research is well articulated by Vogt (2007, p. 5) when he highlights the critical tasks of collecting and analysing evidence for the purpose of creating knowledge. In this regard, there is clear compatibility between the goals of research in both fields of knowledge, health sociology, and public health. Still, there are three important characteristics of sociological research methodology that must be taken into consideration: (a) the kinds of data used in sociology; (b) the levels of measurement applied; and (c) the types of research design followed. Let us consider each characteristic in turn.

What kinds of data are used in sociology? Two kinds of evidence or data are used: *primary* and *secondary* data. Primary data are data collected first-hand by the investigator, for example, data on people's attitudes and behaviour obtained through personal interviews, observation, experiments, or surveys; or data extracted by means of first-hand analyses of documents, letters, records, or other type of 'raw' data. In contrast, secondary data are data previously collected by others, for example, official statistics, population censuses, or databases with processed or coded data sets from surveys or completed studies. Many research institutions keep databases of secondary data, usually codified data from survey research studies that can

be purchased by other researchers together with the respective codebook for secondary and longitudinal analyses (Miller and Salkind 2002, pp. 346–53; Hauser et al. 2010). Many data archives are now accessible online.

What levels of measurement are used in sociology? Sociological research uses four levels of measurement: nominal, ordinal, interval, and ratio levels. The most rudimentary is the *nominal* level which uses names or labels to depict different categories of the phenomenon under study (for example, the labels 'male' and 'female' to record a subject's gender; the labels 'Muslim', 'Hindu', 'Christian', 'Other religion' and 'no religion', to record the subject's religious affiliation). Each name or category may be assigned a numerical code but the numbers have no quantitative meaning, they are only labels. This conversion of alphabetical data into numerical data is done for digital data analysis using computerized statistical models, although there are now computer programmes designed for the analysis of alpha and alpha-numerical data. *Ordinal* measurement assigns ranks to categories of the observed phenomenon (example: 'slender', 'plump', 'obese' to record body appearance) but 'the distances between ranks in an ordinal scale are not necessarily equal'. *Interval* measurement uses ranks with a standard and measurable distance between categories but 'have no meaningful zero point'. The typical illustration of an interval level of measurement is the Fahrenheit temperature scale. A common sociological example is the range of a person's attitudes towards a problem or situation. Here are two sociological interview questions that illustrate the *interval* scale: 'Would you say you are very confident, only slightly confident, slightly anxious, or very anxious about what needs to be done to handle the patient?'; 'How would you rate your quality of life? 'Very poor', 'Poor', 'Neither poor nor good', 'Good', or 'Very good'?' The interval scale is more accurate than the nominal or ordinal levels of measurement, but less precise than the *ratio* scale that has both 'equal intervals between categories and a true zero point' (Vogt 2007, pp. 9–10). Examples of ratio scales in sociology are the measurement of the subject's age in years; income in dollars earned per month; formal education in number of years of completed schooling; number of children; and years of marriage.

One of the most widely used interval scales in the sociological analysis of health and illness is the 'Quality of Life' index popularized by the World Health Organization as the WHOQOL (WHO 2004; WHO 2017). The long and brief versions of the WHOQOL and other modalities of the scale are

usually included in studies of a wide range of health conditions from stress reduction to autism, hepatitis C, coronary heart disease, cancer, obesity, gastric bypass, bariatric surgery, neuropathic pain, and periodontal diseases, among other health conditions (e.g. Hamoen et al. 2015; Buset et al. 2016; De Vibe et al. 2017; WHO 2017; National Academies 2018).

What types of research designs are used in sociology? Depending on the nature of the phenomena under investigation and on the investigator's preferred level of measurement, sociologists may use qualitative or quantitative designs or a combination of both. Researchers who have a preference for qualitative research tend to steer clear of measurement altogether or use only nominal levels of measurement. Some of the most common qualitative research designs are participant and non-participant observation of social phenomena, and conversations with research subjects individually or in small groups (Schwartz and Jacobs 1979; Chongo et al. 2018) following the 'grounded theory' approach (e.g. Thapa et al. 2018). One modality of the small group method is the focus group approach whereby the researcher, acting as moderator, gathers together a small group of people—preferably not acquainted with each other—to discuss a particular topic. The focus group method is probably the weakest approach and it should be used with extreme caution in health research and perhaps only in exploratory studies, due to its three most serious limitations: (1) considering that the conversation is public, that is, in front of strangers, the researcher cannot guarantee confidentiality to the focus group participants, but confidentiality is an important component of informed consent required when conducting research with human subjects (Citro et al. 2003) and particularly if the study is on their state of health; (2) the validity and reliability of data collected in focus group discussions are low or non-existent; and (3) focus group participants are typically influenced by social pressure given the dynamics of small group interaction. Thus, the focus group approach is more suitable for exploratory studies of group dynamics (Mechlenborg and Grønkjaer 2018).

In contrast to qualitative designs, a quantitative research design may involve all four levels of measurement but mostly interval and ratio levels of measurement of social phenomena. Similarly, a quantitative research design may include one or more methods of data collection: document analysis, observation, personal interviews with structured or unstructured questionnaires, surveys, experiments, or quasi-experiments (Boudon 1993,

pp. 158–71; Vogt 2007, pp. 8–10). Naturally, as it happens in all fields of knowledge, research methods have their limitations and researchers need to consider the suitability of the methods selected and take steps to reduce as much as possible the probability of error. With the objective of error reduction in mind, medical sociologists may use in the same study a combination of methods from the array available: participant and non-participant observation; in-depth unstructured interviews; and structured interviews using questionnaires with a variety of question formats, from open-ended questions to attitudinal scales. Structured questionnaires are usually the main instrument of data collection in survey research. Survey research is a methodological design in sociology created by Paul Lazarsfeld (Boudon 1993). A prominent sociologist, Paul Lazarsfeld (1901–1976) identified three phases in the history of surveys. The earliest phase was before 1930, when surveys were used for 'the collection of factual information which could help to improve social conditions'. The second phase covered the period 1930 to 1948 when surveys were used to collect data on public opinion and consumer preferences. The third phase, from 1949 onwards, started with the publication of the seminal sociological study *The American Soldier* when the survey method became an important sociological tool for the collection of 'a large body of data' that could be 'made coherent and meaningful by careful statistical analysis' (Lazarsfeld 1968, pp. vii–x; Boudon 1993).

