Important questions are still to be answered to carry out action, which is accomplished through research. The question remains about the research that should be put in place as the needs are great. Research in this area should follow the large framework that is being proposed here. There are needs at the policy level and there are needs at the practice level. At the policy level, there are important unsolved questions about what policies could make the job done regarding prevention of MSDs, access to healthcare and improvement of severity of disability (Vos et al. 2017). At the practice level, there are needs specifically regarding best clinical practices and new treatments. An important area of research priority includes assessing the impact of modifiable risk factors through innovative treatment approaches. Public policy that addresses these risk factors may help significantly reduce the public health burden and cost of MSDs (Haldeman et al. 2008).

Research on the specific risk factors that should be targeted in specific populations is still pending. For example, there is a dearth of epidemiologic research from low and middle-income countries on musculoskeletal disorders (Hoy et al. 2014). Due to significant demographic and environmental differences influencing the onset and progression of various musculoskeletal disorders in these regions, it becomes challenging to reasonably extrapolate some of the risk factor finding from high-income countries to low and middle-income countries. In developing

countries, trends in obesity, the burden of heavy physical labour, diminished access to healthcare variations in the approach to pain treatment and linguistic variation all contribute to differences in reported and treated MSDs (Fransen et al. 2011). Nonetheless, these observations could be lower or higher estimates of the true value, given the general lack of epidemiologic data in these developing countries that could support the development of better policy (Gabriel and Michaud 2009).

Practice level

While research progresses, much is already known on what to do and it should be put in practice. We already know what the major modifiable risk factors are; and ways to improve access to healthcare. While they may require adjustment to be applied in specific contexts, the basic understanding of the problem and potential ways to tackle it have already been proposed.

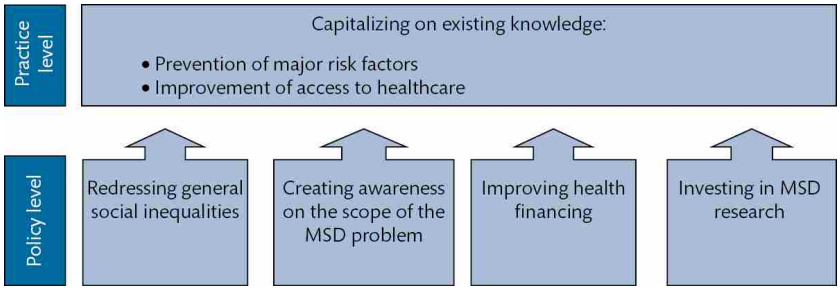

Fig. 8.9.3 Conceptual model for practice and policy levels approaching to addressing musculoskeletal disorders.

For example, in the case of LBP treatment, there are several new scientific and clinical investigations underway to understand innovative technologies, new drugs, and strategic management approaches for individuals with LBP. The healthcare community should be encouraged by the fact that we already know so much about this the challenges of LBP that is affected by a host of genetic, physical, psychological, environmental, cultural, and societal factors (Balagué et al. 2012). Unfortunately individuals with musculoskeletal disorders are too often ignored, and their complaints often misunderstood by healthcare providers. Large population studies have shown that successful management of musculoskeletal pain must occur during the acute phase in order to hinder progression to a more chronic state. Adoption of broader standards of care for these conditions, particularly in low-resources areas is needed (Walsh et al. 2008). This is especially the case when MSDs are comorbid with other health conditions. For example, research has shown that MSDs are closely associated with mental health and physical disability. Among older with MSDs, depression is common, and is associated with functional disability (Punzi et al. 2010). Studies have shown that the older adults depression and pain are better predictors of disability than findings from radiographic imaging. These findings can inform the development of practice guidelines to screening for other comorbid conditions that might improve the overall health of the person with MSDs (Punzi et al. 2010).

Regarding the prevention of known modifiable risk factors for MSDs, practice efforts should focus on new ways to prevent and control obesity and exposures to mechanical demands in the workplace. However, little has been done globally, nationally, or regionally to address systematically obesity (Popkin 2006). From the 1980s to 2008, trends in the mean population BMI have varied substantially between nations. Developing interventions and drafting policies that modify this observed increase in BMI by targeting these modifiable risk factors are highly needed in most countries (Finucane et al. 2011).

Practice efforts to address MSDs should include education on diet. Two noteworthy country efforts can be seen in Finland and South Korea (Holveck et al. 2007). Finland has been reported as one of the countries that have made efforts in the direction of using intersectoral collaboration (Pietinen et al. 2010). They have developed an integrated national price and food-labelling policy coupled with educational programmes on diet and nutrition as well as advocacy efforts from select organizations. A second example is South Korea that has long promoted the use of a traditional diet rich in vegetables and low in fat—very distinct from observed trends in other middle-income countries that have experienced a westernized shift in dietary consumption (Lee et al. 2012). Over the years, the South Korean government has provided educational community workshops to new brides on how to

prepare traditional dishes and avoid incorporation of western style dishes. These efforts have resulted in lower obesity levels and lower intake of energy-dense foods that would be expected from high-income level countries.

Regarding treatment options and practice, there is a need to translate what is already known scientifically to guidelines for clinicians. In the advent of the information age, healthcare professionals can easily become bogged down with multiple sources of information from professional organizations, drug developers, and scientific journals. Data from all these sources could be combined, digested, and presented in a more systematic fashion so that the end user (i.e. healthcare professionals) can benefit from a uniform and up-to-date source of information on best practices to treat MSDs. Translating our basic and clinical science knowledge based into real world bedside practices should be warranted (Punzi et al. 2010). Clinical recommendations that consider presence of comorbidity and treatment burden in such circumstances should also be prioritized (Duffield et al. 2017). However, it appears clear that the formulation of clinical recommendations is not enough to introduce changes in clinical practice; therefore, research on how to permeate effectively these practices is warranted (Buchbinder et al. 2015).

Regarding access to healthcare, efforts need to be made so that available treatments permeate all people in need, especially in more vulnerable populations. This is of course, related to the financing aspect mentioned earlier. For example, among rural regions of the developing world, access to joint replacement surgery is scarce and likely leading to a large number of older adults living with high-grade degenerative joint disease and poor quality of life. The new possibilities of the digital era should be explored to improve health access, considering ethical issues and new barriers related to the access to technology (Lupton 2015; Howard and Kaufman 2018).

Despite access to new information that is made readily available to healthcare providers in developing countries other barriers may be present (Turner 2009; Doughty et al. 2010; Vargas et al. 2010). For example, in order to minimize the sequelae from a bout of LBP, providers in developing countries could incorporate the use of evidence-based guidelines to standardize their management approach and improve MSD treatment outcomes in their community setting. However, despite the progress made in the past two decades in developing and updating guidelines, and adapting them on a national basis, uptake by healthcare providers is not optimum (Global Alliance for Musculoskeletal Health). There are challenges with implementing guidelines in low-resource setting, including the use of specific drugs or technologies that might not be readily available in those areas, as well as pressure from industry or healthcare providers who challenge changes in medical and public health practice (Balagué et al. 2012).

Neurological diseases, epidemiology, and public health

Walter A. Kukull, Kumeren Govender, and James Bowen

Introduction to neurological diseases, epidemiology, and public health

Included in this chapter are brief descriptions of headache, traumatic brain injury (TBI), epilepsy, dementia, peripheral neuropathy, parkinsonism, and multiple sclerosis (MS). Diagnosis is critical to epidemiological study but is often difficult because of long, preclinical undetectable periods. Clinical criteria rather than pathological evidence can lead to misclassification of disease and spurious inferences. To some extent biomarkers are becoming accepted as a preclinical indicator of disease or a means to add diagnostic certainty among the symptomatic.

Population-based studies are the best method to avoid spurious, biased, or non-generalizable results, but for most neurological diseases these are seldom performed. Selecting ‘control’ subjects from the same base that gave rise to the cases is methodologically essential but often a luxury ignored by investigators. Cohort studies must start with people free of disease but if preclinical detection of disease process is not possible, risk factor associations may be severely biased.

Determination of risk factor exposure, and estimating whether it may have occurred during a time window which had potential to result in the disease in question (and not to have resulted from the disease) is critical. In acute TBI this becomes obvious, while for Alzheimer’s disease, which may have a 30-year preclinical period, it is cryptic. Researchers seldom have records, biological specimens, or even accurate self-reporting sufficient to establish previous exposure patterns. Biological markers of exposure (except for genotype) are occasionally employed in cancer studies (e.g. DNA adducts), are seldom available for neurological diseases, but may

provide some hope for the future. Biopsy is seldom feasible and autopsy results reflect cross-sectional cumulative effects of disease, leaving the picture additionally confusing.

In less developed countries, the problems of diagnosis and exposure measurement grow in magnitude. Differences in available facilities and local practices are likely the easiest to overcome. Addressing political concerns and suspicions to gain cooperation necessary to begin a study may take additional time and preparation.

Headache

Clinical overview of headaches

Headache is among the most common medical complaints however the pathogenesis of most headache is poorly understood. The nosology of headaches is based on the cause when known and the clinical picture when the cause is unknown. As many as 90% of all primary headaches fall under a few categories, including migraine, tension-type, and cluster headache. While episodic tension-type headache is the most frequent headache type in population-based studies, migraine is the most common diagnosis in patients presenting to primary care physicians with headache. The International Classification of Headache Disorders (ICHD) is the most commonly used system of classifying headaches, now in its third edition based on greater scientific evidence (Headache Classification Committee of the International Headache Society) (Box 8.10.1). This system classifies individual headaches, as most patients may have more than one type of headache. Headaches associated with neurological or systemic diseases are comparatively rare. Idiopathic conditions are far more common and include migraine (with or without aura), tension-type headaches, and cluster headaches. Because these idiopathic headaches are the overwhelming majority, they have the greatest impact on epidemiological studies.

Migraine without aura, previously named common migraine, is a recurrent headache disorder that typically is unilateral. Some people have throbbing pain while others have constant non-throbbing pain. Nausea, photophobia, and phonophobia may occur. The pain often builds over a few hours. The typical length of the headache is 4–72 hours.

Migraine with aura, previously named classic migraine, has an aura consisting of a fully reversible alteration of neurological function that usually precedes the headache. This commonly consists of a central area of visual loss surrounded by a rim of shimmering light (scintillating scotoma). Non-visual auras may include paraesthesias, numbness, weakness, aphasia, or vertigo. Auras usually precede the headache by about 20 minutes, though timing may vary. The headache is most commonly, though not always, unilateral, throbbing, and often associated with nausea and vomiting. It typically lasts a few hours. It may have premonitory symptoms preceding the headache and aura.

Tension-type headaches, the most common type of headache, are usually bilateral with a sensation of pressure or a tight band around the head. They are less likely to have premonitory symptoms or nausea or vomiting. They do not have auras. They usually last longer than migraine headaches, typically an entire or several days. They build up more slowly than migraine headaches.

Box 8.10.1 International Headache Society, abbreviated classification of headache

1. Migraine
    - 1.1 Migraine without aura
    - 1.2 Migraine with aura
2. Tension-type headache
3. Trigeminal autonomic cephalagias (TACs)
4. Other primary headache disorders
5. Headache attributed to trauma or injury to the head and/or neck
6. Headache attributed to cranial and/or cervical vascular disorder
7. Headache attributed to non-vascular intracranial disorder
8. Headache attributed to a substance or its withdrawal
9. Headache attributed to infection
10. Headache attributed to disorder of homoeostasis
11. Headache or facial pain attributed to disorder of cranium, neck, eyes, ears, nose, sinuses, teeth, mouth, or other facial or cranial structure
12. Headache attributed to psychiatric disorder
13. Painful lesions of the cranial nerves and other facial pain
14. Other headache disorders

Source: data from International Headache Society, The International Classification of Headache Disorders: 3rd edition, *Cephalalgia*, Volume 38, Supplement 1, pp. 1–211. Copyright © International Headache Society 2018.

Cluster headaches are named after the tendency to occur in clusters lasting weeks to months. However, other types of headaches may also occur in clusters and the diagnosis is based on the characteristics of the headache rather than the clustering. The headache develops abruptly. During a cluster, it usually occurs between one and eight times a day, often at the same time of day. The pain is more short-lived than that of other idiopathic headaches and generally subsides within 3 hours. The pain is often more severe than that seen with migraine and patients are often agitated during the attack.

In a single patient, less severe headaches tend to be tension-type while more severe headaches are migraine. Over time a patient's headaches often change from classic migraine in youth to tension-type headaches in middle age. Headache frequency may increase with age, becoming chronic daily headaches. Some term these headaches as 'transitioned migraines'. This term is not included in the ICHD and many of these cases are actually due to medication overuse.

Prevalence of headaches

Case definition, sample characteristics, methodology, and analytic designs have differed, sometimes substantially, raising questions of comparability. One-year prevalences vary from 20–90% (all headaches), 3–24.6% (migraine), 9.8–72.3% (tension-type), and 0.5–7.3% (chronic headache) (Stovner et al. 2007).

Several studies have evaluated the prevalence of migraine, reflecting the availability of validated survey instruments for this disease (Natoli et al. 2010). For migraine, age-standardized prevalence from the Global Burden of Disease Study 2016 was 14.4% (95% confidence interval (CI) 13.8–15) (Stovner et al. 2018). Prevalence peaks at 30–39 years of age, and is higher in women, White people, and those with lower incomes (Lipton et al. 2007). Less than half report their migraines to a physician and approximately 40% of these did not receive a correct diagnosis (Lipton et al. 1998). Susceptibility to migraine may be affected by ethnicity since migraine appears to be more common in Caucasians compared to Africans,

African Americans, or Asian Americans (Osuntokun et al. 1992; Stewart et al. 1996).

There are far fewer studies on tension-type headaches, though it is the most common type of headache. Up to 89% of people suffer tension-type headaches at some time, but for most this is infrequent (Kaniecki 2012). About 25% have weekly tension-type headaches and 2–3% chronic tension-type headaches (Lyngberg et al. 2005a). The prevalence appears to be increasing, though the factors leading to this are not entirely clear. About half of people with tension-type headaches improve within a decade (Lyngberg et al. 2005b). Chronic daily headache from medication overuse is increasingly recognized (Tepper 2012).

Cluster headaches are the least common of the idiopathic headache disorders. Pooled data showed a lifetime prevalence of 124 per 100,000 [CI 101–151] and a 1-year prevalence of 53 per 100,000 (CI 26-95) (Fischera et al. 2008).

Familial and genetic risks of headaches

Genetic influences on migraine have investigated principally familial aggregation and twins. Studies of single genes responsible for familial hemiplegic migraine provide insight into migraine pathophysiology (Ward 2012). The overall lifetime prevalence of migraine with aura for monozygotic (MZ) and dizygotic (DZ) twins is 7%, similar to population surveys (Gervil et al. 1999; Ulrich et al. 1999). Concordance in MZ twins is 34% compared to 12% for DZ twins. For migraine without aura the concordance for MZ twins is 28% and 18% for DZ. This indicates a potential genetic contribution but modifying environmental influences must also be important. Concordance is higher for MZ than DZ twins whether raised together or apart, and about 50% of the variance is explained by genetic factors with the remaining half ‘non-shared environmental factors’, and measurement error (Ziegler et al. 1998; Russell et al. 2007).

The relative risk (RR) of migraine in first-degree relatives of migraineurs is 1.88 compared to a control group (Stewart et al. 2006). The RR was higher in relatives of those whose headaches began before 16 years of age (RR = 2.50) than those whose headaches began later (RR = 1.44). The risk in relatives of those with severe headaches had a relative risk of 2.38 (CI 1.56–3.62) while relatives of those with less severe pain had a relative risk

of 1.52 (0.99–2.34). A few candidate genes have been associated with migraine, including the KCNK18 gene that encodes for TRESK, a two-pore domain potassium channel (Lafrenière et al. 2010) and the CSNK1D gene, which encodes casein kinase I isoform delta (Brennan et al. 2013). However, in a systematic re-evaluation of 27 promising candidate migraine genes in a large data set compiled from genome-wide association studies, with over 5,175 migraineurs and 13,972 control subjects, found that none of the candidate genes reached the threshold for statistical significance (de Vries et al. 2016). Thus, which candidate loci and genes are truly implicated in the pathogenesis of migraine is still uncertain.

Risk factors for headaches

Stress or psychological factors are often cited as contributing to tension-type headaches. However, the frequency of these factors is similar in patients with migraine and tension-type headaches. With chronicity, psychological changes increase in frequency, suggesting that psychological issues are secondary to chronic headaches rather than causative. There is an increased risk of depression in migraineurs and also an increased risk for migraine among those with prior depression, suggesting the two disorders may have mechanisms in common. The issues of migraine and depression have been reviewed (Frediani and Villani 2007).

Chronic daily headaches are more common in women, white people, and those with less education. An improvement in headache frequency after 1 year was more common in those with higher education, non-white people, and those who were married (Scher et al. 2003). However, in adolescents with a family history of migraine, migraine prevalence is the same in low- versus high-income groups suggesting that genetic factors overwhelm environmental risk factors in those genetically susceptible (Hagen et al. 2002). One of the strongest risk factors for headaches is prior headaches (RR = 4.15) (Boardman et al. 2006). Pain in other areas of the body is associated with headache (RR = 1.43).

Stroke and migraine

Migraine has been associated with ischaemic stroke and to a lesser degree with haemorrhagic stroke in a number of studies (Alhazzani and Goddeau

2013). Additional study will be needed to adequately describe the true relationship between migraine and stroke.

Costs and public health impact of headaches

The estimated 23 million people with migraines in the United States may miss 150 million workdays each year with an associated cost of up to US$17 billion (Cady 1999; Hu et al. 1999). Many more people suffer with decreased effectiveness at work than actually miss work days (Schwartz et al. 1997). In Europe, costs of headaches are substantial with mean per-person annual costs of €3,561 for medication overuse, €1,222 for migraine, and €303 for tension-type headaches (Linde et al. 2012). Health-related quality of life is lower in those with migraine, and this is related to the frequency of attacks (Wang et al. 2001). There are many challenges in making cost determinations due to limits on available epidemiological data (Leonardi et al. 2005). However, the best estimate suggests that migraine accounts for 1.4% of all years of healthy life lost worldwide. It is the 19th leading cause of years of healthy life lost in men and 12th in women. Although new advances such as neurostimulators and a recent new class of compounds called gepants to treat migraine attacks have been developed, this major public health issue deserves continued attention.

Traumatic brain injury

Clinical overview of traumatic brain injuries

TBI is commonly divided into two categories by mechanism of action: (1) penetrating or (2) closed head injuries. These also may be characterized as resulting from direct contact injuries or from concussive ‘acceleration deceleration’ types of injuries (Werner and Engelhard 2007). Among penetrating injuries, greater tissue damage is caused by high-velocity penetrating objects than by lower-velocity ones. Both penetrating and closed injuries may perturb or impair cerebral blood flow (CBF) leading to ischaemia and altered cerebral metabolism. Impaired CBF resulting from cerebral vasospasm predicts poorer outcome and may occur in approximately 30% of TBI cases (Werner and Engelhard 2007). Brain

contusions may lead to both blood vessel and cell membrane injury resulting in vasogenic or cytotoxic oedema. Hydrocephalus may develop due to blockage of the routes of normal cerebrospinal fluid (CSF) flow. Finally, closed head injuries may lead to diffuse axonal injury. Diffuse axonal injury results in balls of axonal material occurring at axon transection sites or sites of altered axonal flow. Intracranial pressure monitoring is a concern; however, a recent trial does not support it as superior to other forms of neurological monitoring (Chesnut et al. 2012). Neurological damage due to TBI may grow after the injury because of impaired cerebral perfusion and other factors.

For mild head injuries, including skull fracture, concussion, and unspecified intracranial or head injury (Bazarian et al. 2005), the severity of the injury is usually measured by the degree of post-traumatic amnesia. More recently, concerns for chronic traumatic encephalopathy (CTE) due to repetitive mild head injuries have become a substantial concern as a cause of dementia and dysfunction years later, especially for those engaged in contact sports (Baugh et al. 2012; McKee et al. 2013). Head injury severity is usually classified by the Glasgow Coma Scale (GCS): scores of 13–15 are minor, 9–12 are moderate, 5–8 are severe, and 4 or less are very severe; and by length of coma (Jennett et al. 1976; Sherer et al. 2007). The GCS is universally accepted as a tool for TBI classification because of its reproducibility, simplicity, and predictive value for overall prognosis. Though it is limited by confounding factors such as endotracheal intubation, medical sedation, and paralysis and intoxication. An alternative to this scoring system is the Full Outline of UnResponsiveness (FOUR) Score which includes a brainstem examination however may be somewhat complicated to perform by non-neurologists and has a shorter track-record of prognostic prediction.

Incidence and prevalence of traumatic brain injuries

The US Centers for Disease Control and Prevention (CDC) estimates there were 2.5 million emergency department visits for TBI in 2013 in the United States, an increase from 534 per 100,000 in 2007 to 787 in 2013 per 100,000, with at least part of the increase attributable to falls in older adults (CDC 2003, 2007). Approximately 52,844 of those resulted in death (TBI mortality 17.1 per 100,000 population) based on all reported emergency

department visits, hospitalizations, and deaths. Cassidy et al. (2004) compiled a review of more than 160 published studies and found that approximately 70–90% of all treated TBIs are likely to be mild which results in an expected rate for *treated* mild TBI of 100–300 per 100,000 population. Almost paradoxically, Rivara et al. found that among children with TBI the burden of disability caused by TBI was primarily due to mild TBI (Rivara et al. 2012). TBI incidence in 2013 among children aged 0–4 was the highest of all age groups at 1,591.5 per 100,000, while hospitalization and death rates were highest among those aged 65 and older. In 2013, falls accounted for 47.2% of TBIs, struck by/against events for 15.4% and motor vehicle traffic for 13.7%. Overall, males had higher rates of TBIs compared with females (959 versus 810.8 per 100,000). Males had a more than fivefold higher rate of intentional self-harm-related TBIs (11.7 versus 2.3 per 100,000). The leading cause of TBI-related deaths varied by age. While falls were the most common cause of mortality for persons 65 years and older, intentional self-harm was the leading cause of death for persons between 45–64 years. Motor vehicle collisions were the leading cause of death for persons 15–24, while homicide was the leading cause of death for children ages 0–4 years (Taylor et al. 2017).

Risk factors of traumatic brain injuries

Falls

Falls are perhaps the most common cause of TBI and incidence increases dramatically with advanced age. Those aged ≥75 years had the highest rate per 100,000 population of fall-related TBIs (1,859), followed by 0–4 years (1,119.3), and 65–74 years (539.8) (Taylor et al. 2017). Use of four or more medications may significantly increase risk of TBI from falling.

Falls are also an important cause of TBI among the very young. The 15-State CDC surveillance system allowed calculation of TBI hospitalization rates due to unintentional falls for children aged 0–11 months compared to those aged 12–23 months. Fall-related TBI hospitalizations were 71.5 per 100,000 person-years in the younger group as compared to 36.5 per 100,000 person-years in the older group. Although TBI in toddlers and young children is due primarily to household or playground falls, motor vehicle accidents are the predominant cause in older children (Keenan and Bratton 2006).

Intentional self-harm

The most common cause of TBI-related death changed, from motor vehicle crashes in 2007 to intentional self-harm in 2013. Fatalities due to intentional self-harm were found predominately among males, while firearms were the predominant principal mechanisms of injury. This increase in fatalities is consistent with an overall increase in the United States suicide rates and represents the importance of providing comprehensive and coordinated prevention efforts including social support enhancement, reducing stigma for help seeking and providing help for those greatest at risk (Curtin et al. 2016; Taylor et al. 2017).

Vehicle accidents

The highest rates of TBIs attributable to motor vehicle crashes per 100,000 population were among those aged 15–24 years (258.3), 25–34 years (182.9), and 35–44 years (126.5). Injuries resulting from motor vehicle accidents, whether occurring to occupants or as pedestrian or cyclist versus motor vehicle, result in many of the more severe TBIs. Mandatory seat belt and child seat laws could have an effect on reducing occupant injuries, while bicycle and motorcycle helmet use may reduce the occurrence of TBI in those constituent categories.

Violence

Assaults are estimated to have accounted for approximately 10% of the TBIs occurring in the United States in 2003 or roughly 160,000 TBIs (Rutland-Brown et al. 2006).

As much as 20% of TBI may be the result of violence, roughly half of these are due to firearms. The age group at highest risk is 15–24 years. While males appear to be more likely to sustain an injury due to violence, women may be more likely to die as a result. The incidence of firearm-related injury or death was 42 per 100,000. The homicide rate varies dramatically by age and ethnic group. Overall it was about 14 per 100,000, but rose to 73 per 100,000 in African American males and further to 164.2 per 100,000 among 15–34-year-old African American males.

Abuse and domestic violence are important causes of TBI among women and among children (Monahan and O'Leary 1999; Valera and Berenbaum 2003; Banks 2007). Monahan estimates that about 35% of the 2–3 million

women battered each year by their domestic partner sustain TBI as a result. Keenan et al. (2003) found that physical abuse may be the most frequent cause of TBI in children aged less than 2 years with an estimated incidence rate of approximately 17 per 100,000 person-years; infants had a higher incidence than older children and boys were at somewhat greater risk than girls.

War and sociopolitically directed violence

By the end of 2012 approximately two million US and UK men and women will have served in the wars in Iraq and Afghanistan resulting in thousands of deaths and tens of thousands of severe injuries. TBI is a major problem for the United States military; the Department of Defense reports that between 2000 and 2017, 375,230 military personnel suffered TBI. Injuries related to explosive blasts may account for many or most of these (Warden 2006) and effects of these types of injuries years later could have important individual and public health consequences for many years to come. Not only do blasts account for much of the observable and immediate injuries, but they may also lead to more mild or unreported TBI that can be coupled with post-traumatic stress disorder (PTSD) (Hoge et al. 2004; Holbrook et al. 2005; Okie 2005). People who may have experienced TBI or blast-related TBI could ultimately be at higher risk for dementia as they enter ages 60–80.

Implications for public health

The potential years of productive life lost due to TBI varies with its cause, and causes are differentially age-related. The risk of seizures following TBI is increased up to 17-fold in patients with severe injuries (Annegers et al. 1998). While injuries related to falls and motor vehicles are the most common, those who are most severely affected, have the poorest outcomes, and require the most continuing care, tend to be the very young and the elderly. Sports injuries tend to be mild and resolving, but in the case of repetitive injury may result in serious sequelae years later. War-related TBIs could be the source of an unexpected public health burden because of the large numbers of soldiers serving and the high incidence of blast and other injuries coupled with the development of PTSD, psychiatric symptoms,

cognitive deficits, and degenerative dementias or other neurological disorders.

Epilepsy

Clinical overview of epilepsy

The International League Against Epilepsy (ILAE) Commission on Classification and Terminology is currently the most commonly used means of organizing epileptic syndromes and has proposed substantial changes to the 1989 classification system in 2010 and made further revisions in 2017 (Table 8.10.1) (Fisher et al. 2017). The current framework allows for diagnosis at four levels, depending on information and resources that are available, and also addresses the broad concepts of aetiology and associated comorbidities at all levels.

Seizures are classified into generalized onset, focal onset, and unknown onset. Characteristics of individual seizures are divided into focal onset seizures (formerly named partial or local seizures) that begin in a localized part of the brain, and generalized onset seizures that begin diffusely in the brain. The areas of brain initially involved determine the symptoms of location-related seizures. A focal aware seizure corresponds to the previous term ‘simple partial seizure’. A focal impaired awareness seizure corresponds to the prior term ‘complex partial seizure’. The seizure type ‘focal to bilateral tonic-clonic’ is a special seizure type, corresponding to the 1981 phrase ‘partial onset with secondary generalization’.

Generalized seizures (formerly *grand mal*) begin in widespread areas of the brain. The most common type of generalized seizure is noted for muscle stiffening followed by jerking (tonic-clonic). Generalized seizures are divided into motor and non-motor (absence) seizures. Further subdivisions are similar to those of the 1981 classification. Absence seizures (formerly *petit mal*) consist of brief episodes of staring and lack of responsiveness. Myoclonic seizures involve brief jerks of muscles rather than repetitive clonic movements. Tonic seizures have generalized muscle stiffening. Atonic seizures involve sudden loss of muscle tone.

Table 8.10.1 The International League Against Epilepsy 2017 classification of epileptic seizures

I. Generalized onset seizures	
Motor	*Non-motor (absence)*
Tonic-clonic Clonic Tonic Myoclonic Myoclonic-tonic-clonic Myoclonic-atonic Atonic Epileptic spasms	• Typical • Atypical • Myoclonic • Eyelid myoclonia
II. Focal onset seizures	
Motor onset	*Nonmotor onset*
Aware Impaired awareness	• Aware • Impaired awareness
Automatisms Atonic Clonic Epileptic spasms Hyperkinetic Myoclonic Tonic	• Autonomic • Behaviour arrest • Cognitive • Emotional • Sensory
Focal to bilateral tonic-clonic	• Focal to bilateral tonic-clonic
III. Unknown onset seizures	
Motor	*Nonmotor*
Tonic-clonic Epileptic spasms	• Behaviour arrest
IV. Unclassified seizures

Incidence and prevalence of epilepsy

Aspects of epilepsy epidemiology have been reviewed (Fiest et al. 2017). Epidemiological studies of epilepsy are challenged by the difficulty in making a correct diagnosis and the sophisticated technology and expertise required for proper diagnosis and classification. A substantial number of patients diagnosed with epilepsy do not have seizures on careful testing (Uldall et al. 2006). There is also difficulty with standardizing case ascertainment with markedly different prevalence rates using different definitions of epilepsy (Svendsen et al. 2007).

In a meta-analysis the overall incidence of epilepsy was 61.4/100,000, with 139 in low/middle-income countries and 48.9 in high-income countries (Fiest et al. 2017). Population-based and prospective studies had higher incidence rates than clinic-based and retrospective studies. Incidence is higher in children but both incidence and prevalence decrease with calendar time among children and increase among the elderly (Hauser et al. 1996; Hirtz et al. 2007). Others found an increased incidence in men, older people, black people, and those with pre-existing disability or comorbid conditions (Kaiboriboon et al. 2013). A study of children in the United Kingdom found a cumulative incidence of epilepsy by age 5 to be 1% in those born between 1994 and 1996 and 0.53% in those born between 2003 and 2005 (Meeraus et al. 2013). The annual incidence declined by 4%/year from 2001 to 2008. However, a longitudinal study from Rochester, Minnesota, United States, found a slightly higher estimate of epilepsy incidence over time (Zarrelli et al. 1999).

The prevalence of epilepsy is estimated to be 7.6/1000 (Fiest et al. 2017). However, prevalence varies in different regions. In an African population, a greater than twofold variability was found in prevalence across regions (Ngugi et al. 2013). Younger patients more commonly had seizures attributable to trauma and older patients to infectious causes. There were similar findings between regions of Taiwan (Chen et al. 2012). In general, poor countries have more than twice the burden of epilepsy compared to higher-income regions with much of the difference explained by preventable infections, perinatal care, and trauma (Newton and Garcia 2012). Differences in study methodology, survey methods, case definition,

the availability of sophisticated medical technology in a community, and cultural differences make epilepsy prevalence studies particularly challenging.

Mortality of epilepsy

People with epilepsy may experience two to three times the risk of death as their unaffected counterparts (Thurman et al. 2017). The standardized mortality ratio for people with recurrent seizures was approximately fourfold higher than expected. A longitudinal study found a threefold excess in all-cause mortality, and a sevenfold increase among those under age 20 (Shackleton et al. 1999). Some of the risk of death in epilepsy reflects underlying diseases like brain neoplasms and cerebrovascular disease. However, there is also an increased mortality compared to the non-epileptic population due to accidents (often drowning and burns) and suicide (Lhatoo and Sander 2005). Sudden unexplained death in people with epilepsy (SUDEP) is increasingly recognized as an important cause of death in epilepsy. This increases with the duration and severity of epilepsy (Devinsky 2011). It is more common in adults. The incidence of SUDEP varies from 0.09 to 2.65 in community samples, 1.2 to 5.9 in epilepsy centres, and 6.0 to 9.3 among patients referred for surgery for epilepsy. In a population-based cohort of children with epilepsy who were followed for 40 years, SUDEP occurred in 9%, accounting for 38% of all deaths.

Infectious causes of epilepsy

In developing countries, infections are a much more important cause of epilepsy than in the United States and Europe. Parasitic, bacterial, and viral infections combine with hereditary factors, perinatal damage, head trauma, and toxic exposures to contribute to high rates of epilepsy in these countries (Newton and Garcia 2012). An example of an important infectious risk factor is advanced human immunodeficiency virus (HIV) disease whereby HIV itself or associated opportunistic infections such as toxoplasmosis or tuberculomas may lead to epilepsy. Another important infectious cause is *Taenia solium* cysticercosis (pork tapeworm) which causes neurocysticercosis. This is a major cause of epilepsy worldwide (Del Brutto

2012). Other infectious causes of epilepsy are various febrile illnesses, particularly encephalitis, and malaria.

Genetics of epilepsy

A genetic aetiology is commonly based on family aggregation and twin studies. However, only a small proportion of patients have a known genetic mutation, but this is changing rapidly with advances in molecular technologies. Over 200 genes are now associated with epilepsy and include monogenic, complex, mitochondrial, chromosomal, and imprinting. Screening methods have been proposed for evaluating patients with epilepsy (Lemke et al. 2012). Epigenetic factors may also influence circuit excitability and neurogenesis in epilepsy (Roopra et al. 2012). Many types of epilepsy are now recognized as genetic disorders. However, these are rare forms of epilepsy and the genetic contribution to the majority of cases remains unexplained. First-degree relatives of people with epilepsy have a two- to fourfold increase in epilepsy risk (Annegers et al. 1982). A number of epilepsies have now been shown to be due to channelopathies, mutations in ion channels (Avanzini et al. 2007). It is expected that many more genes associated with epilepsy will be identified.

Costs and public health burden of epilepsy

Only 42% of those over age 18 with epilepsy are employed compared to 70% of those without epilepsy (Libby et al. 2012). People with epilepsy have higher work absences. Holding other variables constant, people with epilepsy had a loss of productivity of $9,504 compared to people without epilepsy. Indirect costs may account for 85% of the total, and the largest share of direct costs is attributable to patients with intractable epilepsy (Begley et al. 2000). Seizure frequency is inversely associated with health-related quality of life (Leidy et al. 1999). Seizure-free individuals report a quality of life similar to the general population; however, more seizures lead to a poorer quality of life, regardless of additional comorbidity, and irrespective of gender. Effective seizure control appears to be important in reducing costs as well as increasing patient quality of life.

Dementia

Clinical overview of dementia

Dementia presents with a progressive loss of a person's usual and customary cognitive function from any of several domains. The deficits must represent a decline from previous level of function and be severe enough to interfere with daily function and independence. This often begins with memory problems in Alzheimer's disease (AD) but could also begin with language deficits or disinhibition in frontotemporal lobar degeneration (FTLD), or with deficits in executive function in vascular cognitive impairment, or with sleep disorders or hallucinations in Lewy body disease. Regardless of the beginning domain, cognitive impairment associated with most dementia tends to progress and affect other cognitive domains with time. Dementia often includes behavioural changes, such as agitation, wandering, personality change, or depression, as well as sleep disturbances and psychiatric symptoms. As knowledge of specific subtypes of dementia has grown, the research community has come to rely more on specific clinical criteria for those subtypes. While the Diagnostic and Statistical Manual (DSM) (American Psychiatric Association 1994) criteria were originally constructed to provide for mutually exclusive diagnostic subgroups, it is now widely acknowledged that more than one underlying 'brain disease' may coexist and lead to the expression of dementia.

Dementia has many causes including neurodegenerative, vascular, infectious, and traumatic. Among the neurodegenerative dementias that predominate with ageing are AD, Lewy body disease (aka dementia with Lewy bodies (DLB) or PD dementia) and FTLD dementias. Cerebrovascular disease may coexist with and contribute to any of these or may be a primary cause on its own as vascular dementia (VaD). Prion disease, and associated spongiform encephalopathies (e.g. Creutzfeldt–Jakob disease (CJD) and variant CJD) are rare, but potentially transmissible from ingestion of animal tissue or from contact or transplantation of human tissue. Other disorders and insults which can result in dementia include drug-induced conditions, alcoholism, Huntington's disease, subdural hematoma, brain tumours, hydrocephalus, vitamin B_{12} deficiency, multiple medical conditions, hypothyroidism, and neurosyphilis.

Criteria for the clinical diagnosis of AD dementia (McKhann et al. 2011), mild cognitive impairment due to AD (Albert et al. 2011), and preclinical

AD (Sperling et al. 2011) emphasize the addition of biomarkers to characterize the underlying disease pathology. Amyloid imaging and CSF assays for amyloid-beta protein, tau, and phospho-tau proteins are of greatest importance in preclinical AD because no cognitive symptoms are present. Neuropathological criteria formerly were the clinical-pathological NIA-Reagan consensus criteria (Anonymous 1997) ranking the likelihood that pathological features (amyloid plaques and neurofibrillary tangles) existed in sufficient frequency to have caused the clinically observable dementia. New neuropathological criteria (Hyman et al. 2012) form a diagnosis based only on pathological features present, regardless of clinical dementia. The research community thus has taken a major step to define AD by pathology that is present (in both clinical and neuropathological criteria) and has recognized formally that asymptomatic AD occurs. This opens the door to conceptualization of secondary prevention.

Mild cognitive impairment

Clinically observable cognitive decline, not yet at the level meeting criteria for dementia, has been called mild cognitive impairment (MCI) (Petersen 2004). As a prodrome to dementia or simply an impaired state, it may have many underlying causes; MCI itself is not an aetiological diagnosis, but a characterization of affected cognition. The portion of MCI which is due to AD has now been provided with formal clinical criteria and biomarker indications (Albert et al. 2011). Recognition that the disease process in AD may have been underway for as many as 10–25 years and is potentially detectable by CSF biomarkers and/or amyloid imaging (Sperling et al. 2011; Bateman et al. 2012) changes the way epidemiologists should look at risk factor studies and the timing of exposures sufficient to cause disease onset. Pathological onset also explains in part why potential treatments given to mild or moderately impaired subjects would have little chance of success. What would a rehabilitative treatment for dementia due to AD potentially look like? Possibly in addition to slowing or stopping the formation of pathology, it would need to facilitate neuronal regeneration, branching, and connections, if recovery might happen.

Tracking and describing prognostic factors associated with cognitive decline has been the subject of many investigations. However, in the case of AD and probably other underlying causes, the timing and course of decline

may be more likely to be tied to the frequency and location of damage due to pathology than it might be to education, for example. Determining and describing potentially modifiable factors which might change the course of decline in those with symptomatic disease, is one of the major challenges of AD and other dementias. The original criteria for MCI (Petersen 2007) allowed MCI to represent a variety of aetiologies in addition to AD. On the non-amnestic side, it could easily include vascular cognitive impairment as well as cognitive impairment due to FTLD or Lewy body disease. However, the amnestic side of MCI is regarded by many to represent primarily early AD (Morris et al. 2001; Morris and Cummings 2005; Morris 2006). People diagnosed with MCI also are known to recover and not go on to develop dementia. The potential progression of cognitive decline is described well by Sperling et al. (2011) as a continuum, rather than reclassification into separate categories of dementia or MCI.

Dementia and Alzheimer's disease

Prevalence and incidence of dementia and AD

Almost two decades ago, Evans and colleagues reported prevalence estimates for dementia and AD based on a community study in East Boston, Massachusetts, United States (Evans et al. 1989), placing an heuristic upper bound on estimated prevalence of dementia in United States' communities: rising from 3% among those 65–74 years of age to 47% in those over age 85, with over 80% of the observed dementia classified as AD. Evans later projected that 10.3 million people would have AD in the year 2050. A recent meta-analysis of prevalence studies worldwide (Prince et al. 2013) shows remarkably similar age-specific prevalence and age-adjusted summary prevalence across all regions of the world, with the lowest prevalence being in sub-Saharan Africa and possibly the highest in Latin America and the Caribbean. The global estimate of people living with dementia in 2016 is reported to be 43.8 million by the Global Burden of Disease Study (Nichols et al. 2019). By 2050, it is estimated that 115.38 million people will be living with dementia. An estimated $420 billion was spent on dementia care in the United States and Western Europe in 2010; worldwide $604 billion were spent (Wimo et al. 2013). An incidence rate meta-analysis (Jorm and Jolley 1998) gathered data from 23 studies.

Incidence was estimated for Europe, the United States, and East Asia; dementia, AD, and VaD rates were computed. Incidence rates for clinically diagnosed dementia rose from 3.6 per 1,000 person-years (aged 65–69) to 37.7 per 1,000 person-years (aged 85–89) in Europe and from 2.4 to 27.5 per 1,000 person-years for the same age groups in the United States.

Similarly Rocca et al. (1998) re-analysed dementia and AD incidence data for 1975 through 1984 and observed that annual age-specific incidence rates have appeared to stay quite stable with time during that interval. Launer et al. (1999), combining cohorts enrolled in Denmark, France, the Netherlands, and the United Kingdom, determined that the incidence of dementia rose from 2.5 per 1,000 person-years at age 65–69 to 85.6 per 1,000 person-years in those aged 90 and older; while AD rose from 1.2 per 1,000 person-years to 63.5 per 1,000 person-years across the same age groups.

Suppose that the incidence of AD were estimated by the development of positive biomarkers including asymptomatic people. How would such a change shift the age distribution and the incidence rates?

While the tendency has been to attempt to count primary cause or pathologically ‘pure’ cases, dementia causing aetiologies (e.g. Alzheimer, vascular, Lewy body, FTLD) appear to commingle frequently in community dwelling cases. This commingling is consistent with the view that these diseases may exist as multiple amyloidoses resulting from aggregation of misfolded proteins (Morimoto 2006).

Distinguishing between normal people, those with MCI and those asymptomatic people with occult dementia-related pathology, is now possible to some degree as noted in Sperling et al. (2011) based on newly developed neuroimaging techniques (Klunk et al. 2003; Mathis et al. 2003; Small 2004) and CSF biomarkers. These ‘biomarkers’ may provide important clues about pathological onset of disease as well as inform the study of risk factors and critical periods of exposure prior to disease onset (Mintun et al. 2006; Bacskai et al. 2007; Fagan et al. 2007; Rowe et al. 2007).

Risk (and protective) factors for AD

The attempt to identify environmental risk factors for AD has been disappointing and conflicting, for methodological as well as biological

reasons. Because the pathological disease may begin from 10 to 25 years prior to any symptoms, the time window for exposures which could be relevant for onset is shifted even further back in time. Few observational studies were able to place any exposures except for genetic factors in this time range. Thus case–control studies were likely to be methodologically compromised by diagnostic misclassification, as well as ill-timed or missing exposure data. Cohort study designs fare only slightly better because the initial cohort would include asymptomatic people; for example, the base cohort would not effectively exclude prevalent disease, causing diagnostic misclassification. Thus, the risk or protective factors reported by epidemiological case–control or cohort studies to date must be viewed with considerable caution; the notable exception is the genetic risk factor, apolipoprotein E (APOE) e4 allele. APOE may exert independent effects or it may modify or confound the effect of environmental risk factors (Corder et al. 1993; Launer et al. 1999; Mehta et al. 1999).

Higher educational level has been proposed as decreasing risk of AD, but the relationship is complex (e.g. Hendrie 1998; Geerlings et al. 1999; Koepsell et al. 2007). The idea that higher education confers greater ‘cognitive reserve’ to be accessed when disease strikes is tantalizing, though biologically unsubstantiated. Koepsell et al. in a clinico-pathological study found that there was ‘no evidence of larger education-related differences in cognitive function when AD neuropathology was more advanced’, concluding further that ‘Higher Mini-Mental State Examination scores among more educated people with mild or no AD may reflect better test-taking skills or cognitive reserve, but these advantages may ultimately be overwhelmed by AD neuropathology’ (Koepsell et al. 2007). Quality of early life environment, as measured by number of siblings and area of residence, was associated with developing AD in late life, but educational level was not significantly associated with risk of AD (Moceri et al. 2000).

Anti-inflammatory medications have been studied for their potential protective effect on AD (Breitner 1996; In t’Veld et al. 2001; Szekely et al. 2007). The Alzheimer’s disease anti-inflammatory prevention trial (ADAPT) was launched in 2001. The trial enrolled 2,625 subjects, aged 70 years or older, and randomized them to placebo, celecoxib, or naproxen sodium treatment arms. The trial itself was stopped early because of an excess of cardiovascular events in the treatment arms. A preliminary analysis based on data available following trial closure showed no

significant effect of either celecoxib or naproxen as compared to placebo for the prevention of AD.