Sociologists using quantitative research methods aim to ascertain and reduce the level of error in the calculation of correlations among phenomena and in inferences drawn from representative samples to the total population (inferential Type I and Type II errors). This objective is facilitated by the application of statistical analysis models ranging in complexity and sophistication from simple measures of association such as chi-square, Pearson's coefficient, ANOVA, and path analysis, to multilevel models such as ordinal logistic regression, structural equation modelling, and hierarchical linear modelling, among others. Examples of some of the most recent health sociology studies applying multilevel models are: the impact of alcohol drinking on academic performance of secondary school students (Crosnoe et al. 2012), perceived discrimination and health among adolescents and young adults (Grollman 2012), the influence of social networks in the management of hypertension (Cornwell and Waite 2012),

and factors leading to sleep disturbance among US adults (Ailshire and Burgard 2012).

Another important aspect of sociological research that must be mentioned is the commitment that mainstream sociology shares with all other fields of scientific research: to pay serious attention to data validity and reliability. Reliability means consistency in the measurement: getting the same results every time the phenomenon is measured with the same instrument. The relation between validity and reliability is important: a reliable instrument may have low validity (Vogt 2007, p. 118). Validity has two general dimensions: internal and external. Internal validity focuses on the research question. The most elementary form of internal validity is content validity and it addresses the question: is the instrument measuring what it intends to measure or something else? There are two additional types of internal validity: criterion-related validity and construct validity. The second dimension is external validity that is, 'the potential for a study's findings to be generalized from one setting to others' (Burchett et al. 2011, p. 238). Similarly, qualitative research methodologists have made efforts to strengthen the credibility and transferability of their findings (Baum 2016; Lincoln and Guba 1985).

This brings us to the matter of sampling. From the perspective of public health, perhaps one of the most relevant methodological features of sociology, and in particular, health sociology, is the study of population trends through the analysis of representative samples, also known as probability samples. A representative sample is a sample drawn from the target population following a procedure that gives each individual in the target population the same probability of being selected. Probability samples allow the researcher to make inferences to the total population while non-probability samples do not. The application of inferential statistical tests such as chi-square, t-test and ANOVA indicate the probability that what was found in the sample does not reflect the situation in the population but it is due to chance or sampling error (Neuman 2000, p. 217; Vogt 2007, p. 12).

On the matter of sampling, two caveats are in order. The first caveat is that there are research topics and research situations for which random sampling is impossible to obtain or is unsuitable. This is the case of health conditions socially seen as stigmatizing, or deviant, so that the affected subjects and/or their families refuse participation in the study; or there is no

comprehensive and reliable record of all members of the target population that could be used as the sampling frame to draw a representative random sample. In situations like these, the researcher may opt for a non-probability sample. The 'purposive sample' is one form of non-probability sample whereby subjects are selected based on specific criteria, rather than randomly (Vogt 2007, p. 81). Naturally, non-probability samples preclude any inferences to the total population as only a probability sample has external validity (Vogt 2007, p. 82).

The second caveat is on the size of the sample. Besides the options of representative or purposive sampling of large populations, there is also the case study approach whereby the researcher studies only one or a few 'cases' of the social phenomenon under investigation. This approach is useful in at least two ways. First, in emergency situations, a case study may be conducted when rapid information about a condition is required, for example, the case study of a person or a family affected by a rare or 'new' illness that may be potentially contagious; or a unique event that could seriously affect large numbers of people. Second, in non-emergency situations, a case study approach is commonly used in exploratory research: that is in situations where the social phenomenon is new or never studied before and the researchers wish to familiarize themselves with the nature of the phenomenon in order to plan a more comprehensive and systematic study (Ragin and Becker 1992).

Psychology in public health

It is generally agreed that the discipline of psychology was born in the late nineteenth century (Norcross and Karpiak 2012) as a continuation of the discovery of 'the neurophysiological location of psychological faculties' among other advances in the study of the human body (Greenwood 2009). The period 1890–1910, was particularly fruitful for the discipline: it produced the seminal book *Principles of Psychology* by American William James in 1890, and Sigmund Freud's *Die Traumdeutung* published in 1900, often deemed as the framework of psychoanalysis and of Freud's subsequent studies of the thread linking personality, mind, and illness (Friedman 2002).

Just as the subfield of health sociology plays an important role within the discipline of sociology, the most relevant area of specialization in psychology for public health is health psychology (Luecken and Gallo 2008). Health psychology is also referred to by some analysts as clinical psychology or clinical health psychology (Boyer and Paharia 2008), and as a distinct and growing subfield (Romanow and Marchildon 2003). Health psychology has a relatively recent history (Albery and Munafò 2008). Introducing his *Health Psychology* textbook, Howard S. Freeman wrote that although health psychology has 'its roots in the fields of medical sociology … public health' and other fields, 'until the late 1970s, there were no programs of study in health psychology' (Friedman 2002, p. 23). The formal introduction of health psychology as a subdiscipline of psychology is highlighted by three chronological signposts: 1974 when health psychology was first proposed as a new subject in the curriculum at the University of California–San Francisco School of Medicine; 1977 when Health Psychology was approved as a new division of the American Psychological Association; and 1984 when the 'First International Symposium of Health Psychology' was held (Stone 1991, p. 3). As Friedman reports, the number of health psychologists has been growing rapidly not only in the United States but in many countries (2002, p. 23).

However, until about one decade ago health psychology had traditionally 'maintained … a pronounced unidimensional focus on mental health' (Arnett 2001, p. 38). Arnett argued that the field of health psychology 'would be significantly enhanced by a more comprehensive understanding of the epidemiology, pathophysiology, and natural history of the wide range of health disorders amenable to psychological interventions' (Arnett 2001, p. 43). Among the health areas that Arnett suggested could be studied by health psychology—in addition to mental health—are weight control, and addictions to alcohol, nicotine, and hard drugs (Arnett 2001, p. 41). Health psychology has developed significantly since the 1970s (Kenkel et al. 2005) although at different pace in different countries. Sweden is seen as a pioneer based on the development of 'psychophysiology of stress at the Karolinska Institute in Stockholm' in the early 1970s (Stone 1991, p. 9).

Psychological theories and public health

One of the best known names in the history of Psychology is Sigmund Freud (1859–1939). Freud was trained as a physician. He launched a new 'school' of psychoanalysis in psychology with his colleague Joseph Breuer promoting the idea that neuroses had a psychological, not a physiological basis (Ritzer 1992, p. 32). Freud based his theories on his observation of patients, making general inferences from individual cases.

In its early development, psychology had a similar concern found in sociology: a positivist trend following the goals of science, to identify universal laws 'expressed in theories that allowed prediction and explanation' (Looren de Jong 2010, p. 746). Over the years this quest promoted a range of theories including psychoanalysis, neuropsychology, and various personality theories some of them spanning the disciplines of sociology and psychology, usually clustered into four groups. These clusters are: (1) social cognition models addressed to the explanation of individual's health-related behaviour and comprising the theory of planned behaviour, the Health Belief Model, the transtheoretical model, and the health action process model; (2) self-regulation models focus on risk behaviours and include cognitive adaptation theory, self-regulation model and the model of self-efficacy; (3) the psychophysiological models cluster that 'describes how psychological processes, particularly in response to stressors, can influence physiological functioning', and includes the gate control theory of pain, the cognitive perceptual model, and the general adaptation syndrome, among others; (4) the fourth and final cluster is the environmental models cluster that includes the operant learning theory, conservation of resources theory, and the demand-control model of work stress (Weinman et al. 2007a, pp. xxx–xxxv; Weinman et al. 2007b). Given the space constraints of this chapter, this is only a summary of the main theories but it conveys the idea of the large and growing array of conceptual perspectives underpinning research in psychology today. Marshall H. Becker and his colleagues (Becker et al. 2007) provide an excellent discussion of the conceptual collaboration between sociology and psychology in the analysis of health behaviour—exemplified by the Health Belief Model—and the fruits of that collaboration in the form of conceptual models and abundant and advancing research (e g. Harmon-Jones et al. 2015; Rivard and Butler 2017; Anderberg and Dahlberg 2018; Diaz-Quijano et al. 2018).

Seen from a different and more abstract perspective, psychology—and all its subfields including health psychology—is engaged in a debate between

two contrasting positions: a contemporary version of the positivistic approach termed ‘rational reconstruction and theory building’ and ‘critical deconstructivism’. The latter approach ‘focuses on theory as dialogue and critique’ and on ‘the collective construction of meaning, not the discovery of objective facts about the mind’ (Looren de Jong 2010, pp. 747–8). The two positions are seen as the bases for ‘two research traditions within academic psychology, that is, social constructionism and cognitive neuroscience’ (Praetorius 2003, p. 511).

The debate over theoretical paths that can strengthen psychology’s contribution to science and psychologists’ professional identity continues unabated (Romanow and Marchildon 2003), but some intermediate schools of thought recognize that theory is an important part of mainstream psychological research (Looren de Jong 2010). At the same time, some psychologists like C.R. Cooper and J. Denner have recommended the inclusion of culture in the discipline’s research repertoire acknowledging that culture affects behaviour. Their recommendation springs from the engagement of psychologists in interdisciplinary research and the fact that culture is a long-standing subject of investigation in sociology and other social sciences but has not received sufficient attention in psychology (Cooper and Denner 1998). Another reason is their concern with the problem of external validity in psychology. They wrote, ‘Psychologists continue to generalize beyond their samples; while studying only their own countries … they assume that psychological phenomena are universal enough to make such studies representative’ (Cooper and Denner 1998 p. 579).

Psychological research and services relevant to public health

The general scope of health psychology research was well delineated by Canadian psychologist John L. Arnett (2001, p. 45) thus: ‘the diagnosis and prevention of illness, the promotion of health, and the amelioration of suffering related to the whole range of health conditions … across the whole spectrum of health’.

Clinical/health psychologists provide direct healthcare but their actual clinical practice is determined by government regulations and, more broadly, by the political system and ideology guiding the healthcare system. American psychologists succeeded in obtaining official licensing and

getting federal statutes modified ‘to gain autonomous inclusion in most federal programs’ providing paid healthcare and to practice in managed healthcare organizations. However, for most of the twentieth century, the training and practice of psychology and health psychology did not attend to the profession’s participation in the public policy process or in ‘programs that … address society’s public health priorities and perceived needs’ (De Leon et al. 1995, p. 493). This situation is common in other countries but it has been changing. For example, in most OECD (Organization for Economic Cooperation and Development) countries, people have access to paid psychotherapy services only if provided by physicians specialized in psychiatry. However, while both psychologists and psychiatrists can provide psychotherapy, ‘PhD-level clinical psychologists receive far more extensive training and education in psychotherapy than physician-trained psychiatrists’ (Romanow and Marchildon 2003, p. 286). In the realm of ideology, in countries with ‘centralized planning for health care’ or in community-based healthcare programmes such as Cuba, Costa Rica and India, ‘the concept of health psychology appeared early and its approach tended to be community-oriented’ in contrast to the individual orientation of the field in the European tradition (Stone 1991, pp. 12–13). Community-oriented psychology today goes beyond ideology. In addition to community-based counselling in disaster situations, other illustrations of the community-oriented approach involve the treatment of ‘mass psychogenic illness’ also known as ‘mass hysteria’ (Friedman 2002, pp. 64–5) and interventions designed for members of particular communities such as homeless youth (Trickett 2009).

The practice areas among health psychologists also vary across countries. In the first two decades of the field, while clinical work was the most common area of activity in the United States and the United Kingdom, the main work of health psychologists in Germany, Austria, France, and Argentina was teaching at medical schools (Stone 1991, p. 10). An overview of current health psychology work relevant to public health is suggested in the 2010 study of American health psychologists by Norcross and Karpiak (2012). These researchers found that the most common area of professional work among American health psychologists is psychotherapy practised either on individuals or as group therapy. Indeed, 76% of the professional health psychologists spent about 35% of their professional activity in psychotherapy in 2010, and it has been the most common area of

work since 1986 when comparative data collection started. The four other main professional activities are: diagnosis/assessment (58%); teaching (49%); clinical supervision (47%) and research/writing (47%) (Norcross and Karpiak 2012, pp. 5–6).

Psychologists propose that some of the services they offer do increase the productivity of health services by lowering public health expenditure. One illustration of this type of services is the provision of individual or group psychotherapies for breast cancer patients, and the treatment of depression and addiction-related conditions through cognitive behaviour therapies (Romanow and Marchildon 2003). Another example is 'evidence-based parenting interventions' to assist parents with the effective management of children and adolescents affected by 'behavioural and emotional problems' (Sanders 2010). In his Presidential address to the Canadian Psychological Association, M.R. Sanders suggested that psychologists could offer evidence-based parenting interventions as a 'public health approach' because the aim of his proposal was 'to reduce the prevalence rates of inadequate parenting at …[the]… population level', a drastic departure from the traditional focus of psychology on 'individual clinical interventions' (Sanders 2010, p. 17). Similar intervention programmes have been tried in the United States, England, and several European countries.