Oestrogen replacement therapy as a protective factor has shown a remarkably similar chequered research results history as anti-inflammatory medications, with the bulk of epidemiological evidence favouring protection and a fair amount of biological plausibility also marshalled in its support. Despite this large accumulation of epidemiological and laboratory evidence supporting the potential protective effect of oestrogen against the onset of AD, the Women's Health Initiative Memory Study (a randomized controlled trial of oestrogen and oestrogen plus progestin vs. placebo) showed a statistically significant *increased* risk of dementia among those given the active treatments (Shumaker et al. 2003, 2004). As a potential treatment for AD dementia, results also have shown no effect on AD (Henderson et al. 2000; Mulnard et al. 2000).

Factors related to cardiovascular disease and metabolic syndrome (including diabetes) may have an influence on AD and other dementias even though the exact mechanisms of interaction may not yet have been elucidated (Launer et al. 2000; Yaffe et al. 2004; Kivipelto and Solomon 2006; Laitinen et al. 2006; Li et al. 2007; Muller et al. 2007). The rationale for this approach appears to be that it is sound medical practice to treat hypertension, high cholesterol, diabetes, and obesity, and if more complete and effective treatment can be accomplished it may also, secondarily, serve to reduce the occurrence of dementia through vascular or other pathways which may or may not directly impact AD pathology. Cholinesterase inhibitors and memantine are currently the only available symptomatic medications for global functioning and cognition in these patients. Cholinesterase inhibitors target the acetylcholine deficit arising from the loss of neurons in the nucleus basalis of Meynert and its projections in patients with dementia. These may be considered symptomatic therapies and are not to be neuroprotective or to alter the underlying disease trajectory.

Genetics and AD

Great progress was made regarding the genetics of AD during the late 1980s and 1990s with the discovery of presenilin-1 and -2 and amyloid precursor protein mutations as familial, autosomal dominant causes and the

APOE e4 allele as a ‘risk factor’. Several reviews of AD genetics describing this period of growth in greater detail include: Hardy et al. (1998), Levy-Lahad et al. (1998), St George-Hyslop (2000), and Haass (2004).

The strongest and most consistent genetic risk factor for late-onset, non-autosomal dominant AD today is the APOE genotype. The association was first described from Dr Allen Roses’ laboratory (Corder et al. 1993; Saunders et al. 1993; Strittmatter et al. 1993). APOE naturally occurs as three different alleles (epsilon 2, epsilon 3, and epsilon 4) which pair to form one of six genotypes for each individual. Genotypes containing the epsilon 4 allele are associated with increased risk of AD; homozygous epsilon 4 greatly increases risk (e.g. greater than eightfold). Since the initial description of increased risk associated with the epsilon 4 allele, many investigators have observed the association. Discussion of APOE genotype is now included in nearly all genetic and risk factor studies of AD, either as a focus or as a potential confounder/effect modifier of an association. Despite the huge volume of studies including the APOE genotype, relatively little is known concerning how the e2, e3, and e4 alleles actually work to influence the risk of AD.

There have been a number of GWAS of AD, using large numbers of subjects (e.g. Hollingworth et al. 2011; Naj et al. 2011), which have identified and replicated a range of new common variants. Recently two important studies have shown an increased AD risk due to TREM2 (Guerreiro et al. 2013) and in African Americans an increased risk associated with ABCA7 (Reitz et al. 2013). Because these and other current GWAS have included strong replication they are regarded as superior to most candidate gene studies that occurred between the mid-1990s and 2010. More such studies have been performed; in addition, data sharing has allowed other investigators to examine associations between these identified loci and clinical characteristics (endophenotypes) such as cognitive decline.

Vascular dementia

VaD is difficult to describe clinically and neuropathologically. The search for ‘pure’ cases of VaD and AD may have obstructed progress of understanding how these diseases act and interact. Vascular features

commonly coexist with AD in the elderly: newer sophisticated imaging and other measures, as well as neuropathology, bear this out (Au et al. 2006). Several different criteria have been developed to diagnose VaD (Chui et al. 1992; Roman et al. 1993; American Psychiatric Association 1994). Much of the pioneering work in the clinical definition and recognition of VaD can be attributed to Hachinski and colleagues. The Hachinski Ischaemic Score continues to be used to indicate the extent of cerebrovascular involvement in cognitive decline (Hachinski 1994).

Pathologically, VaD is an enigma, because of the lack of clear definitions for white matter damage, infarcts, and lesion location in strategic areas of the brain—VaD, in effect, lacks a pathological gold standard against which to compare the clinical diagnosis or clinical criteria and measure their effectiveness (Murray et al. 2007). Thus, the clinical diagnostic criteria have been shown to be difficult and potentially unreliable in practice, even when applied by well-experienced research investigators (Chui et al. 2000).

Lewy body disease and frontotemporal lobar degeneration

Two additional types of dementia, Lewy body disease (McKeith 2006) and FTLD (Cairns et al. 2007a), have been separated from AD based on their clinical presentations but more specifically on their pathology. Lewy body disease or DLB may be diagnosable in up to 30% of dementia cases. PD is also a ‘Lewy body’ disease and if Parkinson’s cases survive long enough they will become demented as a result (Zaccai et al. 2005; Tsuang et al. 2006). Lewy body disease or DLB often presents with fluctuating cognitive performance, visual hallucinations, REM sleep behaviour disorder, and/or parkinsonism. Memory impairment may not be as prominent in the early stages of the disease as deficits in attention, frontal subcortical skills, and visuospatial ability (Knopman et al. 2001; Korczyn and Reichmann 2006).

FTLD has undergone a revolution in classification since initial work on progranulin (Gass et al. 2006; Rademakers et al. 2007) followed by the careful study of the involvement of TDP-43 (Neumann et al. 2006; Van Deerlin et al. 2010) and the discovery of association with C9ORF72 (DeJesus-Hernandez et al. 2011) includes specific disease subtypes and may be the most frequently occurring dementia in people under the age of 65 (Mackenzie and Rademakers 2007). Behavioural variant frontotemporal dementia (bvFTD) represents a behavioural subtype with changes such as

loss of personal awareness, loss of social graces, disinhibition, overactivity, restlessness, impulsivity, distractibility, hyperorality, withdrawal from social contact, apathy, or inertia, and stereotyped or perseverative behaviours. The memory loss is variable and often appears to be due to lack of concern or effort. Frontal lobe impairments are notable including abstraction, planning, and self-regulation of behaviour. FTLD may also be associated with parkinsonism or motor neuron disease. Pathologically, approximately 40% of FTLDs are related to mutations in the microtubule-associated protein tau (*MAPT*) gene on chromosome 17 and are therefore 'tauopathies'; these include Pick's disease, corticobasal degeneration, and progressive supranuclear palsy (Rademakers and Hutton 2007; Tolnay and Frank 2007). About 50% of FTLDs are not tauopathies but are reactive to ubiquitin (FTLD-U) rather than mutations in *MAPT* (Mackenzie and Rademakers 2007). Recently, it was discovered that mutations in the progranulin gene, also on chromosome 17, were an important cause of FTLD-U disorders (Baker et al. 2006; Cruts et al. 2006; Gass et al. 2006) including primary progressive aphasia (Mesulam et al. 2007). The pathological protein involved in these disorders as well as in motor neuron disease is TDP-43 (Mackenzie et al. 2006; Neumann et al. 2006; Cairns et al. 2007b; Kwong et al. 2007). These are arguably the most exciting and important findings for dementia and FTLD in recent times. FTLD is rare compared to AD and even so is thought to be frequently misdiagnosed as a psychiatric disorder because of its early onset and unusual clinical symptoms.

Peripheral neuropathy

Clinical overview of peripheral neuropathy

Though 'peripheral neuropathy' may refer to any disease of peripheral nerves, it usually describes systemic diseases that affect peripheral nerves rather than focal diseases affecting an isolated nerve. Most of these diseases affect longer nerves first with symptoms developing first in the feet and progressing up the legs. Few peripheral neuropathies affect shorter proximal nerves first. By the time symptoms reach the knees, the hands become symptomatic followed by the anterior trunk and crown of the head. Symptoms depend on the type of nerve fibre involved. Involvement of motor fibres leads to weakness, muscle wasting, and hyporeflexia. If

longstanding, motor neuropathies may lead to high arches (pes cavus) or hammer toes. Sensory nerve involvement leads to loss of sensation, distorted sensation (dysaesthesias), or spontaneous unpleasant sensations (paraesthesias). Autonomic neuropathies lead to postural hypotension, sexual dysfunction, bowel dysfunction, bladder dysfunction, and gastroparesis. The size of the affected nerve fibre can often be suggested by the history with large fibre disease causing reflex loss, vibration loss, and joint position loss. Small fibre disease often leads to autonomic dysfunction, dysaesthesias, loss of pain sensation, and loss of temperature sensation.

Electrodiagnostic testing is used to diagnose and classify peripheral neuropathies. Nerve conduction velocities can classify peripheral neuropathies into demyelinating and axonal types. Demyelinating neuropathies have disproportionate slowing and increased latencies of nerve conduction speeds. Axonal diseases cause disproportional loss of amplitude with relative preservation of conduction speed. Nerve conduction studies measure only the fast-conducting large diameter fibres. Electromyography (EMG) measures the electrical activity of muscle fibres. A loss of muscle fibre innervation by large myelinated neurons leads to increased insertional activity, positive waves, fibrillation potentials, polyphasic motor unit potentials, and decreased recruitment patterns on EMG. Occasionally, nerve or muscle biopsies are used for diagnosis of polyneuropathies.

Generally, polyneuropathies involve many peripheral nerves and result in autonomic neuropathies, sensory loss, or weakness. Mononeuropathies, as the name implies, involve a single nerve injury or entrapment, for example, carpal tunnel syndrome (CTS) or Bell’s palsy. Peripheral nerve disorders are often classified as hereditary or acquired. Charcot–Marie–Tooth syndrome is a well-known hereditary form. Acquired nerve disorders are associated with trauma/compression, diabetes, alcoholism, and other nutritional and metabolic problems. They may also be related to infectious causes such as Guillian–Barré syndrome, leprosy, Lyme disease, or HIV infection; or they may be caused by toxic exposures to metals (e.g. lead, mercury), industrial chemicals, or therapeutic drugs (e.g. antineoplastic agents) (Rowland and Merritt 1995). Little is known about the epidemiology of peripheral neuropathies, though they are common. The few studies that have been conducted find prevalence rates ranging from 2.4 to

8% (Martyn and Hughes 1997). Prevalence increases considerably with age to 54% of those aged 85 and older (Mold et al. 2004).

Carpal tunnel syndrome

CTS is probably the most common neuropathy. Carpal tunnel release surgery is one of the most common hand surgeries. Occupational CTS from repetitive, higher-impact actions differs from non-occupational CTS by occurring nearly equally among men and women and at a lower mean age (37 vs. 51 years) than non-occupational CTS (Franklin et al. 1991). Based on US workmen's compensation records, an incidence of 1.74/1,000 full-time equivalent jobs was observed.

In contrast to the occupational incidence, the general population CTS incidence was 3.46/1000 person-years (Nordstrom et al. 1998). The apparent increase in incidence may reflect a true change or may be affected by popular knowledge of the condition and diagnostic suspicion. Prevalence of symptoms in relation to true disease prevalence is also a consideration (Atroshi et al. 1999). Reported CTS symptoms of tingling, pain, and numbness have a prevalence of about 14%, whereas CTS was confirmed in less than 3%.

CTS patients with inflammatory arthritis, diabetes, and hypothyroidism were more likely to receive CTS release surgery (Solomon et al. 1999). Heredity is the single strongest predictor of CTS with half of the risk of CTS due to genetic factors (Hakim et al. 2002). Using MZ and DZ twins, the heritability was estimated to be 0.46 (95% CI 0.34–0.58). There is a bimodal age distribution with peaks at 50–54 and 75–84 years of age (Bland and Rudolfer 2003). In a case–control study, elevated body mass index was more common among cases than among control subjects (Stallings et al. 1997).

Diabetes mellitus

Diabetes is a common, yet complex cause of both mono- and polyneuropathies. Diabetic peripheral neuropathy may affect 26–47% of those with diabetes (Barrett et al. 2007) though others have found lower rates of 7.8–17.4% (Dyck et al. 2012). More effective glucose control could reduce the risk to some extent. The cost of diabetic peripheral neuropathy,

particularly in those with pain, can be substantial (Currie et al. 1998; Barrett et al. 2007).

Microvascular disease, chronic hyperglycaemia, and type of diabetes are the most important predictors of polyneuropathy (Dyck et al. 1999). Autonomic neuropathy is strongly influenced by hyperglycaemia and is associated with increased mortality (Orchard et al. 1996). Elevated diastolic blood pressure, ketoacidosis, elevated fasting triglyceride level, and microalbuminuria are also risk factors for diabetic polyneuropathy (Tesfaye et al. 1996).

Nutritional neuropathies

Vitamin B_{12} deficiency is the most common of a number of nutritional deficiencies that can lead to peripheral neuropathy. A Cuban epidemic of peripheral neuropathy from 1992 to 1993 affected over 50,000 people with an incidence of 461 per 100,000 people caused by a lack of availability of meat and dairy products (Roman 1994). Optic and peripheral forms of the disease were observed. A nutritional deficiency is suspected and treatment with multivitamins, in particular B vitamins, stopped the outbreak.

Peripheral neuropathy due to infection

HIV infection is an important cause of peripheral neuropathies including diffuse peripheral neuropathy, Guillain–Barré syndrome, mononeuropathies, neuropathies due to secondary infections, and neuropathies due to medications (Brew 2003). The incidence and prevalence vary too much between studies to allow accurate estimates.

Guillain–Barré syndrome is due to an autoimmune attack on the peripheral nerve myelin. Previously considered an idiopathic disease, it is now recognized that a significant proportion of cases are associated with prior infections including *Campylobacter jejuni* and cytomegalovirus (Hardy et al. 2011). Though the prevalence of leprosy is declining, it remains one of the most important causes of peripheral neuropathy in the developing world (Suzuki et al. 2012). Fortunately, early treatment can prevent many of the disabling and disfiguring effects of the disease.

Parkinsonism and Parkinson's disease

The Parkinson's research community is somewhat fragmented with regard to how idiopathic PD should be described and characterized: a) should full clinical symptomatology (e.g. cardinal signs) be required; b) should evidence of PD pathophysiology (e.g. Lewy body pathology) be sufficient to say PD exists; c) should PD be viewed as a systemic neurodegenerative disorder in contrast to focus on movement disorder (Langston 2006; Litvan et al. 2007)? The argument for expanding the view of PD continues that limiting the clinical and pathological view of the disease itself limits the potential for research progress (Langston 2006).

Clinical overview of PD

There are four cardinal features of clinical PD: tremor, rigidity, bradykinesia, and in the later stages postural gait changes. The clinical diagnosis of PD usually requires two or more of these symptoms. In severe cases, patients may be unable to move (freezing) when they encounter minor obstacles such as doorways or cracks. While movement disorder specialists make the diagnosis of parkinsonism with some degree of confidence, PD usually requires histopathological confirmation. In an attempt to increase the accuracy and validity of clinical diagnosis, improvements in clinical diagnostic criteria have been proposed (Gelb et al. 1999; Jankovic et al. 2000).

Parkinsonism includes several major subclasses: idiopathic parkinsonism (PD), symptomatic parkinsonism (e.g. drug induced, toxin induced, and other specific causes), 'parkinson-plus' syndromes (e.g. multiple system atrophy (MSA), progressive supranuclear palsy), and hereditary degenerative diseases (e.g. Hallervorden–Spatz disease, Huntington disease). PD or idiopathic parkinsonism comprises approximately 80% of parkinsonism.

MSA is sometimes misdiagnosed as PD; it is a relatively rare and very debilitating condition usually involving progressive autonomic failure plus poor responsiveness to levodopa or cerebellar ataxia. There is new evidence that MSA like PD and DLB is a synucleinopathy (Goedert and Spillantini 1998; Dickson et al. 1999; Armstrong et al. 2006).

Incidence and prevalence of PD

The frequency of PD varies according to the diagnostic criteria, study population, and epidemiologic methods used. The prevalence of PD in industrialized countries is generally estimated at 0.3% of the entire population and about 1% in people over 60 years of age (Nussbaum and Ellis 2003). PD prevalence has been reported with dramatic inconsistency; typically prevalence has been reported in the range of about 50 per 100,000 to 200 per 100,000 of the population, with a maximum of about 350 per 100,000 people. Combined results of five European studies (de Rijk et al. 1997) included 14,636 people age 65 or older; after age adjusting to the European 1991 standard population the prevalence of PD was reported as 1.6 per 100 population (presumably age 65 or older), this translates to about 1,600 per 100,000. In addition, the age-specific prevalence of PD was reported to increase per 100,000 population as follows: 41 in 40 to 49 years; 107 in 50 to 59 years; 173 in 55 to 64 years; 428 in 60 to 69 years; 425 in 65 to 74 years; 1,087 in 70 to 79 years; and 1903 in older than age 80 (Pringsheim et al. 2014).

Incidence rates for PD and parkinsonism carry many of the same caveats as for prevalence. A review estimates standardized incidence rates of PD are 8–18 per 100,000 person-year (De Lau and Breteler 2006). Onset of PD is rarely before age 50 years and a sharp increase of the incidence is observed after age 60 years. Age-specific incidence rates are, of course, able to be compared directly whereas summary population rates may be dependent on age structure of the population. How ageing contributes to the clinical expression or degenerative processes of PD, as well as how ageing may act with genetic and environmental risk factors, to initiate pathophysiology or onset of clinical symptoms remain key questions for the epidemiology of parkinsonism and PD.

Risk factors of PD

Researcher hopes to identify consistent environmental causes of PD were increased by the observation that 1-methyl-4-phenyl-1, 2,3,6-tetrahydropyridine (MPTP) caused acute PD shortly after ingestion (Langston and Ballard 1983; Langston et al. 1983). The structure of MPTP and its metabolism products are somewhat similar to common pesticides

raising interest in such exposures as risk factors or causes of PD. The past predominance of environmental causes has at least partially given way to studies of genetic and pathophysiological aetiologies (Litvan et al. 2007; Do et al. 2011).

An excellent review of pesticide/herbicide exposure as risk factors for PD was recently published by Tanner et al. (2011). Determination of critical exposure time periods and duration of exposures is always an obstacle to overcome when studying PD risk factors because the initiation of pathophysiology may occur many years prior to any symptoms of the diagnosis of PD. Further, the time from exposure to onset of pathophysiology or clinical disease may vary dramatically. Consider the rather immediate onset of clinical symptoms following MPTP exposure compared with what may be the case with agricultural pesticides (Gorell et al. 1998; Petrovitch et al. 2002; Firestone et al. 2005). Interest in pesticide exposure as a potential cause led to a biotransformation gene approach for evaluating the occurrence of susceptible people. Specifically, some people may be more, or less, able to metabolize environmental toxins because of polymorphic genes involved in metabolism. One of the family of cytochrome P-450 biotransformation genes, *CYP2D6*, is involved in metabolism of debrisoquine (structurally similar to pesticides); some polymorphic forms are 'poor' metabolizers and others are normal or rapid metabolizers of debrisoquine. Initial studies appeared to show that poor metabolizers were at increased risk of PD but later studies and meta-analyses fail to support this conclusion (Maraganore et al. 2000; Scordo et al. 2006). A similar approach has been taken to identify susceptibles focusing on polymorphic forms of glutathione transferases (GST) which are involved in the metabolism of pesticides and other xenobiotics (Menegon et al. 1998). Continued effort to identify gene–environment interaction in this way may eventually prove fruitful, but success is rather limited to date.

An association between exposure to metals and PD has been described by Gorell et al. (1999). And more recently an association with welding has been reported by Racette et al. (2012). Heavy metals such as iron, copper, manganese, and lead have been raised as potential risk factors in the past and Racette et al. may provide some measure of replication to those findings.

Smoking has been rather consistently associated with decreased risk of PD in reported reviews and in individual studies. Although the negative

association with smoking is one of the more consistent findings, it is not completely without alternative explanations. Reasons for the plausibility of such an association revolve around the neuroprotective potential of nicotine. Another possible explanation is that patients who develop PD are more likely to quit smoking or less likely to smoke in the first place than those who don't develop the disease. This is explained as dopamine is an important component of the brain's reward system, and those who will later develop signs of PD do not engage in reward-seeking behaviours, including smoking, because dopamine is significantly reduced in the basal ganglia years before symptoms of PD appear. Most epidemiological studies of PD use 'prevalent' or existing cases in their studies. The low incidence of PD effectively precludes concentrating on only newly diagnosed cases in all but the largest of studies (or in very large cohort studies). When attempting to identify a cross-sectional sample of cases for enrolment into a case–control study, it can be shown that those patients who have had the disease the longest are the most likely to be included. The most severe, short-duration, or rapidly declining cases tend to be missed. If PD cases who had a history of smoking were much more likely to die sooner than 'controls' who were smokers, then smoking would appear to be protective because of the excess of smoking 'controls'. Despite such an argument, however, the PD research community appears to be relatively confident in the potential protective effect of smoking (Ritz et al. 2007).

Dietary-related factors have been shown in some studies to reduce risk of PD: fish and vegetables (Gao et al. 2007), coffee and caffeine (Ross et al. 2000), dietary folate, and vitamin B_{12} among others (de Lau et al. 2006). Body mass index has been reported to increase the risk of PD (Hu et al. 2006), while gout and hyperuricaemia has been reported to protect against it (de Lau et al. 2005; Alonso et al. 2007).

As recently as two decades ago it was commonly taught that PD was caused entirely by environmental factors. Now with the explosion of genetic knowledge and technology and an understanding of some of the proteins potentially involved in pathogenesis, Hardy states that nearly half of the disease risk has been explained by genes so far discovered (Hardy 2010). Do et al. (2011) discuss the recent GWAS and genes involved in PD risk. Glucocerebrocidase has been found to be deficient in PD brains and similarly the *GBA* gene is associated with Lewy body disease causing PD and dementia (Tsuang et al. 2012). While the list of genes involved in PD

continues to grow, the acknowledged recessive gene causes appear to be *parkin* (*PARK2*), *PINK1* (*PARK6*), and *DJ-1* (*PARK7*). Autosomal dominant and genetic risk factors include *SNCA*, *UCHL1*, *LRRK2*, *GBA*, and *MAPT*. As discussed by Do and others, the list continues to grow as do the parallels with other neurodegenerative diseases such as AD and FTLD.

Public health impact of PD

PD is progressive and debilitating. While initial treatments with levodopa and similar medications effectively quell most motor symptoms, their effectiveness begins to subside in about 50% of patients after 3–5 years. To date, there have been no true disease-modifying treatments available and we are only beginning to examine genetic pathways leading to pathogenesis or to drug targets that may modify the disease process prior to onset of symptoms (Siderowf et al. 2012). This aspiration is still a long way off, it appears. With increasing motor problems comes increased healthcare cost and decreased quality of life (de Boer et al. 1999); dementia is now regarded as an almost inevitable consequence of PD, assuming the patient survives long enough, leading to the need for long-term care in many instances. The overlap between PD dementia and DLB is of great interest because of the potential underlying synuclein pathology and therefore the potential genetic relationships as well (Rocca et al. 2007; Tsuang et al. 2012).

Multiple sclerosis

Clinical overview of MS

Although MS is relatively uncommon, it has a great impact on society. The impact of this disease is disproportionately large because it strikes young adults, is expensive to treat, and can cause disability. Only 21% of MS patients have no work limitations and 29% remain in the workforce (Minden et al. 2004). MS has substantial medical costs (Minden et al. 2004; Adelman et al. 2013). Because of lost earnings and increased healthcare costs, MS is the third leading cause of significant disability in the 20–50-year age range (LaRocca et al. 1984).

Clinically, MS is characterized by demyelinating lesions of central nervous system white matter causing motor, sensory, cerebellar, visual, brainstem, autonomic, spinal cord pathways, and other symptoms. These often occur in attacks with complete or partial recovery, with symptoms remaining stable between exacerbations (relapsing/remitting disease) (Lublin and Reingold 1996). Alternatively, symptoms may slowly progress in the absence of exacerbations (primary progressive disease). Relapsing/remitting cases may evolve into secondary progressive disease with a slow worsening of baseline function. When the disease results in death, the immediate cause is usually infectious, secondary to urinary tract involvement or pneumonia.

The length of exacerbations can be shortened by corticosteroids. There are currently nine US Food and Drug Administration-approved medications to slow the disease, with others under review. In addition to disease-modifying therapies, symptomatic treatments are often required. A multitude of new treatments are being tested, giving hope for more effective treatments in the future.

Definition of MS

The current diagnostic criteria are the revised McDonald criteria (Polman et al. 2011). These require two or more episodes of neurological deficit at different times and different locations within the nervous system. MS attacks used to fulfil the criteria must have symptoms typical of those seen with MS and have objective findings on examination or paraclinical tests. The new criteria allow diagnosis by clinical presentation alone, but also allow magnetic resonance imaging (MRI) findings to be used to demonstrate dissemination in time or location. The revised McDonald criteria allow the disease to be diagnosed at an earlier stage than previous criteria.

Case ascertainment of MS

Because of the necessity for neurological expertise and special studies to make reliable diagnoses, reported worldwide prevalence may not be completely comparable, especially where differences in the availability and quality of healthcare exist. This is especially true in light of the highly

variable clinical presentation of the disease, and the variable course. The requirement for repeated attacks before a diagnosis is made and the often vague nature of the initial clinical symptoms leads to difficulties in determining exact incidence figures in a timely manner.

Prevalence of MS

MS prevalence is easier to determine than incidence, particularly considering the difficulty in determining the time of disease onset. With the new McDonald criteria, MRI availability, and increasing awareness of the disease, the time from symptom onset until diagnosis is rapidly shortening (Marrie et al. 2005). The reported prevalence of MS varies widely with latitude, from one per 100,000 or less near the equator, to over 150 per 100,000 in some high-latitude areas (Koch-Henriksen and Sorensen 2011). Migrants carry the risk of their geographic residence before their mid-teens (Alter et al. 1966a, 1966b). The universal association between latitude and risk of MS has been challenged by findings from a 2010 systematic review and meta-analysis of epidemiologic studies of MS (Koch-Henriksen and Sorensen 2011). The results showed that, while the prevalence of MS increased with geographic latitude in Western Europe, North America, and Australia/New Zealand, the incidence of MS increased with latitude only in Australia/New Zealand, and not in Western Europe or North America. Hence, there was no latitudinal gradient for MS incidence in the northern hemisphere. In the absence of association with incidence, the observed latitudinal gradient of MS prevalence could be explained by other factors, such as survival time, diagnostic accuracy, and ascertainment probability.

Risk factors of MS

Gender

Approximately 75% of people with MS are female. However, in the first half of the twentieth century, males predominated (Kurtzke 2005). Gender rates changed to a female preponderance about mid-century and the female/male ratio continues to increase by about 0.85%/year (Orton et al. 2006; Wallin et al. 2012). The disease is less active during pregnancy and more active during the 3 months immediately postpartum (Confavreux et al. 1998; Langer-Gould and Beaber 2013). The changes in MS activity with

hormones and pregnancy may be due to alterations in immune system function, but the temporal changes in gender ratios remain unexplained.

Ethnic background of MS

In general, MS occurs with greater frequency in white people, particularly those of northern European ancestry. Other ethnic groups have a lower incidence and prevalence of MS, but this appears to be changing. The relative risk of MS in black compared with white male veterans increased from 0.44 in the Second World War/Korean conflict to 0.67 in Vietnam to 1.16 in the Gulf War (Wallin et al. 2012). During the same time periods the relative risk among black females compared to white males increased from 1.28 to 2.86 to 3.62, catching up to white females with 1.79, 2.99, and 3.54 respectively.

Genetic susceptibility of MS

In Caucasians, some alleles of the HLA complex are associated with MS susceptibility, particularly HLA-DRB1.1501 (Haines et al. 1996). In addition, other groups of genes that influence the immune response or myelin structure have been investigated (Sadovnick et al. 1991). To date, large GWAS have identified over 100 polymorphisms associated with MS, but associations are modest, explaining less than 25% of the heritability of the disease (Hafler et al. 2007; Sawcer et al. 2011; Lin et al. 2012). Nevertheless, these studies confirm the importance of genes related to immune function.

In the Danish twin study, there was concordance for MS in 24% of MZ twins and 3% of dizygotic twins (Hansen et al. 2005). The standardized incidence ratio for MZ twins compared to non-twins was 1.23 and 0.78 for DZ twins. There is also an increased risk of MS in other first-degree relatives of people with MS. In a Danish study, the relative risk of MS in first-degree relatives of people with MS was 7.1 (95% CI 5.8–8.8) (Nielsen et al. 2005). The lifetime risk was calculated to be 2.8% for male and 2.9% for female first-degree relatives. Some have found that the risk of MS is higher in children of MS fathers than MS mothers (odds ratio 1.99, 95% CI 1.05–3.77) (Kantarci et al. 2006). This increased rate of transmission to offspring by a subgroup in which the disease is less common (men) suggests a genetic contribution in which genes are concentrated in men with the disease. However, others have reported that the risk of MS in children whose parents have MS is similar regardless of whether the affected parent

was the father or mother (Herrera et al. 2007). A Canadian study found that the age-adjusted risk of MS in siblings was 3.11% (95% CI 2.39–3.83) (Ebers et al. 2004). This group also found an excess of mother–daughter pairs compared to father–son pairs and suggested that epigenetic factors may contribute (Chao et al. 2010). These studies indicate that there is an important genetic contribution to the disease, but environmental factors also play a major role.

Environmental factors of MS

In the presence of inherent susceptibility, some external factors seem to be associated with MS. People with MS have a later age of exposure to common childhood exanthematous diseases, and lower birth orders though not all studies have supported this finding (Bager et al. 2006). There have been reports of clusters of disease, thought to have been related to environmental exposures, but on investigation these supposed clusters have generally not been beyond expected variability.

The strong relationship between MS and latitude has led some to postulate that areas with less sun exposure, and thus lower levels of vitamin D, may be responsible for the disease (Simon et al. 2012). Military recruits with low 25-hydroxyvitamin D (25(OH) D) levels had a subsequent increased risk of MS. Low vitamin D levels are associated with risk of MS in children. The risk of MS is lower in offspring of mothers with increased vitamin D intake. Patients with MS generally have low 25(OH)D levels. A small trial of 25(OH)D supplementation in MS patients found no difference in MRI activity (Stein et al. 2011). Other randomized treatment trials of 25(OH)D are underway.

The relationship between MS prevalence, latitude, migration, and socioeconomic factors has led some to suggest that MS is related to the degree and timing of exposure to various infectious organisms (Fleming and Cook 2006). This hygiene hypothesis states that exposure to infectious agents later in life (due to high levels of hygiene) leads to changes in the immune system that eventually lead to MS. Epstein–Barr virus (EBV) is associated with MS (Ascherio and Munger 2007; Owens and Bennett 2012). MS is extremely rare in people who have never had EBV. Furthermore, those exposed to EBV later in childhood have a two- to threefold increase in risk relative to those who acquire EBV in early childhood. Antibody titres to EBV are increased in MS, often years before

recognition of the disease, but this may reflect a general upregulation of the immune system. Cytomegalovirus appears to be protective in children (Waubant et al. 2011).

Both ever-smokers and current smokers have an increased risk of MS (Jafari and Hintzen 2011). Children exposed to cigarette smoke have a higher risk of developing MS (Mikaeloff et al. 2007). Smoking is associated with increased disability, more MRI activity, and conversion to secondary progressive MS.

Overview of MS

The risk of MS appears to be due to environmental factors acting on genetically predisposed people. Eventually, these factors lead to an immune attack on the central nervous system, resulting in symptoms. The genetic factors are polygenetic. The environmental factors remain uncertain. Immunomodulating treatments have played an important role in slowing the disease, but their benefits are only partial. Much remains to be clarified about the mechanisms of the disease process, and it is hoped that a better knowledge of these mechanisms will lead to improved treatments.

Conclusion

Presenting current and useful research information on a number of neurological conditions is a difficult task. This chapter has attempted to address that challenge for some selected neurological conditions and referencing heavily to current or classic research papers. Conditions such as headache have substantial public health impact because of the age groups affected, their prevalence, and the lost productivity (or economic loss) related to them. MS, a relatively common neurological disease, can affect individuals in young adulthood, decrease their productivity, and ultimately make them dependent on others. TBI occurring in youth or young adulthood can cause years of extra medical care in addition to lost productivity among those who survive the immediate event. Epilepsy may have onset throughout the life course, it may result from trauma or may be caused by specific genes, among other causes. While there are intractable forms of epilepsy, great strides have been made in seizure control enabling

patients to lead relatively full and normal lives. Neurodegenerative diseases, such as PD and AD, rob productivity, functional ability, and independence from older individuals; they also force huge increases in healthcare costs. Without question neurological diseases have substantial public health effects.

Determining the incidence and prevalence for most of the diseases and conditions in this chapter is quite an inexact science. The conditions are often difficult to define and detect in the population and for the most part they are not regarded as ‘reportable’ conditions. Therefore, we gain insight as to disease occurrence primarily from limited but (hopefully) well-designed and conducted studies. As mentioned in the introduction to this chapter, the epidemiological study of neurological conditions is a complicated matter. Problems with diagnostic inaccuracy and insidious disease onset influence our ability to observe risk factor associations; factors related to survival may be mistaken for risk/protective factors.

The recent work of the Human Genome Project and the HapMap Project have greatly influenced technology and have now made possible genome-wide studies that could not have been imagined a decade ago. The contribution of genes that in and of themselves cause disease may be smaller than that of genes which act together with other genes in complex ways or act to metabolize or potentiate environmental exposures. The epigenetic interaction between gene and environment will be increasingly well studied in the future. Description of gene products and functions may lead to specific drug therapies never before possible. The genetic information presented in this chapter, while relatively current, may become obsolete quickly. The fields of genetics and molecular biology are moving rapidly. It is a challenge also for epidemiologists to apply the knowledge gained by the genetic researchers to the design and analysis of epidemiological studies. The diagnosis of neurological conditions may be made more accurately and earlier with genetic information. Science and the public health will benefit beyond even our current expectations.

Epidemiology must take advantage of these molecular advances. Many scholars have written on pros and cons of reductionism in science. Much of epidemiology lies in its public health context, and the same is likely to be true for genetic influences on neurological diseases. Arrays of genes may identify susceptible individuals; however, those individuals may avoid disease unless met with specific environmental or behavioural exposures.

The tasks of public health and epidemiology will still involve prevention, the non-random occurrence of disease, and its environmental context—in addition to heredity. The tools to address those tasks will continue to be refined.

Infectious diseases and prions

Davidson H. Hamer, Amira Khan, and Zulfiqar A. Bhutta

Introduction

Despite considerable progress in attaining reductions in global morbidity and mortality, infectious diseases continue to account for a substantial burden of global morbidity, disability, and mortality. While non-communicable diseases (NCDs) continue to be the leading cause of global mortality (Liu et al. 2016), diseases such as lower respiratory infections (LRIs), diarrhoea, and tuberculosis (TB) are still among the top ten killers for all ages and sexes (World Health Organization [WHO] 2018b). Moreover, the emergence of many new viral, bacterial, fungal, and parasitic pathogens as well as rising antimicrobial resistance are current challenges.

As a result of changes in a variety of different environmental, social, economic, and public health factors, morbidity and mortality due to infectious diseases have declined in industrialized countries during the last 150 years with the result being a gradual transition to chronic diseases including cardiovascular disease, diabetes mellitus, and cancer as major causes of mortality in these countries today. However, in contrast, in less-developed countries, infectious diseases continue to contribute substantially to the overall burden of disease.

Detailed information on the definitions of infectious diseases, modes of transmission, and their control are provided in Chapter 11.3. An overview of issues related to emerging and re-emerging infections is provided in Chapter 8.17. Similarly, detailed information on diseases caused by sexually transmitted infections, HIV/acquired immunodeficiency syndrome (AIDS), tuberculosis, and malaria can be found in Chapters 8.12–8.15. This chapter will review the global burden of common infectious diseases in children and adults, determinants of the high infectious disease burden in resource-poor countries, and important aspects of the clinical manifestations, diagnosis, and

treatment of the handful of infectious diseases that account for the major share of morbidity and mortality in children and adults worldwide.

Burden of infectious diseases

At the beginning of the twentieth century, infectious diseases were the leading cause of death throughout the world. At that time, three diseases—pneumonia, diarrhoea, and tuberculosis—were responsible for about 30% of deaths in the United States. During the last century, there has been a decline in infectious diseases mortality in the United States from 797 deaths per 100,000 in 1900 to 36 per 100,000 in 1980.

In the late twentieth century, substantial reduction in child mortality occurred in low- and middle-income countries (LMICs). The fall in the number of child deaths from 1960 to 1990 averaged 2.5% per year and the risk of dying in the first 5 years of life halved—a major achievement in child survival. In the period from 1990 to 2001, mortality rates dropped an average of 1.1% annually, mostly after the neonatal period. Deaths among children under 5 years of age dropped from 12.7 million in 1990 to about 5.9 million in 2015 and further decreased to 5.6 million in 2016 (UN IGME 2017). The annual rate of under-5 mortality reduction showed a steady increase from 1.8% in 1990–2000 to 3.9% in 2000–2015 (UN IGME 2015). Much of this decline in under-5 deaths is attributable to the reduction in mortality secondary to infectious diseases. The WHO estimates that between 2000 and 2012, mortality in children due to measles, diarrhoea and pneumonia reduced by 80%, 50% and 40%, respectively (WHO 2018c).

However, despite this promising decline, Millennium Development Goal (MDG) 4, which called for a two-thirds reduction in under-5 mortality rate from 1990 base figures, was not met. It has been recognized that this was largely due to the relatively slower progress in reducing neonatal mortality. Neonatal mortality has decreased by 49% as compared to a 62% reduction in mortality in children 1–59 months (UN IGME 2017).

As deaths in children under the age of 5 have decreased, the proportion of these deaths that occur during the newborn period has increased. Out of the 5.6 million under-5 deaths in 2016, 2.6 million were neonates, which accounts for nearly half of all under-5 mortality. Preterm birth complications (16%), pneumonia (16%), intrapartum-related events (11%), and diarrhoea (8%) account for more than half of the child deaths globally (UN IGME 2017).

Thus, despite many public health successes, infectious diseases remain one of the main killers of children under-5. Moreover, neonatal sepsis, malaria, and AIDS account for 7%, 5% and 1% of all under-5 mortality, respectively (UN IGME 2017). The distribution of these major causes of mortality in various WHO regions is presented in Figure 8.11.1.

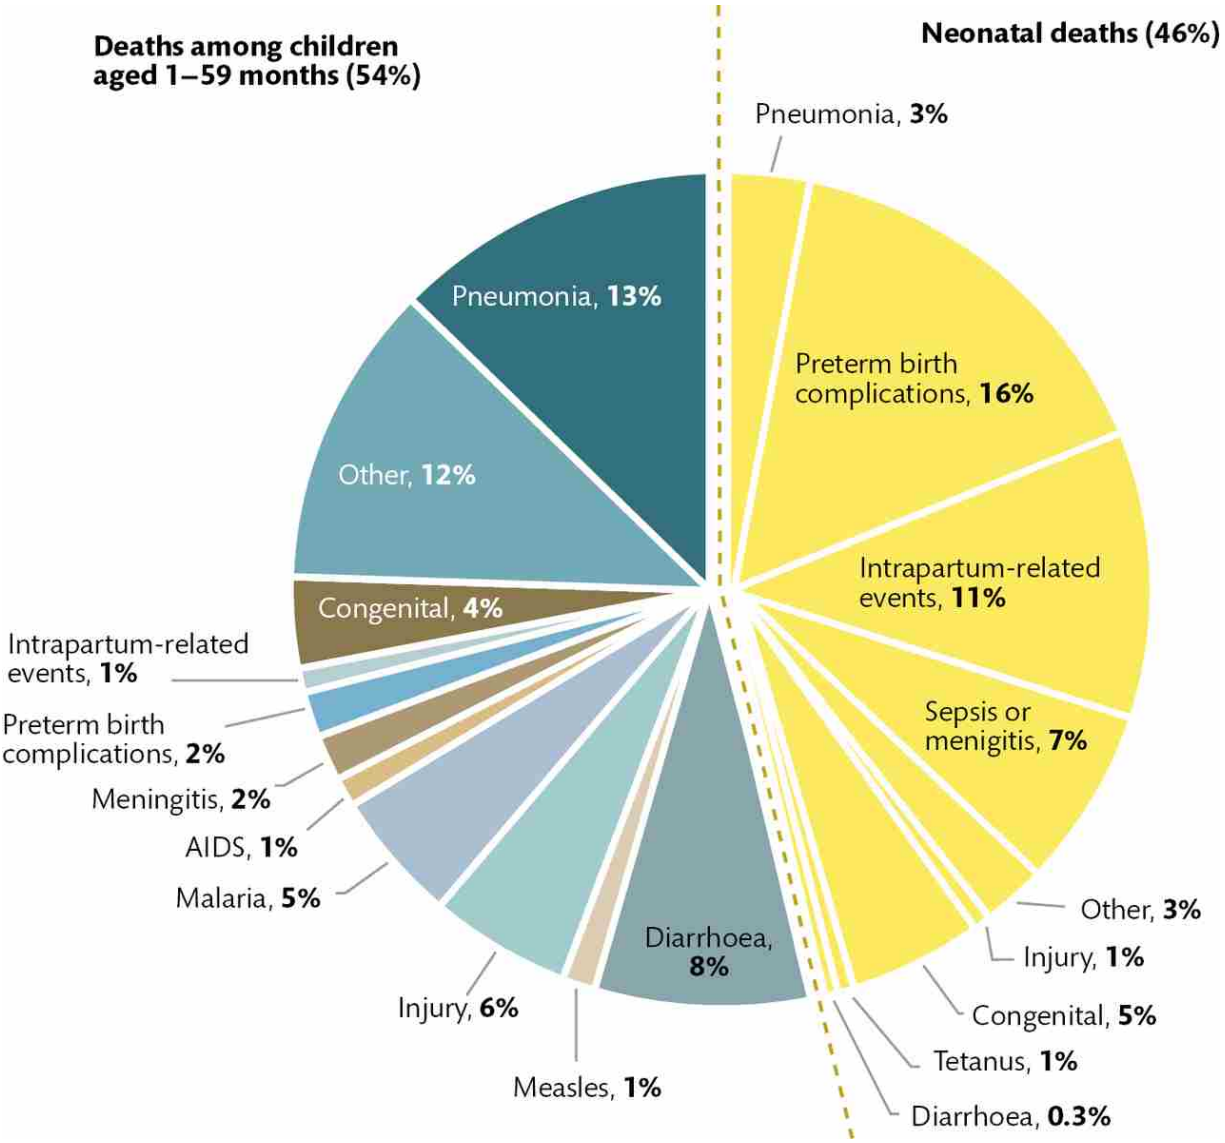

Fig. 8.11.1 Levels and trends in child mortality, 2017.

Reprinted from United Nations Inter-agency Group for Child Mortality Estimation (UN IGME), 'Levels & Trends in Child Mortality: Report 2017, Estimates Developed by the UN Inter-agency Group for Child Mortality Estimation', United Nations Children's Fund, New York, 2017, with permission from UNICEF.

Nearly 80% of all under-5 deaths occur in two regions of the world; sub-Saharan Africa and Southern Asia (UN IGME 2017). With an under-5 mortality rate of 79 deaths per 1,000 live births, sub-Saharan Africa remains the deadliest region for young children. Only six countries (India, Nigeria, Pakistan, the Democratic Republic of Congo, Ethiopia, and China) account for half of global deaths in children less than 5 years with the predominant causes being neonatal disorders and preventable infections such as pneumonia and diarrhoea. (Fig. 8.11.2; Table 8.11.1)

Source: data from *The Lancet*, Volume 390, Issue 10100, GBD 2016 Causes of Death Collaborators, Global, regional, and national age–sex specific mortality for 264 causes of death, 1980–2016: a systematic analysis for the Global Burden of Disease Study 2016, pp. 1151–210, Copyright © 2017.