One of the relevant areas of health psychology for public health is stress management. An interesting input was borne out of the collaboration between a public health practitioner and a psychologist: preventive stress management programmes for corporations based on the 'theory of preventive stress management (TPSM)' devised by J.C. Quick and J.D. Quick in 1979 and focused on both physiological stress and organizational stress (Hargrove et al. 2011). According to the TPSM, individuals and organizations react to stressors either positively or negatively. The response to a stressor, or distress, 'is the psychophysiological response of the individual as well as … of a group or organization to fight or to flee'; the outcomes of that response may be 'either positive, such as a heightened alertness and enhanced performance, or negative, such as medical, psychological and behavioural distress' (Hargrove et al. 2011, pp. 182–3). As mentioned earlier, research on stress management was one of the earliest contributions in the field of health psychology by Sweden's Karolinska Institute. Swedish researchers analysed the impact of stressors produced by the individual's social and physical environment including the work setting,

home environment, transportation, and retirement among other factors (Stone 1991, p. 9).

Family psychotherapy is yet another area of psychology that is relevant to public health. It involves various modalities two of which are perhaps the best well-known. They are family therapy involving children and adolescents, and family therapy with older adults. Family psychotherapy involving children and youth is typically offered in collaboration with the school system in the community and deals with children's mental illness as well as with behavioural problems including drug abuse, truancy, and academic performance issues among other aspects. Family psychotherapy involving older adults is gaining ground in countries with a growing elderly population. Psychologists involved in family psychotherapy with older adults deal with a wide range of issues from dementia and other mental illness to intergenerational conflict, the significance of home setting, pain management, mobility, and physical impairment, among other problems (Curtis and Dixon 2005). In their review of recent developments in family psychotherapy with older adults in the United Kingdom, Curtis and Dixon found 'a lack of empirical research into family therapy with late life families' that needs to be addressed and an insufficient number of family psychotherapists doing this type of work compared to the larger number involved in family therapy with children and younger adults (2005, pp. 56–7).

Change in health-related behaviour is another area of work of health psychologists that is relevant to public health. Psychologists apply one or more social cognition theories (used in sociology as well) in individual and group therapy interventions with youth and adults to modify risk-taking behaviours such as alcohol drinking and cigarette smoking, and to reinforce preventive health behaviours such as condom use and healthy diet (Thirlaway and Upton 2009).

Psychological research methods relevant to public health

A distinguishing feature of psychology is its permanent state of critical introspection. This situation applies to its research methodology. Discussing the methodological landscape in psychology, Lambdin (2012, p. 68) argues that a dominant feature is the rift between two camps: experimental psychologists who claim their work 'is science because it is experimental'

and the work of their non-experimental colleagues. Both psychology camps are searching for ways to advance the discipline and correct research gaps and bias. But, as Lambdin rightly points out, common sources of bias are found in all scientific research—irrespective of the knowledge area, whether it is psychology, sociology, biomedicine, or any other: 'the results of any study can be preordained by the selection of stimuli, how variables are operationally defined, the construction of the experimental protocol, the level at which the data are aggregated, or the particular analysis the researcher chooses to utilize' (2012, p. 69). Lambdin suggests that researchers should explain their findings 'without reference to inferential statistics'; and advises applying instead 'a lot of hard thinking and critical reasoning' and focusing on 'effect sizes and confidence intervals which … are together far more informative and meaningful' (2012, pp. 70–1).

The use of statistical inference is only one of several aspects under discussion within the field of psychology. Four main fundamental issues that impact research are actively discussed today: the 'scientific versus humanistic' cultures in psychology; two ontological issues, the 'subjective-objective' and the 'individual-collective tensions'; 'the problem of evaluative criteria'; and 'the problem of competing worldviews or value systems' (Goertzen 2008). The beneficial ongoing debate ranges from critiques of conceptual schools of thought in psychology to practice-oriented assessment of diagnostic material, including approaches to improve the *Diagnostic and Statistical Manual of Mental Disorders*, the internationally recognized prime classification of psychopathology published periodically by the American Psychiatric Association (Acton and Zodda 2005).

Most if not all health psychologists are inclined to see conclusions obtained from an experimental design also known as randomized clinical trial, as significantly better than findings from case studies, but unfortunately it is not possible to use random allocation and true experiments in health psychology (Friedman 2002, p. 21). Thus, in addition to other forms of systematic observation, psychologists have traditionally used attitudinal scales and questionnaires to collect systematic responses from subjects in laboratory situations or one-to-one interviews or small group contexts. In addition to this long-established psychological methodology, some psychologists may occasionally borrow methods from sociology and other fields to study psychological phenomena. For example,

in their investigation of people's beliefs about medicine, Kienhues and Bromme (2012) used a survey technique by sending a questionnaire online to 284 higher school students.

The distinction made between quantitative and qualitative methods of research—discussed earlier—is the same as in sociology. Thus, in general, psychologists have a preference for quantitative methods and for the application of advanced statistical models in data analysis. However, Wienman and colleagues (2007b) suggest that qualitative methods are used now more often than before and discuss several methods that are undergoing improvement. Three examples suffice. The first illustration is studies of health-related behaviour where investigators may use 'self-report, observation by video or audio recording'. Subjects' self-reports are the most common method of data collection in psychology 'but it is open to problems of error and bias'; thus this method is under close scrutiny and efforts are underway to improve it with a view to make it more 'psychometrically sound'. The second illustration is the assessment of stress as the occurrence of negative life events and emotional changes using attitudinal scales such as the 'Impact of Event Scale' and the 'Hospital Anxiety and Depression Scale' or HADS. The third illustration is the measurement of 'health and illness cognitions' such as the perception of health risks through the use of questionnaire scales such as the Multi-dimensional Health Locus of Control scale and the Illness Perception Questionnaire (Wienman et al. 2007b). As is the pattern in sociology, psychologists dedicate considerable effort at examining and improving the validity and reliability of their research instruments (Sutton 2007).

Formalizing the contributions of sociology and psychology to public health training

The relevance of sociology and psychology to public health is amply recognized today not only in public health research and practice but also in public health education, particularly graduate training in public health.

Some researchers maintain that the United Kingdom was the first country to formalize the field of public health (Paccaud et al. 2011, p. 68). It is not surprising then, that the first training programme in public health was launched in 1871 in the United Kingdom. That programme was the

Diploma in Public Health comprising only three subjects, ‘epidemiology, population statistics and communicable diseases’, and given ‘a growing interest in how social determinants of health and illness interacted with disease since the 1930’s’, sociology and psychology were ‘incorporated into public health education’ in the United Kingdom in the 1960s (Cole et al. 2011, pp. 89–90).