MDG 6 focused on arresting the spread of infectious diseases, with a specific mention of HIV and malaria. Although the goal was not achieved in

full, some of the targets were met, with the incidence of HIV and malaria declining. Of the 36.7 million people living with HIV in 2016, more than 20 million had access to antiretroviral therapy (ART). With increasing access to ART, the incidence of HIV decreased by 40% between 1990 and 2013 (WHO 2015). Moreover, since 2010 new HIV infections have gone down by nearly 11%; 1.7 million in 2016 as compared to 1.9 million in 2010 (UNAIDS 2017).

The Joint United Nations Programme on HIV/AIDS (UNAIDS) estimates that 43% of all new HIV infections occur in Eastern and Southern Africa, and the region carries the greatest burden of the disease. However, the proportion of AIDS-related deaths in the area has declined by an estimated 42% between 2010 and 2016. Similarly, most other regions such as Asia and the Pacific, Western and Central Africa, and Middle East, and North Africa saw a decline in new HIV cases during this period.

LRIs are the third leading cause of disability-adjusted life years (DALYs) worldwide, with 60% of the LRI DALYs coming from children under-5. Diarrhoeal diseases are the fifth leading cause of global DALYs. HIV/AIDS is tenth on the list as compared to fifth in 2006, while malaria and tuberculosis rank thirteenth and eighteenth, respectively. No communicable disease is among the top ten leading causes of DALYs in high-income countries. In contrast, pneumonia, HIV/AIDS, diarrhoea, and malaria rank among the top ten causes of death and DALYs in LMICs (Murray et al. 2012; GBD 2016 DALYs and HALE Collaborators 2017). Table 8.11.2 shows the estimated number of deaths in under-5 children by cause while Table 8.11.3 shows a comparison of infectious disease mortality in children in 2000 and 2015.

Table 8.11.2 Estimated numbers of deaths by cause in 2015 in children under 5

	Estimated number (millions)
Neonates aged 0–27 days	
Preterm birth complications	0.943 (0.832–1.066)
Intrapartum-related complications	0.631 (0.550–0.723)
Sepsis or meningitis	0.402 (0.280–0.522)
Congenital abnormalities	0.305 (0.260–0.382)
Pneumonia[a]	0.161 (0.111–0.239)
Tetanus	0.034 (0.018–0.084)
Diarrhoea[b]	0.018 (0.010–0.070)
Other conditions	0.187 (0.142–0.240)
Children aged 1–59 months	
Pneumonia[a]	0.760 (0.651–0.943)
Diarrhoea[b]	0.509 (0.401–0.661)
Injuries	0.326 (0.272–0.410)
Malaria	0.306 (0.225–0.452)
Congenital abnormalities	0.207 (0.165–0.259)
Meningitis	0.115 (0.091–0.162)
Preterm birth complications	0.112 (0.061–0.168)
AIDS	0.086 (0.076–0.101)
Measles	0.074 (0.038–0.268)
Intrapartum-related complications	0.058 (0.028–0.092)
Pertussis	0.054 (0.053–0.060)

Uncertainty range (UR) is defined as the 2.5–97.5 centile. Other conditions among children aged 1–59 months included causes originated during the perinatal period, cancer, severe malnutrition, and other specified causes. Intrapartum-related events were formerly referred to as ‘birth asphyxia’.

Pertussis	0.056 million	0.054 million

* Neonatal sepsis/meningitis, neonatal pneumonia, neonatal tetanus, childhood pneumonia, childhood diarrhoea, meningitis, diarrhoea, measles, malaria, and AIDS all showed >30% decline in mortality rates from 2000 to 2015

Source: data from Liu L., et al. (2016) 'Global, regional, and national causes of under-5 mortality in 2000–15: an updated systematic analysis with implications for the Sustainable Development Goals' *The Lancet* 388(10063) pp. 3027–35.

Factors responsible for the decline in infectious diseases in industrialized nations during the last century include improved nutrition, safer food, and water supplies, improved hygiene and sanitation, the introduction of antimicrobial agents, and immunizations, all of which resulted in decreased host susceptibility and reductions in disease transmission (Nakatani 2016). While there have been substantial reductions in morbidity and mortality due

to communicable diseases in the last century, there remain significant gaps in child and adult mortality between rich and poor countries.

Apart from the immediate causes of infections in childhood, a number of determinants contribute to the high burden of infectious diseases in LMICs. These include several distal determinants such as income, social status, and education, which work through an intermediate level of environmental and behavioural risk factors. These risk factors, in turn, lead to the proximal causes of death (nearer in time to the terminal event), such as undernutrition, infectious diseases, and injury (WHO 2008). The major social determinants affecting the mortality and morbidity of young children include poverty, indoor air pollution, malnutrition, inequity, lack of education, inadequate health-related social behaviours and practices, and other social and cultural determinants of health.

Specific disease categories

As described in the previous section, a limited number of infectious diseases are responsible for a substantial proportion of the total global burden of morbidity and mortality, especially in resource-limited areas of the world. This section will provide an overview of the major types of infectious diseases responsible for the bulk of acute and chronic morbidity and mortality of children and adults worldwide. Detailed information on approaches for the prevention and control of these diseases is available in Chapter 11.3.

Neonatal sepsis

Sepsis and meningitis are significant causes of morbidity and mortality in newborns, particularly in preterm and low birth weight (LBW) infants, and are estimated to cause 420,000 deaths annually; nearly 16% of neonatal mortality (Laxminarayan and Bhutta 2016). Neonatal sepsis may be defined using clinical criteria (Table 8.11.4) and/or microbiological testing, by positive blood and/or cerebrospinal fluid (CSF) cultures. It may also be classified according to the time of disease onset: early onset sepsis (EOS) and late onset sepsis (LOS). Meningitis can occur as a part of sepsis in both the EOS and LOS time periods or as focal infection with LOS disease. The distinction has clinical relevance, as EOS disease is mainly due to bacteria acquired before and during delivery, and LOS disease to bacteria acquired

after delivery (nosocomial or community sources). In the literature, however, there is little consensus as to what age limits apply, with EOS ranging from 48 hours to 6 days after delivery. Notwithstanding this limitation, the most commonly used cut off is <7 days (EOS) versus ≥7 days (LOS).

Table 8.11.4 Clinical criteria for diagnosis of neonatal sepsis and meningitis

Sepsis	Meningitis
Symptoms [a] Convulsions Inability to feed Unconsciousness Lethargy Fever (>37.7°C or feels hot) Hypothermia (<35.5°C or feels cold)	**General signs** • Drowsiness • Reduced feeding • Unconsciousness • Lethargy • High-pitched cry • Apnoea
Signs Severe chest indrawing Reduced movement Crepitations Cyanosis	**Specific signs** • Convulsions • Bulging fontanelle

[a] The more symptoms a neonate has, the higher the probability of the disease.

Global and regional epidemiology

An estimated 2.6 million neonates died in 2016, 46% of the total under-5 deaths that year. Among newborn deaths, major causes included preterm birth complications (35%), intrapartum-related complications, previously labelled as birth asphyxia (24%), whereas sepsis or meningitis accounted for 15% of neonatal deaths (UN IGME 2017). Despite major progress in neonatal care, overall case fatality rates from sepsis range from 2 to as high as 50%.

Unfortunately, hospitals in developing countries are also hot beds of infection transmission, especially multidrug-resistant nosocomial infections. Reported rates of neonatal sepsis vary from 6.5 to 38 per 1,000 live hospital-

born babies and the rates of bloodstream infection range from 1.7 to 33 per 1,000 live births, with rates in Africa clustering around 20 and in South Asia around 15 per 1,000 live births. According to estimates, nearly 40% of neonatal mortality in LMICs is associated with hospital-acquired infections (Zaidi et al. 2005). Factors responsible for hospital-acquired neonatal sepsis include lack of aseptic technique for procedures, inadequate hand hygiene and glove use, deficient sterilization and disinfection practices, overuse of invasive devices, re-use of disposable supplies without adequate sterilization, re-use of single-use vials, overcrowded and understaffed labour and delivery rooms, unhygienic bathing and skin care, contaminated bottle feedings, inappropriate and prolonged use of antibiotics, and lack of effective infection control practices.

Aetiology

In general, Gram-negative pathogens are responsible for a substantial proportion of EOS. In contrast to industrialized countries where group B streptococci (GBS) are common causes of neonatal sepsis, *Klebsiella pneumoniae* is an important aetiology in developing countries. LOS is most commonly due to *E. coli*, *S. aureus*, *S. pyogenes*, *S. pneumoniae*, and *Salmonella* spp. The organisms causing neonatal sepsis and meningitis in LMICs are listed in Table 8.11.5. More recently the results of the Aetiology of Neonatal Infection in South Asia (ANISA) study were published; these showed a similar pattern as previously for LMICs (Table 8.11.6) (Saha et al. 2018).

Table 8.11.5 Distribution of all isolates by age of onset

Organism isolated	N	<7 days of life % (95% CI)	N	8–59 days of life % (95% CI)	N	60–90 days of life % (95% CI)
Staphylococcus aureus	47	14.6 (10.8–18.5)	276	14.3 (12.7–15.9)	1	2.3 (0.0–6.7)
Group A streptococci/*Streptococcus pyogenes*	4	1.2 (0.0–2.4)	55	2.8 (2.1–3.5)	8	18.2 (6.8–29.6)

[1] Rates are based on the estimated pathogen prevalence among pSBI episodes, derived from partial latent class model (see text for methods) that evaluated 5,253 pSBI episodes identified from a population of 63,114 registered live births.

[2] The pathogen class 'Other Blood Culture' includes all bacteria that grew on blood culture but did not have an associated assay on the ANISA molecular diagnostic panel; this class was not estimated directly from the model but indirectly by calculating the product of the number of blood culture isolates in the 'Other Blood Culture' class and the average estimated etiologic proportion attributed to pathogens with multiple tests that included blood culture.

[3] The pathogen class 'Other/None' includes any pSBI episode that was not attributed by the partial latent class model (see text for details) to one of the evaluated ANISA pathogen classes.

[4] Aggregated incidence was calculated by weighting site-specific incidence estimates by average registered live births per month.

Evidence-based interventions to address neonatal infections

The lack of success in achieving the fourth MDG is largely attributable to the relatively slow reduction in neonatal mortality. Newborn survival, now a focus of global and regional agendas, is very visible in the Sustainable

Development Goals (SDGs). The SDGs call for a reduction of neonatal mortality to at least 12 per 1,000 live births, by 2030. Real progress in saving newborns will depend upon provision of a good mix of preventive and therapeutic services. Scaling up proven interventions addressing maternal risk factors and underlying causes could reduce neonatal infections by 84% (Bhutta et al. 2014).

Medical treatment

Reaching and treating sick newborn infants promptly is critical to survival. Normally, health facilities use a combination of ampicillin and gentamicin, with or without vancomycin, for cases of neonatal sepsis (Table 8.11.7). If there is a high risk of *S. aureus*, cloxacillin with gentamicin is a recommended option. However, increasing antibiotic resistance among common organisms causing neonatal sepsis in both community and hospital settings presents a challenge to the selection of appropriate antibiotics. Case management of neonatal infections is mainly provided through child health services, both in facilities and through family-community care. Similarly, integrated management of childhood illnesses (IMCI) has been widely implemented as the main approach for addressing child health in health systems. However, IMCI management guidelines rely on the sick child being brought to a health facility. The modification of IMCI to include the neonatal period (IMNCI) and recent expansion to community settings has now been included as a public health strategy in many countries including India.

Following the demonstration of significant reduction in neonatal mortality with the use of oral co-trimoxazole and injectable gentamicin by community health workers (CHWs), this strategy could be employed in circumstances where referral is difficult. Moreover, the African Neonatal Sepsis Trial (AFRINEST) showed that simplified antibiotic regimens, of injectable gentamicin, oral amoxicillin and, in certain cases, injectable procaine benzylpenicillin, given at home or a primary healthcare facility, for possible serious bacterial infections (PSBI), were comparable in effectiveness to parenteral WHO-recommended antibiotic regimens (Tshefu et al. 2015). The current WHO recommendation for treating PSBIs is 7-day treatment with parenteral benzylpenicillin with gentamicin or ampicillin with gentamicin at a hospital or treatment by frontline health worker with intramuscular gentamicin and oral amoxicillin (WHO 2015). Currently in some health systems, outreach health workers, community nutrition, and child

development workers are being trained to visit all mothers and neonates at home two to three times within the first 10 days, starting soon after birth, to provide home-based preventive care/health promotion and to detect neonates with sickness requiring referral.

Table 8.11.7 Antimicrobial therapy of neonatal meningitis and sepsis

Patient group	Likely aetiology	Antimicrobial choice	
		Developed countries	**Developing countries**
Sepsis			
Immunocompetent neonates	***Developed countries:***	Ampicillin or penicillin plus an aminoglycoside	Ampicillin or penicillin plus gentamicin
	Group B streptococci, *E. coli*		
	Developing countries:		Or co-trimoxazole plus gentamicin
	Klebsiella spp.		
	Pseudomonas spp.		
	Salmonella spp.		
Meningitis			
Immunocompetent neonates (age <3 months)	***Developed countries:***	Ampicillin plus ceftriaxone or cefotaxime	Ampicillin plus gentamicin
	Group B streptococci		
	E.*coli*		
	L.*monocytogenes*		
	Developing countries:		
	S.*pneumoniae*		
	E.*coli*		
Immunodeficient	Gram-negative bacilli	Ampicillin plus ceftazidime	
	L.*monocytogenes*		

Preventive measures

Preventive interventions need to bridge the continuum of care from pregnancy, through childbirth and the neonatal period, and beyond. Lack of positive health-related behaviour, education, and poverty are underlying causes of many neonatal deaths, either through increasing the prevalence of risk factors such as maternal infection or by reducing access to effective care.

Attempts to reduce the proportion of LBW births at the population level have had limited success. Many deaths in preterm babies and in those born at term with LBW can be prevented with extra attention to warmth, feeding, and prevention or prompt treatment of infections. In LMICs, 90% of mothers deliver babies at home without a skilled health professional present; globally 50 million births occur at home (Lawn et al. 2014). Simple low-cost interventions, notably tetanus toxoid vaccination, provision of clean delivery kits, exclusive breastfeeding, counselling for birth preparedness, and breastfeeding promotion through peer counsellors and women's groups, have been shown to reduce newborn morbidity and mortality (Bhutta et al. 2014). Postnatally, kangaroo mother care for LBW infants, topical emollient therapy, hand washing, attention to environmental hygiene and sterilization, and antibiotics for neonatal infections, are additional health system measures. Alcohol-based antiseptics for hand hygiene are an appealing innovation because of their efficacy in reducing hand contamination and their ease of use, especially when sinks and supplies for hand washing are limited.

Early initiation of breastfeeding affects neonatal health outcomes through several mechanisms. Mothers who suckle their offspring shortly after birth have a greater chance of successfully establishing and sustaining breastfeeding throughout infancy and provide a variety of immune and non-immune components that accelerate intestinal maturation, resistance to infection, and epithelial recovery from infection. Prelacteal feeding with non-human milk antigens may disrupt normal physiological gut priming. WHO currently recommends dry cord care for newborns, and application of chlorhexidine for those born at home in areas with high mortality risk (WHO 2013). Chlorhexidine application to the cord stump in such settings can reduce omphalitis by 27% and provide a 23% decrease in risk of neonatal mortality (Imdad et al. 2013). A closely related issue is the need for general skin care. Topical emollient therapy has been shown to decrease risk of nosocomial infections by 50% and neonatal mortality by 27% (Salam et al. 2013).

At least two doses of tetanus toxoid should be given during pregnancy so that protective antibodies can be transferred to the foetus, to protect it from

neonatal tetanus. Women with a history of prolonged rupture of membranes, especially if preterm, should be given prophylactic antibiotics. Maternal antibiotic therapy in this situation is effective in reducing maternal and neonatal infection-related morbidities. A detailed review of antenatal, intrapartum, and postnatal interventions noted that antibiotics for preterm premature rupture of membranes (PPROM) could reduce infection-related neonatal mortality and preterm-related complications by 2% each (Bhutta et al. 2014). A domiciliary cadre of trained birth attendants potentially can be trained to recognize PPROM and provide referral and, possibly, initial antimicrobial therapy.

An important aspect of prevention of neonatal infection in developed countries relates to GBS disease. The joint guidelines developed and implemented in the United States have led to a significant reduction in the burden of disease. Most newborns born to mothers with risk of GBS colonization undergo a full diagnostic evaluation and empiric therapy.

In recent years, the importance of hospital-acquired infections in newborn infants, frequently with multidrug-resistant organisms, has been recognized. It is imperative that preventive strategies such as hand washing, preventing unnecessary hospital stay and environmental control are strictly enforced.

Gastrointestinal tract infections

Diarrhoea, the most common manifestation of intestinal tract infections, is a leading cause of preventable death in most developing countries where its greatest impact is seen in infants and children. Infectious diarrhoea may be accompanied by numerous complications (Table 8.11.8).

Table 8.11.8 Complications of gastrointestinal infections

Complication	Causative pathogens
Dehydration	*Vibrio cholerae*, *Cryptosporidium parvum* (especially in immunocompromised hosts), enterotoxigenic *Escherichia coli* (ETEC), rotavirus
Severe vomiting	Staphylococcal food poisoning, norovirus, rotavirus
Haemorrhagic colitis	*Campylobacter jejuni*, enterohaemorrhagic *E. coli* (EHEC), *Salmonella*, *Shigella*, *V. parahaemolyticus*
Toxic megacolon, intestinal perforation	EHEC, *Shigella*, *C. jejuni* (rare), *Clostridium difficile* (rare), *Salmonella* (rare), *Yersinia* (rare)
Haemolytic uraemic syndrome (HUS), thrombotic thrombocytopenic purpura (TTP)	EHEC, *Shigella*, *C. jejuni* (rare)
Reactive arthritis	C.*jejuni*, *Shigella*, *Salmonella*, *Yersinia*
Malabsorption/malnutrition	*Cyclospora cayetanensis*, *Giardia lamblia*, *C. parvum* or *C. hominis* (especially immunocompromised hosts)
Distant metastatic infection	*Salmonella*, *C. jejuni* (rare), *Yersinia* (rare)
Guillain–Barré syndrome	C.*jejuni* (rare)

Invasive diarrhoea refers to diarrhoea caused by bacterial pathogens that invade the bowel mucosa, causing inflammation and tissue damage and may cause blood in stools (bloody diarrhoea). Invasive diarrhoea accounts for approximately 10% of diarrhoeal episodes in children under 5 years of age and approximately 15% of diarrhoea-associated deaths in this age group worldwide (GBD Diarrhoeal Diseases Collaborators 2017). Although less frequent, bloody diarrhoea generally lasts longer, is associated with higher risk of complications and case fatality rates, and is more likely to adversely affect a child's growth. The burden of disease is mainly in younger age groups; 72% of deaths from diarrhoea and 81% of deaths from pneumonia happen in children younger than 2 years.

Global and regional epidemiology

The aetiology and severity of gastrointestinal infections are determined by several epidemiological factors. Young children and the elderly are at greatest

risk for more severe disease and complications. Childhood malnutrition and unsafe water, sanitation, and hygiene are considered the two leading risk factors for diarrhoea. The presence of underlying medical conditions, especially those that compromise immunity, greatly enhances the risk of acquiring an infection and its ultimate severity. Poor sanitation, inadequate water supplies, and increasing globalization of food transport systems all predispose to the development of large epidemics of food- and water-borne outbreaks of gastrointestinal disease. Seasonal or cyclic weather variations also influence the epidemiology of diarrhoeal disease and food poisoning (see Hamer and Gorbach 2010).

Several reviews have evaluated diarrhoea burden and mortality rates. A review carried out more than two decades ago estimated that 4.6 million children died annually from diarrhoea. Kosek et al. updated these estimates by reviewing 60 studies of diarrhoea morbidity and mortality published between 1990 and 2000 (Kosek et al. 2003). They concluded that diarrhoea accounted for 21% of all deaths at less than 5 years of age and caused 2.5 million deaths per year, although morbidity rates remained relatively unchanged. More recently, the GBD study estimates that diarrhoea incidence and mortality fell by nearly 6% and 21%, respectively, between 2005 and 2015. However, there were 2.39 billion episodes of diarrhoea in 2015 and it killed more than 1.3 million people in 2015, with nearly 0.5 million of these deaths occurring in children under-5 (GBD Diarrhoeal Diseases Collaborators 2017). Accounting for 8% of under-5 deaths, persistent high rates of diarrhoea morbidity may have significant long-term effects on linear growth and physical and cognitive function in children. Fortunately, the leading risk factors for diarrhoea are on the decline, with diarrhoea DALYs attributable to unsafe water and poor sanitation having fallen by 13.4% and those secondary to childhood undernutrition by 10% between 2005 and 2015. Figure 8.11.3 shows the 2015 country-specific global trends for diarrhoea mortality in children under-5.

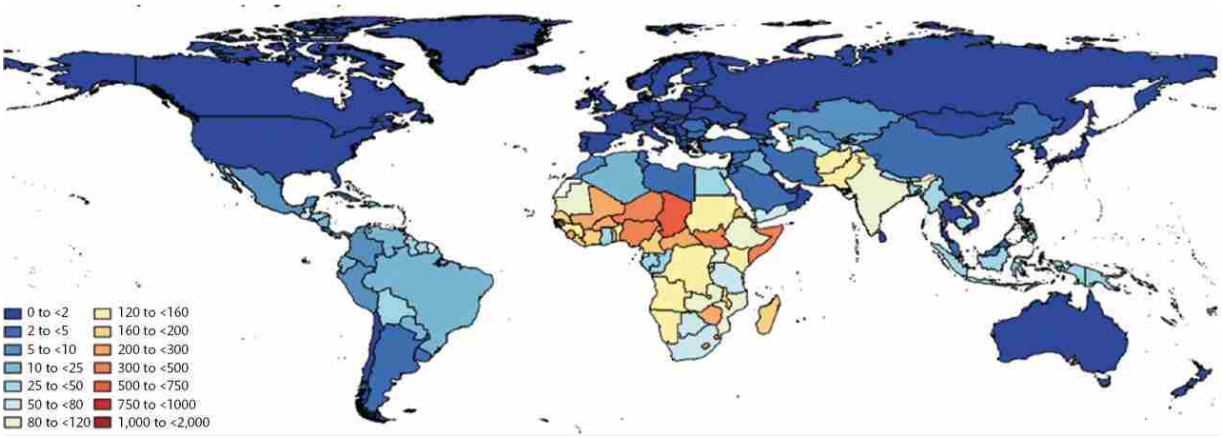

Fig. 8.11.3 Diarrhoea mortality rate in children younger than 5 years in 2015.
Reprinted from GBD Diarrhoeal Diseases Collaborators (2017). Estimates of global, regional, and national morbidity, mortality, and aetiologies of diarrhoeal diseases: a systematic analysis for the Global Burden of Disease Study 2015. Aetiology

Common aetiologies of non-inflammatory diarrhoea include enterotoxigenic *E. coli* (ETEC) and other strains such as enteroaggregative (EAEC), diffusely adhering, and enteropathogenic *E. coli*, *Vibrio cholerae*; non-01 choleras such as *V. vulnificus*; parasites including *Giardia lamblia*, *Cryptosporidium parvum*, and microsporidia; and several different virus species including rotavirus, noroviruses, and astroviruses. Acute inflammatory diarrhoea is the result of infection with bacterial enteropathogens such as *Shigella*, *Campylobacter*, *Salmonella* spp., enterohaemorrhagic *E. coli* (EHEC), *V. parahaemolyticus*, and *Clostridium difficile*. Among the parasites, *Entamoeba histolytica* is the most common cause of dysenteric illness although *Balantidium coli*, *Schistosoma mansoni*, *S. japonicum*, *Trichuris trichiura*, hookworms, and *Trichinella spiralis* can all cause bloody, mucoid diarrhoea. In 2015, rotavirus, *Shigella*, and *Salmonella* were responsible for the most diarrhoeal deaths. While aetiology of diarrhoeal mortality was similar in the under-5 age group, the top three causes of diarrhoeal deaths were rotavirus, *Cryptosporidium* and *Shigella* (GBD Diarrhoeal Diseases Collaborators 2017). The MAL-ED study conducted in eight LMICs reported norovirus, rotavirus, and *Campylobacter* spp. among the commonest diarrhoea-causing pathogens in children under 2 years (Platts-Mills et al. 2015). Estimates of

rotavirus and cholera as major diarrhoea aetiologies associated with increased risk of mortality are shown in Table 8.11.9.

Table 8.11.9 Diarrhoea episodes and deaths by WHO region

Several diarrhoea episodes	African region	American region	Eastern Mediterranean region	European region	Southeast Asian region	Western Pacific region	World
Rotavirus							
Episodes (×103)	2,557 (1,901–3,026)	1,129 (833–1,330)	1,344 (990–1,576)	660 (488–781)	2,382 (1,753–790)	1,781 (1,312–2,090)	9,853 (7,277–11,593)

Infectious microorganisms in contaminated food and drink are the main source of travellers' diarrhoea. High-risk foods include uncooked vegetables, salsa, meat, and seafood. Tap water, ice, unpasteurized milk and dairy products, salads, and unpeeled fruits are also associated with an increased risk. Although many different pathogens may be responsible, the leading culprits are various forms of *E. coli*, particularly ETEC and EAEC. Food poisoning is most commonly caused by the consumption of food contaminated with bacteria or bacterial toxins. Food poisoning can also be due to parasites (e.g. trichinosis), viruses (e.g. hepatitis A), and other toxins (e.g. *Amanita* mushrooms). The most well-recognized causes of bacterial food poisoning are the following: *Clostridium perfringens*, *S. aureus*, *Vibrio* spp. (including *V. cholerae* and *V. parahaemolyticus*), *Bacillus cereus*, *Salmonella* spp., *C. botulinum*, *Shigella* spp., toxigenic *E. coli* (ETEC and EHEC), and certain species of *Campylobacter*, *Yersinia*, *Listeria*, and *Aeromonas*.

Issues in presentation and diagnosis

Gastrointestinal infections usually result in three principal syndromes: non-inflammatory diarrhoea, inflammatory diarrhoea, and systemic disease. Non-inflammatory diarrhoea primarily involves the small intestine, whereas inflammatory diarrhoea predominantly affects the colon. The location of infection influences the clinical characteristics and certain diagnostic features of the diarrhoeal disease (Table 8.11.10). Thus, organisms that target the small intestine tend to produce watery, potentially dehydrating diarrhoea, while those infecting the large intestine cause bloody mucoid diarrhoea associated with tenesmus.

Table 8.11.10 Clinical features and aetiologies of diarrhoeal diseases

Feature	Site of infection	
	Small intestine	**Large intestine**
Pathogens	• *Escherichia coli* (enteropathogenic *E. coli*, enterotoxigenic *E. coli*) • *Cryptosporidium parvum* • *Giardia lamblia* • Norovirus • Rotavirus • *Vibrio cholerae*	• *E. coli* (EIEC, EHEC) • *Entamoeba histolytica* • *Shigella* spp.
Location of pain	Mid-abdomen	Lower abdomen, rectum
Volume of stool	Large	Small
Blood in stool	Rare	Common
Faecal leucocytes	Rare	Common (except in amoebiasis)
Sigmoidoscopy	Normal	Mucosal ulcers, haemorrhagic foci, friable mucosa

Acute watery diarrhoea can be rapidly dehydrating, with stool losses of 250 mL/kg/day or more, a quantity that quickly exceeds total plasma and interstitial fluid volumes, and is incompatible with life unless aggressive fluid therapy can be provided. Such dramatic dehydration is usually due to rotavirus, ETEC, or *V. cholerae*, and it is most dangerous in the very young.

Persistent diarrhoea is defined as diarrhoea lasting 14 days or longer, is manifested by malabsorption, nutrient losses, and wasting, and is typically associated with malnutrition. Although persistent diarrhoea accounts for 8–20% of diarrhoea episodes, it is associated with a disproportionately increased risk of death. Persistent diarrhoea more commonly follows an episode of bloody diarrhoea and is associated with a tenfold higher risk of mortality.

Inflammatory diarrhoea is a manifestation of invasive intestinal infection that is associated with intestinal damage and nutritional deterioration, often with systemic manifestations including fever. Although clinicians often use the term bloody diarrhoea interchangeably with dysentery, the latter is a

syndrome consisting of the frequent passage of characteristic, small-volume, bloody mucoid stools, abdominal cramps, and tenesmus. Bloody diarrhoea is usually caused by *Shigella* or some strains of *E. coli*. Agents that cause bloody diarrhoea or dysentery can also provoke a form of diarrhoea that does not present clinically with visible blood in the stool, although mucosal damage and inflammation are present and faecal blood and white blood cells are usually detectable by microscopy.

Because of the significant morbidity and costs associated with infectious diarrhoea, making a specific laboratory diagnosis can be useful epidemiologically, diagnostically, and therapeutically. A definitive diagnosis is achieved mainly through study of faecal specimens, using bacteriological culture, viral culture, or direct electron microscopy for viral particles, and identification of microbial antigens (viruses, bacteria, parasites, or toxins). DNA probes, polymerase chain reaction (PCR), and immunodiagnostic tests can now be used to identify several pathogens in stool specimens.

Evidence-based interventions

Increased use of oral rehydration therapy, improved nutrition, increased breastfeeding, better supplemental feeding, and improvement in hygiene and sanitation are believed to have contributed to the decline in morbidity and mortality of diarrhoea. Syndromic diagnosis provides important clues to optimal management and is both programmatically and epidemiologically relevant. The correct treatment of diarrhoea requires mothers to recognize the problem and seek medical care promptly, and health workers to give oral rehydration solution (ORS) or other fluids to prevent or treat dehydration, dispense an appropriate antibiotic when needed, provide advice on appropriate feeding, and provide follow-up, especially for children at increased risk of serious morbidity or death. Low-osmolarity ORS and zinc supplementation (10–20 mg/day) have led to significantly improved diarrhoea outcomes. A recent series in *The Lancet* (Bhutta et al. 2013b) highlighted the role of 15 core interventions to address childhood pneumonia and diarrhoea, of which several are also common nutrition interventions underscored recently (Table 8.11.11) (Bhutta et al. 2013a).

Medical treatment

Since the most devastating consequences of acute infectious diarrhoea result from fluid losses, the major goal of treatment is the replacement of fluid and electrolytes. While the intravenous route of administration has been traditionally used, ORS has been shown to be effective and logistically more practical and less costly to administer, especially in developing countries. ORS is the treatment of choice for mild-to-moderate diarrhoea in both children and adults, as long as vomiting is not a major feature of the gastrointestinal infection. ORS can also be used in severely dehydrated patients after initial parenteral rehydration.

Table 8.11.11 Interventions for prevention and treatment of diarrhoea, pneumonia, and undernutrition

Diarrhoea	Pneumonia	Nutrition
• Breastfeeding promotion • Improved water source, sanitation, and hygiene • Preventive vitamin A supplementation • Preventive zinc supplementation • Rotavirus vaccine • ORS • Zinc—for treatment of diarrhoea • Antibiotics for dysentery	• Breastfeeding promotion • Improved water source, sanitation, and hygiene • Preventive vitamin A supplementation • Preventive zinc supplementation • Hib vaccine • Pneumococcal vaccine • Case management of neonatal infections • Oral antibiotics: case management of pneumonia in children	• Breastfeeding promotion • Improved water source, sanitation, and hygiene • Preventive vitamin A supplementation • Preventive zinc supplementation • Periconceptional folic acid supplementation or fortification • Appropriate complementary feeding • Maternal balanced energy protein supplementation • Maternal calcium supplementation • Multiple micronutrient supplementation in pregnancy • Management of moderate and severe acute malnutrition

Source: data from *The Lancet*, Volume 382, Issue 9890, Bhutta, Z.A. et al., Evidence based interventions for improvement of maternal and child nutrition: what can be done and at what cost?, pp. 452–77, Copyright © 2013 Elsevier Ltd All rights reserved.

Although there is no doubt about the value of ORS in treating dehydrating diarrhoea, the optimal sodium concentration of the solution remains in dispute, particularly in regard to the treatment of mild-to-moderate diarrhoea.

The high concentration of sodium (90 mmol) in the standard WHO ORS formulation may cause hypernatraemia and even seizures in children with non-cholera watery diarrhoea. Consequently, lower concentrations of sodium and a reduced osmolarity solution have been found to be effective for rehydration and not to be associated with any serious adverse clinical events. Thus, United Nations Children's Fund (UNICEF) and WHO recommend the use of low-osmolarity ORS to prevent and treat dehydration. ORS has major advantages over home fluids in the management of children with significant dehydration and coupled with zinc therapy (20 mg zinc sulphate daily for 10 days) is the mainstay of treatment of childhood diarrhoea. At current global coverage, it is estimated that ORS reduces diarrhoea mortality by 69%, which would increase to 93% if coverage was 100% (Munos et al. 2010). Moreover, zinc supplementation has been shown to reduce the duration of a diarrhoea episode by 25% and a 30% reduction in stool volume.

Dietary abstinence, the traditional approach to an acute diarrhoeal illness, restricts the intake of necessary calories, fluids, and electrolytes. During an acute attack, the patient often finds it more comfortable to avoid spicy, high-fat, and high-fibre foods, all of which can increase stool volume and intestinal motility. Although giving the bowels a rest provides symptomatic relief, continued oral intake of fluids and foods is critical for both rehydration and the prevention of malnutrition. In children, it is particularly important to restart feeding as soon as the child is willing to accept oral intake.

Because certain foods and fluids can increase intestinal motility, it is wise to avoid fluids such as coffee, tea, cocoa, and alcoholic beverages. Ingestion of milk and dairy products can potentiate fluid secretion and increase stool volume. Besides the oral rehydration therapy outlined earlier, acceptable beverages for mildly dehydrated adults include fruit juices and various bottled soft drinks. Carbonated drinks should be allowed to 'de-fizz' by letting them stand in a glass before ingestion. Soft, easily digestible foods are generally acceptable to the patient with acute diarrhoea.

Since most patients with infectious diarrhoea, even those with a recognized pathogen, have a mild, self-limited course, neither a stool culture nor specific treatment is required for such cases. For more severe cases, however, empirical antimicrobial therapy should be instituted, pending the results of stool and blood cultures. Gastrointestinal infections likely to respond to antibiotic treatment include cholera, giardiasis, cyclosporiasis, shigellosis, *E. coli* diarrhoea in infants, symptomatic travellers' diarrhoea, and *C. difficile* diarrhoea. The choice of antimicrobial drug should be based on *in vitro*

sensitivity patterns, which vary from region to region. A fluoroquinolone antibiotic is a good choice for empirical therapy, since these agents have broad-spectrum activity against virtually all bacterial pathogens responsible for acute infectious diarrhoea (except *C. difficile*). Resistance to fluoroquinolones in South and Southeast Asia is an increasing problem.

In patients with severe community-acquired diarrhoea—characterized by more than four stools per day lasting for at least 3 days or more with at least one associated symptom such as fever, abdominal pain, or vomiting—there is a high likelihood of isolating a bacterial pathogen. In this setting, a short course of a fluoroquinolone, namely 1–3 days' duration, will generally provide prompt relief with a low risk of adverse effects. Fluoroquinolones will not be effective for parasitic infections—specific antiparasitic drugs should be prescribed after identification of the offending pathogen in stool smears.

The duration of antimicrobial therapy has not been clearly defined. While courses of anywhere from 3 to 10 days of treatment have been recommended, there are several studies that included severe forms of diarrhoea which suggested that a single dose is as effective as more prolonged therapy. When treatment is indicated, a number of studies have shown that the combination of an antimicrobial drug and an antimotility drug provides the most rapid relief of diarrhoea.

Preventive measures

Diarrhoeal disease affects rich and poor, old and young, and those in developed and developing countries, yet a strong relationship exists between poverty, an unhygienic environment, and the number and severity of diarrhoeal episodes—especially for children under 5 years. Poverty also restricts the ability to provide age-appropriate, nutritionally balanced diets, or to modify diets when diarrhoea develops so as to mitigate and repair nutrient losses. The impact is exacerbated by the lack of adequate, available, and affordable medical care. Thus, preventive and management strategies for diarrhoea must have an equity focus.

Malnutrition is an independent predictor of the frequency and severity of diarrhoeal illness and can lead to a vicious cycle in which sequential diarrhoeal disease leads to increasing nutritional deterioration, impaired immune function, and greater susceptibility to infection.

Family knowledge about diarrhoea must be reinforced in areas such as prevention, nutrition, hand washing, and hygiene, measles vaccination, preventive zinc supplements, and when and where to seek care. It is estimated that, in the 1990s, more than 1 million deaths related to diarrhoea may have been prevented each year, largely attributable to the promotion and use of these therapies.

A 2016 meta-analysis estimates that nearly half of all diarrhoea episodes can be prevented by breastfeeding (Victora et al. 2016). Not breastfeeding is associated with a 165% increase in diarrhoea incidence in 0–5-month-old infants (Bhutta et al. 2014). Continued breastfeeding during the diarrhoea episode provides nutrients to the child, prevents weight loss, and improves recovery from diarrhoea. Contaminated and poor-quality complementary foods are associated with increased diarrhoea burden and stunting. Appropriate, safe, and aptly initiated complementary feeding has been shown to reduce mortality by 6% in young children. Diarrhoea frequently causes fever, altering host metabolism and leading to the depletion of body stores of nutrients. These losses must be replenished during convalescence, which takes much longer than the illness does to develop. For these reasons, appropriate feeding strategies during diarrhoea episodes are a cornerstone of treatment.

Various studies suggest that zinc-deficient populations are at increased risk of developing diarrhoeal diseases, respiratory tract infections, and growth retardation.). A recent systematic review concluded that zinc therapy reduces diarrhoea-related admissions by 23%, duration of acute diarrhoea by 0.5 days and persistent diarrhoea by 0.68 days (Lazzerini and Wanzira 2016). Poor sanitation, lack of access to clean water, and inadequate personal hygiene are responsible for an estimated 90% of childhood diarrhoea. A recent Cochrane review estimates that promotion of hand washing in high-income and low-middle-income settings can reduce diarrhoea incidence by 30% (Ejemot-Nwadiaro et al. 2015) while some other reviews have shown hand washing with soap to lead to a diarrhoea risk reduction of nearly 48% (Black et al. 2003, 2008). Hand washing promotion strategies have also been shown to reduce diarrhoea burden with ancillary benefits in community settings.

Immunization represents an ideal way to prevent certain bacterial and viral diseases, but has not yet proved successful for combating many gastrointestinal pathogens. The cholera vaccine that has been available for decades suffers from low efficacy, a moderate risk of side effects, and a short duration of action. Newer oral cholera vaccines, such as the inactivated B

subunit vaccine, are highly effective for prevention of severe cholera. The rotavirus vaccine is estimated to reduce the incidence of severe rotavirus infection by nearly 74% and in 2009, the WHO recommended the vaccine be incorporated into national immunization programmes, particularly in LMICs (Khan and Bhutta 2017). According to GAVI, since programme inception the rotavirus vaccine has reached more than 54 million children (GAVI 2016). Measles is known to predispose to diarrhoeal disease secondary to measles-induced immunodeficiency, and it is estimated that measles vaccine at varying levels of coverage (45–90%) could prevent 44–64% of measles cases, 0.6–3.8% of diarrhoeal episodes, and 6–26% of diarrhoeal deaths among children under 5 years. A review of the Demographic Health Survey data from four LMICs concluded that measles vaccination was associated with a decrease in diarrhoea as well as acute respiratory infection (ARI) in children (Bawankule et al. 2017).

Acute respiratory infections

ARIs are classified as upper or lower respiratory tract infections. Upper respiratory tract infections include the common cold, otitis media, sinusitis, and pharyngitis while lower respiratory tract infections include laryngitis, tracheitis, bronchitis, bronchiolitis, pneumonia, and any combination thereof. ARIs are not only confined to the respiratory tract but may also have systemic effects due to extension of infection into the bloodstream, the production of microbial toxins, inflammation, and reduced lung function.

LRIs, especially bronchiolitis and pneumonia, are the most common causes of both illness and mortality in children under 5 years. In adults, pneumonia and influenza are major causes of morbidity and mortality in developed as well as less-developed nations.

Global and regional epidemiology

The Global Burden of Disease (GBD) study estimates that 2.75 million deaths in 2015 were a consequence of LRIs, which include pneumonia and bronchiolitis. The major proportion of pneumonia deaths, nearly 704,000 according to GBD (920,000 as per UN IGME estimates), occurred in children under-5; however, owing to widely available antibiotic therapy and vaccines such *Haemophilus influenzae* type B (Hib) and pneumococcal conjugate, the number of LRI deaths in this age group have fallen by nearly 37% between

2005 and 2015 (Institute for Health Metrics and Evaluation n.d.). However, LRI mortality is significant in even older age groups, especially in the elderly. The GBD study notes that LRIs caused an estimated 1.27 million deaths in adults 70 years or older (GBD 2015 LRI Collaborators 2017).

Pneumonia causes most ARI deaths, and is the second largest killer of children under-5, causing almost 16% of all under-5 deaths globally. Among under-5 children pneumonia continues to be the leading killer, with 12.8% of deaths attributable to it (Liu et al. 2016). However, in sub-Saharan Africa pneumonia remains the leading cause of under-5 deaths with nearly 490,000 deaths, 16.6% of the total under-5 mortality. South Asia, a high-burden region, saw a decrease in under-5 deaths attributable to pneumonia, where in 2015 nearly 15.1% of all under-5 deaths were due to pneumonia as compared to 19.2% in 2000. Notably, 65% of total episodes of childhood pneumonia occur only in 15 high-burden countries, namely, Afghanistan, Angola, Burkina Faso, China, Democratic Republic of the Congo, Ethiopia, India, Indonesia, Kenya, Mali, Niger, Nigeria, Pakistan, Tanzania, and Uganda. The global incidence of pneumonia in the 0–4 age group is estimated at 0.19 episodes per child per year. Regional incidence was estimated to be highest in Southeast Asia (0.26) and Africa (0.27) (Walker et al. 2013). Serious neonatal infections account for nearly 25% of neonatal mortality globally, and it is difficult to disentangle sepsis and deaths from pneumonia. With the inclusion of neonatal pneumonia, recent estimates indicate that pneumonia is the single largest contributor to child mortality, accounting for about 16% of all under-5 deaths globally. It is also important to note that in contrast to diarrhoeal deaths where mortality rates have declined dramatically, despite the introduction of a global programme for the control of ARIs decades ago, there has been only a small reduction in the overall burden of pneumonia deaths. A comprehensive review of the global burden of pneumonia estimated that 81% of the deaths from childhood pneumonia occur in the first 2 years. Twelve per cent (12%) of childhood pneumonia episodes progress to severe disease, with a case fatality ratio of 8.9% for severe pneumonia. Predictably, the highest proportion of severe pneumonia cases were in Southeast Asian (39%) and African (43%) regions. Most severe pneumonia cases in children are attributable to *Streptococcus pneumoniae* (18.3%), which also accounts for 33% of childhood pneumonia mortality worldwide.

Despite gains in the availability and quality of healthcare in industrialized countries, ARIs, especially lower respiratory tract infections, remain a major cause of morbidity and mortality for adults and children. In fact, even today

pneumonia and influenza together are the eighth most common cause for death among adults in the United States. Recovery from pneumonia in the elderly takes longer and complications and mortality are also more frequent than in younger populations. Pneumonia is one of the most common causes of hospitalization and decreased activities of daily living among the elderly. Risk factors for death from pneumonia in adults include advanced age, alcohol consumption, leukopenia, bacteraemia, hypoxaemia, comorbid conditions such as diabetes mellitus, congestive heart failure, active malignancies, and immunosuppression, and certain signs and symptoms including hypothermia, hyperthermia, tachypnoea, hypotension, and altered mental status. Many factors such as the presence of certain comorbid medical conditions, use of certain drugs, changes in physiochemical characteristics of the non-specific host defence system such as cilia and mucus of the respiratory tract, malnutrition, and mechanical devices contribute to an increased incidence of pneumonia among the elderly. However, an important predisposing factor to the increased incidence of infections is the age-associated decline in immune responsiveness. Changes in immune response not only decrease resistance to pathogens but also contribute to increased morbidity and mortality due to respiratory infections.

Aetiology

A wide range of different bacterial and viral pathogens is responsible for community-acquired pneumonia in children and adults. Foremost among them is *S. pneumoniae*, which accounts for up to half of all cases (Table 8.11.12). During recent years, the role of viral pathogens in the aetiology of acute lower respiratory infections (ALRIs) has been increasingly described. While influenza is well recognized as a cause of viral pneumonia, several studies have demonstrated the importance of parainfluenza virus, respiratory syncytial virus (RSV), adenovirus, and human metapneumovirus.