The incorporation of sociology and psychology in public health curricula has been sluggish in European countries but in the United States, two private universities included both fields as the forerunners of graduate training in public health: Johns Hopkins and Harvard (Paccaud et al. 2011, p. 69). The American framework for public health training at the university level—the origins of which can be traced back to the Welch-Rose Report published in 1915—implemented in schools of public health include social and behavioural sciences as one of five core areas of the curriculum. The five areas are required by the Council on Education for Public Health (CEPH) that regulates Masters and Doctoral Public Health programmes in the United States (Gebbie et al. 2007; Calhoun et al. 2011, pp. 152–3; CEPH 2011a, p. 14; CEPH 2011b, p. 17; Imperato et al. 2011; Rosenstock et al. 2011, pp. 43–6).

The past two decades have seen serious efforts to improve the quality of medical education curriculum worldwide (WHO 2005). Other international organizations such as the World Federation for Medical Education are leading the improvement of medical education standards by incorporating in the graduate public health curriculum ‘basic biomedical, behavioural and social sciences, general clinical skills, clinical decision skills, communication abilities and medical ethics’ (WFME 2003, pp. 5–10). As part of that effort to improve public health training, the experience of the University of North Carolina—Charlotte [UNC] is illustrative of the trend towards inclusion of health behaviour in the curricula of public health graduate and undergraduate programmes accredited by the Council on Education for Public Health. At UNC the expansion of the public health curricula was motivated by the aim to establish ‘a thriving research base that emphasized population health and health behaviour research’ and ‘responsive and progressive health and human service training programmes’ within an interdisciplinary model (Thompson et al. 2009, p. 3). The UNC’s current 45-credit curriculum for the Master of Science in Public Health consists of professional practice and research in

epidemiology, biostatistics, research methods, 'behavioral and environmental determinants of health' as well as programme planning and evaluation; and the core curriculum includes 'Social and Behavioral Foundations of Public Health' (Thomson et al. 2009, p. 6). A case was made as well for the inclusion of health sociology modules in the Columbia University Medical Center's curricula for internal medicine residents to expose them to 'important societal health issues such as health disparities, social determinants of health and health literacy' (Fiebach et al. 2011, p. S268). Besides training, another important input of sociological and psychological research is the analysis of decision-making processes of junior doctors when selecting post-graduate programmes (Gale et al. 2017).

Public health programmes in Europe have followed the same trend of incorporating social and behavioural sciences as core subjects in graduate schools of public health following accreditation requirements set by the European Agency for Accreditation in Public Health Education or APHEA (Otok et al. 2011; Tulchinsky and McKee 2011). Outside the western sphere, however, the incorporation of social and behavioural sciences into the public health curriculum started only recently. Today, health sociology and health psychology are standard components of many graduate public health programmes in some non-Western countries (Bangdiwala et al. 2011; Pino and Solimano 2011).

A final word is in order. The development of multidisciplinary research on human subjects involving biomedicine, sociology, and psychology in various combinations, has led regulatory agencies to support collaboration by creating and expanding ethical guidelines. This effort also reinforces the fact that research ethics is as important in health sociology and health psychology research as it is in biomedical research. Two of the most relevant dedicated guidebooks have been published by the National Academies Press: *Protecting Participants and Facilitating Social and Behavioral Sciences Research* (Citro et al. 2003) and *Conducting Biosocial Surveys* (Houser et al. 2010). Multidisciplinary research on health and illness continues to expand with the increasing recognition of the relevance of social sciences in public health as well as in clinical medicine (Daw et al. 2012; Betts and Hodgson 2018; WHO 2018).

Conclusions

The preceding pages present a succinct description of what two social sciences—sociology and psychology—and their respective subfields, health sociology and health psychology, offer to the discipline of public health. Perhaps the strongest tie binding health sociology and health psychology is their interest in the systematic analysis of health-related behaviour and their attention to applicability of research findings to the solution of health-related problems in the community.

The essential focus of sociology is on the individual's *social* behaviour, that is, the person's actions and motives addressed to the actions and motives of others in primary and formal relations, as well as in collective entities ranging from small groups to institutions, social systems, nations, and global organizations. Therefore, health sociology analyses actions, beliefs, attitudes, and knowledge of individuals on matters of health and illness; health-related activities of groups, organizations and institutions at all levels of society; and the impact of the socioeconomic, cultural, political, and physical environment upon the actions, attitudes, and beliefs of individuals and collective entities of any size. Consequently, health sociology involves the study of both the micro-level and the macro-level spheres of social action: from the trilogy of individual action (preventive health behaviour, illness behaviour, sick-role behaviour), to dyads and primary groups (for example, doctor-patient relations; family's health, impact of small social networks on health risks), to large and complex organizations and social systems (for example, the analysis of healthcare organizations, insurance, and pharmaceutical corporations, the medical profession, government health policies, and impact of ideologies on the distribution of health resources in the population).

Health psychology's original focus was on the analysis of the individual's mental health. However, over the past two decades health psychology has re-oriented its attention to the analysis of all other aspects of health behaviour in addition to and beyond mental illness. This re-alignment of research interests is a positive development for public health because public health practitioners may now benefit not only from the growing body of knowledge produced by health sociology and health psychology, but they also benefit from the conceptual and methodological expertise of both disciplines.

Knowledge production in the twenty-first century is increasingly leaning towards multidisciplinary collaboration across knowledge domains. This

modality presents a unique challenge: multidisciplinary collaboration works well as long as each participating discipline has something distinct to offer to the collaborative enterprise. Each discipline must continue to push the boundaries of knowledge to increase its own expertise. Health sociology and health psychology continue creating knowledge in their respective areas of interest through research and constant critical examination of their own theories and methodological approaches. At the same time, both disciplines collaborate actively with each other, with public health, and with other biomedical fields for the improvement of people's health. The collaboration involves both applied and theoretical knowledge. The increasing pace of collaboration among health sociology, health psychology and public health is already evident not only in the joint authorship of scientific publications in books and refereed journals, but also in the multidisciplinary composition of the faculty in schools of public health around the world. Indeed, high-ranking public health schools tend to have a greater proportion of faculty from different disciplines.

[1] The name of the ISA Research Committee was changed from 'Medical Sociology' to 'Sociology of Health' in 1986 but, the essential nature of the discipline did not change, and the work and objectives of the ISA Research Committee remained the same.

[2] Sociological research over the past six decades around the world has demonstrated with systematic empirical evidence a universal phenomenon first hinted by French sociology pioneer Henri de Saint-Simon in 1819: different occupations are allocated different levels of prestige or deference and rewarded accordingly financially (from low paid, unskilled occupations such street cleaners or bricklayers, to high salary, highly skilled occupations such as neuroscientists). Occupational prestige is measured by means of population surveys whereby each person from a representative sample of the total population is asked to rate in a five-point scale (5 'excellent standing'; 4 'good standing'; 3 'average standing'; 2 'below average standing'; and 1 'poor standing') a comprehensive list of occupations in their society.

6.2

Sexuality and public health

Richard Parker, Jonathan Garcia, Miguel Muñoz-Laboy, Marni Sommer, and Patrick Wilson

Introduction

Over the course of the past 25 to 30 years, there has been an explosion of public health research and programmes focusing on sexuality. Never before in the history of public health have sex and sexual issues been seen as more worthy of attention. In communities around the world, researchers, practitioners, and policymakers have sought to develop new knowledge, to design new programmes and policies focusing on sexual health or sexuality-related health issues.

This recent public health interest in sexuality contrasts significantly with the way in which sexuality was addressed in earlier times. In the late nineteenth and early twentieth centuries, sexuality was considered at best to be a marginal concern to the health of individuals, with attention focused primarily on seeking to control what at the time were called venereal diseases (VDs) (Brandt 1987). Such diseases were characterized as indicators of moral failures, and the primary concern seemed to be with protecting mainstream society from the moral threat posed by such diseases.

Over the course of the mid-twentieth century, this situation gradually changed, as growing interest began to focus not so much on sexually transmitted infections, but on the wider range of what might be thought of as ‘normal’ sexual behaviours of both men and women—less with the goal of protecting them from disease than to seek to promote their health and well-being. This focus reached its zenith in the late 1940s and the early 1950s with the publication of the Kinsey studies in the United States (Kinsey et al. 1948; Kinsey et al. 1953). Yet the significant controversy that surrounded the publication of the Kinsey reports, especially in the cold war political climate of the 1950s quickly led to an almost total curtailment of

work on (and financial support for) the topic of sexuality during the ensuing decades (Corrêa et al. 2008).

It was only in the wake of the emerging HIV/AIDS epidemic in the early 1980s, the consequences of this long-term neglect of public health work focusing on sexuality became apparent. As the devastating proportions of HIV/AIDS—a global epidemic transmitted primarily through sexual contact—began to be perceived, the urgent need for greater understanding of sexual behaviour and for innovative new approaches to sexual health promotion quickly became evident. Thus, a new wave of public health research, intervention, and sexual health promotion began and continued to gain strength over the course of the 1990s and the 2000s.

This chapter seeks to provide an overview of this rapidly growing body of work in public health. It describes the initial public health response to sexuality in the context of HIV and AIDS, as well as the ways in which that response has been gradually broadened over time in order to provide a more comprehensive approach to sexual health and well-being. It also focuses on both the local and the global dimensions of this work, in both developed and developing countries, and as much in the work of local communities struggling to respond to the needs of their own populations, as well as on the part of a range of international agencies that are increasingly seeking to address a range of challenges to sexual health.

The impact of AIDS

The emergence of the HIV and AIDS epidemic in the early 1980s led to a major transformation in the ways in which public health has addressed issues of sexuality. During the early years of the HIV epidemic, one of the most frequently repeated laments of public health officials was the lack of data on sexual behaviour and the need to rely on findings from studies, such as the work of Kinsey and his colleagues in the United States, that were nearly 50 years out of date. The urgent need to respond to the epidemic with more contemporary knowledge on sexual behaviour provided the justification for a massive increase in research funding for work on sexuality among diverse population groups, and made the development of public health interventions to reduce the risk of sexual transmission of HIV an urgent priority (Turner et al. 1989).

Driven by epidemiological concerns, research on sexuality in relation to HIV and AIDS was initially developed in medical institutions, and was shaped by Western biomedical assumptions. Much of the early research carried out in response to the epidemic focused on surveys of risk-related sexual behaviours and on the knowledge, attitudes, and practices linked to risk of HIV infection. Most studies collected quantitative data on numbers of sexual partners, specific sexual practices, sexually transmitted infections, and similar topics related to transmission of HIV. Behavioural research sought to build a scientific foundation for public health policies and intervention programmes that would more effectively prevent HIV infection (Parker et al. 1991).

Very early in the epidemic, however, critical public health and social science research also highlighted the extent to which HIV and AIDS needed to be understood as what Paula Treichler described as ‘an epidemic of signification’ (Treichler 1988). Such work emphasized the ways in which complex cultural meanings shaped social understandings of the epidemic and surrounded it in deeply rooted forms of stigma, discrimination and denial (Parker and Aggleton 2003). It highlighted the importance of critically examining epidemiological and biomedical categories as well as popular understandings related to the epidemic, and emphasized the need to investigate local sexual cultures and the social organization of sexual practices in different social and cultural contexts (Parker 2001).

In early work on HIV among gay and bisexual men, for example, it became clear that many men who have sex with other men may not identify themselves as homosexual on the basis of this behaviour, and that Western biomedical categories such as ‘homosexuality’, ‘bisexuality’, or ‘heterosexuality’ might not adequately describe the lived sexual experience of many individuals. Increasingly, descriptive categories such as ‘men who have sex with men’ (or ‘MSM’) were adopted both in research and in public health practice in order to avoid imposing culturally inaccurate or inappropriate labels and classifications. This led, in turn, to important work rethinking the relationship between sexual orientation, sexual identity, and sexual behaviour. Based on this work, it became evident that assumptions about the relationship between sexual desire, sexual behaviour, and sexual identity—in particular, the assumption that feeling desire necessarily led to enacting behaviour, and that enacted behaviour necessarily led to forming a

distinct sexual identity based on that behaviour—needed to be re-examined and investigated empirically (Dowsett 2003).

Work on homosexuality and MSM opened the way for a broader critique of other key categories that had been used in seeking to understand the epidemiology of HIV infection. Research on 'prostitution', for example, highlighted extensive cross-cultural diversity in the ways in which sex is exchanged for money, gifts, or favours, and emphasized the importance of sex work and sex workers, on the one hand, and other forms of transaction that might characterize many sexual relationships without constituting sex work or identifying those involved as sex workers or clients (de Zalduondo 1991). Similarly, while the female sexual partners of male injecting drug users (or the male sexual partners of female injecting drug users) might constitute meaningful epidemiological categories, they have little or no sociological significance, and members of groups identified through such categories have little or no sense of self-identity or group identification based on these circumstances, making them largely useless for purposes of health promotion and HIV prevention (Kane and Mason 1992). As a result of HIV and AIDS, then, the ways in which public health has approached issues of sexuality have changed significantly, and new understanding of sexual health promotion have been developed that have important consequences for other areas of sexual health, independent of HIV and AIDS.