S. pneumoniae is implicated in 55.4% of LRI mortality in all ages, and nearly the same (55.8%) for LRI deaths in the under-5 age group. Following *S. pneumoniae*, Hib, RSV, and influenza were the leading aetiological agents for pneumonia mortality in children less than 5 (GBD LRI 2015). However, with a changing disease burden, more urbanization, and widespread vaccination, there is an increasing interest to study the changing aetiology of childhood pneumonia, to inform newer treatment options and vaccines (Levine et al. 2012).

Issues in presentation and diagnosis

The WHO has defined pneumonia solely on the basis of clinical findings obtained by visual inspection and setting respiratory rate cut-offs. Currently, the standard WHO algorithm for ARIs in children 2–59 months defines non-severe pneumonia as cough or difficult and fast breathing (respiratory rate of 50 breaths per minute or more for children aged 2–11 months; or respiratory rate of 40 breaths per minute or more for children aged 12–59 months) and/or chest indrawing. Severe pneumonia is defined as having cough or difficult breathing, with at least one or more of the following signs: central cyanosis, severe respiratory distress, inability to drink, lethargy, or convulsions. Additionally, severe pneumonia could also have fast breasting and chest indrawing. This current algorithm is based on the updated classification WHO introduced in 2013 (WHO 2014). The previous classification categorized ‘chest indrawing pneumonia’ as severe pneumonia requiring referral and treatment with parenteral antibiotics. However, with updated research and evidence, WHO now recommends classifying and treating ‘chest indrawing pneumonia’, the same as ‘pneumonia’, i.e. therapy at home with oral antibiotics. This has major implications for saving lives of children with pneumonia in difficult circumstances where referral may not be possible. It is recognized that mortality in children due to ARIs could be reduced by one-half if early detection and appropriate treatment could be provided.

Table 8.11.12 Pathogen-specific causes of childhood and adult pneumonia

Age range	Most common causative organism
Neonates (from birth to 30 days after birth)	*Streptococcus pyogenes*, *Staphylococcus aureus*, and *Escherichia coli*
Infants (from 3 weeks to 4 months)	S.*pneumoniae*
Infants older than 4 months and preschool-aged children	Respiratory viruses and *S. pneumoniae*
Children in developing countries	S.*aureus* and *Haemophilus influenzae* including non-typable strains
Adults—outpatient	S.*pneumoniae*, *Mycoplasma pneumoniae*, *H. influenzae*, *Chlamydophila pneumoniae*, and respiratory viruses
Adults—inpatient	S.*pneumoniae*, *M. pneumoniae*, *C. pneumoniae*, *H. influenzae*, *Legionella pneumophila*, respiratory viruses, and aspiration
Adults—intensive care unit	S.*pneumoniae*, *S. aureus*, *L. pneumophila*, Gram-negative bacilli, and *H. influenzae*

In contrast to the simple, clinical definition of pneumonia recommended by the WHO for use in developing countries, pneumonia in resource-rich countries is usually based on the presence of characteristic signs and symptoms (e.g. dry or productive cough, tachypnoea, fever, focal findings on respiratory examination), hypoxaemia, and the presence of infiltrates on chest radiograph. In general, the elderly tend to present with fewer or atypical symptoms of pneumonia than younger patients and therefore non-specific features such as fever or mental status change may be indicators of an underlying lower respiratory tract infection.

Microbiological studies can also be pursued to support the diagnosis of pneumonia due to specific infectious agents and to facilitate decision-making for antibiotic management. While broad-spectrum empirical antimicrobial coverage is recommended in various guidelines, there is a potential risk for clinical failure and increased mortality if inappropriate antibiotic therapy is initiated. If available and adequate quality specimens can be obtained, blood cultures and sputum Gram stain and culture should be performed, especially with increasing severity of illness. Rapid diagnostic tests may be useful when specific diagnoses are being considered such as RSV, influenza, or *L. pneumophila*.

Clinical approaches for the management of childhood pneumonia are significantly hampered by the lack of a gold standard, as classic microbiological methods have poor sensitivity and current algorithms lack sufficient specificity. It is therefore likely that community strategies for the recognition and management of pneumonia by ancillary health workers that rely on simple clinical criteria, other than auscultation, will overdiagnose bacterial pneumonia. There are legitimate concerns that widespread use of first-line antibiotics for all ARIs will lead to loss of effectiveness.

Evidence-based interventions

Only in the early 1980s, long after immunization and diarrhoea-control programmes were launched, did the international community become aware of the epidemiological magnitude of pneumonia in children. This led the WHO and the UNICEF to decide that reduction of mortality from pneumonia should be the main objective of the initial ARI programme. Since early microbiological studies of lung aspirates taken from hospitalized, untreated children with pneumonia in developing countries showed that bacteria were present in more than 50% of cases and it was recognized that bacterial pathogens were responsible for the most severe cases, it became apparent that prompt treatment with a full course of effective antibiotics could be life-saving. However, healthcare providers see only 43% of children with pneumonia in LMICs, wand only 29% receive antibiotics (Bhutta et al. 2013b).

Antibiotic treatment of pneumonia

Although recommendations for antibiotic therapy for pneumonia are based on aetiological diagnosis, identification of the causative organism in routine clinical care is very difficult and empirical antibiotic therapy is often instituted. Guidelines for the treatment of pneumonia in immunocompetent adults in industrialized nations generally recommend a macrolide or doxycycline for outpatients; an advanced macrolide such as azithromycin or clarithromycin plus a beta-lactam or a respiratory fluoroquinolone alone for less acutely ill inpatients; and a beta-lactam plus either an advanced macrolide or respiratory fluoroquinolone for adults requiring intensive care (Mandell et al. 2007).

The various modalities for antibiotic treatment in children according to disease severity, as recommended by the current WHO guidelines, are shown in Table 8.11.13.

The revised WHO treatment guidelines for ARIs also provide empiric treatment recommendations for childhood pneumonia treatment in HIV-affected areas. Ampicillin plus gentamicin or ceftriaxone are recommended as first-line treatment for HIV-infected and HIV-exposed children under 5 years, who develop pneumonia or severe pneumonia, while ceftriaxone alone is recommended as second line if the ampicillin/gentamicin combination is not effective. Moreover, the guidelines recommend cotrimoxazole therapy, as an additional treatment, for suspected *Pneumocystis jirovecii* (formerly *P. carinii*) pneumonia in HIV-infected and HIV-exposed infants (2–12 months) (WHO 2014). There are calls for further research into WHO's severe pneumonia treatment protocols for children with severe acute malnutrition (SAM) to reduce treatment failure and mortality in this group (Chisti et al. 2015a).

Table 8.11.13 Treatment of paediatric pneumonia according to disease severity

Signs/symptoms		
Cough or difficulty in breathing with:	**Classification**	**Treatment**
Fast breathing: ≥ 50 breaths/min in child aged 2–11 months ≥ 40 breaths/min in child aged 1–5 years Chest indrawing	Pneumonia	• Home care • Give appropriate antibiotics for 5 days • Advise the caregiver to return if danger signs appear • Soothe the throat and relieve the cough with a safe remedy • Follow-up after 3 days
Central cyanosis, severe respiratory distress, and/or danger signs (inability to drink, lethargy, convulsions)	Severe pneumonia	• Admit to hospital • Give the recommended antibiotics • Give oxygen • Manage airway • Antipyretics

Oxygen therapy for severe pneumonia can be life-saving. Recent evidence indicates that, where available, oxygen delivery by continuous positive airway pressure (CPAP) improves outcomes in paediatric severe pneumonia cases (Chisti et al. 2015b).

Integrated management of childhood infections (IMCI)

In the mid-1980s, the WHO initiated a control programme for ARIs focusing on management of cases by health workers. The current case management of ARIs has been incorporated into the global IMCI which train health workers to recognize fast breathing, lower chest wall indrawing, or danger signs in children with respiratory symptoms (such as cyanosis or inability to drink).

Evidence from Asia and Africa has shown that well-trained CHWs can use the WHO algorithm to classify fast breathing and/or chest indrawing pneumonia and provide home-treatment with amoxicillin and refer severe pneumonia cases. Community case management (CCM) of pneumonia can play a key role in providing prompt care in low-resource settings and

reducing pneumonia morbidity and mortality. However, there is concern that this approach may lead to an overdiagnosis of pneumonia and inappropriate antibiotic therapy, thereby contributing to antimicrobial resistance.

Recognizing the key role CHWs can play when adequately trained and equipped, the UNICEF and WHO are supporting the integrated community case management (iCCM) strategy in many LMICs, where CHWs identify and treat children for pneumonia, diarrhoea and malaria (in malaria-endemic areas) using appropriate treatment methods such as ORS and zinc, oral antibiotics or artemisinin-based combination therapy (ACT).

Preventive measures

Poverty, overcrowding, air pollution, malnutrition, harmful traditional practices, and delayed and inappropriate case management are important underlying determinants for high ARI case fatality rates. Preventive strategies for pneumonia include immunizing children, hand washing, promoting adequate nutrition (including exclusive breastfeeding and zinc intake), and reducing indoor air pollution (Bhutta 2007).

Three vaccines have the potential to substantially reduce deaths from pneumonia in children under-5. Two kinds of vaccines are currently available against pneumococci: a 23-valent polysaccharide vaccine (PPSV23), which is more appropriate for adults than children, and different formulations of protein-conjugated polysaccharide vaccines (PCV), most important of which contain 7, and 13 serotypes of *S. pneumoniae* (PCV7 and PCV 13, respectively). Rates of invasive pneumococcal disease (IPD) have decreased since the introduction of the PCV7 for use in infants in the United States in 2000 and PCV13 in 2010. While the Hib vaccine is now being used in many resource-poor countries, scaling up of the PCV lags behind. Evidence indicates that Hib vaccination can reduce pneumonia by 18% while the pneumococcal conjugate vaccine can reduce it by 23–35% (WHO/UNCF 2013).

Controlled trials of hand washing promotion in child-care centres in developed countries have reported significant reduction (12–32%) in rates of upper respiratory tract infections. A community-based cluster randomized trial of hand washing promotion from Pakistan also reported that frequent hand washing (with or without soap) led to a 50% reduction in pneumonia incidence (Luby et al. 2005).

About 3 billion people still rely on solid fuels, 2.4 billion on biomass, and the rest on coal, mostly in China. More than half of all the deaths and 83% of DALYs lost attributable to solid fuel use occur as a result of lower respiratory tract infections (LRTIs) in children under-5. Reduction in household air pollution by 50% by appropriate use of clean fuels and lower emission stoves, could reduce severe pneumonia by 33% (WHO/UNICEF 2013). A recent Cochrane review concluded that zinc supplementation is associated with a reduction in the incidence and prevalence of pneumonia in children 2–59 months (Lassi et al. 2016). However, the evidence is still not sufficient for WHO to recommend zinc supplementation in LRIs.

Public health implications

Despite a long-standing global programme for the control of ARIs there have been limited reductions in the overall burden of deaths from pneumonia. The bulk of deaths from childhood pneumonia disproportionately affect the poor who have higher exposure rates to risk factors for developing ARIs, such as overcrowding, poor environmental conditions, malnutrition, and also limited access to health services. The importance of reaching the poor with pneumonia in community settings must be underscored. Such strategies involve recognizing and ambulatory management of pneumonia in community settings through CHWs, assuring transportation and access to facilities for severe pneumonia and availability of antibiotics.

Meningitis in neonates, children, and adults

Acute meningitis is a potentially fatal infection caused by several microorganisms including bacteria, viruses, parasites, and fungi. In addition, meningitis is associated with a risk of chronic morbidity and developmental disability. Although the exact incidence of meningitis in developing countries is uncertain, case fatality rates range from 10 to 30%. The recent GBD 2016 study estimated that there were 318,400 deaths from meningitis in 2016, a decrease of 8.4% from 2006 (GBD 2016 Causes of Death Collaborators 2017). Even if effective treatment is provided, between 10 and 50% of survivors still develop neurological sequelae. Successful outcome of meningitis relates to several factors including age, time, and clinical stability before effective antibiotic treatment, species of microorganism, number of bacteria or quantity of active bacterial products in the CSF at the time of

diagnosis, intensity of the host's inflammatory response, and time elapsed to sterilize CSF cultures.

Aetiology

The three most common bacterial pathogens, *S. pneumoniae*, *H. influenzae*, and *N. meningitidis*, account for more than 80% of cases of bacterial meningitis in the United States (US) overall (Brouwer et al. 2010), although *Listeria monocytogenes* is a greater problem for the elderly, immunocompromised, and pregnant women (Table 8.11.14). Although *S. pneumoniae* remains the leading cause of bacterial meningitis in the US, its incidence fell from 0.8/100,000 people (1997) to 0.3/100,000 people, a decrease attributable to vaccination (Castelblanco et al. 2014). There is a relative paucity of microbiological information from developing countries, but beyond the neonatal period, the main agents of meningitis include Hib, *S. pneumoniae*, and *Neisseria meningitidis* with reported case fatality rates of 7.7, 10, and 3.5%, respectively.

Table 8.11.14 Aetiology and treatment of bacterial meningitis

Patient group	Common organisms	Antimicrobial therapy
Immunocompetent children (age ≥ 3 months–18 years)	H.*influenzae* S.*pneumoniae* N.*meningitidis*	Developing countries: ampicillin plus chloramphenicol Developed countries: vancomycin plus a third-generation cephalosporin (cefotaxime or ceftriaxone[a])
Immunodeficient, pregnant, and elderly (> 50 years)	L.*monocytogenes* S.*pneumoniae* N.*meningitides* Aerobic Gram-negative bacilli	Vancomycin plus ampicillin plus either cefepime or meropenem
Neurosurgical problems and head trauma	S.*aureus* S.*pneumoniae*	Vancomycin plus a third-generation cephalosporin or meropenem

[a] For resistant *S. pneumoniae*, the American Academy of Pediatrics recommends vancomycin plus cefotaxime or ceftriaxone as empiric therapy.

Issues in presentation and diagnosis

The clinical features that may help in diagnosing meningitis are summarized in Table 8.11.15. In general, clinicians should have a low threshold for investigating and excluding meningitis in children, as features may be non-specific. The clinical diagnosis can be confirmed by lumbar puncture and the examination of CSF. The CSF will have a cloudy appearance, elevated protein, increased leucocyte counts with a predominance of neutrophils, and the presence of pathogens on Gram stain and/or culture provide a definitive diagnosis of bacterial meningitis. A bacterial meningitis score has been shown to be a reliable clinical scoring system to help in decision-making with regards to meningitis (Nigrovic et al. 2012). If patients do not have one of the following factors—positive CSF Gram stain, CSF absolute neutrophil count ≥1,000 cells/microlitre, CSF protein ≥80 mg/dl, peripheral blood absolute neutrophil count ≥10,000 cells/microlitre, or history of seizure before or at the time of presentation—they are very unlikely to have bacterial meningitis (negative predictive value = 99.9%) (Nigrovic et al. 2007). In recent years, PCR techniques for diagnosis of bacterial meningitis have become available with sensitivities ranging from 80 to 100% and specificities of 95 to 100% (Brouwer et al. 2012). Moreover, PCR can be used to detect enteroviruses and help in distinguishing bacterial vs. viral meningitis.

Table 8.11.15 Signs and symptoms of paediatric meningitis

Symptoms or presenting history	Signs
Vomiting, inability to feed and drink Headache or pain in back of neck Convulsions Irritability Signs of raised intracranial pressure History of recent head trauma Unequal pupils Rigid posture or posturing Focal paralysis in any limbs or trunk Irregular breathing	• Stiff neck, repeated convulsions • Fontanelle bulging • Petechiae or purpura • Irritability • Lethargy, evidence of head trauma

Medical treatment

The mainstay of treatment is prompt antibiotic therapy for suspected bacterial meningitis. Antibiotics need to be started before the results of CSF culture and sensitivity are available. This requires selection of an appropriate antibiotic, known to be effective against the common bacterial pathogens prevalent locally. An increasing number of beta-lactamase-producing strains of Hib are resistant to ampicillin, and a smaller number of chloramphenicol acetyltransferase-producing strains are resistant to chloramphenicol. Additionally, the proportion of CSF isolates of *S. pneumoniae* that is non-susceptible to penicillin, ceftriaxone, and cefotaxime has also increased. Currently, the drugs for suspected or confirmed bacterial meningitis include vancomycin plus an extended spectrum cephalosporin with the addition of ampicillin if *L. monocytogenes* is suspected (Table 8.11.14). If these options are not available, then ampicillin plus either gentamicin or chloramphenicol may be used. If sepsis is suspected, then cases should be treated with ampicillin or penicillin plus an aminoglycoside, until meningitis is confirmed.

Very early parenteral administration of corticosteroids (before or with initiation of antibiotics) significantly reduces severe adverse outcomes and case fatality rates. Similarly, there is evidence to suggest that restriction of fluids in the first 48 hours may improve outcomes. A recent Cochrane systematic review found that corticosteroids protect against severe hearing loss and neurological sequelae, however, did not reduce overall mortality among individuals with community-acquired bacterial meningitis in high-income countries. The beneficial effect was not seen in low-income settings (Brouwer et al. 2015).

Preventive measures

Although poverty, malnutrition, overcrowding are important risk factors for disease, delayed and inappropriate case management is a common determinant of adverse outcomes. The development of effective vaccines has been a major factor in the reduction of the burden of meningitis in the developed world. These include the Hib, pneumococcal conjugate, and meningococcal vaccines.

Haemophilus influenzae type b vaccine

Currently three Hib conjugate vaccines are available for use in infants and young children with comparable efficacy. Hib vaccines also protect against other infections caused by the pathogen such as pneumonia, joint infections, and bacteraemia. All industrialized countries now include Hib vaccine in their national immunization programmes, resulting in the virtual elimination of invasive Hib disease. There is comparable impressive evidence of benefit from several developing countries following introduction of Hib vaccine. With support from GAVI, Hib coverage, as part of the pentavalent vaccine, in the 73 GAVI-supported countries is nearly 80% (pentavalent third dose coverage). WHO recommends the vaccine be given as a three-dose primary series at the same time as diphtheria, pertussis, and tetanus (DTP) vaccine, starting at 6 weeks of age, with the second and third dose at 4–8 week intervals.

Pneumococcal vaccine

The older 23-valent pneumococcal polysaccharide vaccine is unsuitable for use in young children. The development of the 7-valent, 10-valent, and 13-valent PCVs is a major advance in the control of IPD. In the US, the 7-PCV was included in routine vaccinations of infants and children under 2 years in 2000 and by 2001 the incidence of all IPD in this age group had declined by 69%. With GAVI support, 57 countries, mostly from Latin America, Asia, and sub-Saharan Africa, have introduced pneumococcal conjugate vaccine as part of their routine immunization programmes.

Meningococcal vaccine

Meningococcal polysaccharide vaccine is available for serogroups A, C, W-135, and Y. This quadrivalent vaccine has been introduced in several developed countries as part of routine vaccine schedules, especially for adolescents who will be rooming in crowded dormitories while attending university. In many LMICs, this vaccine has been replaced by the quadrivalent meningococcal conjugate vaccine, which is more immunogenic and, because it induces memory cells, is likely to lead to a longer lasting protective immune response. Recent evidence of the efficacy and safety of a conjugate meningococcal B vaccine suggests that in the near future we will have highly effective vaccines for all major meningococcal serogroups (Vesikari et al. 2013). The success of MenAfriVac (meningococcal A

conjugate vaccine) mass vaccination campaigns and trials in the African meningitis belt is notable and has led to revised WHO recommendations for these countries to introduce the vaccine into routine immunization subsequently (WHO 2015).

Typhoid fever

Typhoid fever, a systemic disease caused by *Salmonella enterica* serovar Typhi, is an acute illness characterized by protean and non-specific symptoms, including fever and gastrointestinal infection. The systemic disease caused by *S. Paratyphi* (A, B, or C) is also clinically similar; both typhoid and paratyphoid are collectively labelled as enteric fevers. The emergence of drug-resistant strains, especially multidrug-resistant (MDR) and extensively drug-resistant (XDR) *S. Typhi*, resistant to ampicillin, chloramphenicol, trimethoprim–sulphamethoxazole, fluoroquinolones and more recently third-generation cephalosporins is a growing problem (Klemm et al. 2018).

Global and regional epidemiology

The global incidence of typhoid fever in 2000 was estimated to be 21.6 million cases, with more than 200,000 deaths (Crump et al. 2004). More recent literature shows varied estimates of 11–21 million cases and nearly 145,000–161,000 deaths per year, with the highest incidence in sub-Saharan Africa, followed by North Africa/Middle East and South Asia (Mogasale et al. 2014; Antillón et al. 2017). In South Asia, community-based studies indicate that a large proportion of cases occur in children under-5, with significant morbidity and mortality. Table 8.11.16 shows the regional distribution of typhoid in LMICs.

Table 8.11.16 Total cases and incidence of typhoid for the Global Burden of Disease regions and subregions made up of low- and middle-income countries

Area/region	Cases (millions)	Incidence (per 100,000 person-years)
All LMICs	17.8	293
Central Europe, Eastern Europe, and Central Asia	0.1	28
Latin America and Caribbean	1.0	169
North Africa and Middle East	2.6	557
Sub-Saharan Africa	7.2	762
Southeast Asia, East Asia, and Oceania	2.21	108
South Asia	3.6	204

Source: The burden of typhoid fever in low- and middle-income countries: A meta-regression approach Marina Antillón1, Joshua L. Warren, Forrest W. Crawford, Daniel M. Weinberger, Esra Ku¨ru¨m, Gi Deok Pak, Florian Marks, Virginia E. Pitzer. 2017. PLoS NTD.

There have been dramatic point-source outbreaks of typhoid related to contamination of food sources or water supply. The use of contaminated ground water, consumption of street foods, and poor personal hygiene are common risk factors for infection.

Issues in presentation and diagnosis

After ingestion in contaminated food or water, *S. Typhi* penetrates the small bowel mucosa and makes its way rapidly to the lymphatics and the bloodstream. Following an initial bacteraemia, the organism is sequestered in cells of the reticuloendothelial system where it multiplies and re-emerges several days later in recurrent waves of bacteraemia, an event that initiates the symptomatic phase of infection. The incubation period ranges from 5 to 14 days.

Typhoid fever is a febrile illness of prolonged duration, characterized by delirium, persistent bacteraemia, splenomegaly, and a variety of systemic manifestations. Children commonly present with fever, headache, and abdominal discomfort, diarrhoea, anorexia, dry cough, or myalgia and constipation. In the later phase of illness, more specific physical signs

including hepatomegaly and splenomegaly may be observed. Rose spots may be seen in an early stage of the illness in fair-skinned children and large proportions have a centrally coated tongue. Pulse–temperature dissociation is present in some patients. In approximately 50% of patients, there is no change in bowel habits; in fact, constipation is more common than diarrhoea in children with typhoid fever.

In LMICs, as per WHO recommendations, healthcare providers are advised to consider typhoid (if malaria has been excluded) in children if there is fever (especially fever ≥7 days) and any of the following; abdominal pain, vomiting, constipation, headache, cough or transient rash (Khan and Bhutta 2017). Moreover, in infants, typhoid can present as an acute febrile illness occasionally leading to hypothermia and shock.

As a result of recurrent waves of bacteraemia, patients with typhoid fever can develop pneumonia, pyelonephritis, osteomyelitis, septic arthritis, and meningitis. Intestinal haemorrhage and perforation, the most common complications, often occur in the third week of infection or during convalescence. The most serious complication, intestinal perforation, occurs in 0.5–3% of the patients with typhoid, and because they occur most commonly in areas where optimal medical care is not readily available, it may be associated with case fatality rates ranging from 4.8 to 30.5%. The elucidation of a *S. Typhi*-specific toxin (Song et al. 2013) not only provides exciting new information on the pathogenesis of typhoid fever but also opens exciting possibilities of development of newer vaccines and interventions for this disease.

Diagnosis of typhoid and paratyphoid fever requires culture of blood, bone marrow, stools, or urine to confirm growth of *S. Typhi*. Laboratory findings commonly include leukopenia, thrombocytopenia, proteinuria, and elevated transaminases, but these are relatively non-specific and uncommon. In developing countries, culture facilities are expensive and mostly confined to hospitals, while most typhoid patients are diagnosed clinically and treated in outpatient settings. In other instances, serological diagnosis may be made with the Widal test. The latter, though low-cost, is insufficiently sensitive in endemic areas. Other diagnostic tests, such as the Typhidot and Tubex, which detect IgM antibodies against specific *S. Typhi* antigens have been developed (Bhutta 2006). Since these newer assays have not proven to have adequate sensitivity and specificity for routine use in community settings, there is a need for further refinement in serological or molecular diagnosis of the

disease. PCR and ELISA tests are modern diagnostic techniques which are rapid and reliable, though at a higher cost.

Medical treatment

In the pre-antibiotic era, typhoid fever case fatality rates approached 20%. In addition to supportive measures such as rest, hydration, soft diet and fever management, antibiotic therapy is central in the treatment of typhoid. Treatment with effective antimicrobial agents—ampicillin, chloramphenicol, co-trimoxazole, and later ciprofloxacin—has progressively reduced case fatality rates to less than 1%, except for MDR isolates. Fluoroquinolones and third-generation cephalosporins are effective in MDR typhoid but over the last few years there have been increasing reports in Asia of *S. Typhi* strains with reduced fluoroquinolone susceptibility. The presence of nalidixic acid resistance *in vitro* is associated with clinical treatment failures with fluoroquinolones. Alternative therapies including azithromycin or third-generation cephalosporins are recommended in these circumstances. However, in recent years a new MDR strain, named 'extensively drug-resistant (XDR) *S. Typhi*' by the researchers, resistant to chloramphenicol, ampicillin, cotrimoxazole, fluoroquinolones, and third-generation cephalosporins has been identified (Klemm et al. 2018). Patients with this strain were successfully treated with azithromycin and meropenem.

Given the considerable morbidity and higher mortality rates reported with MDR typhoid in children, appropriate antibiotic therapy must be instituted promptly and, when appropriate facilities are available, treatment choices should be guided by susceptibility testing.

Preventive measures

Detection of sources of infection related to recent typhoid fever in household contacts, commercial food handlers, or contaminated drinking water sources is essential to design effective preventive measures for disease containment.

The WHO, since 2000, has recommended two licensed vaccines for prevention of disease in children >2 years and adults: Ty21a (an attenuated strain of *S. Typhi* administered orally) and Vi (the purified bacterial polysaccharide vaccine, given parenterally). More recently, WHO has recommended the typhoid conjugate vaccine for routine use in children over 6 months of age and adults up to 45 years of age in typhoid-endemic countries

(WHO 2018a). The WHO recommends the typhoid conjugate vaccine above the previous two vaccines, given its improved immunological properties and long-lasting protection.

Dengue fever

In recent years, dengue fever, has become the most common mosquito-borne viral infectious disease and now represents a major international public health concern. Dengue virus belongs to the genus *Flavivirus* (single-stranded, non-segmented RNA viruses), which includes four serologically distinct serotypes (DEN-1, DEN-2, DEN-3, and DEN-4). Variations in virus strains within and between the four serotypes influence disease severity. There is limited protection across serotypes. Secondary infections (particularly with serotype 2) are more likely to result in severe disease and dengue haemorrhagic fever.

Global and regional epidemiology

Humans and mosquitoes are the principal hosts of dengue virus although some non-human primates can also be infected. Dengue epidemics occur during the warm, humid, rainy seasons, which favour breeding conditions for the mosquito vector, *Aedes aegypti*. More than two-fifths of the world's population (~2.5 billion) lives in areas potentially at risk for dengue, which is endemic in more than 100 countries across the globe, with tropical areas of Asia, the Western Pacific, Latin America, and the Caribbean being the most seriously affected regions.

In some case series, dengue fever has been reported as the second most frequent cause of hospitalization (after malaria) among travellers returning from the tropics. There are an estimated 390 million dengue infections annually, with nearly 100 million manifesting clinically (Bhatt et al. 2013). Around 95% of cases occur in children less than 15 years of age, with infants representing 5% of the cases.

Issues in presentation and diagnosis

The incubation period can vary from 3 to 14 days (typically between 5 and 7 days) and viraemia can persist up to 12 days (typically 4–5 days). Fever usually lasts for 5–7 days; fevers persisting beyond 10–14 days suggest another diagnosis. The clinical features of dengue vary with patient age. Most dengue infections, especially in children, are minimally symptomatic or

asymptomatic. Children may also present with atypical syndromes such as encephalopathy and fulminant liver failure.

Classic dengue fever is characterized by a high fever of abrupt onset, sometimes with two peaks (saddle back fevers), severe myalgias, arthralgia, retro-orbital pain, headaches, and any of the three types of rashes, including a petechial rash, diffuse erythematous rash with isolated patches of normal skin, and a morbilliform rash, haemorrhagic manifestations, and leukopenia. Other manifestations include flushed facies, sore throat, cough, cutaneous hyperaesthesia, and taste aberrations. Convalescence may be prolonged and complicated by profound fatigue and depression.

Warning signs preceding onset of severe disease include abdominal pain or tenderness, persistent vomiting, mucosal bleed, clinical fluid accumulation, liver enlargement, lethargy, and an increase in haematocrit with a fall in platelet count. Appearance of any of these signs indicates the need for strict observation and prompt management to avoid complications.

WHO defines severe dengue (dengue haemorrhagic fever) by the presence of one or more of the following signs; plasma leakage that may cause shock and/or fluid accumulation and/or severe bleeding and/or severe organ impairment. An estimated 20–30% of cases of severe dengue progress to shock (dengue shock syndrome) and 40–50% of those with shock die.

Infection with one serotype is thought to produce lifelong immunity to that serotype but only partial immunity to the others. Previous infection with a specific serotype followed by infection with a new serotype greatly increases the risk of dengue haemorrhagic fever.

Dengue virus serotypes are distinguishable by complement fixation and neutralization test. Other diagnostic tests for patients with dengue include packed cell volume, platelet count, liver function tests, prothrombin time, partial thromboplastin time, electrolytes, and blood gas analysis. Laboratory findings commonly associated with dengue include leukopenia, lymphocytosis, increased concentration of liver enzymes, and thrombocytopenia. Diagnosis can be confirmed with several laboratory tests, especially the haemagglutination inhibition test and IgG or IgM enzyme immunoassays.

Evidence-based interventions

Rapid urbanization has led to an increase in the environmental factors that contribute to the proliferation of *Aedes* mosquitoes. These include

uncontrolled urban development, inadequate management of water and waste, presence of a range of large water stores, and disposable, non-biodegradable containers that become habitats for the larvae. Addressing these issues is key in controlling the dengue vector and spread of disease.

Medical treatment

No specific therapeutic agents exist for dengue fever apart from analgesics and medications to reduce fever. Treatment is supportive; steroids, antivirals, or carbazochrome (which decreases capillary permeability) have no proven role. In contrast, ribavirin, interferon alpha, and 6-azauridine have shown some antiviral activity *in vitro*. Mild or classic dengue is treated with antipyretic agents such as acetaminophen, bed rest, and fluid replacement (usually administered orally and only rarely parenterally); most cases can be managed on an outpatient basis.

The management of dengue haemorrhagic fever and the dengue shock syndrome is purely supportive. Aspirin and other non-steroidal anti-inflammatory drugs should be avoided owing to the increased risk for Reye's syndrome and haemorrhage.

Preventive measures

In the absence of a vaccine, vector control is the only effective preventive measure. At a personal level, the risk of mosquito bites may be reduced using protective clothing and repellents. The most effective preventive measure for travellers in areas where dengue is endemic is to avoid mosquito bites by using insect repellents containing *N*, *N*-diethyl-3-methyl-benzamide (DEET) or picaridin. The insect repellents should be used in the early morning and late afternoon, when *Aedes* mosquitoes are most active.

At a public health level, the risk of dengue fever outbreaks can be reduced by removing neighbourhood sources of stagnant water, especially within homes, using larvicides (especially for containers that cannot be eliminated), use of aerosolized insecticides, and introduction of predatory crustaceans.

The first dengue vaccine (CYD-TDV), Dengvaxia, manufactured by Sanofi, a live recombinant tetravalent vaccine was licensed in 2015, for use in individuals 9 years and older (Sabchareon et al. 2012). However, a 2017 mass vaccination campaign in Philippines was halted after 14 deaths were reported out of the 800,000 children who were vaccinated. Following that, after much deliberation and review of evidence, WHO issued recommendations to only

use the vaccine in dengue-seropositive persons, as vaccinating those not previously infected can lead to a reaction (WHO 2018c). However, in the absence of rapid diagnostic tests for dengue serostatus the utility of this vaccine remains limited. In the meantime, phase 3 trials are in progress for the Takeda Dengue vaccine (TAK-003) and one from the Instituto Butantan in Brazil.

Parasitic infections

A broad range of parasites plagues humans worldwide. While certain parasites, such as the *Plasmodium* species that cause malaria, are well recognized and have received intensive international support for research and programmatic control interventions, others are considered among the world's most neglected diseases. Some of the main neglected tropical parasitic diseases include the protozoan infections such as human African trypanosomiasis, visceral leishmaniasis, and American trypanosomiasis (Chagas disease) and helminthic infections such as the soil-transmitted nematodes (ascariasis, hookworms, trichuriasis), schistosomiasis, lymphatic filariasis, onchocerciasis, and dracunculiasis.

Of the 20 major helminth infections of humans, the commonest are the geohelminths. The most prevalent species are the roundworm (*Ascaris lumbricoides)*, whipworm (*Trichuris trichiura)* and hookworms *(Necator americanus and Ancylostoma duodenale)*. In many low-income countries, it is more common to be infected than not. Indeed, a child growing up in an endemic community can be infected soon after weaning, and continue to be infected and constantly re-infected for life.

Global and regional epidemiology

Recent global estimates indicate that more than a quarter of the world's population is infected with one or more helminths. The geographic distribution of roundworms in many tropical and subtropical regions closely parallels socioeconomic and sanitary conditions. In locales where several species of intestinal parasites are found, co-infection with *A. lumbricoides*, *T. trichiura*, and hookworms is common. In LMICs, about 1.2 billion people are infected with the roundworm, while more than 700 million are infected with hookworm or whipworm (Hotez et al. 2004). However, some recent studies report lower numbers attributing hookworm infection to nearly 440 million,

roundworm to 820 million and whipworm to 465 million people (Pullan et al. 2014). The GBD 2010 study estimated that 152,300 people died from neglected tropical diseases, which were predominantly parasitic infections with the notable exception of rabies (Lozano et al. 2012). While mortality is not common, parasitic infections are responsible for substantial morbidity and indirectly contribute to death from other diseases due to their negative impact on nutritional status. The World Bank ranks geohelminths as the greatest cause of poor health in children 5–15 years of age globally compared to any other infection.

Issues in presentation

Children of school age are at greatest risk from the clinical manifestations of disease. Studies have shown associations between helminth infection and undernutrition, iron deficiency anaemia, stunted growth, poor school attendance, and poor performance in cognition tests. Some 44 million pregnancies are currently complicated by maternal hookworm infection, placing both mothers and children at higher risk of anaemia and death during pregnancy and delivery. Intense whipworm infection in children may result in trichuris dysentery syndrome, the classic signs of which include bloody diarrhoea, anaemia, growth retardation, and occasionally rectal prolapse. Heavy burdens of both roundworm and whipworm are associated with protein energy malnutrition and deficiencies of certain micronutrients such as vitamin A.

Medical treatment

The WHO recommends the use of albendazole, mebendazole, pyrantel pamoate, and levamisole (Table 8.11.17). Albendazole and mebendazole, have high efficacy against roundworm and moderate efficacy against whipworm. Single-dose mebendazole is much less effective against hookworm, with cure rates typically below 60%.

Preventive measures

Better sanitation reduces soil and water transmission as transmission of geohelminths depends on transmission in environments contaminated with egg-carrying faeces. At high coverage, the provision of adequate sanitation is the most effective intervention to eliminate helminthic infections. With high

costs, implementing this strategy is difficult where resources are limited. Both the World Bank and the WHO promote helminth control programmes and consider it as one of the most cost-effective strategies to improve health in developing countries. These programmes emphasize mass drug administration as a major component of control.

Recommended drugs for use in public health settings include albendazole (single dose: 400 mg, reduced to 200 mg for children, 12 and 24 months), mebendazole (single dose: 500 mg), and levamisole or pyrantel palmoate. Medicines are recommended annually where prevalence is >20%, but twice annually where it is >50%.

Home delivery of antihelminthics is problematic for several reasons and thus school-based deworming programmes are preferred. These have been shown to boost school participation and are practical as schools offer a readily available, extensive, and sustained infrastructure with a skilled workforce that can be readily trained. In Kenya, such a programme reduced school absenteeism by a quarter, with the largest gains among the youngest children. Perhaps even more importantly, this study showed that those children who had not been treated benefited from the generally lowered transmission rate in the schools. However, more recently a Cochrane review concluded that although individual treatment of children had nutritional benefits, mass treatment programmes did not improve average nutritional status, haemoglobin levels, cognitive skills, or school performance (Taylor-Robinson et al. 2015). These measures must be coupled with community behaviour change strategies with the aim of reducing contamination of soil and water by promoting the use of latrines and hygienic behaviour. Without a change in defecation habits, periodic deworming cannot attain a stable reduction in transmission.

Table 8.11.17 Diagnosis and treatment of major intestinal nematode infections

Organism	Type of specimen	Specimen preparation	Size of eggs or larvae (µm)	Drug of choice	Alternative therapies
Trichuris trichiura	Stool	Direct smear or concentration	50–54 × 23	Mebendazole, 100 mg orally (PO) twice daily (bid) × 3 days	Albendazole, 400 mg PO once
Ascaris lumbricoides	Stool	Direct smear or concentration	45–70 × 35–50	Mebendazole, 100 mg PO bid × 3 days or albendazole, 400 mg PO once or pyrantel pamoate, 11 mg/kg PO once (max 1 g)	Piperazine citrate, 75 mg/kg twice daily (max. 1 g) by nasogastric tube × 2–3 days until resolution of obstruction
Ancylostoma duodenale Necator americanus	Stool	Direct smear or concentration	55–70 × 35–45	Mebendazole, 100 mg PO twice daily × 3 days	Albendazole, 400 mg PO once or pyrantel pamoate, 11 mg/kg PO × 3 days (max. 1 g)
Enterobius vermicularis	Adhesive tape preparation	Direct microscopy	50–60 × 20–30	Mebendazole, 100 mg PO once or pyrantel pamoate, 11 mg/kg PO once Repeat in 2 weeks	Albendazole, 400 mg PO once. Repeat in 2 weeks
Strongyloides stercoralis	Stool, duodenal aspirate	Concentration or Baermann method	400–500 × 15	Ivermectin, 150–200 µg/kg PO × 1–2 days[a]	Albendazole 400 mg PO once or twice daily for 3 days

[a] Intrarectal ivermectin is an option for treatment of high-grade strongyloidiasis.

Antimicrobial resistance

Overuse and misuse of antimicrobials, especially antibiotics, lead to genetic changes in the organisms, making them resistant to therapeutic agents. In addition to the threat of infectious diseases, antimicrobial resistance (AMR) is a growing crisis in global health. Bacteria, viruses, and parasites have

developed resistance to antimicrobials, rendering standard treatments ineffective. Infections with these ‘super bugs’ tend to persist and spread swiftly. According to an estimate, globally, 70 billion doses of antibiotics are consumed yearly. However, the burden of morbidity and mortality attributable to AMR can only be estimated broadly, especially in LMICs where indiscriminate use of antimicrobials is common, and surveillance is lacking. Realizing the importance of addressing this issue, the WHO now supports a system, the Global Antimicrobial Resistance Surveillance System (GLASS) that supports the collection and study of the regional and global data on AMR.

A recent ground-breaking study conducted in three countries of Africa found that mortality was lower among post-neonatal, preschool children following mass distribution of the antibiotic azithromycin in that group (Keenan et al. 2018). The potential effect of such an intervention in high-childhood mortality regions can be huge, however, implementation has to be with caution considering the danger of antibiotic resistance.

Prions

Prion diseases, also known as transmissible spongiform encephalopathies (TSEs), are responsible for rapidly progressive, fatal neurodegenerative diseases of humans and several other mammalian species. The term ‘prion’ is derived from *pro*teinaceous and *in*fectious. An unconventional transmissible protein that lacks nucleic acid is the probable cause; this prion protein appears to consist of a modified isoform of a normal cellular prion protein (PrP^{c}) that is converted into PrP^{Sc}, which results in major changes in the physicochemical properties of the PrP leading to abnormal folding of normal cellular proteins. Prion diseases are associated with brain pathology characterized by diffuse spongiform degeneration. The transmissibility was established by intracerebral inoculation of various primate species using passaged prions from infected humans.

Epidemiology

Human prion diseases can be sporadic, inherited, or transmissible. The sporadic forms include kuru where infection occurs through ritualistic cannibalism and sporadic Creutzfeldt–Jakob disease (CJD). CJD can also occur in a familial manner due to germ-line mutations in the PrP gene or as a

result of infection from bovine prions (variant CJD (vCJD)). The TSEs include bovine spongiform encephalopathy (BSE) in cattle; scrapie in sheep; chronic wasting diseases in deer, elk, and mules; feline spongiform encephalopathy in cats (possibly secondary to ingestion of prion-contaminated bovine tissues and bone meal); transmissible mink encephalopathy; and exotic ungulate encephalopathy in kudu, nyala, and oryx (Ramasamy et al. 2003). Despite surveillance in the United States and Canada, there is limited evidence of cross-species infection of chronic wasting disease from animal reservoirs to humans (Waddell et al. 2018).

The major human forms of infection are sporadic CJD, vCJD, and an inherited form, the prion disease called Gerstmann–Straussler–Scheinker disease. Iatrogenic CJD can also occur as a result of infected dura mater grafts, improperly sterilized depth electrodes, transplanted corneas, and human growth hormone and gonadotrophin derived from cadaveric pituitaries.

An epidemic of BSE in the United Kingdom that began in 1986 affected nearly 200,000 cattle and was followed by human cases of vCJD starting in 1994 (Brown et al. 2001). The source of the BSE outbreak resulted from a change in the process of rendering carcasses of livestock, which were used as a protein-rich nutritional supplement for feeding ruminants and other animals. Banning the use of meat and bone meal helped to eventually control the epidemic of BSE. In the mid-1990s, the United Kingdom saw a rise in human vCJD cases with 87 definite or probable cases occurring there by November 2000 and a few cases identified as well in France and Ireland. Since the incubation period of vCJD is not known, it was hypothesized to be as short as 5–10 years if the BSE outbreak in the mid to late 1980s was the source. Between 2000 and 2005, the number of annual deaths due to vCJD gradually declined. In total, there were 176 cases between 1995 and 2011 in the United Kingdom and 49 recorded in 11 other countries.

Clinical manifestations

Classic CJD usually presents in the elderly (median age of onset 68 years) and is characterized by memory loss, visual problems, and psychiatric symptoms, followed by progressive cognitive impairment and finally progression to an akinetic mutism state (Iwasaki I. 2017). Death usually occurs within 4–5 months. In contrast, vCJD presents at a median age of 27 years, with an illness duration of 13–14 months, and is clinically

characterized by prominent behavioural and psychiatric symptoms, painful dysaesthesias, and the delayed onset of neurological signs. In addition, vCJD cases all are homozygous for methionine at codon 129 of the PrP gene and have marked accumulation of protease-resistant PrP in brain tissue and florid plaques on neuropathology in large numbers in contrast to classic CJD where these are rare to absent.

Diagnosis and treatment

Neuropathological evaluation by Western blot or immunohistochemistry is the definitive approach for diagnosing human prion diseases. This method can also be used to monitor for vCJD and other forms of CJD. Electroencephalography (EEG) and magnetic resonance imaging (MRI) may be useful adjuncts to diagnosis in patients with CJD. Periodic sharp waves on EEG are often present in classic CJD but absent in vCJD whereas the 'pulvinar sign', an abnormal signal in the posterior thalami on T2- and diffusion-weighted MRI images, is present in the majority of patients with vCJD but is rare or absent in CJD. An important recent advance in diagnostics is the real-time quaking-induced conversion test of CSF, which has high sensitivity and specificity for sporadic and variant CJD (McGuire et al. 2016).

There is no known therapy for any of the prion diseases. Prognosis is poor with progression to death in a median of 4–5 months for CJD and a little over a year for vCJD.

8.12

Sexually transmitted infections

Noah Kojima and J.D. Klausner

Introduction to sexually transmitted infections

Sexually transmitted infections (STIs) refer to many pathogens that are commonly spread through sexual contact including vaginal and anal intercourse and oral sex. *Chlamydia trachomatis* (chlamydia), *Neisseria gonorrhoeae* (gonorrhoea), and *Treponema pallidum* (syphilis) cause the majority of worldwide bacterial STIs. Viral STIs include: human papillomavirus (HPV), herpes simplex virus type 1 and 2 (genital herpes; HSV-1 and HSV-2), hepatitis A, B, and C (unrelated viruses that can cause liver disease), as well as human immunodeficiency virus (HIV). Parasites like *Trichomonas vaginalis*, the causative agent of trichomoniasis, are also a major contributor to the global burden of STIs. In total, there are over 30 organisms and hundreds of those organism subtypes that have been recognized as sexually transmissible (Table 8.12.1). The newest agents recognized as sexually transmissible include Zika and Ebola viruses.

STIs are common. The global annual incidence of curable (bacterial and protozoal) STIs estimated by the World Health Organization (WHO) was 357.4 million cases in 2012 (WHO 2015). Furthermore, among countries with public health surveillance systems, STIs are among the most frequently reported infections. However, compared to bacterial or protozoal STIs, viral STIs are far more prevalent with an estimated 708 million cases of Herpes Simplex Virus and HPV infection.

Given the high numbers of STIs that exist in almost every nation, it is not surprising to find that regardless of a nation’s resources, STI-related symptoms can account for a large number of healthcare visits and substantial costs. STIs are also stigmatized and may also result in psychosocial consequences such as anxiety, shame, and stress. Additionally, sequelae like

infertility, adverse pregnancy outcomes, and malignancies, and the morbidities of STIs increase healthcare costs.

Although STIs are commonly associated with genital sores, discharges, or rashes, most STIs are asymptomatic. Many countries around the world continue to use syndromic management (the identification and management of persons with symptoms) as a way to manage STIs clinically, however many non-specific symptoms can lead to overtreatment for suspected STIs and lack of symptoms can lead to under treatment. Therefore, in countries with available infrastructure, screening asymptomatic people at risk for STIs is important for individual prevention and public health. While STI case rates are highest in adolescents and young adults, the most serious health outcomes occur later in life and are disproportionately borne by women and infants. For those reasons, STI prevention and control is an important public health investment for every country.

There are many methods that can be used to reduce the risk of STI acquisition. Vaccinations protect against some viral STIs, like hepatitis A, hepatitis B, and wart or cancer-causing HPV types. Additionally, barrier protection, e.g. male and female condoms, reduce or even eliminate the risk of STI spread or acquisition.

There are many diagnostic tests for STIs. Various fluids, including saliva, urine, blood, vaginal or anal secretions, and self-collected tip of the urethra swabs, can be used for testing. It is important to test any orifice that may have been exposed to an STI during sexual activity because STIs are often localized mucosal infections that are not detected systemically in the blood or urine. Additionally, tests utilize many different biochemical mechanisms that can allow rapid point-of-care testing for some STIs, like HIV and syphilis. Other testing systems, like polymerase chain reaction (PCR), normally require specialized laboratory equipment although new point-of-care PCR-based systems enable detection of STIs in 60–90 minutes.

Bacterial STIs and trichomonal infections are curable. Unfortunately, individuals do not gain immunity to an STI, and are equally susceptible to reinfection. In contrast to bacterial STIs, viral STIs are not medically curable with the exception of hepatitis C infection (rarely sexually transmitted). Other STIs like genital herpes and HIV infection are incurable, although medicines exist to manage chronic infections and reduce the risk of transmission. Some viral STIs and their sequelae are preventable with vaccines, e.g. HPV, hepatitis B virus (HBV), and hepatitis A virus (HAV).

Others, like HPV, HBV, and HCV infection can spontaneously clear without medical intervention.

The field of STIs is constantly changing. New threats, like the Zika virus are emerging, and some cases were sexually transmitted, while known STIs continue to cause challenges, for example, antibiotic-resistant *Neisseria gonorrhoeae*. At the same time, new infection prevention tools are being created. For example, pre-exposure prophylaxis for HIV infection as well as post-exposure prophylaxis for syphilis and chlamydia. Additionally, new methods for diagnosis, like point-of-care HIV and syphilis testing, are being mobilized around the world.

In this chapter we summarize the global epidemiology of STIs and their associated health consequences, and report on factors affecting the spread of STIs in the community. We also discuss STI prevention and control as a public health intervention, relying on many interrelated interventions working together to reduce STI incidence and prevalence in the community. Finally, we consider some of the most likely challenges and opportunities in STI prevention anticipated over the next few decades.

Table 8.12.1 Sexually transmitted pathogens and associated diseases or syndromes

Pathogen	Associated disease or syndrome
Bacteria	
Neisseria gonorrhoeae	*Adult:* cervicitis, urethritis, proctitis, pharyngitis, Bartholinitis, endometritis, pelvic inflammatory disease (PID), infertility, chronic pelvic pain, orchitis, epididymitis, urethral stricture, prostatitis, perihepatitis, disseminated infection, inflammatory arthritis syndrome, enhanced HIV risk, often asymptomatic (up to 2/3 women, 1/3 men)
	Maternal: ectopic pregnancy, maternal death, preterm rupture of membranes *Infant:* neonatal conjunctivitis, corneal scarring, blindness, premature birth, low birth weight (LBW)
Chlamydia trachomatis	*Adult:* cervicitis, urethritis, proctitis, pharyngitis, Bartholinitis, endometritis, PID, infertility, chronic pelvic pain, orchitis, epididymitis, urethral stricture, prostatitis, perihepatitis, disseminated infection, inflammatory arthritis syndrome, lymphogranuloma venereum (LGV)—anogenital ulcer or inguinal swelling, enhanced HIV risk, often asymptomatic (up to 2/3 women, 1/3 men)
	Maternal: ectopic pregnancy, maternal death, preterm rupture of membranes
	Infant: neonatal conjunctivitis, pneumonia, premature birth, LBW
Mycoplasma genitalium	*Adult:* urethritis, cervicitis, PID, enhanced HIV risk
Treponema pallidum (syphilis)	*Adult:* genital ulcer (chancre), local adenopathy, skin rashes, condyloma lata, hepatitis, arthritis, enhanced HIV risk; bone, cardiovascular (e.g. aortic disease) and central nervous system disease (e.g. meningitis, stroke, cranial nerve abnormalities, optic atrophy, tabes dorsalis, general paresis)
	Maternal: fetal loss, stillbirth, preterm delivery *Infant:* neonatal death, congenital syphilis, LBW
Haemophilus ducreyi (chancroid)	*Adult:* genital ulcers, inguinal adenitis, disfiguring lesions, tissue destruction, enhanced HIV risk
Calymmatobacterium granulomatis (Donovanosis)	*Adult:* Nodular swellings and chronic ulcerative lesions of inguinal and anogenital areas (also called granuloma inguinale)
Shigella spp.	*Adult:* shigellosis in homosexual men
Salmonella spp.	*Adult:* enteritis, proctocolitis in homosexual men

Pathogen	Associated disease or syndrome
Campylobacter spp.	*Adult:* enteritis, proctocolitis in homosexual men
Viruses	
Human immunodeficiency virus types 1 and 2	*Adult:* HIV-related disease, opportunistic infections, lymphomas, AIDS *Maternal:* vertical transmission to infants
	Infant: HIV infection
Herpes simplex virus types 1 and 2	*Adult:* anogenital vesicular lesions and ulcerations, recurrent genital ulcers, cold sores, cervicitis, urethritis, pharyngitis, proctitis, chronic pain, arthritis, aseptic meningitis, hepatitis, enhanced HIV risk
	Maternal: vertical transmission to infants
	Infant: ulcerations of skin, eye, mucous membranes; encephalitis, disseminated infection with hepatitis, pneumonitis, encephalitis; neurological abnormalities
Human papilloma virus (> 30 genital genotypes identified)	*Adult:* anogenital and oral warts; intraepithelial neoplasia and carcinoma of the cervix, penis, vulva, vagina, anus; oropharyngeal cancer; recurrent respiratory papillomatosis
	Maternal: vertical transmission to infant *Infant:* recurrent respiratory papillomatosis
Hepatitis B virus	*Adult:* acute hepatitis, liver cirrhosis, end-stage liver disease, hepatocellular cancer
	Maternal: vertical transmission to infant
	Infant: cirrhosis, end-stage liver disease, primary liver cancer
Hepatitis A virus	*Adult:* acute hepatitis A
Hepatitis C virus	*Adult:* acute hepatitis C, liver cirrhosis, end-stage liver disease, hepatocellular cancer
Cytomegalovirus (CMV)	*Adult:* heterophil-negative infectious mononucleosis, hepatitis *Infant:* primary infection of the newborn, hepatitis, sepsis, deafness, mental retardation
Molluscum contagiosum virus	*Adult:* genital molluscum contagiosum
Human T-lymphotrophic retrovirus, type 1	*Adult:* human T-cell leukaemia or lymphoma

Pathogen	Associated disease or syndrome
Human herpesvirus 8 (HHV-8)	*Adult:* Kaposi's sarcoma, primary effusion lymphoma, Castleman's disease
Zika	*Maternal:* vertical transmission to infant
	Infant: microcephaly
Protozoa	
Trichomonas vaginalis	*Adult:* vaginitis, cervicitis, urethritis, endometritis, salpingitis, enhanced HIV risk *Maternal:* chorioamnionitis, preterm delivery *Infant:* LBW, pneumonitis, fever, vaginal discharge in female infants
Entamoeba histolytica	*Adult:* amoebiasis in men who have sex with men
Giardia lamblia	*Adult:* giardiasis in men who have sex with men
Ectoparasites	
Phthirus pubis	*Adult:* pubic lice infestation
Sarcoptes scabiei	*Adult:* scabies, Norwegian (disseminated) scabies
	Infants: Norwegian (disseminated) scabies

Sexually transmitted infections

The global burden of STIs includes the overall number of cases of infection, a host of short- and long-term adverse health outcomes in individuals including death, and the financial consequences (healthcare and other costs) associated with STIs and their associated health, and psychosocial impact for both individuals and economies.

Global STI numbers

The WHO estimated that approximately 357 million new cases of four curable STIs, i.e. *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, *Treponema pallidum*, and *Trichomonas vaginalis*, occurred in 2012 (WHO 2015). There were 130.9 million cases of chlamydia, 78.3 million cases of gonorrhoea, 5.6 million cases of syphilis, and 142.6 million cases of trichomoniasis. The majority of countries, 108 of 198, have an STI

surveillance system in place, however STI surveillance has not been globally standardized, so it is difficult to assess the spread of concerning infections, like untreatable *Neisseria gonorrhoeae*. While new cases of STIs were common, the areas with the highest rates of STIs were Africa, the Americas, and the Western Pacific. Compared to prior STI prevalence estimations, the overall global prevalence of curable STIs seems to be decreasing. However, due to differences in STI surveillance practices, many STI prevalence estimations are poor because they are limited to small studies among accessible populations and case-based surveillance reports.

Compared to the WHO report on curable STIs from 2008, there were fewer overall cases of STIs estimated in 2012 (357 million versus 498.9 million, respectively). While the number of cases of chlamydia increased from 105.7 million cases to 130.9 million cases, the worldwide number of cases of gonorrhoea, syphilis, and trichomoniasis decreased (Fig. 8.12.1). In accordance with the WHO global strategy for STI prevention and control, over 90% of countries worldwide have adopted syndromic management of STIs. The WHO has recommended monitoring two syndromes: urethral discharge among men and genital ulcer disease among men and women. Urethral discharge is most commonly caused by *Neisseria gonorrhoeae* infection and *Chlamydia trachomatis* infection. Genital ulcer disease is classically caused by syphilis and chancroid, however viral infections, like herpes simplex virus, can also cause this syndrome. Genital ulcers facilitate HIV transmission. In 2014, 56 countries reported data on genital ulcer disease (Fig. 8.12.2). From those data, the African Region had the highest burden of genital ulcer disease, followed by the Americas and the Western Pacific.

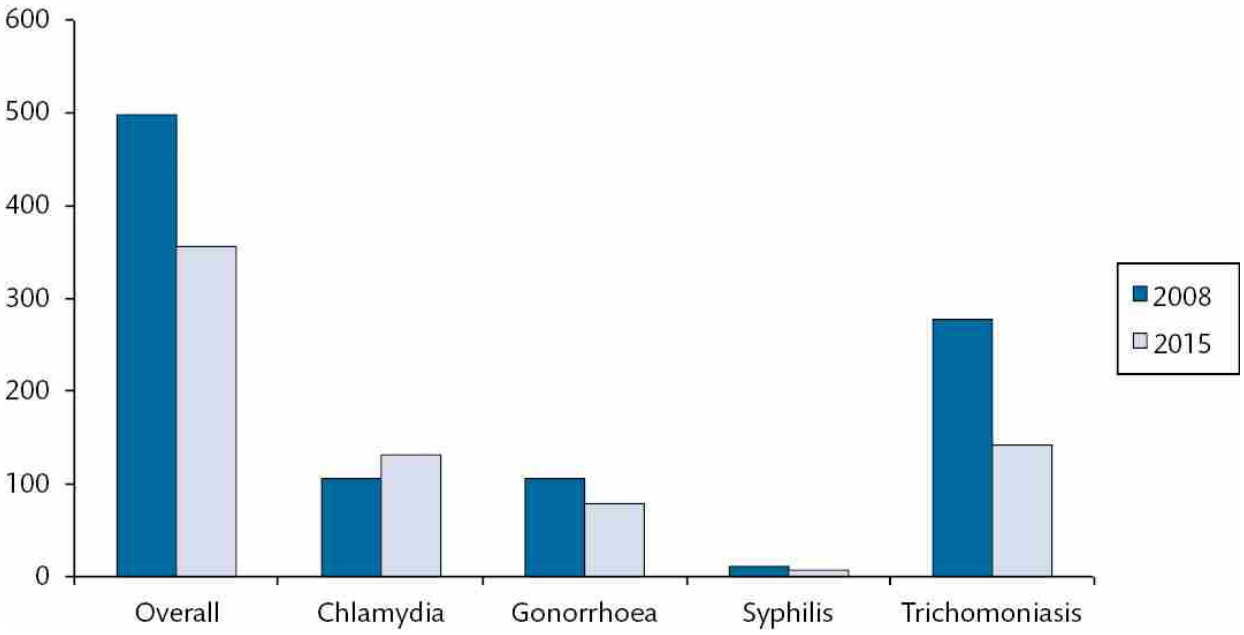

Fig. 8.12.1 New cases (millions) of four curable STIs in 2008 and 2015.

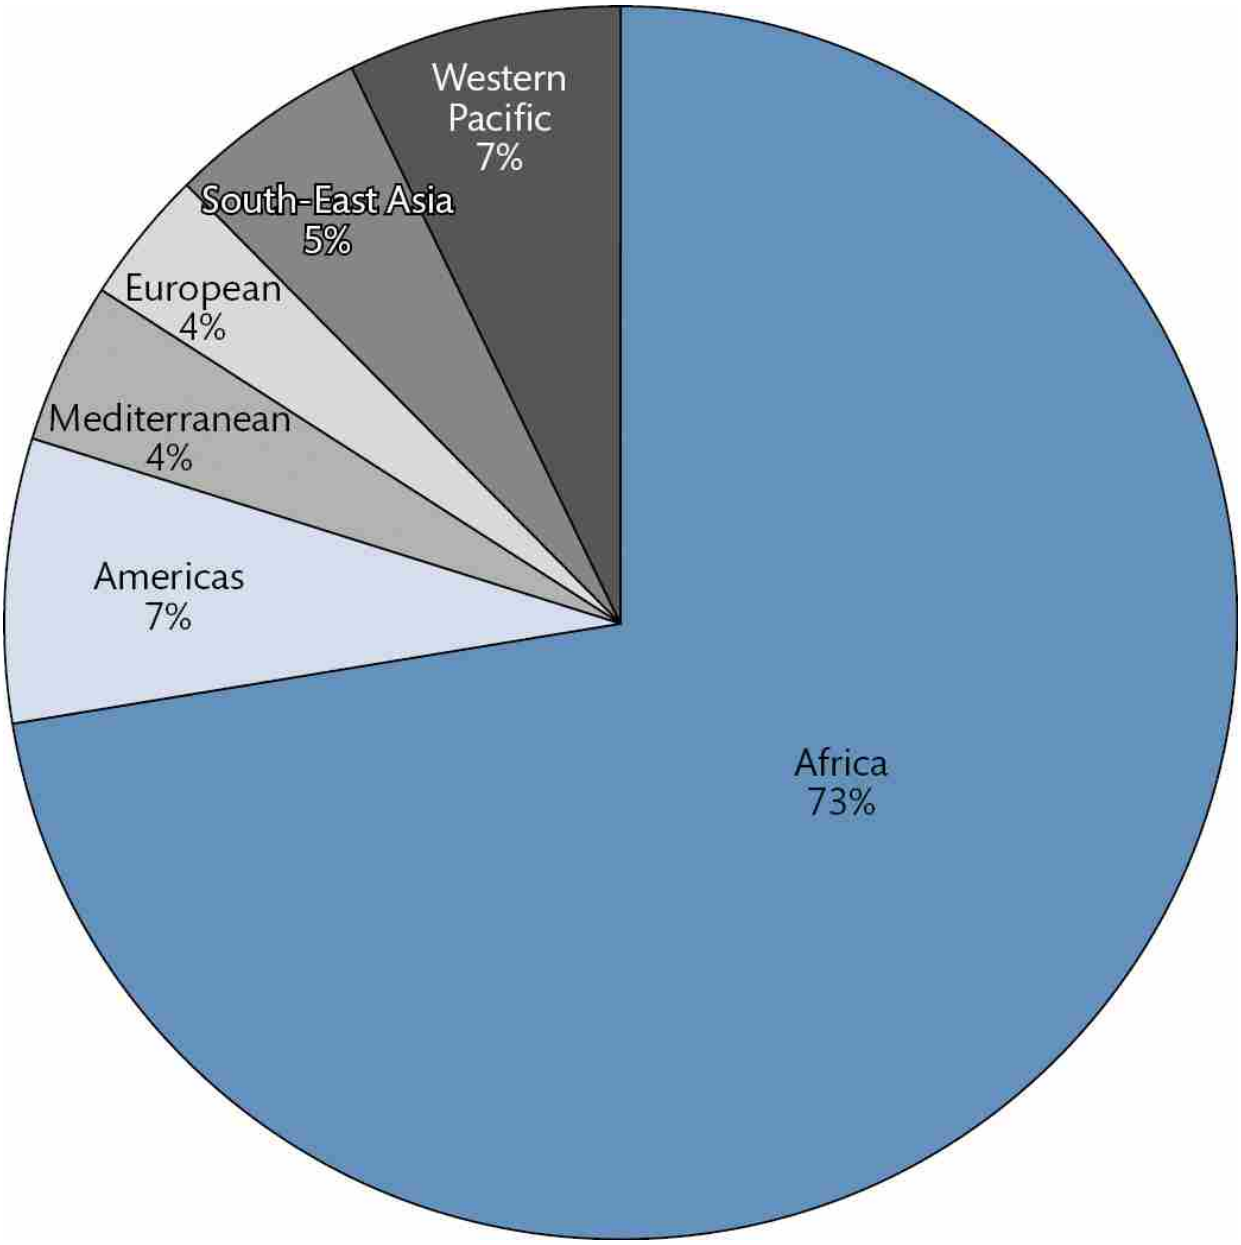

Fig. 8.12.2 Proportion of genital ulcer disease burden by geographic regions, 2014.

While syndromic management is a useful strategy to treat STIs in those presenting to clinics and estimate disease burden, laboratory-based STI testing has superior STI sensitivity and specificity. However, the accessibility and feasibility of laboratory-based STI testing is more limited worldwide due to the lack of political will, absence of infrastructure, and the cost of testing. There are many different laboratory-based methods to test for STIs, mainly *Neisseria gonorrhoeae* infection and syphilis. Microscopy with Gram stain and bacterial culture can detect *Neisseria gonorrhoeae*. Newer

nucleic acid-amplification-based tests have become increasingly useful in the detection of *Neisseria gonorrhoeae* due to their higher sensitivity and specificity. Point-of-care, rapid syphilis tests have become useful in initial syphilis screening, however that test must be used on those without a known history of syphilis or treatment, because the test cannot distinguish between past or current infection. The confirmation of a diagnosis of syphilis necessitates two tests, treponemal and non-treponemal tests, which are not always available worldwide. Therefore, national syphilis estimates can be discordant with the actual burden of syphilis.

Viral STIs

In contrast to bacterial STIs, the only curable viral STI is hepatitis C. Other STIs like genital herpes and HIV infection are incurable; however, they can be managed with antiviral medicines. While HIV infection may be the most well-known viral STI and contributes to a total of 36.9 million people living with a chronic infection, there are an estimated 417 million cases of herpes simplex virus type-2 infection, and roughly 291 million women are infected with human papillomavirus at any given time, worldwide.

Genital herpes infection is a chronic, life-long viral infection caused by HSV-1 or HSV-2. It was estimated that in 2012, there were 417 million people aged 15 to 49 years living with HSV-2 infection. More women had HSV-2 infection when compared to men (267 million persons versus 150 million persons), and this was attributed to women being more susceptible to infection than men. Worldwide, Africa had the highest prevalence of HSV-2 infection, followed by the Western Pacific and Southeast Asia (Fig. 8.12.3) (Looker et al. 2015). Genital herpes disease and transmission can be reduced with medical therapy.

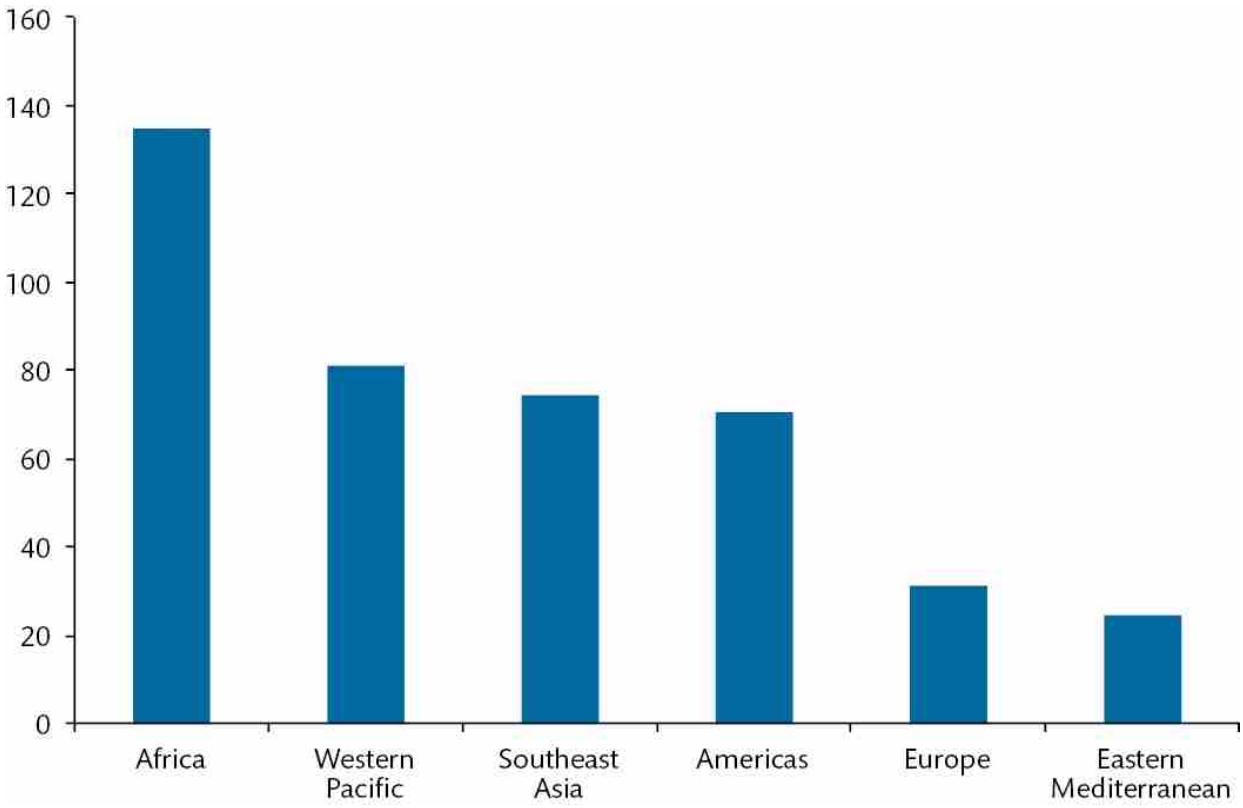

Fig. 8.12.3 Estimated prevalence (millions) of Herpes simplex virus-2 infection by region, 2012. Source: data from Looker K. et al 'Global Estimates of Prevalent and Incident Herpes Simplex Virus Type 2 Infections in 2012'. *PLoS One*, 10, e114989.

Roughly 291 million women worldwide are infected with human papillomaviruses, a group of viruses that consist of over 100 different sub-types of viruses, of which about 30 primarily infect the oropharynx (throat) and genitals. Among those viruses, there are at least 13 cancer-causing varieties, which are classified as 'high-risk' viruses. Cervical cancer is the second most common cancer among women worldwide. In 2012, nearly 270,000 women died from cervical cancer, and nearly 230,000 of those deaths occurred in low- and middle-income countries. In low-income countries, the relevant disability-adjusted life years (DALYs) lost to cervical cancer are second only to oropharyngeal cancer (American Cancer Society 2015). Two human papillomaviruses, type 16 and 18, cause 70% of cervical cancers and precancerous cervical lesions. Worldwide, human papillomaviruses type 16 is the most prevalent, followed by type 18 (Bruni et al. 2010). In the United States, there are 35,000 HPV-associated cancers annually (61% in females and 39% in males), with an annual cost of US $8

billion for screening and treatment of HPV-associated health outcomes (Jemal et al. 2013).

HIV infection continues to cause significant morbidity and mortality. Since access to antiretroviral drugs expanded in the early 2000s, an estimated 20 million have been treated and 5.2 million AIDS-related deaths have been averted in low- and middle-income countries (UNAIDS 2013b). Furthermore, children have seen the largest decrease in HIV incidence, which has been reduced by over half in the last 10 years (UNAIDS 2013a). While great progress has been made in the reduction in the spread of HIV, 36.9 million people are living with chronic HIV infection. Sub-Saharan Africa continues to carry the largest burden of those living with, dying from, and acquiring HIV infection (Fettig et al. 2014).

Viral hepatitis caused 1.34 million deaths in 2015, with an increasing trend (WHO 2017a). Many unrelated viruses that all cause liver disease are grouped together as viral hepatitis. While sexual transmission of hepatitis A, B, C, and D have been observed; hepatitis B is the most commonly sexually transmitted hepatitis virus. Most deaths caused by the viral hepatitis were due to chronic liver disease (720,000 deaths due to cirrhosis), and followed by primary liver cancer (470,000 deaths due to hepatocellular carcinoma). Hepatitis B and C were responsible for 96% of all hepatitis related mortality. Globally, it is estimated that 257 million people are living with chronic hepatitis B infection and 71 million people were living with a chronic hepatitis C infection in 2015. Hepatitis B has the highest prevalence in Africa and Western Pacific, whereas hepatitis C has the highest prevalence in the Europe. In May 2016, the World Health Assembly endorsed a Global Health Sector Strategy on viral hepatitis 2016–2021 to reduce new infections by 90%, and mortality by 65% by 2030. Other viral hepatitides are described in Table 8.12.2.

Table 8.12.2 Viral hepatitis

A	Caused approximately 11,000 deaths in 2015. A vaccine is available. It is primarily transmitted through exposure to contaminated food or water. It can be acquired through sexual activity.
B	Caused over 880,000 deaths in 2015. A vaccine is available. It is primarily transmitted through blood or semen.
C	Caused over 400,000 deaths in 2015. Medicine is available to cure chronic hepatitis C infections. It is primarily transmitted through blood.
D	Older interferon-based medicines can be used to treat this virus with suboptimal results. It is an incomplete virus and can only infect persons with a current hepatitis B infection. It is transmitted mostly through exposure to blood. Persons with hepatitis B infection with a hepatitis D coinfection lead to worse health outcomes. Most experts estimate that 5% of persons infected with hepatitis B are co-infected with hepatitis D.
E	Caused approximately 44,000 deaths and 20 million infections in 2015. A vaccine to prevent hepatitis E infection has been developed and licensed in China; however, it does not have a wide global availability. Hepatitis E is transmitted via the faecal-oral route, primarily by contaminated water. It has a higher case fatality among pregnant women.

While most STI acquisition occurs during sexual activity, mother-to-child transmission (MTCT) of STIs can occur *in utero* or perinatally. In 2018, UNAIDS estimated that 180,000 children acquired HIV infection, predominantly through perinatal transmission or contaminated breast milk (UNAIDS 2018). Antenatal HIV screening and maternal treatment programmes have greatly reduced the frequency of MTCT of HIV infection, when compared to the estimated 420,000 children that acquired HIV infection at the peak of the epidemic in 2003. In eastern and southern Africa, the area with the highest frequency of MTCT of HIV infection in the world, 93% of the 940,000 pregnant women with HIV infection received antiretroviral prophylaxis in 2017, reducing the average frequency of MTCT of HIV to less than 10%.

T. pallidum, the causative agent of syphilis, can readily cross the placenta during pregnancy and can cause morbidity and mortality among mothers and newborns. Between 2008 and 2012, the estimated total number of maternal infections and adverse pregnancy outcomes attributed to congenital syphilis decreased by 38% from 520,000 to 350,000 cases, which consisted of 143,000 early fetal deaths/stillbirths, 62,000 neonatal deaths, 44,000 preterm/low weight births, and 102,000 infants with syphilis (WHO 2015). While declines in congenital syphilis were seen in all regions, the largest

declines were observed in South-East Asia. As of 2018, many countries have been successful in the dual elimination of MTCT of HIV and syphilis, including Cuba, Thailand, Belarus, Anguilla, Antigua, and Barbuda, Bermuda, Cayman Islands, Montserrat, and St. Kitts and Nevis (WHO 2014; WHO 2017b). The WHO acknowledged Armenia for eliminating MTCT of HIV and the Republic of Moldova for eliminating MTCT of syphilis. Strategies to eliminate MTCT of HIV include prevention of unintended pregnancies, increased access to testing and counselling, medical therapy, safe delivery practices, and appropriate infant feeding practices (WHO 2014). Strategies to eliminate of MTCT of syphilis include early antenatal testing and treatment. Other STIs, like *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and HSV infections, can be transmitted from mothers to newborns as a result of exposure to the pathogen as the neonate passes through the birth canal. Strategies to control those infections are discussed later.

More research has emerged since the 2015 Zika virus outbreak in Brazil. Zika virus is now recognized as sexually transmissible, although its primary route of transmission (>99%) is through mosquitoes (Baud et al. 2017). Among pregnant women, Zika virus infection has been associated with severe adverse infant outcomes including miscarriage, stillbirth, and microcephaly. Additionally, new research supports that MTCT of Zika virus can occur perinatally (Blohm et al. 2018).

For neonatal HSV-1 and HSV-2 infection, a devastating infection of newborns with > 50% mortality, it is estimated that approximately 14,000 cases occurred annually globally between 2010 and 2015 (4,000 cases for HSV-1 and 10,000 cases for HSV-2) (Looker et al. 2017). In the Americas, Europe, and Western Pacific, HSV-1 contributed to more cases than HSV-2, whereas in Africa, HSV-2 contributed to more infections. For congenital cytomegalovirus (CMV) infection, an infection causing deafness and neurodevelopmental problems, it is estimated that the incidence of congenital CMV infection among all live births ranges from 0.6% to 0.7% in developed countries and 1% to 5% in developing counties (Marsico and Kimberlin 2017), far more common than Zika virus.

STI-associated morbidity

The presentation of an STI can range from an asymptomatic infection to a life threatening one. See Table 8.12.1 for a list of STI-related diseases or syndromes. The acquisition of STIs can also lead to stigma, shame, and psychological harm (Cunningham et al. 2009). Additionally, many STIs can lead to longer-term health problems, which can be categorized into four broad categories: female reproductive health disorders, e.g. infertility; adverse pregnancy outcomes, e.g. neonatal death; malignancies, e.g. cervical cancer associated with HPV; and increased risk of HIV infection acquisition.

Chlamydia trachomatis and *Neisseria gonorrhoeae* infections are important causes of infertility (CDC 2018c). While it is possible to test for and treat those infections, 10–15% of women with chlamydial infection who go untreated will develop pelvic inflammatory disease. Infections in the upper genital tract can cause permanent damage from inflammation and scarring of the fallopian tubes, uterus, and surrounding tissues leading to infertility. Scarring of the fallopian tubes also increases the risk of ectopic pregnancy, which can be a serious medical or surgical emergency. *Chlamydia trachomatis* infection has also been associated with HPV-induced cervical cancer (Madeleine et al. 2007). Screening programmes have been shown to be effective in reducing rates of chlamydial and gonorrhoeal female reproductive health disorders (Workowski et al. 2015). Among women with HIV infection, *Trichomonas vaginalis* infection has been associated with increased risk for pelvic inflammatory disease.

Many STIs are associated with adverse pregnancy outcomes, causing morbidity and mortality among newborns. One of the most devastating STIs in pregnancy is syphilis. It is estimated that fetal loss and still birth were 21% more frequent, neonatal deaths were 9.3% more frequent, and prematurity or low birth weight were 5.8% more frequent among pregnant women with syphilis versus pregnant women without syphilis (Gomez et al. 2013). Additionally, 15% of newborns of mothers with untreated syphilis had clinical evidence of congenital syphilis. For *Chlamydia trachomatis* and *Neisseria gonorrhoeae* infections, exposure to the pathogen occurs during delivery. Untreated *Chlamydia trachomatis* infection causes significant perinatal morbidity including blindness and pneumonia. Untreated *Neisseria gonorrhoeae* infection can cause rhinitis, vaginitis, urethritis, blindness, sepsis, arthritis, and meningitis. After delivery, prophylactic antibiotic ointments prevent eye infections from those infections. Prenatal screening and treatment prevent chlamydial and gonococcal infections among neonates

(Workowski et al. 2015). Apart from the well-characterized features of HIV infection, many other viral STIs cause morbidity and mortality among newborns. Neonatal herpes is associated with skin, eye, and mouth disease, lasting neurological impairment, disseminated infection, and, has an estimated 60% fatality rate among newborns without treatment (Looker et al. 2017). Recurrent respiratory papillomatosis can be a serious disease among newborns that acquire perinatal HPV infection (CDC 2017). Among pregnant women with hepatitis B virus, without post-exposure prophylaxis, roughly 40% of infants develop a chronic infection. Among those infants, approximately one-fourth of those will eventually die from sequela of chronic liver disease (CDC 2018d). More recently, it has been found that Zika virus infection during pregnancy is associated with microcephaly, abnormal brain and eye development, hearing loss, and damage to muscles and bones (CDC 2018b).

STIs are also associated with certain malignancies, which can occur during a chronic infection. Major STI-associated malignancies include anogenital cancers associated with HPV, hepatocellular carcinoma associated with chronic hepatitis, some lymphomas are associated with HIV infection, and Kaposi's sarcoma is associated with human herpes virus type 8 infection. Low- and middle-income counties have a higher STI-related cancer burden than high-income counties.

Where there are more than 100 types of HPVs, 13 HPVs have been identified as cancer causing (WHO 2018). Among the cancer-causing HPVs, HPV type 16 and 18 cause 70% of all cervical cancers and precancerous cervical lesions. HPV is also linked with cancers of the anus, vulva, vagina, and penis (Crosbie et al. 2013). Worldwide, cervical cancer is the fourth most frequent malignancy among women. In 2012, there were an estimated 530,000 new cases of cervical cancer among women, with approximately 270,000 deaths (WHO 2018). Over 85% of those deaths occurred in low- and middle-income counties. The progression from chronic HPV infection to cervical cancer is insidious, taking 5 to 10 years to develop among women with weakened immune systems, e.g. infection with HIV, and 15 to 20 years to develop among women with normal immune systems. In high-income counties, routine screening and treatment prevents up to 80% of cervical cancers. As of 2018, cervical cancer can be screened with conventional Pap testing and liquid-based cytology, visual inspection with acetic acid, and molecular testing for cancer-causing HPV types. Highly effective and safe

vaccinations are available for cancer-causing HPV types. Increased use of HPV vaccines has great potential to prevent HPV-associated cancers among women and men worldwide.

In 2015, it was estimated that 470,000 deaths were due to hepatocellular carcinoma secondary to viral hepatitis (WHO 2017a). The majority of cases of hepatocellular carcinoma are associated with chronic hepatitis B and hepatitis C virus infection (El-Serag 2012). Nearly all childhood and approximately half of all cases of hepatocellular carcinoma can be attributed to chronic hepatitis B infection. Additionally, it is estimated that 2.7 million people are living with a hepatitis B and HIV co-infection (WHO 2017a). The prevalence of hepatitis B is highest in the Western Pacific, Africa, and followed by South-East Asia. For prevention, the global coverage of hepatitis B vaccination reached 84% in 2015 reducing rates of transmission in the first five years of life. While challenges are still present, the WHO has created strategies to eliminate viral hepatitis by 2030 by increasing global surveillance, scaling up testing and treatment infrastructure, and the development of new diagnostics and treatments.

Patients with HIV infection are at increased risk of many cancers due to immunosuppression (Yarchoan and Uldrick 2018). AIDS-defining malignancies include non-Hodgkin's lymphoma, Kaposi's sarcoma, and cervical cancer. Patients with HIV infection are also at increased risk of developing lung cancer, anal cancer, Hodgkin's lymphoma, oral cavity cancer, pharyngeal cancer, hepatocellular carcinoma, vulvar cancer, and penile cancer, however those are non-AIDS-defining malignancies.

STIs can also increase risk of transmitting and acquiring HIV infection. STIs that cause genital ulcers, like syphilis or genital herpes, can increase the risk of acquiring or transmitting HIV infection by two to three times (WHO 2016). Other STIs, like *Chlamydia trachomatis* and *Neisseria gonorrhoeae*, and *Trichomonas vaginalis* infections, and STI-related conditions like bacterial vaginosis, seem to increase risk of HIV transmission and acquisition due to mucosal inflammation (Galvin and Cohen 2004; Ward and Ronn 2010). STIs, like syphilis, have been observed to increase HIV viral load and decrease CD4 T-cell counts (Buchacz et al. 2004).

Global STI management costs

The WHO Global Health Sector Strategy to manage global STIs was proposed in 2016, and set goals to end STI epidemics as a major public health concern by 2030. To achieve those targets, 70% of counties need to have a STI surveillance system in place; 70% of countries need to have 95% of pregnant women screened for syphilis and HIV, with 95% of those with syphilis receiving treatment; 70% of key populations need access to STI and HIV services; 70% of countries need to provide or have access to STI services in all HIV, reproductive health, family planning, and ante- and post-natal care services; 70% of countries need to deliver HPV vaccines, and those countries that provide that service need 90% national coverage in at least 80% of districts; and 70% of countries report antimicrobial resistance in *Neisseria gonorrhoeae* infections (WHO 2016). While some targets, like HPV vaccination, will generate significant returns on investment, initial implementation of those goals will be expensive. A recent analysis estimated that the total implementation cost will be US $18.2 billion over 2016 to 2021 in 117 low- and middle-income counties, with an initial $3.26 billion for HPV vaccination, $3.69 billion for HPV screening, $2.54 billion for chlamydial screening, and $1.4 billion for syphilis screening (Korenromp et al. 2017). Clinical STI management will add another $3 billion, with $1.4 billion going to diagnostic testing for *Chlamydia trachomatis* and *Neisseria gonorrhoeae* infection and $0.8 billion going to service delivery.

Transmission of sexually transmitted infections

Many risks factors have been associated with acquiring a STI that include behavioural risks as well as biologic risks. Behavioural risk factors include age of sexual initiation, number(s) and type(s) of sex partner(s), and use of barrier protection. Biological risk factors include sex, age, and developmental physiological changes. In addition to personal risk factors, community risk factors are also present, like the local prevalence of STIs, availability of screening and treatment services as well as social, economic, demographic, and cultural risk factors.

STI transmission dynamics

An important mathematical model to understand the population dynamics of STI transmission was proposed by May et al. in 1987 for HIV infection

(May and Anderson 1987). The model states that the average number of new infections caused by each infected person is determined by three factors: (a) the likelihood that an infected person will transmit the pathogen to an uninfected partner during sexual activity; (b) the average number of new sex partners formed between infected and non-infected people, and (c) the average amount of time an infected person can transmit the pathogen. Increasing any of those factors increases the population prevalence and *vice versa*.

With that model in mind, approaches of STI prevention programmes used to control the spread of STIs can be categorized. Commonly, STI prevention programmes aim to reduce the average amount of time an infected person can transmit the pathogen by testing and treating STIs, however many different interventions have been described and implemented. A list of different STI control strategies is included in Box 8.12.1.

Box 8.12.1 Strategies to control STIs

- Clinical testing and treating
- Community-based screening
- Comprehensive sexual education
- Vaccination
- Barrier protection, e.g. condoms
- Medical male circumcision
- Pre-exposure and post-exposure prophylaxis for HIV and other STIs
- Expedited partner therapy

Medical male circumcision

Medical male circumcision has been proven to reduce risk of male acquisition of HIV and other STIs (CDC 2018a). It is hypothesized that male circumcision reduces the risk of HIV and other STI acquisition because by removing the foreskin, the exposed penile skin thickens creating an effective barrier to infection. Additionally foreskin removal reduces the number of susceptible mucosal immune cells as well as alters the genital microbiota. Three randomized clinical trials showed that adult medical male

circumcision lowered the risk for HIV infection acquisition by 51% to 60% among heterosexual males (Auvert et al. 2005; Bailey et al. 2007; Gray et al. 2007). Additionally, male circumcision reduced the risk of genital ulcer disease prevalence by 47% and cancer-causing HPV prevalence by 23% to 47% (Auvert et al. 2009; Tobian et al. 2009; Serwadda et al. 2010; Mehta et al. 2012). Partners of circumcised men also receive protection from STIs. A large randomized trial performed in Kenyan and Ugandan involving HIV-serodiscordant heterosexual couples, found a reduction in the incidence of syphilis incidence by 42% among men and 59% among women (Pintye et al. 2014). The literature also supports that male circumcision is associated with reduced risk of other STIs among women including oncogenic human papillomavirus (HPV) genotypes and of contracting cervical cancer (Svare et al. 2002; Drain et al. 2006; Wilson et al. 2013; Grabowski et al. 2016). The evidence of the benefits of male circumcision is mixed for some other conditions like herpes simplex virus type 2 (Borkakoty et al. 2010; Mugo et al. 2011; Mujugira et al. 2011; Davis et al. 2017), genital ulcers (Gray et al. 2009), *Chlamydia trachomatis* infection (Castellsague et al. 2005; Nayyar et al. 2014; Russell et al. 2016) and *Trichomonas vaginalis* infection (Gray et al. 2009).

Sexual networks and core groups

Sexual networks are a type of social network that are defined by sexual activity among a group of individuals. Sexual networks can be determined by social, economic, cultural, migratory, or political forces, in addition to the physical or virtual spaces in which those networks can take place (Doherty et al. 2005). STI transmission within a sexual network depends on the number of sexual linkages within a sexual network and temporality of partnerships (concurrently versus sequentially). Bathhouses are an example of a physical space in which a sexual network can form. In the 1970s and 1980s, it was common for some men who have sex with men to find sex partners in bathhouses. Epidemiologic studies on the sexual networks formed in those bathhouses were used to trace the spread of HIV and other STIs. Now, the Internet has given rise to new virtual spaces facilitating sexual contacts through mobile applications and social media sites.

Future directions and challenges

New global initiatives have been enacted with the goal to end STI epidemics as a public health concern. Recently, new methods to prevent HIV infection have been developed, the use of HPV vaccines has increased, and more countries have successfully eliminated of MTCT of HIV and syphilis. However, multi-drug resistant *Neisseria gonorrhoeae* infection continues to spread and challenge STI control programmes.