Public health research on marginalized populations such as female sex workers and male and female injecting drug users and their sexual partners also focused growing attention on the broader synergy that exists in many societies between poverty, racial or ethnic discrimination, gender power inequality, and vulnerability to HIV infection (Farmer et al. 1996). It became increasingly clear that sexual behaviour is not somehow isolated or free-floating, separate from other forms of social experience and social structure. On the contrary, sexuality exists embedded in social hierarchies, and sexual behaviour can only be understood within the context of social processes. One of the lasting lessons of the HIV/AIDS epidemic for understanding sexuality in relation to public health more broadly was therefore that sexual risk behaviour must be understood not just as 'behavioural risk' but as 'social risk'—and, indeed, that the concept of 'risk' should perhaps be abandoned altogether in favour of a greater

emphasis on ‘social vulnerability’ that would be more useful in seeking to understand the social drivers of the epidemic (Parker et al. 2000).

This emphasis on the social determinants of the epidemic also called attention to the synergies that exist between issues and other social problems. For example, two of the major threats to the sexual health of populations in many countries across the globe are substance abuse and imprisonment. The connections between substance abuse and sexuality are complex. On the one hand, substance abuse and binge use of a substance such as alcohol have been associated with condomless sex and coercive or unwanted sexual encounters (O’Hara and Cooper 2015). On the other hand, alcohol, marijuana, opioids, and recreational drugs have been used by different populations to cope with the stressors associated with sexualities and gender expressions that do not conform to heteronormative gender and sexual norms (Slater et al. 2017). Furthermore, for injecting drug users, blood diseases such as HIV can be acquired through use of contaminated syringes or through sexual transmission; which is particularly concerning since sex in exchange for drugs or money or shelter have been associated with people with severe opioid and cocaine use disorders, including injecting drug users (Decker et al. 2012). Thus, there is a complex bidirectional association between substance abuse and the severity of substance use disorders, and populations’ sexual expressions and behaviours, and sexually transmitted infections. While high-risk substance consumption and substance abuse disorders are cause for concern in and of themselves, recent evidence suggests that substance abuse might be associated with the likelihood of sexual risk behaviour, HIV/sexually transmitted infection (STI) infections, late AIDS diagnosis, poor adherence to HIV/STI and substance abuse treatments (Strathdee et al. 2010).

Just as an emphasis on the social dimensions of risk and the multiple social factors that contribute to vulnerability have opened up important insights in our understanding of sexuality in relation to HIV, recent advances in the use of new biomedical approaches for preventing the sexual transmission of HIV infection have opened up new areas for research and intervention in relation to sexuality and public health. The emergence of pre-exposure prophylaxis (PrEP) as an HIV prevention tool for vulnerable communities globally has spurred an ongoing debate within public health regarding the best way to reduce new HIV infections. Efforts have been made to highlight the potential impact that biomedicine (including PrEP

and highly effective anti-HIV treatments) has to eradicate HIV. However, on the ground efforts to disseminate PrEP within marginalized and vulnerable communities have stalled. For example, one study of Black MSM, a group highly disproportionately impacted by HIV in the United States, found that less than one in four were aware of PrEP as a prevention tool (Eaton et al. 2015). Studies have suggested that for many MSM in the United States and globally, stigma related to HIV, lack of access to basic necessities and healthcare insurance, and negative perceptions of PrEP contribute to lack of uptake (Arreola et al. 2015; Garcia et al. 2016b). Additionally, even in cases where access is unhindered, many populations have difficulty adhering to anti-HIV drugs, reducing their potential for prevention and treatment (Wilson et al. 2016). Scholars in the social sciences have provided some context to the problems with placing too much faith in biomedicine to prevent HIV. Sexual minority communities have not always had a voice or choice in HIV prevention, which has led to failures in how public health researchers and practitioners have viewed effective intervention approaches. Understanding the complex personal, social, and political dimensions of using anti-HIV medication for prevention or treatment is critical to next steps in addressing the epidemic (Aggleton and Parker 2015; Auerbach and Hoppe 2015).

The various insights derived from work on sexuality in the context of HIV and AIDS have continued to shape public health approaches to sexuality over the course of the past two decades. They have been especially important in seeking to develop both research and programmes aimed at promoting sexual health among young people, heterosexual women and men, as well as sexual communities and populations outside the mainstream of society that often face special forms of vulnerability due to emerging forms social marginalization and exclusion. Work on sexuality in relation to population health has also heightened awareness of the complex ways in which sexual experience is socially regulated, with consequences that can be highly diverse. A broader focus not just on the absence of disease, but on a fuller realization of true health and well-being, in relation to sexuality as in relation to other aspects of health, requires a broader focus on the relationship between sexual health and sexual rights (Parker 2007). Notably, the work of public health has been shaped, through political agenda setting, cultural framings, and outright displays of indignation with the status quo stemming from AIDS social movements throughout the

world (Altman and Buse 2012). The AIDS social movement has been significant in addressing cultural, structural, and social determinants of health, including sexuality and sexual health (Parker 2011). In the following sections of this chapter, we will seek to address the development of work on these various dimensions of sexuality and public health, explore ways in which sexuality intersects with public health issues such as mental health and violence, and to highlight the ways in which this rapidly growing field of work is developing in the early twenty-first century.

Youth, sexuality, and gendered experience

Young people today represent the largest population across the globe, at 1.8 billion and growing (Patton et al. 2016). This suggests a critical need for attention to their developmental experiences, particularly in relation to sexuality and health. More recently the global health community has advocated for an expanded definition of 'adolescence' (10–24 years old) given the earlier onset of puberty in populations around the world, and the ways in which young people's developmental experience through the life course now expands into their 20s (Sawyer et al. 2018). The definition of 'youth' and the timing of a young person's first experience of sexuality are two important considerations for public health researchers and practitioners designing sexual health interventions. The biologically defined developmental stages of youth tend to place an important emphasis on puberty as the beginning stage of human sexuality Patton and Viner 2007). The onset of puberty brings with it numerous physiological changes and new social pressures for young people transitioning into young adulthood within any given society. Along with adjusting to the new biological changes that are experienced, including the development of secondary sexual characteristics, young people must adjust to the social responses of peers, family, and communities to their obvious physical and emotional sexual maturation. As societies shift from rural to urban, as the advent of formal schooling incorporates greater populations of young people, as influences from globalization and new technologies shape the experience of childhood and young adulthood, and as gender norms continue to evolve, the sexual socialization of young people is being altered and transformed (Blum 2007).