Global and regional initiatives

In 2016, the WHO debuted a new Global Health Sector Strategy on Sexually Transmitted Infections 2016–2021: Towards Ending STIs, which sets a vision, goals, targets, guiding principles, and priority actions to end STIs epidemics as a public health problem (WHO 2016). The strategy emphasized the importance of accelerating and focusing comprehensive prevention efforts through scaling up evidence-based behavioural, biomedical, and structural approaches, facilitating individual's access to information of their STI status, improving access to treatment and comprehensive long-term care, and challenging pervasive stigmatization and discrimination. The 2030 targets for the strategy were (1) a 90% reduction of *Treponema pallidum* infection incidence globally from a 2018 global baseline, (2) a 90% reduction in *Neisseria gonorrhoeae* infection incidence globally from a 2018 global baseline, (3) ≤ 50 cases of congenital syphilis per 100,000 live births in 80% of counties, and (4) to sustain 90% coverage and at least 80% in every district in countries with HPV vaccine in their national immunization programme.

The WHO also made the dual elimination of MTCT of HIV and syphilis a global health priority, with a few countries also aiming to eliminate MTCT hepatitis B infection. So far, 11 countries have been validated by the WHO for eliminating MTCT of HIV or syphilis (WHO 2014; WHO 2017b). Criteria required for validation include 95% of pregnant women receiving antenatal care, 95% of pregnant women receiving HIV and syphilis testing in pregnancy, and 95% of pregnant women diagnosed with HIV or syphilis receiving treatment, with targets of ≤50 new paediatric HIV infections per 100,000 live births and a transmission rate of either <5% in breastfeeding populations or <2% in non-breastfeeding populations and ≤50 cases of congenital syphilis per 100,000 live births. The WHO also requires that this

process be conducted within a context of human rights, gender equality, and community engagement.

Antimicrobial resistance

Since the introduction of effective antibiotic treatments for *Neisseria gonorrhoeae* infection with sulfa drugs in the 1930s, the bacterium has become resistant to every antibiotic used for treatment (Hook and Kirkcaldy 2018). *Neisseria gonorrhoeae* developed resistance to sulfonamides, penicillins, early-generation cephalosporins, tetracyclines, macrolides, and fluoroquinolone drugs (Alirol et al. 2017). Most recently, *Neisseria gonorrhoeae* has been developing resistance to extended-spectrum cephalosporins, which is the last remaining empiric monotherapy for *Neisseria gonorrhoeae* infection. Furthermore, there has been a report of *Neisseria gonorrhoeae* antibiotic resistance to dual therapy (ceftriaxone and azithromycin). In 2015, the WHO adopted a Global Action Plan on Antimicrobial Resistance, which launched the Global Antibiotic Research and Development Partnership. This group aims to accelerate the development of new antibiotics, evaluate the potential of existing antibiotics and various combinations of them for more effective treatment, develop fixed-dose drug combinations, and develop simplified treatment guidelines for antibiotic-resistant bacterium. There are also three new drugs that are being developed to treat antibiotic-resistant *Neisseria gonorrhoeae* infection.

Advancement in technology

While use of mobile geosocial networking applications used for meeting sex partners may increase the risk of STI acquisition (Beymer et al. 2014), other advances like pre-exposure prophylaxis for HIV infection have been shown to be effective in preventing HIV acquisition (WHO 2016). Increased use of STI self-testing and rapid testing has also been shown to be helpful in increasing linkage to care, quality assurance, and partner services (Tucker et al. 2013). Additionally, digital innovations like mobile health-based messaging, Internet-based outreach, and combined interventions have been found to be acceptable, feasible, and impactful. Those interventions have also been useful in engaging harder to reach traditionally healthcare adverse populations (Daher et al. 2017). Finally, innovations in diagnostics may make it feasible to perform home or clinic-based STI testing for multiple

organisms including the characterization of antimicrobial resistance in some organisms in as few as 20 minutes.

Conclusions

STIs continue to be a major global cause of morbidity, mortality, and increased healthcare costs. This chapter outlined major issues regarding STI transmission, prevention, and programmes aimed to reduce global STI burden. While there are new challenges in the field of STIs, advancements in technology and global initiatives set by WHO could help reduce STIs as a public health epidemic in the near future. More effort is needed in research, implementation, and global collaboration and financial investment to eliminate many STIs as major public health problems.

Acquired immunodeficiency syndrome (AIDS)

Quarraisha Abdool Karim, Urisha Singh, Cheryl Baxter, and Salim S. Abdool Karim

Introduction

In May 2016, about 35 years since the first reported cases of AIDS, United Nations (UN) member states adopted the Declaration of ending AIDS by 2030, at a specially convened high level meeting in New York. The impetus for this remarkable announcement emanated from the confluence of new human immunodeficiency virus (HIV) knowledge, centrally around the use of antiretrovirals for treatment and prevention.

Given that a vaccine or cure, much needed tools for elimination and eradication of HIV respectively are still in development, what does 'ending AIDS' mean? Epidemiologically it can be defined as the reduction of disease incidence, prevalence, morbidity, or mortality to a locally acceptable level as a result of deliberate intervention measures. While an epidemiological metric for achieving epidemic control has yet to be defined, it is defined mathematically as the reproductive rate of infection (R_0) reaching below one. There is some consensus that this goal can be reached at an HIV incidence rate of 1/1,000 per annum.

In order to track progress on achieving epidemic control, the Joint United Nations Programme on HIV/AIDS (UNAIDS) developed the Fast Track Strategy that monitors progress towards elimination of AIDS-related stigma and discrimination; AIDS-related mortality and reduction in HIV incidence rates. The intermediate 2020 targets include: (a) 90% of those who are infected know their status; 90% of those who are infected are initiated on antiretroviral (ARV) treatment and 90% of those on ARV treatment are virally suppressed; also referred to as 90–90–90; (b) a 90% reduction of incidence rates compared to 2010 and iii. Reduction in stigma and discrimination.

This chapter traces the history of HIV from its origins, the remarkable scientific advances, and unprecedented global responses through to the current state of the epidemic, progress towards ending AIDS and remaining challenges.

In the beginning

Acquired immune deficiency syndrome (AIDS) was first recognized in 1981 when a cluster of five previously healthy homosexual men from Los Angeles presented with *Pneumocystis carinii* pneumonia (PCP) (now *Pneumocystis jirovecii*) and additional clusters of homosexual men in California and New York presented with Kaposi's sarcoma (CDC 1981; Gottlieb et al. 1981; Greene 2007). Within the next 18 months, additional cases of previously healthy homosexual men with PCP and Kaposi's sarcoma were reported in various large cities in the United States (CDC 1982a). The main presenting symptoms of these men included severely depressed cell-mediated immunity coupled with opportunistic infections and rare malignancies (CDC 1981). The prognosis of the illness was poor with the outcome being rapid death following the manifestation of these symptoms. The predominance of this new disease entity in young homosexual men and linked cases, which suggested it was sexually related, led to the belief that it was a lifestyle-based illness and it was termed gay-related immune deficiency (GRID) or 'gay plague'. A month later, the illness was detected in Haitians and then haemophiliacs which initially led to the belief that it originated in Haiti (CDC 1982b). However, the identification of cases of a new wasting illness in Uganda, which mimicked symptoms of AIDS, termed 'slim disease' placed doubt on the origin of the illness (Serwadda et al. 1985). Between 1982 and 1983, the first case of mother-to-child transmission of AIDS and the first AIDS-related death of an infant, aged 20 months, was reported. Additionally, reports of AIDS infection in haemophiliacs, injecting drug users (IDUs), recipients of blood transfusions and female partners of men with AIDS were released, providing the first indication that AIDS infection was likely also spread through blood and heterosexual sex (CDC 1982b; Greene 2007). At this time the new disease entity was renamed AIDS, all major routes of transmission were identified, however, its cause, diagnosis and treatment remained elusive (Marx 1982; Gottlieb et al. 1983).

The lack of information on the causative agent of AIDS coupled with a lack of treatment and testing methods for the illness imparted great fear, uncertainty, and stigma towards those infected. Many people believed that AIDS could spread through holding hands or sharing a toilet seat. Parents with infected adult children refused to see them, nurses and auxiliary staff refused to take meals to infected patients, doctors argued whether treating infected patients was a moral obligation, and faith communities titled those infected as ‘abominations’ with the belief that AIDS was a form of ‘divine punishment for those with sinful lifestyles’ (Fee and Krieger 1993; Smith and Whiteside 2010). People living with AIDS (PLWA) were; physically attacked, unfairly dismissed from their jobs, unlawfully evicted from their homes and denied various health services. This drove the development of several organizations and activist groups aimed at advocating for and filling the gaps in care for PLWA and initiating civil rights protection policies (Gostin 1990; Herek and Capitanio 1993). The gay rights movement campaigned for AIDS to be viewed as a human rights issue with the argument that, other than the risk of infection with AIDS, there was also a high risk of harmful discrimination against those found to be infected (Bayer and Fairchild 2006). A multitude of public health officials supported this argument and raised additional concerns of stigma being a barrier to testing for the illness and for those with AIDS from accessing health services (Smith and Whiteside 2010). Media coverage of AIDS remained low with social movements and activism propagating the early response to AIDS and encouraging the discovery of its causative agent and diagnostic tests.

The discovery and spread of HIV

The identification and isolation of the causative agent of AIDS was challenging due to the manifestation of clinical signs and symptoms years after infection by which time patients also presented with various additional infections.

In 1983, Luc Montagnier and Francoise Barre-Sinoussi from the Pasteur Institute in France announced the isolation of a new retrovirus; lymphadenopathy-associated virus (LAV), and suggested that it was the cause of AIDS, however, proof of causality was not established. Eighteen months later, Robert Gallo’s group from the US National Cancer Institute announced the identification and isolation of a second retrovirus, the human

T-lymphotropic virus type-III (HTLV-III), and provided sufficient evidence of causality of AIDS (Popovic et al. 1984). Three months later Jay Levy's group in San Francisco isolated an 'AIDS-associated retrovirus' from 22 AIDS infected patients confirming the link between a retrovirus and AIDS (Levy et al. 1984). By 1985, LAV, HTLV-III and the AIDS-associated retrovirus were confirmed to be variants of the same retrovirus (Ratner et al. 1985; Marx 1988), which was then established as the cause of AIDS and renamed HIV (Coffin et al. 1986). A second, less prevalent and virulent strain of HIV was isolated from patients in West Africa in 1986, providing further confirmation of causality. This virus was named HIV-type 2 (HIV-2) with HIV subsequently renamed HIV-type 1 (HIV-1) (Clavel et al. 1986).

Following the identification of the causative agent, its origins were investigated using phylogenetics and statistical modelling of the earliest available HIV sequences obtained between 1950 and 1960. Studies showed that HIV-1 and HIV-2 originated in central West Africa from separate zoonotic transfer of simian immunodeficiency virus (SIV) from primates to humans where primates were butchered and consumed as bush meat (Fig. 8.13.1) (Sharp and Hahn 2008; Tebit and Arts 2011). Cross-species transfer of SIV from old world monkeys to chimpanzees then from chimpanzees to gorillas resulted in variations of SIV that gave rise to HIV-1 in humans. The HIV-1 groups M and N have been associated with SIV from *Pan troglodytes*, a subspecies of chimpanzee, HIV-1 group P and O have been associated with western gorillas and HIV-2 has been associated with SIV from *Cerocebus atys*, a subspecies of the sooty mangabey (Nerrienet et al. 2005; Santiago et al. 2005; Keele et al. 2006; Sharp and Hahn 2008; Plantier et al. 2009).

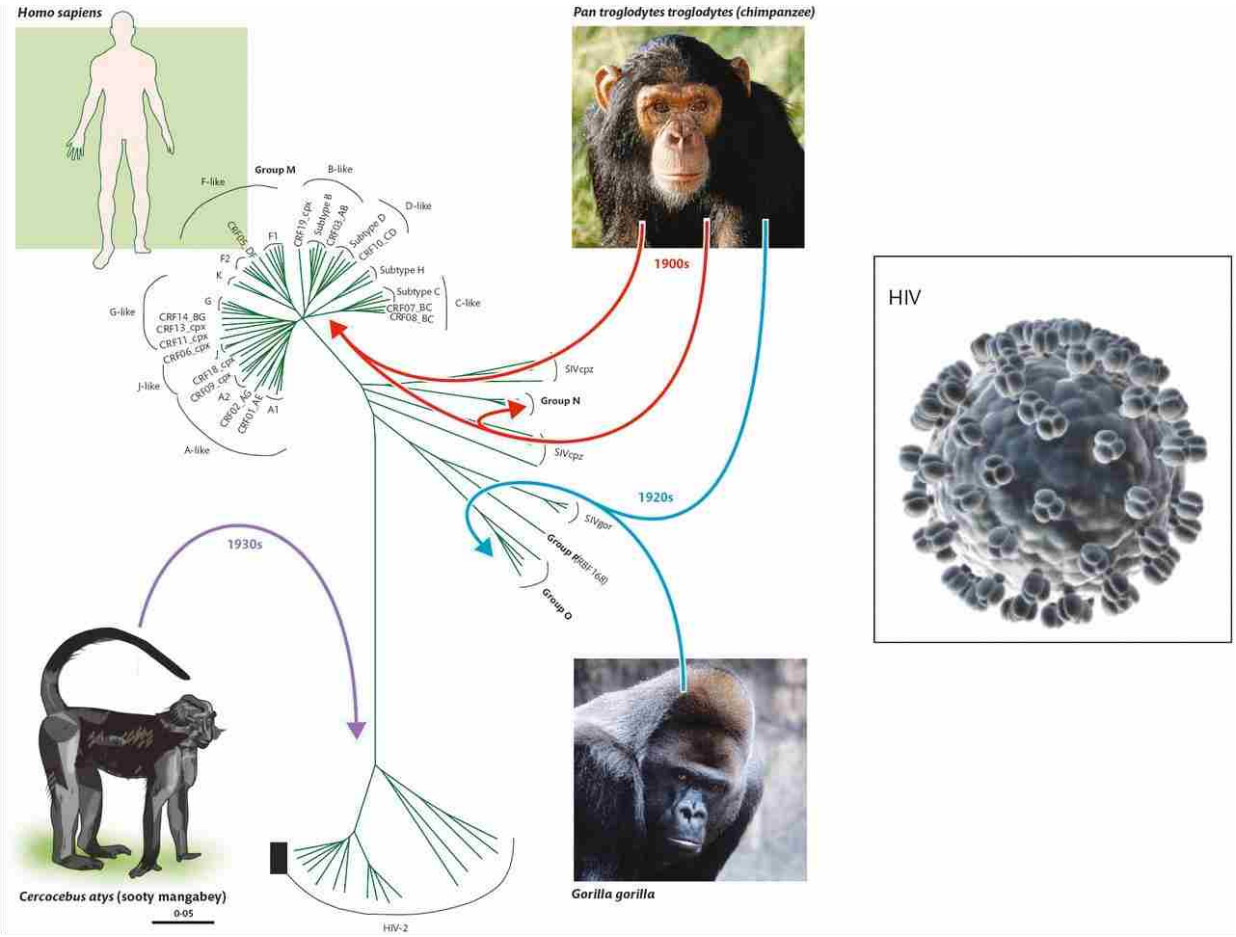

Fig. 8.13.1 Origins of HIV.
Reprinted from Denis M Tebit, Eric J Arts. Tracking a century of global expansion and evolution of HIV to drive understanding and to combat disease. *The Lancet Infectious Diseases*, 11(1):45–56 with permission from Elsevier.

It has been estimated that HIV-1 group M, N and O originated in 1908 (range: 1884–1924), 1963 (range: 1948–1977), and 1920 (range: 1890–1940) respectively, while the origin of HIV-2 group A and B has been estimated to be 1932 (range: 1906–1955) and 1935 (range: 1907–1961) respectively (Korber et al. 2000; Wertheim and Worobey 2009; Tebit and Arts 2011; Sharp and Hahn 2008, 2011). Faria et al. (2014) demonstrated that HIV group M, the oldest lineage of HIV-1, originated in Kinshasa and attributed its spread through central Africa to extensive use of railway transport that linked various regions and enabled interactions between individuals from these regions (Faria et al. 2014). Additional studies cite the growth of cities, migration, urbanization, and improved travel as the main contributing factors towards the exponential spread of HIV and its uneven

distribution of subtypes and circulating recombinant forms of HIV (Tebit and Arts 2011; Sharp and Hahn 2008; Faria et al. 2014).

The development of the HIV antibody test and HIV/AIDS surveillance

Shortly after the discovery of HIV, diagnostic tools started to be developed to identify individuals infected with HIV. By March 1985, an enzyme linked immunosorbent assay (ELISA) was approved as the first HIV diagnostic test. This test recognized the IgG antibody produced in response to HIV-1 only. Blood banks in the USA and elsewhere in the world began routine screening of donated blood (Roberts 1994). Although sensitive and useful in the screening of blood products, the ELISA test had an antibody-negative window of at least 12 weeks post-infection and had a high rate of false negative results in response to other infections, pregnancy, autoimmune diseases, and various unknown conditions (Chappel et al. 2009). By 1986, two confirmatory tests, the western blot immunoassay (CDC 1989) and the HTLV-III immunofluorescence assay were approved with an antibody-negative window of approximately 6 weeks (Hedenskog et al. 1989; Chappel et al. 2009). These confirmatory tests were used in conjunction with the ELISA test and required that tests be performed in duplicate. Second generation HIV tests developed in the late 1980s, were designed to further reduce the antibody-negative window period to 4 weeks and improve the specificity of testing by including: the HIV-1 specific P24 antigen, an HIV-2 specific protein and an HIV-1 group O antigen to the antigen milieu in order to detect antibodies to these antigens. Third and fourth generation tests were subsequently developed, each with reduced antibody-negative windows, however, each of these tests were still used in combination with the confirmatory western blot immunoassays or the HTLV-III immunofluorescence assay. Fifth generation tests developed in 2015, eliminated the need for confirmatory testing as they provided results for the P24 antigen and the HIV antibody and reported separate results for HIV-1 and HIV-2 antibodies (Alexander 2016). Rapid HIV test kits became available in 2002 with 99.6% accuracy and results available within 20 minutes, it is now the predominant test of choice for an initial diagnosis in most settings.

These diagnostic tests enabled surveillance systems to be established to monitor the evolving HIV epidemic. By the end of 1985, every region in the world reported at least one case of AIDS. HIV surveillance (Detels et al. 2012) has remained essential and critical to quantify the magnitude of the epidemic; monitor trends in new infections, identify risk factors associated with infection, target interventions; and importantly, compare clinical manifestations of each case of AIDS that lacked aetiological explanations. In the USA, reporting by name of each newly diagnosed case of AIDS became a state health-department requirement shortly after the initial Centre for Disease Control (CDC) case reports of AIDS in 1981. While AIDS reporting was widely accepted and implemented with ease, HIV case reporting sparked community protest due to the use of name-based reporting of HIV infection (Goston et al. 1997). Gay rights organizations and civil libertarians expressed concern of invasion of privacy and the possibility of information reaching entities that would institute prejudice on those infected concerning employment, insurance, and housing (Gostin et al. 1997). Health officials justified the use of name-based reporting on the basis that it would assist health departments to: monitor those infected and ensure they remain linked to care, enable contact between health departments and those infected to enable counselling on prevention of further transmission of HIV and to monitor the prevalence and incidence of HIV. However, continued protest against the use of names for reporting on HIV incidence resulted in the implementation of confidential case-report systems that used code-identifiers instead of names for reports early in 2003 (Institute of Medicine (US) Committee on the Ryan White CARE Act 1994). These systems laid the basis for unlinked, anonymous HIV surveillance globally.

Each year, UNAIDS releases a report on the global status of the HIV epidemic based on data gathered from member states. Today HIV is found in every part of the world. About 77.3 million people have become infected with HIV and 35.4 million people have died from AIDS-related illnesses since the start of the epidemic. In 2017, there were about 37 million people living with HIV; 960,000 AIDS-related deaths occurred and 1.8 million new HIV infections. Sub-Saharan Africa continues to bear a disproportionate (65%) burden of infection. About three-quarters of all HIV infections are in 15 countries with the majority in sub-Saharan Africa (Fig. 8.13.2).

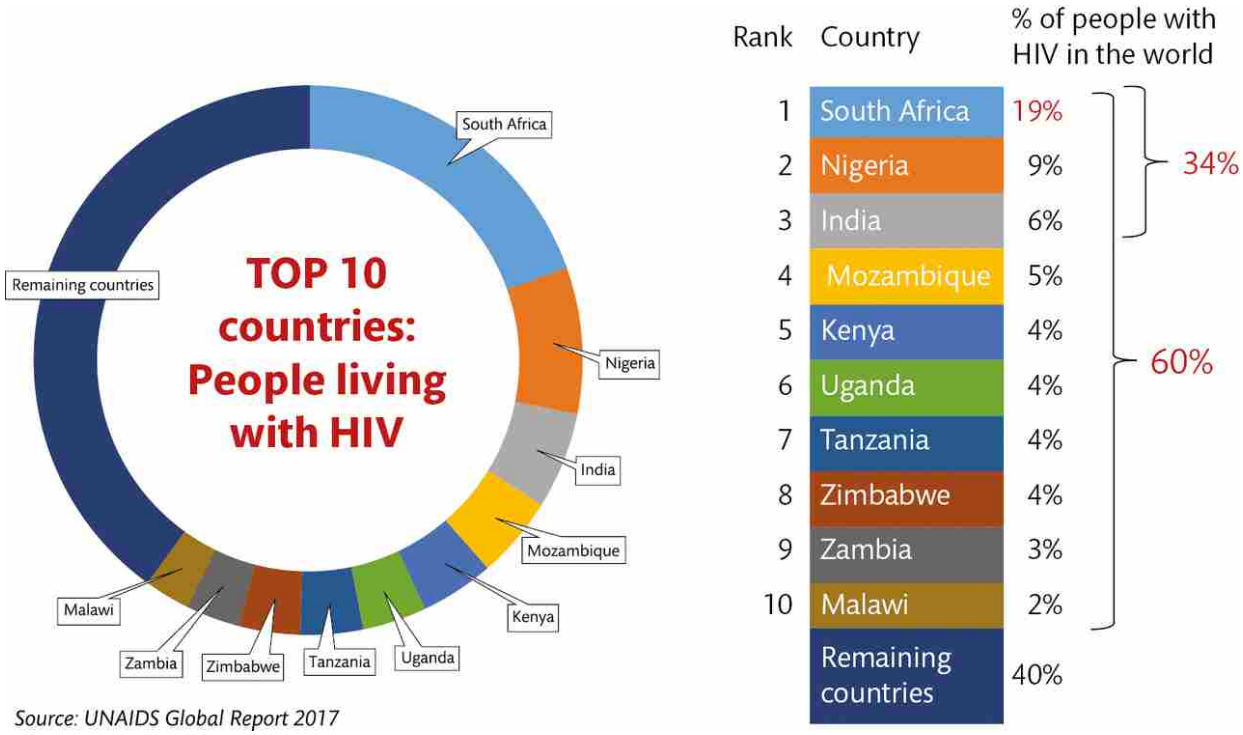

Fig. 8.13.2 Overview of burden of HIV globally.

These global data mask the diversity of epidemics within and between countries. Southern and Eastern Africa for example account for 52% of all new HIV infections that occur globally. Globally about a third of all new infections are taking place in young people between 15 and 24 years of age. In sub-Saharan Africa, adolescent girls and young women account for about 40% of all new HIV infections. Globally, key and priority populations such as men who have sex with men (MSM); transgendered persons, IDUs, and sex workers bear a disproportionately high burden of HIV infection and experience substantial challenges in access to services particularly in settings where they are marginalized or worse if criminalized.

Viral structure

HIV is a retrovirus, so named because it encodes the enzyme reverse transcriptase. This unique enzyme allows a DNA copy to be made from viral RNA. Reverse transcription is a highly error prone process and is the major source of genetic variability that typifies HIV.

Viral particles are spherical with a diameter of approximately 100 nm and as such can only be viewed under an electron microscope (Fig. 8.13.3a). The outer lipid membrane is derived from the human host and contains the two major envelope glycoproteins, gp120, and gp41 (‘gp’ stands for glycoprotein and the number is the molecular weight in kilodaltons) (Fig. 8.13.3b). These proteins are linked together and exist as trimers on the viral surface facilitating binding and entry to the host cell. The envelope protein is referred to as ‘Env’. Other major structural proteins are the group-associated antigens or Gag proteins. The matrix protein (p17), which lies just beneath the envelope, provides structure to the particle, while the capsid protein (p24) encloses the viral RNA. The capsid protein is clearly visible under the electron microscope as a dark conical structure in the centre of the particle (Fig. 8.13.3a). HIV encodes three unique enzymes that are major targets for antiretroviral therapies. These are reverse transcriptase (RT), integrase, and protease, collectively called polymerases or ‘Pol’ for short. All three enzymes are carried inside the viral particle where they remain active. In addition to the major structural proteins, HIV also produces a number of regulatory and accessory proteins that are only produced once the virus infects cells and are not present inside viral particles. These include Tat and Rev, which enhance levels of gene expression and Vif, Vpr, Vpu, and Nef, which function to increase viral production and infectivity.

Treating AIDS

Prior to 1986, the clinical management of AIDS included prophylactic treatment against AIDS-related illnesses and opportunistic infections with patients usually experiencing slow, painful lingering deaths usually within two years of presentation at health facilities. The discovery of HIV, characterization of the virus and the development of diagnostic assays to detect HIV led to a turning point for AIDS patients in 1986 through the discovery of azidothymidine (AZT), the first drug able to suppress HIV replication in culture that emanated from an unprecedented collaboration between the United States National Cancer Institute and the Burroughs Wellcome pharmaceutical company (Mitsuya et al. 1985; Broder 2010). This nucleoside reverse transcriptase inhibitor (NRTI), originally synthesized in 1964 for cancer treatment, was found to act as a DNA polymerase chain terminator with selectivity to the HIV RT (Furman et al. 1986; De Clercq 2005). It was approved for use in treatment of patients with HIV by the USA Food and Drug Administration (FDA) in 1987 and provided the initial proof-of-concept for HIV treatment (Broder 2010). Monotherapy with AZT was the primary treatment for HIV from 1987 to 1995. The discovery of AZT was followed by the development of various additional nucleoside analogues including: didanosine (ddI) (1991), zalcitabine (ddc) (1992), stavudine (d4T) (1994), and lamivudine (3TC) (1995) (Table 8.13.1). By 1995, the first protease inhibitor (PI), saquinavir (SQV), was approved and in 1996 the first non-nucleoside RT inhibitor (NNRTI), nevirapine (NVP) (De Clercq 2009) was approved.

The FDA approval of additional nucleoside analogues, PIs, and NNRTIs following AZT approval, changed the face of HIV treatment, which transitioned from monotherapy (1987–1995) to dual therapy (1992–1996) to the game-changing triple therapy/highly active antiretroviral therapy (HAART), now referred to as combination antiretroviral therapy (cART) (1996-present) (Arts and Hazuda 2012). cART demonstrated significant reductions in plasma viral load in patients treated for at least six months and became the standard of care since 1996 (Carpenter et al. 1997).

Table 8.13.1 Antiretroviral drugs used in the treatment of HIV infection

Brand name	Generic name	Abbreviation	Approved
Nucleoside reverse transcriptase inhibitors (NRTIs)			
Retrovir	zidovudine, azidothymidine	AZT, ZDV	March 1987
Videx	didanosine, dideoxyinosine	ddI	October 1991
Hivid	zalcitabine dideoxycytidine (no longer marketed)	ddC	June 1992
Zerit	stavudine	d4T	June 1994
Epivir	lamivudine	3TC	November 1995
Combivir	lamivudine and zidovudine	3TC/ZDV	September 1997
Ziagen	abacavir sulphate	ABC	December 1998
Trizivir	abacavir, zidovudine, and lamivudine	ABC/ZDV/3TC	November 2000
Videx EC	enteric coated didanosine	ddI EC	October 2000
Viread	tenofovir disoproxil fumarate	TDF	October 2001
Emtriva	emtricitabine	FTC	July 2003
Epzicom	abacavir and lamivudine	ABC/3TC	August 2004
Truvada	tenofovir disoproxil fumarate and emtricitabine	TDF/FTC	August 2004
Nonnucleoside reverse transcriptase inhibitors (NNRTIs)			
Viramune	nevirapine (immediate release)	NVP	June 1996
Rescriptor	delavirdine	DLV	April 1997

Brand name	Generic name	Abbreviation	Approved
Sustiva	efavirenz	EFV	September 1998
Intelence	etravirine	RTR	January 2008
Edurant	rilpivirine	RPV	May 2011
Viramune XR	nevirapine (extended release)	NVP	March 2011
Protease inhibitors (PIs)			
Invirase	saquinavir mesylate	SQV	December 1995
Norvir	ritonavir	RTV	March 1996
Crixivan	indinavir	IDV	March 1996
Viracept	nelfinavir mesylate	NFV	March 1997
Fortovase	saquinavir (no longer marketed)	SQV	November 1997
Agenerase	amprenavir, (no longer marketed)	APV	April 1999
Kaletra	lopinavir and ritonavir	LPV/RTV	September 2000
Reyataz	atazanavir sulphate	ATV	June 2003
Lexiva	fosamprenavir calcium	FOS-APV	October 2003
Aptivus	tipranavir	TPV	June 2005
Prezista	darunavir	DRV	June 2006
Fusion inhibitors			
Fuzeon	enfuvirtide	T-20	March 2003
Entry inhibitors—CCR5 co-receptor antagonist			

Brand name	Generic name	Abbreviation	Approved
Selzentry	maraviroc	MVC	August 2007
HIV integrase strand transfer inhibitors			
Isentress	raltegravir	RAL	October 2007
Tivicay	dolutegravir	DTG	August 2013
Vitekta	elvitegravir	EVG	September 2014
Multiclass combination products			
Atripla	efavirenz, emtricitabine, and tenofovir disoproxil fumarate	EFV/FTC/TDF	July 2006
Complera	emtricitabine, rilpivirine, and tenofovir disoproxil fumarate	FTC/RPV/TDF	August 2011
Stribild	elvitegravir, cobicistat, emtricitabine, tenofovir disoproxil fumarate	EVG/COBI/FTC/TDF	August 2012
Evotaz	atazanavir sulphate, cobicistat	ATV/COBI	January 2015
Prezcobix	cobicistat, darunavir ethanolate	COBI/DRV	January 2015

To combat HIV drug resistance, the development of new drugs continues to progress with the first fusion inhibitor/gp41 inhibitor (enfuviritide (T-20)) developed in 2003, the first CCR5 inhibitor/entry inhibitor (maraviroc (MVC)) developed in 2007 and the first integrase inhibitor (raltegravir (RAL)) developed in 2007. These drugs provide alternate treatment options for patients with complications (i.e. toxicity or incompatibility with other medications) or drug resistance (Arts and Hazuda 2012).

Following the initiation of cART as the standard of care for HIV patients globally, the development of fixed-dose combination (FDC) drugs containing two or three-drug combinations emerged as methods to improve adherence and thus reduce treatment failure and the development of drug resistance. Combivir™, a single pill containing a combination of AZT and

3TC was the first FDC pill developed in 1997. This was followed by the development of additional two-drug combination pills; Kaletra (lopinavir (LPV) and ritonavir (RTV)) in 2002, Epzicom/Kivexa (abacavir (ABC) and 3TC) in 2004 and Truvada (tenofovir disoproxil fumarate (TDF) and emtricitabine (FTC)) in 2004. The first three-drug combination pill, Trizivir, was developed in 2000 and contained a combination of ABC, 3TC, and AZT while Atripla, a combination of TDF, FTC and efavirenz (EFV) was developed in 2006 (Table 8.13.1). Atripla was the first complete FDC regimen for treatment naïve patients and has been the most commonly used FDC treatment (De Clercq 2009; Este and Cihlar 2010).

The face of AIDS in the United States (US) between 1996 and 1997 changed subsequent to the introduction of cART from an inevitably fatal condition to one that is chronic and manageable, however, AIDS-related deaths in resource-constrained settings only started to decline in 2007 (UNAIDS 2013). In sub-Saharan Africa, home to about 70% of the global burden of HIV disease, access to cART was limited due to the high prices of HIV drugs enforced through trade law agreements preventing generic manufacture of patented drugs. In South Africa, for example, the mean income in 1986 was $2,600 per annum while the cost of ARVs at the time was $1,000 per month. Countries like Thailand and India that were excluded from such trade law agreements imposed by the World Trade Organization (WTO) were able to develop and market generic ARVs at a fraction of the price of the patented ARVs enabling their citizens access to affordable cART and realize its life-saving benefits. In contrast to the estimated $10,000 per annum per person cost of patented drugs, the average cost of generic ARVs were $365 per annum per person (approximately $1 per day) (Fisher and Rigamont 2005). Africa still could not gain access to generic ARVs, due to the rights to exclusivity, resulting in millions of people dying from AIDS with substantial reductions in life expectancy and hundreds of thousands of orphans. By the year 2000, a combination of global solidarity, activism, and the establishment of the Global Fund to Fight AIDS, Tuberculosis and Malaria and the US President’s Emergency Plan for AIDS Relief (PEPFAR) facilitated access to life-saving ARVs for millions of Africans.

Through the discovery of ARVs and increased global access to ARVs, AIDS has evolved globally from an inevitably fatal condition to one that is chronic and manageable. In 2017, approximately 22 million HIV-infected people globally were on cART. An estimated 40% still need to have access

to treatment. While mortality rates have been reduced substantially, we still continue to see approximately 1 million AIDS-related deaths each year. Continued stigma and discrimination; limited access to healthcare services and untreated tuberculosis remain critical barriers to realizing the survival benefits of cART for many and ongoing efforts to increase access to cART need to pay more careful attention to these factors.

HIV-infected individuals on cART are living longer, and are experiencing new health challenges associated with ageing. Wing et al. (2016) reported that HIV-positive patients on cART experience more rapid development of dementia, chronic neurological complications, frailty, and geriatric syndromes than HIV-negative individuals (Wing 2016). Long-term ARV use has also been associated with hyperactivation of the immune system, premature immunological ageing, and chronic inflammation (Appay and Kelleher 2016). Various studies suggest that these immune and inflammatory changes drive more rapid ageing, this however remains controversial (Justice and Falutz 2014; Pathai et al. 2014).

The gradual deterioration of immune function, increased occurrence of geriatric syndromes and frailty, increased rates of metabolic syndrome (i.e. chronic comorbidities) and continuous increase in inflammatory markers (referred to as inflammaging), all of which occur at younger ages in HIV positive vs. negative patients, supports the argument that HIV accelerates the ageing process (Franceschi et al. 2000). In contrast, some researchers suggest that adherence to cART translates to HIV-positive patients having suppressed viral loads and CD4 counts of >500cells/µl which supports life expectancy no different to that of HIV-negative individuals and thus HIV does not accelerate ageing (Althoff et al. 2015; Rasmussen et al. 2015). Further research is required to provide clarification.

In addition to the possible association with accelerated ageing, the long-term use of ARVs has also been associated with an increased risk of non-AIDS defining illnesses (or AIDS comorbidities) at all ages (Smit et al. 2015). These comorbidities include diabetes (Kalra et al. 2011; Medapalli et al. 2012), obesity (Freitas et al. 2012) and cardiovascular disease and stroke (Shahbaz et al. 2015). Like with ageing, studies on the association between diabetes and HIV have also been controversial with early studies showing a clear link but later studies demonstrating variations in this link (Ford et al. 2010; Rasmussen et al. 2012; Jarrett et al. 2013; Monroe et al. 2015). While the association between abacavir use and cardiovascular disease also

remains controversial (Martin-Iguacel et al. 2015) the Veteran Aging Cohort Study (Freiberg et al. 2013; Sico et al. 2015) and additional studies (Obel et al. 2007; Klein et al. 2015) reported a non-age-dependant increased risk of myocardial infarction and stroke in HIV-positive individuals even among those with supressed viral loads. Recently, a link between diet and ARVs has also been elucidated whereby ARV use coupled with a high-fat diet was found to impair energy balance, glucose metabolism, inflammatory transcriptional pathways and cause metabolic dysfunction (Pepin et al. 2018).

Collectively these data highlight that notwithstanding the benefits of cART in the treatment of AIDS; given its requirement for lifelong use and long-term effects, the need for a cure remains paramount.

Preventing mother-to-child transmission of HIV

The prevention of mother-to-child transmission (PMTCT) has been a significant milestone in the HIV epidemic and represents one of the greatest successes in the field of human therapeutics. Mother-to-child transmission (MTCT) was first described in 1982 and was attributed to infection *in utero*, intrapartum or post-partum through breastfeeding (CDC 1982a; CDC 1983; Greene 2007). The first PMTCT recommendations were issued by the US public health services late in 1985 and suggested counselling for HIV-positive pregnant women on how to live with HIV and take care of a child with HIV. These guidelines also advised against breastfeeding to prevent postnatal transmission of HIV due to early reports suggesting breastmilk as a route of transmission (CDC 1985; Ziegler et al. 1985). By 1987, the World Health Organization (WHO) confirmed breastfeeding as a route of HIV transmission (WHO 1987) and perinatal transmission of HIV was classified as the main cause of HIV in children. Prevention efforts focused on trying to prevent HIV infection in women of reproductive age through education and advising HIV-positive women against breastfeeding. This, however, did not address HIV acquisition *in utero* or intrapartum for children born to HIV-positive mothers or lack of access to clean water supplies in some regions of the world and, not surprisingly, the incidence of HIV in children continued to increase.

By April 1991, the National Institutes of Health (NIH) in collaboration with the National Institute of Health and Medical Research and the National

Agency of Research on AIDS in France sponsored the paediatrics AIDS Clinical Trials Group (ACTG) Protocol 076 (ACTG 076), a randomized double-blinded clinical trial investigating the efficacy of AZT (also referred to as zidovudine) in PMTCT, based in the USA and France (CDC 1985). Oral AZT was administered from week 14–34 of gestation throughout the pregnancy, intravenous AZT was administered during labour and oral AZT was administered to the baby for six weeks following delivery (CDC 1994). Interim results released in December 1993 demonstrated a 67.5% reduction in risk of perinatal HIV transmission among the selected HIV pregnant women and their infants without significant toxicity (CDC 1994; Connor et al. 1994; National Institute of Allergy and Infectious Diseases 1994). These results led to the termination of the placebo arm enrolment and existing placebo patients were offered AZT. By 1994, the use of AZT for HIV PMTCT was approved with an understanding that the long-term effects of AZT were still unknown and the research on which this recommendation was based was incomplete and required completion with time (CDC 1993). It soon became a standard of care in industrialized countries however, the low-income regions struggled to implement this regimen due to poor infrastructure, drug costs, and local policies among other issues.

Four additional AZT/ZDV clinical trials investigating AZT/ZDV against placebo were conducted; one in Thailand (Shaffer et al. 1999), two in Africa (Wiktor et al. 1999) and one in Cote d'Ivoire/Burkina Faso (i.e. the ANRS 049 DITRAME trial) (Dabis et al. 1999; Msellati et al. 1999). Variations in trial protocols made direct comparison of trials difficult. However, one African study (based in Cote d'Ivoire) and the Thai study had identical protocols and showed efficacies of 37% and 50% respectively. Irrespective of variations in protocols, all AZT/ZDV studies demonstrated a reduction in MTCT with AZT/ZDV. The PHPT-1 trial, a PMTCT trial in which mothers did not breastfeed, investigated the impact on varied durations of AZT/ZDV therapy to the mother and infant and found that longer antenatal treatment with AZT/ZDV was more effective than the shorter treatment, however, longer postnatal treatment provided no added benefit to the infant (Lallemant et al. 2000).

The HIVNET 012 perinatal HIV prevention trial, which began in 1999 in Uganda, aimed to investigate the efficacy and safety of neonatal and intrapartum single-dose NVP and AZT/ZDV (Guay et al. 1999). Additionally, the trial also aimed to compare the efficacy of single-dose

NVP (sdNVP) to short-course AZT/ZDV treatment. The trial reported lower rates of vertical transmission with NVP than AZT without added side-effects or changes in mortality (Guay et al. 1999; Jackson et al. 2003). Aspects of the trial including record-keeping, methodologies and data analysis presented some controversy resulting in the NIH requesting the US Institute of Medicine (IOM) to conduct an independent review of the HIVNET 012 trial which was completed by 2004 and confirmed that the results which were reported were accurate (Delvaux 2004).

By this time, a short course of AZT or a single-dose of NVP administered to mother and infant demonstrated success in reducing vertical transmission of HIV by 50% and presented cost-effective methods for PMTCT in resource-constrained settings, with few side-effects (Guay et al. 1999; Shaffer et al. 1999). Although utilized, at the time, additional clinical trials to elucidate efficacious methods for PMTCT were under investigation, particularly to address drug resistance in HIV, such as that associated with NVP monotherapy (Wainberg and Friedland 1998).

The ANRS 075 trial (no breastfeeding) (Mandelbrot et al. 2001) and the PETRA trial (included breastfeeding) conducted in South Africa, Tanzania, and Uganda (Petra Study Team 2002) assessed the efficacy of combination therapy (AZT/ZDV and 3TC) on PMTCT. While results showed efficacy in PMTCT, both trials demonstrated the development of drug resistance, specifically to 3TC, with the ANRS 075 trials having higher levels of drug resistance due to longer treatment duration with 3TC. Interestingly, the South African SAINT trial, which compared the efficacy of AZT/ZDV+3TC (administered intrapartum and for one week following birth) to sdNVP (one dose given intrapartum and one dose given during labour to the mother and within 72 hours of birth to the infant) on PMTCT, found no significant difference in outcomes (Moodley et al. 2003).

The PHPT-2 Thai trial (Lallement et al. 2004), ANRS1201 DITRAME PLUS study in Cote d'Ivoire (Dabis et al. 2005) and the Malawi based open-label randomized trial (Taha et al. 2004) all investigated the effects of using NVP in addition to AZT/ZDV regimens for PMTC and found no added benefit.

While making comparisons between trials is difficult, the trend showed that a longer course of treatment was associated with improved outcomes and that sdNVP was the most efficacious and cost-effective regimen for prevention of HIV in the infant. Further, the addition of sdNVP to a

AZT/ZDV inclusive regimen only showed added benefits in the case where infants were breastfed.

Until 2009, the most commonly used regimen in developing countries was short-course AZT/ZDV with sdNVP given to mother and newborn during labour and 72 hours after birth respectively, with mothers from high-income settings advised to refrain from breastfeeding. In 2009, the WHO released guidelines advising the administration of cART to all pregnant women with a CD4 count <350 cells/ml (from 14 weeks of gestation) and the daily administration of NVP to infants from birth to 6 weeks if they are to be breastfed, or a course of daily AZT or NVP would be used for infants that were not breastfed. The guidelines also advised 12 months of daily NVP therapy for infants if they are to be breastfed for the duration, as is commonly the case in developing regions. These guidelines changed a few years later, advising the initiation of all pregnant women with CD4 <500 cells/ml (from 14 weeks of gestation onward) on cART. Currently the option B+ treatment strategy states that all pregnant women, irrespective of CD4 count, be placed on lifelong cART as soon as possible to reduce their viral load and prevent MTCT and all breastfeeding women should also receive lifelong cART (Chappell and Cohn 2014).

The use of antiretroviral drugs in PMTCT has led to substantial reductions in MTCT of HIV, however; the goal to eliminate MTCT (EMTCT) is still paramount. The Global Plan launched by the WHO in 2011 targets a reduction in MTCT by 90% (WHO 2011) with the WHO developing guidelines in 2014 on integrated approaches for EMTCT and methods for validation of EMTCT (WHO 2014). The EMTCT of HIV is defined by the WHO as less than 50 paediatric infections per 100,000 live births and a transmission rate of either <5% for breastfed babies or <2% for non-breastfed babies. Additionally, 95% of pregnant women must be receiving antenatal care, HIV testing, and subsequent treatment if HIV positive. Cuba was the first country to receive validation for the EMTCT of HIV in 2015 Caffe et al. 2016), followed by Belarus, Thailand, and Armenia in 2016 (WHO 2016). Showing positive results in PMTCT, were Botswana, Mozambique, Namibia, South Africa, Swaziland, and Uganda (six priority countries identified by the WHO), which all achieved the Global Plan target of reducing PMTCT by 90% in 2015 (UNAIDS 2016a). An additional 14 priority countries still require achievement of the Global Plan and/or EMTCT goals. Interestingly, all these countries, except Nigeria, rolled out

option B+ for PMTCT in 2015 and consequently experienced a decline in AIDS-related deaths among females of reproductive age between 2009–2015 (UNAIDS 2016a).