Girls and boys experience puberty differently biologically and socio-culturally. Puberty is not only experienced at different ages according to sex but may be marked by differing rites of passage (broadly defined) that depend on contextual and structural factors. Sexual differentiation moulded by social norms can shape the transformation of gendered expectations and sexual opportunities for girls and boys. The socializing norms influencing young peoples' development, perceived societal roles, and ultimately their restraint or engagement in sexual risk-taking behaviours are closely linked to local femininity and masculinity norms. In some cultures, girls are de-sexualized at a young age through procedures such as female genital excision, or what has been widely framed by the feminist human rights movement as female genital mutilation (Boyle 2005). Emphasis is generally placed on fertility as the representation of femininity. Boys also undergo sexual rites of passage, but these are often more 'empowering', signifying the acquisition of manhood and emphasizing the importance of virility. Whereas women are sometimes denied sexual pleasure through these procedures, boys that experience male circumcision are ascribed a role in their communities that associates their sexuality with power and responsibility (WHO 2000).

In recent decades, attention has shifted to the social construction of sexuality for understanding the ways in which young people's sexuality and gendered experience are influenced by the societal pressures and traditions around them (Freud 1994). This differentiation based on the social construction of sexuality has concrete implications for gendered disparities in human development related to both education and health. A gendered division of labour presents significant barriers to closing the gap in illiteracy and access to essential health services in resource-poor settings (Blum and Mmari 2006). In addition, girls are often married-off to older men, and boys are sometimes forced to migrate from rural to urban settings to find work. Both intergenerational sex and migration are factors that contribute to sexual risk.

As young people transition into young adulthood, sexual and reproductive health becomes a priority health issue. This is particularly true for young women in low-income countries, for whom adolescent pregnancy presents particular risks of maternal mortality and morbidity (such as obstetric fistula), infection with HIV and AIDS, and STIs (Hindin and Fatusi 2009). Adolescent pregnancy makes girls vulnerable to dropping out

of school and to mental health problems. Campaigns to prevent STIs and HIV are only beginning to target youth facing structural barriers. The risk of sexual violence is an additional challenge, particularly in societies where gendered power dynamics place young women in positions of little negotiation around sexual relations, and where masculinity norms promote aspects of virility and strength for young men.

In recent years, there has been growing attention to the onset of menstruation (menarche) as a window of opportunity for engaging girls prior to the onset of sexual pressures and relationships (Sommer et al. 2015). Although much of the focus on menstruation has emerged from the water and sanitation community, focused on the need to improve water and toilet facilities for menstruating girls in schools (Sommer and Sahin 2013), the sexual and reproductive health community increasingly recognizes the benefit of engaging girls and their families at menarche as an entry point for talking about sexual and reproductive health as a less taboo topic than contraception and family planning (Chandra-Mouli and Patel 2017). The Global Early Adolescent Study (GEAS), launched four years ago, is seeking to build the evidence on this critical developmental phase in 16 study sites (low-, middle-, and high-income countries) around the world (Saewyc 2017). In particular the focus is on understanding the gendered transition from childhood into adolescence, and the factors that promote healthy sexuality or risky sexual behaviours in adolescence.

However, it is also important to question the assumption that sexuality actually begins at puberty. Some studies have shown that sexual experimentation and initiation might begin before this biological landmark (Bankole et al. 2007). Masturbation is a major part of sexual experimentation, and access to pornography on the Internet is widespread. The international community has paid increasing attention to the effects of globalization on trafficking in children and sex work as major public health problems in the contemporary world. This protection of the rights of children is the responsibility of families, communities, and nation-states.

Much of sex education for youth is regulated through kinship networks and schools (Barker 2007). The family and ‘traditional values’ play an important role in sex education for boys and girls. The age of sexual debut continues to change around the world with influences of modernization and delays in the age of marriage secondary to the advent of formal schooling. The quality of communication between parents and youth influences the

ways in which youth are sexually socialized. Religious values that condemn condom use are particularly influential in shaping the types of messages youth receive from their families and in schools. International debates about what constitutes sex education are shaped by progressive advocates for comprehensive approaches (which might include the distribution of condoms to youth for STI and HIV prevention), and by conservatives who believe that sex education should be limited to teaching sexual abstinence until marriage.

More recently, debates over sex education have begun to discuss sexual orientation because at a very young age children begin to experience bullying, especially in schools and on the internet. School and cyberbullying can lead to increased sexual risk, mental health problems, and substance use among youth.

LGBT youth are among the most vulnerable populations globally. Although much of the literature that documents a higher risk of suicide, mental health problems, HIV/STIs, and violence for LGBT youth focuses on the US context, these patterns are documented worldwide (Grangeiro et al. 2012; Roa 2013). LGBT youth are prone to experiencing homelessness due to community and family rejection across cultural contexts (Blondeel et al. 2018). Many studies identify transactional sex as the main source of survival and vulnerability for LGBT youth that experience social rejection (Baral et al. 2015). Although international activists have managed to include protections for young women, it has been more difficult to address the intersectional needs of young transgender women and other sexual minority youth in transnational documents (Barroso 2014).

Structural interventions that target school policies are crucial for the formulation and implementation of comprehensive sex education to prevent bullying based on sexuality (Jones et al. 2009). In terms of the advancement of comprehensive sexuality education (CSE) globally, the UN conducted a review in 2015 which indicated that over 80% of countries now have policies in place to include such content in schools (UNESCO 2015). Such efforts are the result of growing evidence indicating the benefit to adolescent sexual and reproductive health from the inclusion of such content in schools. In 2013, 20 governments in eastern and southern African (ESA) committed to scaling up CSE in their educational systems (UNESCO 2018a), and in 2018, UNESCO updated their global technical guidance on the provision of CSE (UNESCO 2018b). However there continues to be

push back from many governments on the actual implementation of CSE, with growing conservative and religious influences restricting the delivery of such content to youth.

Heterosexual relations

Public health research on heterosexuality has been relatively limited when compared to the focus on non-heterosexuality. Kinsey's studies began to uncover the gradients of sexuality, as opposed to a dichotomous divide between heterosexuality and homosexuality—yet, the curiosity for deconstructing the accepted norms was in some ways aimed at showing the non-existence of an authentic heterosexuality. Historically, the field of sexuality research is laden with bias towards studying 'deviations' from the sexual norm rather than at seeking to more fully understand the ways in which dominant normative patterns of experience are produced and organized (Wilkinson and Kitzinger 1994). The concept of 'heteronormativity' has been used in critical public health to describe the ways in which men and women form both casual and steady partnerships, which are moulded by social and cultural norms (Kitzinger 2005). This concept has theoretical traction for understanding patterns of sexual behaviour with important implications for public health outcomes.