In addition to a decline in PMTCT by 90% in 2015, the Global Plan also set a target for countries to achieve a reduction in MTCT rate to <5% among women that breast fed and <2% among non-breastfeeding women. The 21 Global Plan priority countries collectively demonstrated a decrease in MTCT among breastfeeding women from 22.4% to 8.9% between 2009 and 2015 (UNAIDS 2014) showing decline in the direction of the target.

There are still various challenges that need to be addressed in order to achieve EMTCT, particularly in low- and middle-income settings. The main issues hindering EMTCT in these regions include: delays in seeking pre-natal care, misperceptions over exclusive breastfeeding, HIV discrimination and stigma, lack of resources at a clinic and country level, long waiting times for HIV results for infants, side-effects of treatment, gender dynamics and cultural beliefs (UNAIDS 2014, 2016). These challenges highlight the need for interventions that go beyond the implementation of therapeutics and speaks to the need for a vaccination or cure. Furthermore, it highlights the fact that to achieve EMTCT a decline in incidence of HIV in adults is essential.

Preventing sexual transmission of HIV

There is no risk of HIV infection among those who practice sexual abstinence or lifelong mutual monogamy. Serial monogamy, where there are multiple sequential individual short-lived monogamous partnerships, is associated with an increased risk of HIV, but not to the same extent as the substantial increase in risk of transmission emanating from multiple concurrent sexual partnerships. Reduction in the number of concurrent sexual partnerships and the use of condoms are key components of HIV prevention messages, widely promoted as part of ‘ABC’ campaigns promoting Abstinence, Be faithful, and Condom use. Since 2010, this prevention mantra has been expanded to include knowledge of HIV status; medical male circumcision, pre-exposure prophylaxis (PrEP), and test and treat.

Male and female condoms

Condoms are a pivotal component of the fight against HIV/AIDS. They are inexpensive and relatively easy to use and provide protection against acquisition and transmission of HIV, a wide range of other sexually transmitted infections as well as pregnancy (i.e. an available multipurpose technology).

When used correctly and consistently, the male and female condom is highly effective in preventing the sexual transmission of HIV. The strongest evidence for the role of condoms in preventing the transmission of HIV comes from sero-discordant couple studies, which uniformly show that increased condom use is associated with a substantially reduced risk of HIV transmission.

Despite their increasing accessibility and proven effectiveness in prevention of HIV, a wide range of factors have been implicated as barriers to condom use; the most common being the widespread perception that condoms reduce sexual pleasure and that suggesting the use of condoms represents self-acknowledgement of HIV infection or a lack of trust in the partner. In the context of a marital relationship or stable partnership where pregnancy is desired, or where subordination of women limits their ability to negotiate safer sex practices, attempts to introduce or promote condom use have had limited success.

Several studies have demonstrated that alcohol consumption is associated with inconsistent condom use; this poses a challenge to individuals who meet high-risk sexual partners in social settings where alcohol is available. Condom use is lower in partnerships where an effective form of contraception is being used. This points to the need for interventions that promote dual method use (the simultaneous use of condoms with another form of contraception) among high-risk women.

Sexually transmitted infections

HIV transmission and acquisition during intercourse is enhanced in the presence of sexually transmitted infections, particularly ulcerative infections such as syphilis, chancroid and herpes simplex type 2 virus (HSV-2) infection (Wald and Link 2002; Freeman et al. 2006). Genital ulceration or inflammation caused by sexually transmitted infections increase the infectiousness of HIV-positive individuals and the susceptibility of HIV-

negative individuals. Although only one randomized controlled trial has been able to demonstrate a significant reduction in HIV incidence rates following treatment of sexually transmitted infections (Grosskurth et al. 2000), the significant sexual and reproductive health challenge posed by the high burden of curable sexually transmitted infections needs to be addressed in any HIV prevention effort.

Medical male circumcision

Medical male circumcision is a proven HIV prevention option for men, reducing the risk of female-to-male transmission of HIV by up to 60% (Siegfried et al. 2009). Medical male circumcision has become a priority component of HIV prevention globally. Introduced in 2007, the number of medical male circumcisions has increased from just 5,190 in 2008 to approximately 14.5 million in 2016. Evidence of a population level impact of circumcision in South Africa has recently become available from Orange Farm, where an increase in the male circumcision rate from 12% in 2007 to 53% in 2010 was associated with a 57% reduction in HIV incidence rates (Auvert et al. 2013).

Use of antiretrovirals as PrEP for HIV prevention

In addition to treatment benefits, the prophylactic use of antiretroviral drugs has generated new hope in the HIV prevention landscape. Since July 2010, when ARVs were first shown by the CAPRISA 004 trial (Abdool Karim et al. 2010) to prevent sexual transmission of HIV, the HIV prevention landscape has been transformed, principally through oral tenofovir (TFV)-containing PrEP (Grant et al. 2010; Baeten et al. 2012; Thigpen et al. 2012; Van Damme et al. 2012a; Marrazzo et al. 2015; McCormack et al. 2015).

Although daily oral TDF/FTC has been demonstrated to be consistently effective in MSM and transgender women globally (Grant et al. 2010; McCormack et al. 2015), the results of clinical trials in African women have been inconsistent, most likely due to varying levels of adherence (Thigpen et al. 2012; Baeten et al. 2012; Van Damme et al. 2012a; Marrazzo et al. 2015). In the FEM-PREP trial (Van Damme et al. 2012b) for example, only 24% of the women allocated to the daily oral TDF/FTC group had detectable drug levels. Similarly, in the VOICE trial, only 25%, 29%, and 30% of women

allocated to the daily tenofovir gel, daily oral TDF/FTC and daily oral TDF groups respectively had detectable drug levels (Marrazzo et al. 2015). The challenge of adherence, however, is not simply a behavioural issue. Women are more likely than men to require near-perfect adherence to oral PrEP in order to be protected against HIV (Donnell et al. 2014), indicating that biological factors may also be important to consider. Genital inflammation has been shown to be an independent risk factor for HIV acquisition (Masson et al. 2015) and affects PrEP effectiveness in women (McKinnon et al. 2018). Deep sequencing techniques have shed light on the cause of genital inflammation showing that anaerobic vaginal bacteria, which is common in a dysbiotic vaginal microbiome, is associated with both genital inflammation and HIV risk (Williams and Passmore 2016). Using proteomics, it was recently shown that a dysbiotic vaginal microbiome, comprising <50% *Lactobacillus* spp., directly influenced topical PrEP efficacy (Klatt et al. 2017).

Despite the adherence challenges, oral PrEP is an important HIV prevention option and is now being implemented as part of a comprehensive HIV prevention package in several countries. In industrialized countries, high drug costs remain a major barrier. An increase in sexually transmitted infections has been observed among PrEP users underscoring the importance of barrier protection in addition to PrEP use. Important research is currently underway with novel ARVs and delivery mechanisms that are less user dependent.

Treatment as prevention

There is now compelling evidence from the landmark HPTN 052 trial that antiretroviral treatment of HIV-infected individuals can prevent sexual transmission of HIV (Quinn et al. 2000). Early antiretroviral treatment initiation in the HIV-positive partner showed that HIV transmission was reduced by 96% in HIV discordant couples from nine countries (HPTN052) (Cohen et al. 2016). Taken in conjunction with other observational data, which show significant reductions in HIV transmission among serodiscordant couples receiving ART, onward transmission of HIV can be significantly reduced if viral load is suppressed through ART. This added benefit of cART and viral suppression for preventing HIV infection in

uninfected persons is also increasingly being used as a prevention option captured as ‘undetectable equals uninfectious’ or abbreviated to U=U.

Modern technologies

In recognition of stigma and discrimination as a barrier to test and treat for HIV, modern communication strategies have been introduced to encourage HIV testing, treatment, and support ARV adherence. These strategies include the eHealth and mHealth technologies (Muessig et al. 2015). eHealth is designed to deploy educational messages, to people at risk, either electronically or via a message on a website which the person frequents. To date, eHealth has targeted the MSM population with gay organizations utilizing the tool to develop websites frequented by gay individuals to deliver both educational information and referrals to gay-friendly test and treat sites (Sullivan et al. 2013; Muessig et al. 2015).

Similarly, mHealth, utilizes social media applications (apps) to deliver tailored HIV/AIDS messages to users via their mobile devices or tablets. This technology has for example been incorporated into the Blued app (Blued app 2009), a Chinese gay dating app, which allows the delivery of HIV/AIDS educational messages and messages encouraging testing for HIV via the use of ‘non-judgemental community mobilization campaigns’. In addition to this, mHealth also offers options to encourage ARV adherence, by reminding patients to take pills and asking patients to indicate if pills were taken. The technology also provides reminders to patients for clinic visits.

Phylogenetics, the use of viral sequences from recently infected individuals in a common social network (Villandré et al. 2019) or geographically defined area (de Oliveira et al. 2017), is being used to understand transmission dynamics better and enhancing surveillance efforts and informing more targeted and efficient approaches for responding to HIV.

Microbiome analysis (Williams and Passmore 2016) and proteomics (Klatt et al. 2017) is advancing our understanding of the role of biology in rendering some women more vulnerable to HIV compared to others or the role the microbiome plays in reducing the potency of prophylactic use of ARVs.

Injecting drug use

IDU represents a major risk factor for HIV infection, often of the opiate heroin. It has been estimated that one in ten new HIV infections is caused by sharing of contaminated needles (AIDS Alliance 2016). Approximately one-third of all new HIV infections in regions outside of sub-Saharan Africa occur among people who inject drugs (PWID) (Harm Reduction International 2016a; UNODC 2016). Collectively, China, Russia, and the USA account for 50% of all PWID worldwide and contribute the most to HIV infections among this group (Harm Reduction International 2016a). Eastern Europe and central Asia also have high burdens of PWID, with half of all new HIV infections in these regions occurring among PWID (Harm Reduction International 2016b). Despite PWID categorized as a priority group for HIV prevention and treatment, they represent a group with the least access to treatment, prevention, and testing programmes. This is driven by the legislation, criminalization, and stigma associated with drug use, which detracts PWID from utilizing healthcare and harm reduction programmes (UNAIDS 2016b). The high susceptibility to HIV in this group, is further driven by the criminalization associated with distribution or possession of syringes or needles for non-medical purposes in some regions, which encourages sharing of used needles (Beletsky et al. 2012a, 2012b).

Despite PWID representing a key population independently, there is also bridging between sex workers and drug addiction. Mongolia, Afghanistan, and central Asia have reported a 20 times increased risk of HIV infection in sex workers who inject drugs compared to those who do not inject drugs (Baral et al. 2013). This overlap demonstrates the importance of HIV treatment and prevention programmes for this key population as they place other populations at risk for HIV acquisition as well.

To date, interventions aimed at reducing the risk of HIV acquisition in PWID include needle and syringe programmes (NSPs), opioid substitution therapy (OST) and the use of PrEP, often referred to as harm reduction initiatives, with evidence suggesting a combination of these approaches should be used in PWID (Degenhardt et al. 2010).

NSPs aim not only to reduce the transmission of HIV, but also that of other blood borne infections such as hepatitis C and B. Some programmes provide 200 sterile needles per drug user per year, some sites also provide equipment to prepare drugs such as sterile water, filters and mixing containers. In addition to this, some programmes employ interventions to reduce harm associated with IDU such as; provision of advice on how to

inject drugs safely, information on how to prevent and manage overdoses, information on how to handle and safely dispose of needles and syringes and provision of referrals for HIV testing and treatment and other health services (NICE 2014). Some NSPs are delivered via; fixed sites, mobile units, peer-NSP programmes, street outreach, backpacking services, home delivery, syringe vending machines and pharmacies (Obadia et al. 1999; Riley et al. 2000; WHO 2007; Bryant et al. 2010; Jain et al. 2014). Despite demonstrating success in reduction of HIV incidence among PWID (Jones et al. 2010; Palmateer et al. 2010; Abdul-Quader et al. 2013; Aspinall et al. 2014; MacArthur et al. 2014), the NSP has only been implemented in 90 countries out of the 158 in which it is required in (Harm Reduction International 2016b).

While all 29 regions in eastern Europe and central Asia have NSPs, the success of these programmes are hindered by hostile political reactions and inadequate government support which has forced some NSPs to shut down (Harm Reduction International 2016b). Within Asia and the Pacific, only 17 countries have NSPs with the lack of NSPs in this region driven by harsh drug policies, inflexible working hours, reduction in funding and human resource issues (Harm Reduction International 2016b). The coverage of NSPs is high in western and central Europe and North America, particularly in Canada were an estimated 94.5% of PWID reported to have used a clean needle on last injection. Many countries within Europe though are seeing declines in the number of operational NSPs and have various PWID that are not reached due to people <18 years of age being denied access to services and immigrants not being reached due to underdeveloped services in areas where they live. Latin America, the Middle East, and North Africa all have limited NSPs, which are not adequate for reaching the required number of PWID in the region. Here, criminalization of drug use, restriction of operating hours, inadequate resources, and poorly trained staff contribute to the inadequacy of the existing programmes. Within sub-Saharan Africa, NSPs only exist in five out of 54 countries due to a lack of political will and government support and funding (Harm Reduction International 2016b).

In addition to NSP, OST, a medication-assisted treatment (MAT), is also used to manage injecting drug use and reduce associated harm among PWID. OST provides illegal drug users with replacement medication (i.e. opioids), most often methadone maintenance therapy (MMT) and sometimes buprenorphine, administered orally in a supervised clinical environment.

Various studies have demonstrated the success of OST in reducing the frequency of injection use, improving health and social functioning, improving ARV use, improving linkage to health services, and reducing crime and unsafe injecting practices, particularly in developed countries (Lawrinson et al. 2008; Weber et al. 2009; Gowing et al. 2011; Vorma et al. 2013). Studies also reported a 54% reduction in HIV transmission among PWID with the use of OST (Riley et al. 2000; Aspinall et al. 2014). Studies have also shown that the more time PWID spend on opioid therapy the more positive their health outcomes and less likely they are to engage in risky behaviour (Kumar et al. 2009). Despite the success of OST, it is estimated that only 8% of PWID have access to this intervention. A recent systematic review of coverage of interventions to prevent and manage HIV among PWID shows that there is a high coverage of both NSP and OST in Australia, the Netherlands, Austria, and Norway, moderate coverage in Canada, New Zealand and Vietnam and low coverage in China, Indonesia, Tanzania and several other developing regions while places like the Russian federation have very limited access to NSP and do not provide OST (LArney et al. 2017). This has been attributed to social and structural discrimination, stringent laws that criminalize drug use and the lack of political will to implement interventions like OST due to the belief that abstinence of drug use is the only successful method to treat drug addiction (Connock et al. 2007; Jurgens et al. 2010; Kermode et al. 2011).

Oral PrEP, a daily course of ARVs, which protects HIV-negative individuals from HIV acquisition prior to exposure to the virus, is also a recommended method to reduce HIV transmission among PWID. Oral PrEP typically comprises of a combination of TDF and FTC combined as a single pill Truvada. The success of oral PrEP in reducing HIV transmission among PWID has been reported, however, the high cost of oral PrEP is a major factor hindering its large-scale implementation for PWID (Choopanya et al. 2013; Fu et al. 2018).

Although there is strong evidence to show that NSPs and OST reduce injecting use behaviours and HIV transmission by 48% and 54% respectively, there are still barriers to their implementation in most regions (Aspinall et al. 2014; MacArthur et al. 2014) predominantly driven by the criminalization and stigma associated with drug use and the lack of political support and government funding. While oral PrEP offers an alternate route that is somewhat less controversial and possibly more accessible than OST

and NSP, it comes with its own setback of high costing and does not lower the prevalence of HCV and drug-related infections unless additional drugs are included. It must be recognized that prevention of HIV among PWID has far-reaching consequences on sex workers and on the general population as these individuals overlap and thus reducing incidence of HIV in one group could likely translate to reducing its incidence in various other groups.

Conclusion

Notwithstanding the enormous scientific progress and programmatic success in initiating almost 22 million infected persons on cART and reducing vertical transmission rates to <1%; in 2017, globally there were about 1 million AIDS-related deaths, 1.8 million new HIV infection and about 37 million people living with HIV. These data underscore the challenges that continue to face us. Much more needs to be done to prevent new HIV infections and reach and facilitate access to services by key and priority populations.

While globally, we are on track with meeting the 2020 intermediate targets for treatment; prevention of new infections remains a major challenge with only about 15% reduction in new HIV infections we are way off the 2020 target of 500,000 new infections. Stigma and discrimination, real or perceived, remains a major barrier to knowledge of HIV status or seeking prevention or care services by key and priority populations.

Several countries have reached their 2020 targets and are well on their way to reaching their 2030 ending AIDS goal. Most countries are at different stages of progress towards reaching this 2020 intermediate goal. There is increasing recognition that 90–90–90 treatment targets alone will not be sufficient to get us to the 2030 UN goal of ending AIDS.

Despite huge progress on prevention science research, preventing HIV infection remains a major challenge with little impact on reductions in incidence rates in the past 6 years. With approximately 5,000 new HIV infections occurring each day globally, ending AIDS will remain an elusive goal. Combinations of stigma and discrimination, marginalization, moral and judgemental attitudes, and criminalization of populations on the basis of sexual orientation, occupation or age remain barriers to knowledge of HIV status and access to HIV testing and much needed treatment and prevention services. According to the 2018 UNAIDS report, it is estimated that as much

as 9.4 million HIV-infected individuals globally and much higher proportions in some countries do not know they are infected and, therefore, get neither tested nor treated. It is recognized that transmission persists because of these untested infected individuals and inadequately treated individuals continuing to engage in high risk activities. Peer-led interventions that engage and partner with key and priority populations and communities is critical to reach those we are not reaching with typical healthcare delivery systems and approaches. Given the diversity of epidemics within and between countries in terms of magnitude, modes of transmission and populations at risk no single approach will address all the challenges and implementation science and programming needs to identify optimal combinations of interventions and strategies needed at a local level for prevention success.

Investments in novel prevention approaches need to continue including for the development of a vaccine and a cure to realize the 2030 ending AIDS goal as well as eventually eliminating and eradicating HIV. At the heart of our response and success to date are courageous advocates and people whose rights have to be respected and who have to continue to be part of our responses for success.

Tuberculosis

Roxana Rustomjee

Introduction

Tuberculosis (TB) is the greatest of human scourges, leaving no population in the world unaffected and wreaking havoc since time immemorial. It has exacted a death toll of over a billion human lives since the 1900s, more than any other disease, despite being a treatable and preventable condition (Paulson 2013). This global health catastrophe represents the biggest failure in public health delivery, together with one of the slowest efforts in discovery of new drugs and a paucity in the fundamental understanding of various disease processes. As a result, TB research has suffered from the lack of novel interventions, with a single new diagnostic introduced in 1998 and only two entirely new drugs since the 1950s. Reaching elimination targets, as set out by the World Health Organization (WHO) End TB Strategy therefore presents as a formidable challenge (WHO End TB Strategy http://www.who.int/tb/strategy/en/).

Over the past two decades, addressing the impact of the HIV epidemic on TB disease burden; together with a redoubled effort at TB control; including the implementation of new diagnostics and treatments, has led to a reduction in the global burden of disease (Maher et al. 2007). Nevertheless, the road ahead is not for the faint-hearted. Solutions for ending TB are complex and rooted as much in closing the knowledge gap in understanding pathogenesis as they are in the rapid discovery and deployment of diagnostics drugs and vaccines. In addition, remedying and reorienting the health systems and addressing the economic, social, and behavioural drivers of disease are imperative. It is time to dispel dogma and to take bold and unchartered measures in effecting change, starting with appropriately allocating resources and rapidly translating research findings into policy and practice.

TB is an ‘indicator disease’ of global poverty and inequality (Fox et al. 2017). Prior to the discovery of antibiotics, the ‘Papworth Experiment’ (1918 to 1943) found that improving the social context through improvements in employment, nutrition, and housing reduced TB incidence in children. In contrast the TB incidence rate rapidly, increased post World Wars when populations faced widespread poverty (Fox et al. 2017). The WHO’s ‘End TB Strategy’, which aims to end the global TB epidemic by 2035 while reducing TB deaths by 95% and incidence rates by 90% between 2015 and 2030, emphasizes the role of poverty alleviation, human rights and equity within an effective biomedical and public health response (WHO End TB Strategy http://www.who.int/tb/strategy/en/; Lonnroth et al. 2010; Lonnroth and Raviglione 2016; Fox et al. 2017). This chapter while focussing on biomedical intervention does not minimize the relative contribution of improved socioeconomic status and behavioural interventions in bringing TB to an end.

Burden of TB and global trends

The WHO reported 6.3 million newly notified cases of TB worldwide in 2016 and estimated that TB incidence and mortality appear to be on the decline by about 3% and 2% per year, respectively (WHO 2017). TB incidence is falling at about 2% per year and 16% of TB cases die from the disease. These estimates fall short of the projected 4–5% per year and 10%, respectively, required to reach the 2020 milestones of the End TB Strategy. While the fastest decline in TB incidence has been in the WHO European Region (4.6% from 2015 to 2016); notably, the decline since 2010 has also exceeded 4% per year in several high-TB burden countries, including Ethiopia, Kenya, Lesotho, Namibia, the Russian Federation, Tanzania, Zambia, and Zimbabwe. Twenty-two high-burden, low- to middle-income countries, collectively account for 80% of the global TB burden. The annual number of incident TB cases was under 10 per 100 000 population in most high-income countries; to 150–300 in most of the high-TB burden countries; and above 500 in a few countries including the Democratic People’s Republic of Korea, Lesotho, Mozambique, the Philippines, and South Africa. Alarmingly, almost 39% of cases remain unreported bringing the estimated incidence of TB in the world to approximately 10.4 million; of which 90% were adults and 10% were people living with HIV (PLHIV). In

southern Africa, HIV stands out as the key driver of the TB epidemic as it creates a large pool of susceptible individuals who are either vulnerable to infection or progression from latent infection to active disease (WHO 2017).

Drug-resistant (DR) TB is a continuing threat with 600,000 new cases of resistance to rifampicin (RRTB), the most effective first-line drug, of which 490,000 had multidrug-resistant TB (MDR-TB) and 6.2% of those cases identified as extensively drug-resistant TB (XDR-TB) (WHO 2017). Almost half (47%) of DR cases were in India, China, and the Russian Federation, the majority of whom (72%) remain untreated. A total of 129 689 individuals are initiated on treatment for drug-resistant TB, representing only 22%, with treatment success remaining at a 54% global low. Under-reporting and linkages to care remain a key challenge, particularly for countries in Asia and Africa (WHO 2017).

TB infection

A further 1.7 billion people (close to a quarter of the world's population) are estimated to be infected with *Mycobacterium tuberculosis*, representing a huge reservoir of potential TB disease (Houben and Dodd 2016). **ORCID** http://orcid.org/0000-0001-5825-9347 This substantial number of infected cases highlights ongoing transmission of TB in households and communities and underscores an urgent need for transmission blocking strategies. Progression to active TB occurs in 5–15% of individuals (http://www.who.int/mediacentre/factsheets/fs104/en/). The precise mechanism of disease progression and the complex host-pathogen interactions that are associated with this remain unknown. Traditionally, we have distinguished 'latent infection' from 'active TB' and responded distinctly to these two compartmentalized states both in individual treatment and public health responses. We prefer to describe the disease process as a spectrum of five different states ranging from immunity to TB disease to lack of immune control and active disease (Barry et al. 2009). Following exposure to *M. tuberculosis*, infection may either be eliminated by the innate immune response (without the need for T-cell priming) or eliminated following development of an acquired immune response. Among those who are unable to prevent or eliminate infection following exposure, the majority establish and maintain immune control. Such individuals typically have evidence of T-cell priming and maintain low bacillary numbers that are

difficult to detect or quantify using current diagnosis. A subsequent shift in the host-pathogen balance may permit active mycobacterial replication, leading to subclinical active infection (or incipient TB). The relationship between ‘latent’ and active infection is likely to be a dynamic one over time with bidirectional shifts between the two. Loss of immune control and escalating mycobacterial load, may subsequently lead to the development of symptoms and overt clinical disease as we outline in Figure 8.14.1. Thus, what has been referred to as latent TB infection may represent a dynamic balance between the organisms in a range of metabolic states and variations in immune control. Understanding ‘latent TB infection’ as a spectrum of immune responses, mycobacterial metabolic activity, and organism load redefines approaches to screening, diagnosis, and prevention of TB. An appreciation of these complexities directs the goals for the development of new vaccines and biomarker discovery and emphasizes the effect of HIV on TB reactivation. Also important is the pivotal role of antiretrovirals in regaining immune control of active infection in HIV-infected people. HIV infection is the most potent risk factor for the development of active TB disease. Recurrent TB, due to exogenous re-exposure to *M. tuberculosis* in high-TB prevalence settings is also very likely to play a key role, further increasing bacillary numbers and enhancing the likelihood of progression to disease. Here we consider implications of latent infection for disease control strategies because any strategy aimed at TB elimination needs to address this reservoir of potential infection and disease. Central to this is increasing the fundamental understanding of host factors, including host genetics as well as where bacteria are located during the early stages of TB infection, and whether different locations and environments affect bacterial behaviour and treatment response. Another important question that arises is how similar is the bacterial metabolism along the spectrum between infection and disease? If there are differences, how do we define vulnerable drug targets for latent TB infection? Answering these questions is limited by the inability to meaningfully sample bacteria from latently infected individuals. These knowledge gaps should be addressed simultaneously, as interventions to prevent TB progression evolve.

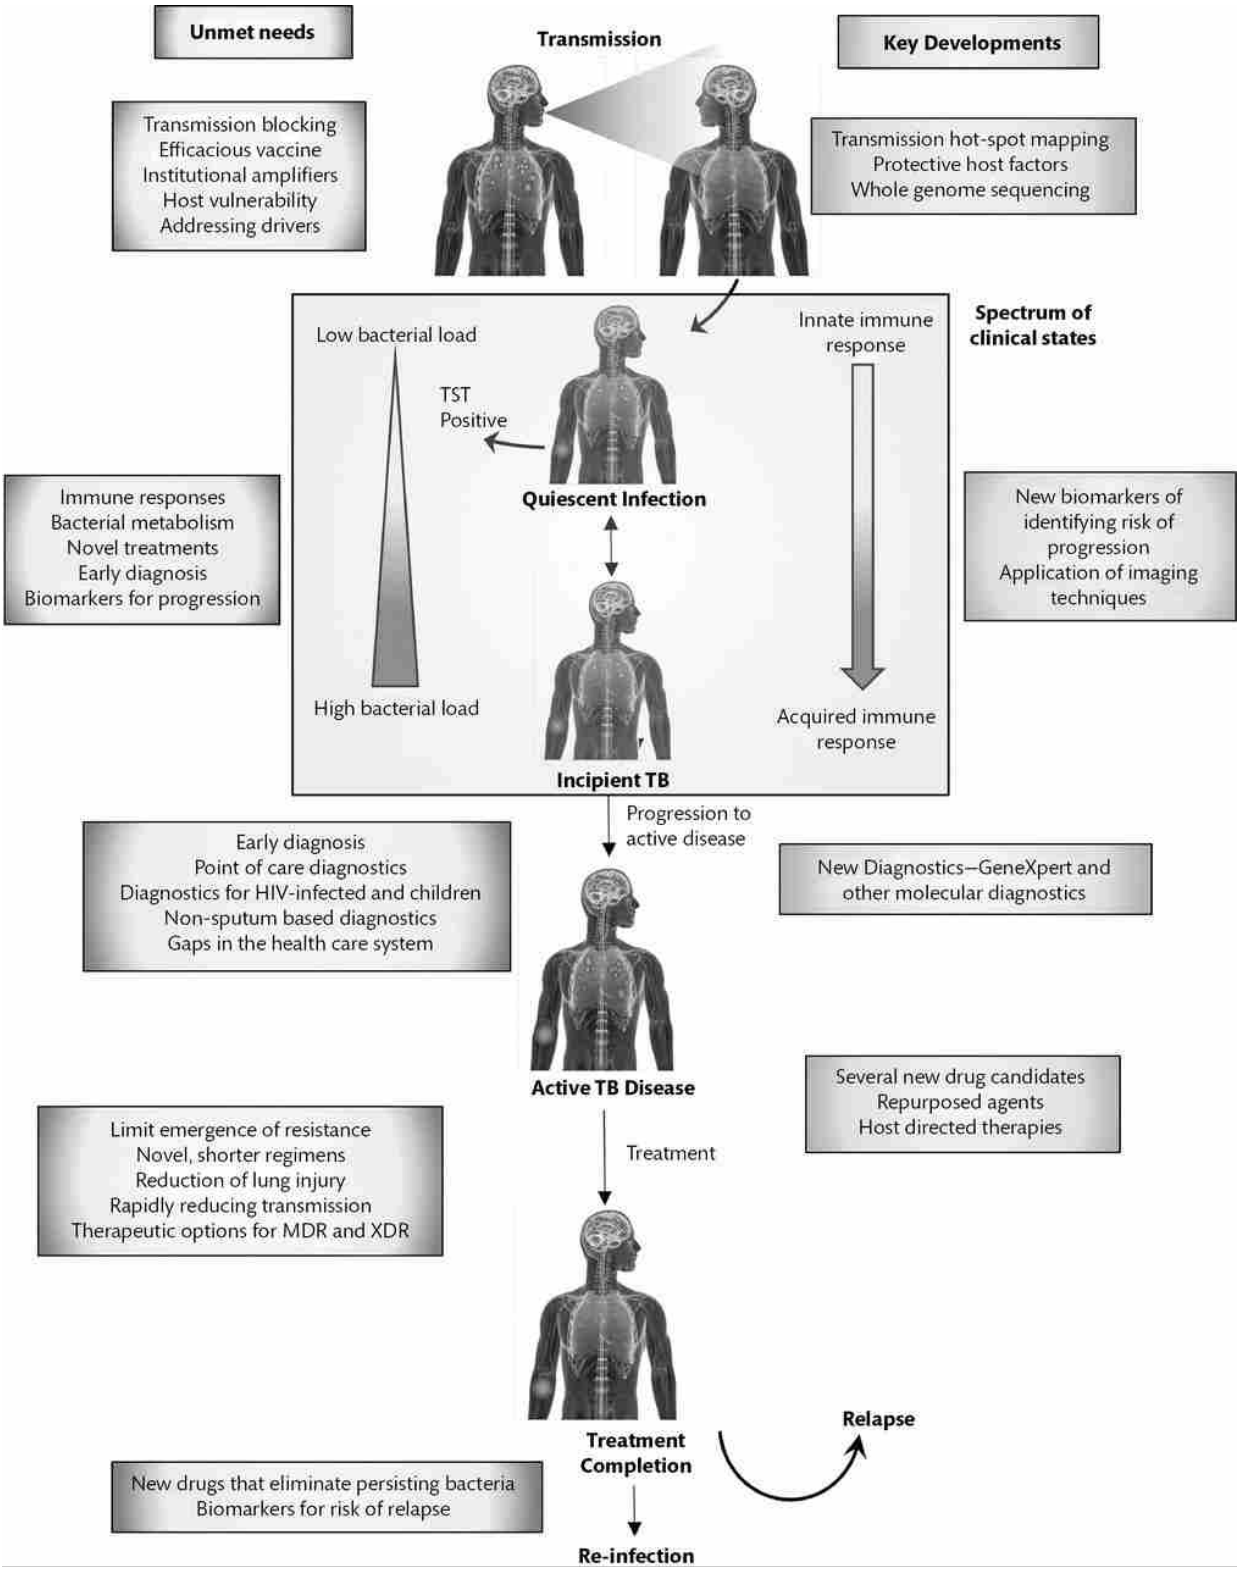

Fig. 8.14.1 Unmet needs and key developments for TB eradication. Shown are the unmet needs and key developments for specific stages of disease. TB transmission is a complex process and blocking transmission is critical to eliminating TB. After infection, a spectrum of infected states is expected to

prevail. These vary in bacterial load and immune responses with increasing bacterial loads reflecting a progression to active disease. Early identification of those individuals that will progress to active disease, using biomarkers, will allow for targeting preventive treatment to the most vulnerable populations. Diagnosis of active TB and rapid engagement into care requires novel diagnostics and addressing gaps in the healthcare system. New TB drugs that shorten duration of therapy and achieve non-relapsing cure are urgently needed.

Interventions to prevent TB progression

Isoniazid preventive therapy (IPT) has been used successfully since the 1950s as part of a comprehensive control strategy to halt transmission at the population level and reduces the risk of active TB by 60%, at the individual level. The Thibela TB trial (2006–2011), where South African mining workforces were randomized to mass IPT or standard of care (mine health services provided comprehensive free medical care. This included tuberculosis diagnostic and treatment services, HIV testing, and antiretroviral therapy), was aimed at interrupting TB transmission by mass screening linked to treatment of either active disease or latent infection (Churchyard et al. 2014). However, the intervention did not reduce TB incidence or prevalence, most likely due to multiple factors including uptake and adherence. Several studies evaluating prevention of drug-susceptible TB infection are underway and use novel drugs or drug combinations (Tiberi et al. 2018). These innovative therapeutic approaches propose to either decrease treatment duration or improve on drug delivery mechanisms. A recent trial (A5279 study; NCT01404312) demonstrated that a 1-month course of weekly isoniazid/rifapentine (INH/RPT), was found to be safe and effective when compared with the usual 9-month course of isoniazid alone in people with HIV infection (Swindells et al. 2018). These results offer HIV-positive individuals who are at risk of developing active TB an additional, shorter-duration prevention option that is safe, effective, and more convenient. Results from other trials simplifying preventive therapy are expected in 2018 including a three-arm comparison between 3-month HP (H-isoniazid, P-pyrazinamide), 9-month H and intermittent 3HP (the WHIP3TB study; NCT02980016) among PLHIV; as well as, a 4 months of rifampicin (4R) vs. 9 months of isoniazid (9H) in adults and children with TB infection (NCT00931736). Further, supervised weekly 3HP is being compared to isoniazid among pregnant and post-partum women (P2001;

NCT02651259). The results of these studies are long awaited and if successful, will greatly simplify preventive therapeutic options.

Nevertheless, the main limitation of widespread TB prophylaxis remains the scalability to entire populations where more than 80% of the adult population is likely to be infected with only a small proportion (<10%) are at risk for progression to active disease. Recent advances in the discovery of correlates of risk, identify inflammatory signals in blood cells from healthy persons that reveal the process of progression from infection to active TB enabling a targeted 'test and treat' approach to TB infection. The CORTIS (Correlate of Risk Targeted Intervention Study) is evaluating the effectiveness of 3HP for high-risk individuals, with the treatment decision based upon a 16-gene, blood-based transcriptional (RNA) biomarker (NCT02735590) (Zak et al. 2016). This approach enables the prospective evaluation of treatment to be targeted to those at elevated risk of developing active TB. If successful, it may result in a point-of-care tool that would have potential to majorly impact the global burden of TB.

With the high prevalence of strains resistant to first-line anti-TB drugs, where isoniazid and rifampin derivatives are of limited utility, different approaches will be needed especially in the absence of international prophylaxis guidelines. If an index case has MDR or XDR-TB, testing of household contacts has revealed significant numbers already infected with latent or active TB infection. Not all household contacts are infected by the same strain as the index case however, significant numbers (10–80% depending on the study) may have been infected by a discordant (sometimes sensitive) strain in the community (Moore 2016). Several drugs or combinations of drugs including fluoroquinolones, ethambutol, pyrazinamide, and ethionamide have been assessed in small trials but none can, at present, be recommended. Most are toxic and even 6 months of treatment cannot be completed by the majority of patients (Moore 2016). For drug-resistant infection, three randomized controlled trials are underway. Six months of daily levofloxacin is being compared to placebo for individuals with presumptive multidrug-resistant TB in the VQUIN MDR Trial (ACTRN12616000215426), in adults, and the TB CHAMP study (ISRCTN92634082), in children under 5 years). In the PHOENIX MDR-TB Trial (https://www.actgnetwork.org/newsletter/oct2015/phoenix), six months of delamanid plus isoniazid will be compared with 6 months of isoniazid alone for patients with MDR- or extensively drug-resistant TB. Results are

expected around 2021. In planning interventions to interrupt transmission through preventive therapy, the epidemiological and health system context must be considered. Population-level impact may not follow unless other interventions (including active case finding linked to effective treatment) are deployed.

The assessment of complete sterilization of TB infection is a far greater challenge because unlike in active disease, where the bacterial burden reduces measurably from high detectable levels to little or no bacteria, the levels of bacteria and antigen present in latent TB infection are very low and discerning clearance is more challenging. Identifying a signature of persistence versus bacterial clearance could aid in identifying those individuals at highest risk for progressing to TB and direct them for TB infection treatment.

Interventions to halt the transmission of TB

Ultimately, it is not simply enough to decrease TB incidence by preventing cases through prophylaxis targeted at close contacts, it is also necessary to understand the strategy and type of interventions most likely to avert the largest proportion of transmission events at the population level. There should be a specific focus on those events that result in secondary cases of infectious TB. As an example, in settings where transmission originates largely from specific and identifiable populations (e.g. young adult men) (Dodd et al. 2016), it may be feasible to target case-finding efforts in those groups. Where reactivation is common in high-risk groups, e.g. HIV-positive individuals (Pretorius et al. 2014), people with risk factors such as diabetes or malnutrition (Odone et al. 2014), elderly populations (Prince et al. 2015), it may be critical to target preventive therapy to those populations. In congregate settings (e.g. prisons or healthcare institutions), infection control and modification of the environment can have major impact in reducing transmission. The key issues include addressing drivers of transmission, measuring transmission, and identifying novel transmission blocking strategies (Shah et al. 2017). The variable success of preventive therapy interventions, alongside a growing number of studies demonstrating that close contacts only account for a minority of transmission events (Verver et al. 2004; Mathema et al. 2006; Chamie et al. 2015; Glynn et al. 2015; Shah et al. 2017) indicate that our current tools and approach for interrupting

transmission are inadequate. Additional gaps in our understanding of the biology and local determinants of transmission underscore the need for more effort in this area.

Drivers of TB transmission

Recent evidence from endemic countries, with varying levels of HIV and drug-resistant TB, implicate ongoing transmission as the driving force maintaining high levels of TB incidence (Li et al. 2007; Becerra et al. 2011; Shah et al. 2017). Drivers of transmission can be seen as a cascade in three stages: (1) sharing of air between infectious and susceptible individuals; (2) infectiousness of an index case; and (3) susceptibility to disease of other exposed individuals (Dowdy et al. 2014). These stages are heterogeneous at regional and national levels and the relative role of each stage is heavily dictated by local attributes including access to healthcare, population age structure, population density and migration (Wood et al. 2010; Liu et al. 2012). Variations in individual host susceptibility, in line with the local prevalence of HIV, diabetes mellitus, and silicosis, can also dramatically alter the transmission cascade (Murray et al. 1996; Hanifa et al. 2009). The strength of local TB control programmes in terms of case finding and treatment strategies is yet another factor that can affect local transmission dynamics. A larger proportion of undiagnosed or untreated patients will contribute to ongoing transmission in a community. This heterogeneity of transmission poses a substantial challenge to TB control. To design efficacious and efficient TB control strategies, it will be necessary to delineate the relative contribution of the various drivers of TB in different settings. Ultimately, drivers of transmission, including, but not limited to infectiousness of index cases, susceptibility of contacts as well poverty, overcrowding, health seeking behaviour, and institutional drivers must be studied and understood at a local level.

Measuring levels of TB transmission

The prolonged natural history of TB means that observed cases of disease reflect a combination of recent transmission and recurrent disease, the latter made up of reactivation and exogenous reinfection. In addition, most cases observed via passive case finding systems (self-referral of patients to

healthcare providers), underestimate the number of undiagnosed, but diagnosable, infectious individuals in the community. Current methods to measure transmission include examining case notification rates and trends in tuberculin skin test (TST) or interferon-gamma release assays (IGRA). However, real-time, definitive diagnosis of recent exposure to *M. tuberculosis* at the individual level is not possible with any of the currently available tests (e.g. TST, IGRA, chest X-ray, sputum analysis). A biomarker of recent exposure as described, but not limited to, the CORTIS trial, would enable precisely targeted preventive therapy and accelerate identification of TB 'hotspots'—areas of high-TB incidence—for earlier and more effective implementation of infection control measures (Wood et al. 2014). Such hotspot detection and elimination represent an immediate measure to interrupt transmission and reduce the global burden of TB while new drugs, diagnostics, and vaccines are progressing through the product development pipeline. These hotspot communities could also serve as priority areas for piloting new transmission interventions, as they become available (Lee et al. 2015).

More recently, molecular epidemiology utilizing whole-genome sequencing has greatly facilitated studies of patient- and population-level transmission (Verver et al. 2004; Mathema et al. 2006; Glynn et al. 2015) Several studies have aimed to estimate the proportion of transmission that occurs within households by comparing genotypes of cases occurring within households or community settings. These studies have found that in medium- and high-TB burden settings, the majority of TB transmission occurs outside of households or with known close contacts (Chamie et al. 2015; Guerra-Assuncao et al. 2015). As such, the yield of contact investigations as a TB control activity may be lower than traditionally anticipated in such settings. Congregate locations that facilitate air exchange between infectious cases with non-infected individuals, such as transport hubs, churches, school classrooms, and prisons have been implicated as 'hotspots' or institutional amplifiers of transmission and may offer opportunities for targeted interventions (Dowdy et al. 2012; Zelner et al. 2016). However, it is unknown whether other, less obvious sites of congregation, may also be driving ongoing transmission. An integrated approach that combines traditional epidemiology with methods drawn from spatial, demography, and whole-genome analysis will undoubtedly be required to identify such drivers (Davies et al. 2015; Vynnycky et al. 2015).

Halting TB transmission need not be limited to biomedical interventions. Historical data from western Europe, where TB incidence declined 10% annually after the Second World War, demonstrates the impact of socioeconomic development on reducing TB transmission. A broader approach regarding how socioeconomic development may interrupt transmission is desperately need together with systematic testing of interventions for impact, including engaging other government sectors equipped with the power and knowledge needed to accelerate economic development for TB-affected communities.

In addition to the devastating impact of TB on families and communities, ongoing nosocomial TB transmission in clinics and hospitals represents a life-threatening risk to the global healthcare workforce. TB has become an occupational lung disease for providers from high-burden countries, including frontline community health workers, nurses, medical students, and physicians (Naidoo and Jinabhai 2006; Barnagarwala 2014). TB as a personal risk associated with a professional choice is unacceptable in the twenty-first century and must be addressed by national and international professional associations, lest their workers succumb to TB.

Ultimately, both established and new interventions will be required to end TB. Given the variable and possibly non-durable success of preventive therapy, particularly in settings where transmission and the force of infection is very high (Comstock et al. 1967; Hanson et al. 1967; Comstock et al. 1979; Ayles et al. 2013; Churchyard et al. 2014); it is conceivable that any new interventions, including a preventive vaccine, which may protect against a single exposure or a low inoculum; may be ineffective against repeated, high-dose exposures. TB control programmes should therefore reduce ongoing transmission using all available methods. Synergy in reducing TB transmission may be attainable by combining interventions that shrink the reservoir of latent TB infection (preventive therapy), shorten time to treatment (case finding and diagnosis), and prevent transmission in key settings.

Ultimately, there is cause for optimism. There are effective interventions available to target each component of TB transmission (and the analytical tools to demonstrate their effectiveness). Furthermore, the lack of an animal reservoir facilitates focus on human populations, behaviours, and environments. The increasing commitment from researchers, funders, and

policymakers to address transmission of TB is supported by a focus on developing innovative approaches to meet the end TB targets.

New approaches to TB diagnosis

Rapid, early, and accurate diagnosis is critical to timeous anti-TB treatment initiation, monitoring, and ultimately TB control. However, 39% of the estimated 10.4 million estimated cases were either undiagnosed or unreported (WHO 2017). Diagnosis of extrapulmonary TB and TB in children, PLHIV, and pregnant women remains particularly problematic. Furthermore, only 41% of TB cases notified globally were tested for rifampicin resistance and just 22% of the estimated drug-resistant TB incidence were initiated on appropriate treatment (WHO 2017). Diagnostic tools should ideally: (1) identify more TB with highly accurate point-of-care tests and replace smear microscopy; (2) include a simple, low-cost point-of-care triage test to exclude TB; (3) enable universal, rapid DST that informs regimen selection (Denkinger 2017); (4) offer point-of-care (POC) alternatives to sputum-based technologies with capability to detect all forms of TB especially paediatric (Kik et al. 2014). Nevertheless, addressing all these critical gaps in current diagnostic tools, without identifying and treating individuals with TB infection who may later progress to active TB disease (Pai et al. 2016) will greatly hamper progress in reaching TB elimination targets. Therefore, we add a further stipulation (5) to identify and differentiate TB across the spectrum of TB infection.

Sophisticated bioinformatic computational tools and systems biology approaches are being applied to the discovery and validation of biomarkers, resulting in substantial progress in the understanding of T-cell responses and T-cell function, protein, and gene expression studies. Alternative diagnostic strategies under investigation as potential screening and triaging tools include non-sputum-based detection with breath-based tests and automated digital radiography. Reviewed herein are current TB diagnostics for disease and infection their application and performance, newer technologies in the pipeline and identify weaknesses and areas of progress that need to be addressed if we are to enhance TB control programmes and transition efforts towards TB elimination.

Microscopy, culture, and nucleic acid amplification tests (NAAT) are currently the three validated diagnostic methods for the detection of active

TB while chest radiography is sometimes used for screening of active TB (Pai et al. 2016). Major drawbacks associated with smear and culture are well described and will not be discussed here except to note the substantially reduced capability to diagnose TB in a large proportion of people living with HIV has enormous public health implications further contributing to disease transmission, morbidity and mortality (Dorman 2010). Because culturing tubercle bacilli is a pre-requisite for detailed phenotypic DST and genotyping (Pai et al. 2016), the protracted time interval required to detect bacterial resistance, technical expertise needed, biosafety requirements and high cost per test are some of the limitations of this method of diagnosis (Dorman 2010).

NAATs are molecular assays that detect *M. tuberculosis* through the amplification of particular regions of DNA (Denkinger and Pai 2017). NAATs are both highly sensitivity and specific, detecting about 100% of smear positive pulmonary TB while differentiating between *M. tuberculosis* and non-tuberculosis mycobacteria (Flores et al. 2005). Sensitivity is however considerably reduced in smear-negative patients, extrapulmonary specimens, and in HIV prevalence settings and as a result, NAAT tests can therefore not be utilized as a rule out test (Denkinger and Pai 2017). There are several NAAT tests on the market and others in development (see https://www.finddx.org/tb/).

Of the NAATs, GeneXpert MTB/RIF (Cepheid, Sunnyvale, CA, USA) allows for rapid and simultaneous detection of *M. tuberculosis* complex DNA and rifampin resistance in just 2 hours directly from clinical specimens and exhibits both high sensitivity and specificity and is the most widely used. GeneXpert MTB/RIF is considerably more sensitive at identifying *M. tuberculosis*, requiring 131 colony forming units per millilitre of sputum in contrast to 10 000 bacilli per millilitre of sputum required for smear microscopy (Steingart et al. 2014). In late 2010, the WHO endorsed the GeneXpert MTB/RIF assay for use in TB endemic settings (WHO 2014). Despite high sensitivity overall, GeneXpert sensitivity is only 60–80% in smear-negative TB. Sensitivity is also reduced in children (66%) and PLHIV (79%) and is variable in extrapulmonary specimens (Detjen et al. 2015; Pai et al. 2016). Despite its revolutionary approach, GeneXpert MTB/RIF was not designed to penetrate all levels of the healthcare system nor can it meet all the diagnostic demands for TB elimination (Pai et al. 2016). The cost of GeneXpert MTB/RIF coupled with the inability to detect latent TB and

resistance to multiple drugs are just some of its notable shortcomings. Moreover, the inability to distinguish between live and dead bacilli, sensitivity to high temperatures and need for a continuous power supply are some of the important limitations of this diagnostic tool that hampers widespread roll-out (Pai et al. 2016).

A new molecular test, GeneXpert MTB/RIF Ultra, exhibits improved sensitivity to GeneXpert MTB/RIF, requiring just 16 bacilli per millilitre of sputum, and similar sensitivity to liquid culture. In March 2017 the WHO recommended its use as a replacement for the current GeneXpert MTB/RIF cartridge (WHO 2017). The Ultra assay should significantly increase TB detection in smear-negative patients and provide more reliable rifampin resistance detection. In addition, GeneXpert Omni, a portable, and POC device is expected to become available in 2018 (Pai et al. 2016). Unlike the other GeneXpert platforms, the Omni is battery operated and can withstand significant temperature variations, enabling it to be used as point of care in clinics for the rapid diagnosis of drug-sensitive and drug-resistant TB, allowing patients to be promptly initiated on effective treatment. This has the potential to improve patient outcomes and, ultimately, reduce TB transmission. The rapid uptake of such new tools in the highest burden countries, where health systems are often under strain, is essential. Ongoing, multicountry evaluations of the accuracy and feasibility are underway (https://www.finddx.org/news/find-ultra-study/).

Line probe assays (LPAs) like that of the GenoType MTBDR (Hain Lifescience, Germany) allow for rapid differentiation of mycobacteria and simultaneous detection of drug-resistant mutations from culture using polymerase chain reaction and reverse hybridization methods (Denkinger and Pai 2017). The MTBDR*sl* test allows for rapid detection of mutations associated with resistance to fluoroquinolone, aminoglycosides, and cycloserine, drugs used to treat MDR-TB. LPAs have demonstrated excellent sensitivity and specificity for rifampin resistance but variable results for isoniazid resistance (Ling et al. 2008; Bwanga et al. 2009). LPAs are more rapid than conventional phenotypic DST methods and offer a lower biosafety risk but require skilled laboratory personnel, good quality control and rely on culture methods thereby limiting its role in resource-poor settings (Pai et al. 2016; Denkinger and Pai 2017). The GenoType MTBDR is endorsed by WHO and with rapid scale-up in high-burden countries through the EXPAND-TB project (Denkinger and Pai 2017). Given the high

proportion of drug-resistant TB attributable to ongoing transmission (Kendall et al. 2015) and the substantial delays often experienced in diagnosing and treating drug-resistant TB, the impact of improved case finding, and diagnosis should be even greater. Broader implementation of a rapid molecular test—even only for passive case detection—has been projected to avert substantial morbidity and mortality due to rifampin-resistant TB in settings like India (Salje et al. 2014).

The massive reservoir of latently infected adults generates an enormous pool for future reactivation cases. In fact, it is estimated that even if prevention of all new TB infections was achieved, the incidence of TB, arising from the 1.7 billion individuals in the global reservoir, would be 16.6 per 100,000 person-years in 2035, making the 2050 target to eradicate TB unattainable. The TST, and interferon-γ release assays (IGRAs) developed in the early 1900s and 2005, respectively, are the two diagnostic tools currently in use for latent TB infection. Both tests evaluate the presence of *M. tuberculosis*-specific T-cell responses to recent sensitization and are therefore unable to distinguish between latent, active, or past TB, or the progression thereof, relapse after treatment or protection after vaccination (except for newer generation IGRAs) (Denkinger and Pai 2017). There is therefore a critical need for the early identification of TB cases with the use of novel non-sputum-based diagnostics. A blood-based triage test, as described in the CORTIS trial, that enables targeted investigation of individuals with active and subclinical TB disease, including asymptomatic individuals with the highest risk of progression from latent infection to active disease status, has the potential to reduce the time to treatment initiation as well as prevent incipient TB disease prior to the onset of symptoms. Recent studies performed in latent TB infection subjects showed that *M. tuberculosis*-specific CD4 T-cells have a characteristic chemokine expression signature with increased numbers of these cells in latently infected subjects compared to healthy participants suggesting a role for subsets of CD4 T-cells in containing TB (Arlehamn et al. 2014). These signatures may have important implications in the identification of individuals with the greatest need for preventive therapy and to determine if targeted short-course preventive therapy can prevent TB disease among individuals found to exhibit the RNA signature (Penn-Nicholson et al. 2016).

While more rapid diagnosis should intuitively result in more rapid treatment initiation—and hence reduction in disease transmission—the

current paradigm of passive case finding constrains the potential transmission impact of improved diagnostic tools (Dowdy et al. 2017). TB patients are generally symptomatic for weeks to months prior to presentation to healthcare providers (Dheda et al. 2016), and they may have detectable bacilli in their sputum for many additional months before developing symptoms (Dowdy et al. 2013). A randomized controlled trial, while shortening the time to diagnosis, did not demonstrate a significant treatment benefit of GeneXpert MTB/RIF over smear microscopy (Theron et al. 2014). By contrast, active case finding (ACF) can detect infectious cases much earlier and hence potentially interrupt disease transmission. A recent randomized trial (XACT I) evaluated the feasibility and impact of GeneXpert MTB/RIF for ACF in South Africa and Zimbabwe, using mobile vans with on-board GeneXpert capacity and staffed by three healthcare workers each (Calligaro et al. 2017). Relative to sputum smear microscopy, GeneXpert MTB/RIF was associated with a 53% increase in the number of patients initiating anti-TB therapy. This trial demonstrates that ACF using newer molecular tools is feasible and substantially increases the proportion of patients initiating treatment in high-burden settings. Importantly, as demonstrated in another cluster-randomized trial in South Africa (Churchyard et al. 2015), scale-up of GeneXpert MTB/RIF is unlikely to impact mortality—or transmission—unless also accompanied by better linkage to care. Multiple ongoing studies are evaluating diagnostic tests of higher sensitivity for example, GeneXpert Ultra and/or greater portability in the context of ACF (https://www.finddx.org/news/find-ultra-study/). Targeted ACF interventions are needed.

In summary, early data suggest that newer molecular diagnostic tools—if combined with ACF—may help reduce TB transmission in high-burden settings. Additional needs include trials to evaluate the effectiveness of more sensitive and/or scalable diagnostic tests (especially in the context of ACF), studies of comparative cost-effectiveness and feasibility, new tools to identify patients with highest transmission risk, and conclusive studies demonstrating that earlier diagnosis and treatment initiation can reduce TB burden at the population level. Despite these promising developments, there remain several unanswered questions regarding interventions to halt TB transmission through diagnosis and case finding. These include cost-effectiveness, feasibility, and impact in different settings, optimal combination of screening tools, and characterization of TB transmission

from immunological, clinical, and healthcare-seeking behaviour perspectives. Ultimately, new diagnostic tools capable of detecting TB at earlier stages will likely only have transformative impact on transmission when used in the context of broader screening and ACF (Dowdy et al. 2017).

TB diagnostics pipeline

Resistance mutations are not fully characterized for all TB drugs, and they are particularly deficient for the second-line and newer drugs used to treat MDR and XDR-TB. Next-generation whole-genome sequencing (NGS) remains the most attractive tool for TB drug resistance testing, with the potential to generate antibiotic susceptibility profiles for all drugs in a single analysis (Dookie et al. 2018) and might eventually become the reference standard for drug resistance identification. Reduced costs and the establishment of high-throughput sequencing centres and easy-to-use analytical tools have greatly increased access to NGS, which is being implemented as a routine service in several countries. However, in most high-burden countries it remains only a means for research with the analysis undertaken overseas. Proof of principle for NGS directly from sputum has been shown, but for comprehensive analysis the need to first isolate and culture the organism to obtain sufficient bacterial DNA hinders its application to patient management. Recent studies have shown some success in this regard (Votintseva et al. 2015; Votintseva et al. 2017; Dookie et al. 2018).

The TB diagnostic pipeline is at its most robust and focused on novel technologies equipped with a better understanding of the variable host immune response and non-sputum-based options (Walzl et al. 2018, https://www.finddx.org/news/find-launches-diagnostic-pipeline-tracker/). Novel approaches being investigated include testing breath for TB metabolites and the application of nanotechnology and microfluidics to increase detection capacity and reduce hands-on sample manipulation (Walzl et al. 2018). Promising results have been reported on the use of new, more sensitive technology to detect lipoarabinomannan and circulating antigen peptides. New platforms capable of assessing molecules of variable size and composition or that detect multiple proteins are under development to support the measurement of host-response biomarkers. Competitors for the GeneXpert MTB/RIF assay are undergoing assessment for regulatory

approval and are closest to launch (FIND). These competitors are devices designed for low-technology microscopy centres or high-throughput instruments with extended drug resistance detection intended for the reference laboratory. Most tests are sputum-based but some aim to use blood or urine, which might detect extrapulmonary TB and TB in children. Ending the epidemic will demand both innovative technologies and an enabling environment. It is hoped that by 2020 the following measures will be implemented: (1) a triage test and highly sensitive detection at the first point of contact; (2) TB confirmation with rapid integrated DST for critical drugs to drive treatment regimen decisions at a dedicated unit, and; (3) comprehensive DST at a reference level compatible with health system strengthening (Denkinger 2017).

The need for new drugs against tuberculosis

Currently treatment for TB is long and toxic, ranging from a 4-month standard regimen for patients who are sputum smear and culture negative with minimal pulmonary disease in the USA, to the WHO standard 6 month short-course treatment for drug-susceptible TB. Short-course chemotherapy for drug-susceptible TB comprises an initial 2-month intensive phase (isoniazid, rifampin, pyrazinamide, and ethambutol daily), continued by isoniazid and rifampin for the last 4 months. In the case of drug-resistant TB, 18–24 months treatment with second-line, less potent and more toxic drugs is required, involving an intensive phase of 6–9 months with aminoglycosides (amikacin/kanamycin) and cycloserine, terizidone, ethionamide, protionamide, capreomycin, aminosalicylic acid, and fluoroquinolones. Treatment success is approximately 85% for drug-sensitive TB, 50% for MDR-TB, and 30% with XDR-TB. To improve on these outcomes, an ideal new regimen should be safe, rapidly bactericidal and possess potent sterilizing activity against subpopulations of persisting bacteria that are drug tolerant in the face of continued chemotherapy. The global vision is to introduce an ultra-short, simple, and affordable TB regimen that works in virtually all people with TB, including children. This requires a multidrug regimen comprised entirely of new drugs. Such a regimen would unify the treatment of all current forms of TB under one cure. There is therefore a shift in focus from single drug development to

regimen building. Drug combinations are needed to eradicate various bacterial subpopulations and prevent the development of resistance.

To develop new drug candidates in order to have a sufficient number and combination of drugs for a new regimen, a multipronged approach has been adopted, which entails the discovery of new antitubercular agents, together with repurposing of previously approved antimicrobials and the development of host-directed therapies. An integrated approach with high-throughput screening of chemical libraries has been used to identify new lead compounds, followed by deconvolution of the drug target, assessing the effects on metabolism and identifying possible mechanisms of resistance (Evans and Mizrahi 2018). This approach, in combination with others, has allowed for repopulation of the TB drug development pipeline, with 14 chemical compounds having progressed along the clinical development pathway, including new chemical classes in preclinical (eight compounds) and clinical (nine compounds) phases (Tiberi et al. 2018). Novel mechanisms of action with activity against both replicating and non-replicating bacteria, reduced drug-drug interactions particularly with P450 enzymes; oral bioavailability with acceptable pharmacokinetic and pharmacodynamic safety and tolerability profiles are desirable attributes of new TB drug candidates. However, many more candidate drugs are needed to populate a pipeline robust enough to build entirely new regimens. An ideal drug combination should consist of at least three drugs that are active against MDR and XDR tuberculosis, and have potent, synergistic, and complementary activities against various subpopulations of *M. tuberculosis*. Such a combination should be equally effective against drug-susceptible and drug-resistant tuberculosis and produce a stable cure in a much shorter period than does the standard treatment. New antituberculosis drugs that do not interact with protease inhibitor-based treatments are also needed for the effective treatment of the HIV co-infected population. For this to be successful innovative trials need identify suitable drug candidates, to be inclusive of children and supported by sufficiently resourced trial capacities and regulatory guidance.

Lead optimization and clinical evaluation

Bedaquiline, the first novel TB drug developed in five decades, with a novel mode of action by binding to the F_oF_1 ATP synthase, which catalyses the

production of ATP using the proton motive force generated by the mycobacterial electron transport chain (Andries et al. 2005). Bedaquiline is highly potent against drug-susceptible and drug-resistant strains of *M tuberculosis* and is approved for treatment of drug-resistant TB. For drug-sensitive TB, bedaquiline will be combined with rifampin, delamanid, and linezolid in five different combinations in the TRUNCATE-TB28 (NCT03474198), Phase 2c open-label trial (Diacon et al. 2009; Belard et al. 2015; Tiberi et al. 2018). Bedaquiline also features in Next-5001, STREAM, and end-TB trials. The success of bedaquiline also highlighted the mycobacterial electron transport chain as a rich source of possible new drug targets, as evidenced by the developed of other similar agents such as Q203 (Bald et al. 2017; Iqbal et al. 2018).

Delaminid and pretomanid are nitroimidazoles that undergo conversion by a F_{420}-dependent nitroreductase to form metabolites that inhibit the synthesis of mycolic acids in the mycobacterial cell wall (Xavier and Lakshmanan 2014). Both these agents are currently in Phase 3 trials for drug-resistant TB and to assess the potential for treatment shortening, for example, through combination with bedaquiline (Tiberi et al. 2018). SQ109, a 1,2-ethylene small molecule that is structurally related to ethambutol, inhibits the incorporation of mycolic acids into the *M. tuberculosis* cell wall (Protopopova et al. 2005; Tahlan et al. 2012; Boeree et al. 2017). Encouraging data from the early bactericidal activity assessment confirm safety, tolerability, and no adverse cardiac effects. In the presence of an optimized background regimen, SQ109 has demonstrated promise in the treatment of drug-resistant TB (Tiberi et al. 2018). Benzothiazinones represent another interesting class of compounds that target the mycobacterial cell wall, in this particular case through inhibition of arabinogalactan biosynthesis (Makarov et al. 2009). One molecule, PBTZ169, a piperazinobenzothiazinone derivative of BTZ043, which has a relatively easy chemical synthesis and promising pharmacodynamics, has been advanced to Phase 2 clinical trials.

Oxazolidinones represent a new class of orally bioavailable inhibitors of protein synthesis that act by binding to the 23s subunit of the ribosome and interrupting protein synthesis., linezolid, is recommended by the WHO to treat drug-resistant tuberculosis as a medicine with ‘unclear efficacy’. Two randomized controlled trials in patients with XDR-TB demonstrated improved rates of sputum culture conversion but linezolid was poorly

tolerated which has limited its widespread application (Lee et al. 2012; Maartens and Benson 2015; Tang et al. 2015). Sutezolid follows in this class, with favourable pharmacokinetic properties (Rausch et al. 2018). However, advancing sutezolid to Phase 2 clinical trials (Wallis et al. 2014) is pending review after recent safety concerns arose from a 6-Month Toxicity Study of sutezolid in rats. Delpazolid (LCB01-0371), a new oxazolidinone with a cyclic amidrazone moiety, and contezolid (also known as MRX) are currently being advanced in the clinical development pipeline.

GSK070, a new candidate drug with an entirely novel model of action, inhibits mycobacterial Leucyl-tRNA synthetase (LeuRS), an enzyme required for protein synthesis. The LeuRS system allows for aminoacylation of tRNAs, together with a proof reading site to remove incorrectly charged amino acids and inhibition of this process affects translation (need ref). GSK070 is currently entering Phase 1 clinical trials.

Regimen building

Various combinations of new agents, together with existing drugs are being tested to develop short-course regimens with low toxicity. Based on promising results from a Phase 2b trial, the NC-005 regimen, BPaMZ (bedaquiline + pretomanid + moxifloxacin + pyrazinamide) will be assessed in the Phase 3 trial (NCT02193776) to provide a more effective, shorter regimen for both drug-susceptible and drug-resistant TB. The Nix-TB trial (NCT02333799) will assess a shorter, orally administered treatment for XDR-TB with pretomanid, bedaquiline, and linezolid. This combination promises to provide a new alternative for drug-resistant TB. Similarly, the ZeNix trial (NCT03086486) will also assess the potential for improved safety with a shorter, oral regimen consisting of pretomanid, bedaquiline, and lower dose linezolid (BPaL).

Clofazimine (CFZ). CFZ, a riminophenazine, has been historically used for the treatment of lepromatous leprosy (Sharma et al. 2017). The drug has several advantages including intracellular accumulation within macrophages, a low prevalence of resistance, anti-inflammatory properties and contributes substantially to the sterilizing activity of TB regimens in mice and to the relapse-free cure of MDR-TB regimens in humans. However optimal dosing, pharmacokinetics/pharmacodynamics, safety and tolerability rates, and treatment duration have not been definitively tested. Reversible but

potentially stigmatizing skin discoloration along with known QT prolongation has tempered enthusiasm. Nevertheless, CFZ has demonstrated significant *M. tuberculosis* killing activity and treatment-shortening potential in murine models. This will be investigated in a 3- and 4-month regimen of standard TB treatment (rifampin/isoniazid/pyrazinamide/ethambutol) with the addition of CFZ (ACTG trial A5362) early efficacy (12-week culture conversion) and treatment shortening in dug-susceptible TB (Treatment Action Group 2017).

Host-directed therapies

Host-directed therapies (HDT) are novel approaches in the field of anti-infectives for overcoming antimicrobial resistance and restoring cellular pathways that are perturbed by the causative pathogen, *M. tuberculosis* (Wallis and Hafner 2015; Yang 2017; Kaufmann et al. 2018). HDT for TB, aims to (i) modulate host cell factors that are required by a pathogen for replication or persistence; (ii) enhance protective immune responses against a pathogen; (iii) reduce exacerbated inflammation; and (iv) balance immune reactivity at sites of pathology. In TB, HDT aims to enhance the antimicrobial activities of phagocytes and to curtail inflammation through modulation of secreted factors (such as eicosanoids and cytokines) or cell membrane proteins (such as co-stimulatory molecules) and modulate granulomas to allow the access of antimicrobials or to restrict tissue damage (Kaufmann et al. 2018). By directly targeting the host, rather than the pathogen, HDTs may be less susceptible to the development of resistance to these therapies. Most HDT approaches are not considered to be stand-alone therapies but are combined with conventional therapy. Several HDTs have been directed at each stage of the macrophage life cycle of *M. tuberculosis* to overcome resistance to microbial killing by: (i) Triggering activation: IFN and TNF modulators and phosphodiesterase (PDE) inhibitors; (ii) inducing antimicrobial peptides: (vitamin d; histone deacetylase [hdac] inhibitors; and phenylbutyrate); (iii) inhibiting lipid formation: (statins and vitamin D); (iv) triggering autophagy (gefitinib, vitamin D, mTOR inhibitors, metformin, statins, verapamil, fluoxetine, nitazoxanide, carbamazepine, valproic acid); and (v) promoting phagosome maturation (metformin, kinase inhibitors, and statins) (Parihar et al. 2014; Singhal et al. 2014; Pauwels et al. 2017). Thus far few have progressed to clinical evaluation with successful results.

Notably the clinical evaluation of metformin has not yielded promising results (Dutta et al. 2017). Results from a large Phase 2 trial designed to examine the safety and preliminary efficacy of multiple adjunctive host-directed TB therapies CC-11050 (PDE-4 inhibitor), auranofin, everolimus (mTOR inhibitor), and vitamin D, to assess their potential to shorten TB treatment and/or prevent permanent lung damage are expected in 2019 (https://clinicaltrials.gov/ct2/show/NCT02968927). Preclinical evaluation of anti-IL-1 blockade; autophagy targets; statins and Imatinib have concluded, and the statin and Imatinib projects are now proceeding to proof-of-concept clinical studies for *M. tuberculosis* treatment in the context of HIV co-infection (Mayer-Barber et al. 2010; Napier et al. 2011; Dutta et al. 2016; Gupta et al. 2016).

While progress is slow and difficult, HDT will undoubtedly feature in the future of TB therapy. Further refinement in the identification of potential genetic predispositions in patients, discovery and validation of host or pathogen biomarkers that may indicate disease stage; treatment responses; type of inflammatory response; will potentially permit targeted HDT. Significant barriers include the potential for some of these agents to be cytotoxic or induce a worsened inflammatory response; lack of supportive preclinical and clinical data in assessing potential efficacy and selecting suitable candidate; and not least the potentially higher cost of adding these agents to already expensive treatments for MDR and XDR-TB.

Vaccines for TB

Vaccination is the most effective intervention for the prevention, control, and/or eradication of an infectious disease. Mathematical modelling estimates that without new interventions, particularly those that blocks transmission such as protective vaccines, it will not be possible to reduce the incidence of TB to less than 10 per 100,000 by 2035. The growing burden of extensively resistant and untreatable TB as well a compelling argument for the return on investment emphasizes the need, and incentive for the development of an effective vaccine to prevent TB. This section highlights key challenges and recent advances in TB vaccine research. The current discovery, preclinical, and clinical pipeline have been described in detail elsewhere. Recent advances offering a broader diverse repertoire of TB vaccine candidates together with an enthusiasm to leap-frog TB vaccine

development and include broadening both antigen selection and the range of vaccine-mediated immune responses as well as experimental design in both in animal models and smaller human clinical trials offer an unprecedented opportunity to expand demonstration of vaccine efficacy for the prevention and possibly the treatment of TB.

Based on animal and human studies of TB, a robust cellular immune response is required for protection against Mtb infection and disease (Evans et al. 2016) whereas, most successful, licensed vaccines available today induce neutralizing antibodies that provide protective immunity. For this reason, the majority of current clinical TB vaccine candidates are based on a variety of vectors, adjuvants and antigens that induce CD4 or CD8 T-cell responses with TH1 cytokines such as IFN-γ or TNF-α. These clinical candidates are based on a variety of vaccine approaches, such as inactivated whole cell or whole cell extracts (*Mycobacterium indicus pranii*, *Mycobacterium vaccae*, DAR-901 (*Mycobacterium obuense*), RUTI and *Mycobacterium smegmatis*), viral-vectored candidates (vaccinia-based MVA85A, influenza, and human adenovirus 5 and 35 and chimpanzee adenovirus), fusion protein subunits with TH1-inducing adjuvants (M72/AS01, Hybrid 1/CAF01, Hybrid 1/IC31, H4/IC31, H56/IC31 and ID93/GLA-SE), and live recombinant BCG or attenuated TB vaccines (VPM 1002, Aeras 422, rBCG30, and MTBVAC). DNA vaccines are being developed in different countries, notably emerging economies, but have not yet entered into human clinical trials. To date, clinical trials characterizing these candidate vaccines have included studies of safety and immunogenicity in diverse populations, including healthy, TB-naïve adults, and infants, latently infected adolescents, and adults, HIV-infected adults, as well as patients undergoing drug treatment for TB (Evans et al. 2016).

Vaccination against TB can be divided into one of three categories: (1) preventive pre-exposure vaccines (or priming vaccines) typically administered to neonates for prevention of infection (POI); (2) preventive post-exposure vaccines (or boost vaccines) that can be administered to adolescents and adults with latent TB infection or those that have previous vaccination and (3) therapeutic vaccines which are administered together with TB drugs to shorten and ameliorate the course of therapy and prevent recurrent disease. Different vaccines may be required to induce immune responses in diverse populations, such as infants, young adults, those already

latently infected with *M. tuberculosis* or on treatment for TB, and those co-infected with HIV.

The first candidate to be tested for efficacy, MVA85A (a modified vaccinia Ankara virus vector expressing the antigen 85A), failed to show protection (Tameris et al. 2013), other candidates remain in the clinical pipeline, with efficacy results expected (2018) from a Phase 2b prevention of disease trial with M72/AS01, the GSK adjuvanted fusion protein vaccine in 3,600 HIV-uninfected, adults latently infected with *M tuberculosis*.

Iterative approaches focused on prevention of disease by viral-vectored vaccine candidates are yet to yield promising results. Innovation in trial design, vaccine approaches, constructs and routes of administration aimed at demonstrating biologic activity of vaccine candidates using more focused populations specifically selected to reduce sample size, are providing encouraging new evidence and pathways for vaccine developers. In a prevention-of-infection Phase 2 trial conducted in South Africa, revaccination with BCG significantly reduced sustained TB infections in high-risk adolescents. An experimental vaccine candidate, H4:IC31, a fusion protein of the immunodominant antigens TB10.4 and Ag85B, formulated with IC31 adjuvant, also reduced sustained infections, although not at statistically significant levels. However, the trend observed for H4:IC31 is the first time a subunit vaccine has shown any indication of ability to protect against TB infection or disease in humans. These results indicating that sustained QFT-GIT conversions are preventable by BCG revaccination, provide novel insights into possible mechanisms of protection in humans. Results from a concluded Phase 3 trial investigating the efficacy of killed *M. vaccae* lysate vaccine to prevent TB in adults with latent disease from Guanxi province China are expected while a ‘Prevention of Recurrence’ trial with the vaccine candidate ID93 is designed to determine whether the vaccine can prevent the 4–6% relapse and/or reinfection rate typically observed following successful treatment of active TB. All these experimental designs follow a non-traditional clinical development path, but attempt increase efficiencies by reducing sample size requirements of demonstrating biological signals earlier than conventionally phased product development plan.

Recently a novel vaccine approach using a weakened form of a common herpes virus, cytomegalovirus (CMV) as a vector expressing *M. tuberculosis* Ag85A demonstrated complete protection in 41% and reduced overall TB

disease by 68% in vaccinated rhesus macaques. Cytomegaloviruses persist lifelong *in vivo* and induce powerful adaptive and innate immune and increasing ('inflationary') responses (Beverley et al. 2014).

The BCG control group showed no evidence of protection. It is critical to rapidly understand the mechanisms by which this re-engineered CMV creates and maintains a high state of immunity against the pathogen in vaccinated monkeys especially because this approach has the potential to work better than standard vaccines. The results demonstrate that a small Ag-specific response may be highly effective in synergy with the correct innate activation, in this case involving IL-21 and natural killer (NK) cells and hold promise for future development of this candidate vaccine. Human trials are expected by 2019.

The development of appropriate preclinical models to prioritize the best vaccine candidate for advancement in human studies represents a key unmet need. Many TB vaccine animal challenge models have a narrow dynamic range of responses that do not allow for easy differentiation among candidates. This limitation is being addressed by refinement of the mouse, guinea pig, and macaque models to better approximate natural infection by *M tuberculosis* and better mimic human disease. The use of low dose challenge, sophisticated PET/CT imaging techniques, and novel vaccine candidates (such as H56, *Cytomegalovirus* [CMV] approaches, aerosolized adenovirus vaccines and IV administration of BCG) have recently shown that the macaque model may potentially be useful to delineate correlates of vaccine-induced protection.

The lack of known correlates of protection and surrogate biomarkers of immune responses associated with different stages of TB infection and disease has been a barrier against the clinical evaluation of the vaccine candidates (Abubakar et al. 2016). We have discussed the implications of gene expression patterns of inflammatory biosignatures correlated with risk for TB disease progression, in both active and latent TB cases (Evans et al. 2016). Similarly, a broad unbiased systems biology approach in which gene expression signatures are compared in samples from various time points (Evans et al. 2016) and then correlated to either specific measures of immunogenicity, or to protection in efficacy studies are likely to yield potential correlates of vaccine-induce protection.

Given no validated immunological correlates of protection, significant limitations of animal models and the strained capacity to fund and perform

efficacy trials, a TB human challenge model would facility vaccine development by offering an option to investigate candidate selection, route of vaccination, dose optimization, and the identification of immune correlates despite the need to overcome significant safety, measurement/reporter, ethical, and regulatory challenges. If successful potential TB vaccines are tested in healthy donors challenged with attenuated *M. tuberculosis* strains that are viable, capable of replicating but do not cause infection or disease or be transmittable. Experiments in non-human primates are scheduled to start in mid-2019. A safer option, using BCG challenge has been pursued, while vaccines that target antigens unique to M tuberculosis would not be suitable for the BCG challenge model promising results have been demonstrated.

Exponential advances in TB vaccine development have occurred over the past 5 years. Results from efficacy trials will provide insights into what is needed from a vaccine to deliver protective immunity and new tools will accelerate TB vaccine development, not only by providing a less expensive and rapid method for assessing potential vaccine efficacy, but also by permitting more rapid progress towards the identification of an immune correlate of protection. While the challenges in developing TB vaccines are great, the research community is embracing this challenge.

Closing the Gap—addressing global threats

Financing for TB care and prevention has been increasing for more than 10 years, but a crippling funding gap still exists, estimated at US$ 2.3billion in 2017. Total health spending also falls short of the resources needed to achieve universal health coverage. TB kills more people than any other bacterial agent and when this fact is contrasted with the reducing investments in TB research, it becomes clear that the governments of endemic countries, together with those of donor nations, have yet to commit appropriate resources to realize the End TB Strategy. Closing these gaps requires more resources from both domestic sources (especially in middle-income countries) and international donors (especially in low-income countries). Given this complex funding landscape, TB is particularly susceptible to sudden changes in the global political landscape. The UK referendum to leave the European Union has created a risk that the sixth largest contributor to TB research will most likely adopt a trade-focused

approach and withdraw support from global health efforts. Similar concerns prevail in the USA where the low incidence of TB makes it an issue of international development and foreign aid, rather than a concern for public health. TB also ranks low in terms of the research and development agenda globally, especially in the context of emerging infectious diseases such as Ebola, which grab international attention and resources. In this context, political will from endemic countries become mission critical to nucleate international support and must therefore feature centrally in efforts to eliminate TB.

Profits from TB research and development are perceived to be minimal, owing largely to the fact that the disease is mostly prevalent in the poorest settings, which are unable to provide a financially lucrative market to drive drug discovery and development. TB research and development n is being currently driven by collaborative efforts involving public–private partnerships. Although the total funding for TB research and development increased from US $ 358.1 million in 2005 to 620.6 million in 2015, this has been insufficient to meet costs of discovery. Since 2009, approximately 2.8 billion US$ has been spent on TB research by public institutions, with the National Institutes of Health (NIH) contributing more than half this amount. Other sources of funding for TB research include Japanese pharmaceutical company Otsuka contributing 60% of industry spending, the Gates Foundation contributing 89% of philanthropic funding, and Unitaid contributing 47% of total multilateral funding. It is noteworthy that the largest multilateral supporter of TB research and development to date has been the Global Fund to Fight AIDS, Tuberculosis, and Malaria, contributing US$ 120.2 million from 2002 to 2015 on TB operational research There have been substantial advances in HIV/AIDS within three-four decades, from huge investments by governments and donor agencies. Relative this this, investments in TB research and development has remained vastly inadequate and should be prioritized.

Conclusion

TB has defined the fabric of modern medicine in the developing world and continues to claim the lives of the economically and socially disadvantaged. To address this, the WHO has set bold goals in the End TB Strategy and to achieve these, a higher level of annual decline in incidence is required.

While a bold approach is needed to eradicate TB, it is questionable whether achieving these milestones places an unreasonable burden of performance on the crippled healthcare systems of endemic countries, which may require a slower, but steady, rate of sustainable decline. This can already be achieved through more effective deployment of current tools, together with safe-guarding the fidelity of available antibiotics using medical practices that limit the emergence of resistance. That said, new tools for diagnosis and treatment of TB are urgently required, in addition to an integrated approach for bolstering the healthcare system. Identifying and addressing gaps in the cascade of care for TB is critical and central to this is strong political will, which is required to create resources, build infrastructure, and attract much needed funding. Another challenge that needs to be addressed is the implementation of TB control programmes in the context of limited laboratory capacity and treatment barriers, which threaten to undermine any gains that the introduction of new interventions may bring. Hence, strengthening healthcare delivery and linkage to care is pivotal for TB eradication. As with many other infectious diseases, a cross-disciplinary approach to the development of health interventions promises success and, in this regard, it is critical to support research and development efforts across the value chain to advance new drugs and vaccines and to lay the foundation for future elimination efforts. Furthermore, considering comorbidities such as HIV infection and diabetes is required to ensure future control programmes consider those most at risk for progressing to active disease. While the treatment of drug-sensitive disease is affordable for most endemic countries, treating drug-resistant TB is prohibitive. This creates a research and development environment which calls on all stakeholders, including academic institutions, governments, and big pharma to shift cost paradigms and invest in the development of novel, cheaper regimens. For success in these endeavours, coordination between donors is essential to leverage the best value for money in terms of prioritizing research questions and for attracting further funding to the field. Finally, the world can no longer afford to ignore the growing menace of antimicrobial resistance. Considering that more than half of the recorded cases of bacterial resistance involve drug-resistant *M. tuberculosis*, the inability to eliminate TB threatens to plunge humanity back into the pre-antibiotic era. As a society, we simply cannot let this happen.

Malaria

Frank Baiden, Keziah L. Malm, and Fred Binka

Introduction

Malaria is a life-threatening infectious tropical and subtropical disease of major global health concern. It is caused by parasites that are transmitted through the bites of infective female Anopheles mosquito. According to the 2018 World Malaria Report released by the World Health Organization, there were 219 million cases of malaria in 2017. These resulted in 435,000 deaths, nearly 61% of which were in children below 5 years of age. The World Health Organization (WHO) Africa Region carries the highest burden of malaria cases (92%) and deaths (93%).

In 2017, five countries accounted for nearly half of all malaria cases. The countries are Nigeria (25%), the Democratic Republic of the Congo (11%), Mozambique (5%), India (4%), and Uganda (4%) (Fig. 8.15.1). Malaria is an important cause of underdevelopment and poverty in these and other countries in malaria-endemic sub-Saharan Africa. It reduces gross domestic product in sub-Saharan Africa by about 1.3% per year. In continued high transmission settings, malaria could be reducing life expectancy at birth by more than six years (Bawah and Binka 2007; WHO 2018a).

Per global population, the number of cases and deaths from malaria has seen steady decline since the 1990s. The period from 2000 to 2015 witnessed year-on-year reduction in the number of cases. Since 2015 however, this trend has stalled and there is a real threat that gains made over the past two decades could be reversed if urgent steps are not taken. Malaria thus remains an important threat to the achievement of the Sustainable Development Goals (SDGs) (Rowe 2017).

Malaria: past to present

The earliest evidence of malaria parasites was found in fossils of mosquitoes that dates to approximately 30 million years old. Hippocrates described the manifestations of malaria, and related them to where patients lived, and time of the year. His description is preceded by references to malaria and its symptoms by Nei Ching (Chinese Canon of Medicine) in 2700 BC and in the Cuneiform tablets of 6th century BC (Ross 1923; Neghina et al. 2010).

The pioneering work of Alphone Laveran in Algeria in 1879 led to vastly improved understanding of the infectious basis of the disease. His discovery of black pigment in the blood of people suffering from malaria ultimately led to the knowledge of plasmodium as the infectious agent (Sundberg 2007; Cox 2010). Experiments conducted by Donald Ross in the late 1800s led to an understanding of the life cycle of the parasite. The use of the microscope to identify the plasmodium parasite and the deployment of interventions to break the chain in the life cycle of the parasite have remained the basis for the diagnosis, treatment, and control of the disease (Dobson 1999; Cox 2017).

Interventions for the prevention and treatment of malaria preceded a full understanding of the plasmodium parasite and its life cycle. The perception of association between malaria and stagnant waters (ultimately to be appreciated as the breeding grounds for mosquitoes) led the Romans in 1930s to undertake drainage programmes (Majori 2012). Derivatives of the *Artemisia annua*, used in early traditional Chinese Medicine, remain an importance part of malaria treatment to date (Krishna et al. 2008). Peruvian Indians used the bitter bark of the Cinchona tree, later processed as quinine, in the treatment of fever. Quinine continues to be an important drug in the treatment of malaria. Between 1955 and 1969, a Global Malaria Eradication Programme (GMEP), resulted in the elimination of malaria from many regions in south Europe and parts of the Americas. There was however very little success from the rather limited efforts in sub-Saharan Africa (Bruce-Chwatt 1974; Krishna et al. 2008; Najera et al. 2011; Cohen et al. 2012; Majori 2012). The launch of Roll Back Malaria (RBM) in 1998 by Dr Gro Harlem Brundtland, then Director-General of the WHO set in motion a momentum of increased investments and support to endemic countries (Nabarro 1999; Remme et al. 2001).

Compared to the 1980s and 90s, malaria transmission has substantially reduced in many countries; to a point there is now a push for country-by-

country elimination and eradication (Mendis et al. 2009; Alonso et al. 2011) (Fig. 8.15.1).

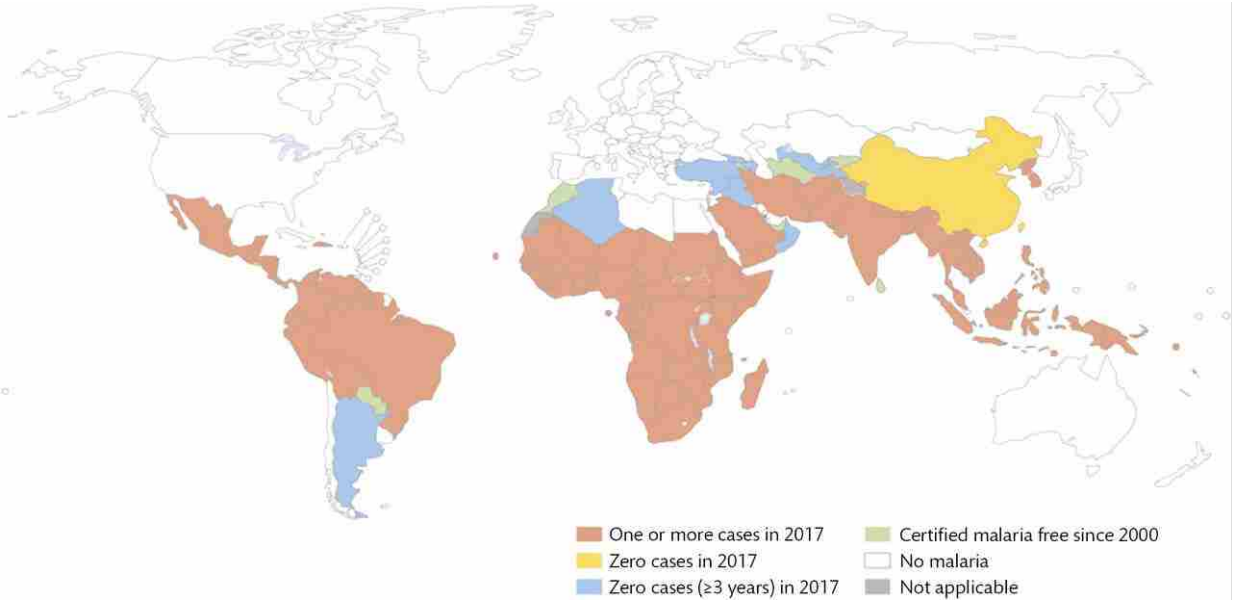

Fig. 8.15.1 Countries and territories with indigenous cases in 2000 and their status by 2017. Reprinted from World Malaria Report 2018. Geneva: World Health Organization; 2018. License: CC BY-NC-SA 3.0 IGO, with permission from the World Health Organization.

Countries with zero indigenous cases over at least the past 3 consecutive years are eligible to request certification of malaria-free status from WHO. All countries in the WHO European Region reported zero indigenous cases in 2016. Kyrgyzstan and Sri Lanka were certified malaria free in 2016.

Human *Plasmodium* parasites

Malaria is caused by the protozoa that belongs to the genus Plasmodium. Out of the over 100 species of *Plasmodium* which infect mammals, five are so far known to cause disease in humans. These are the *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium malariae*, *Plasmodium ovale*, and *Plasmodium knowlesi*.

Plasmodium falciparum

Plasmodium falciparum (*P. falciparum*) is responsible for over 90% of cases and deaths worldwide. It is the most dominant form of malaria in sub-Saharan Africa. Children, pregnant women, and non-immune adults are vulnerable to the severe forms of the disease. According to the 2018 World Malaria Report, children under 5 years of age are the most affected, and account for 61% of the total deaths (WHO 2018a). Repeated infections in people who live in high transmission settings lead to the development of some partial immunity. This is the reason adults living in high transmission are less vulnerable to the severe forms of *P. falciparum* malaria. *P. falciparum* malaria is associated with the development of Burkitt's lymphoma, a B-lymphocyte cancer (Thorley-Lawson et al. 2016). *P. falciparum* lacks a fixed structure. It undergoes continuous change during its life cycle as part of survival strategies (Dhangadamajhi et al. 2010). The incubation period for *P. falciparum* malaria ranges from nine to 14 days.

Plasmodium vivax

Plasmodium vivax infection is the most geographically widespread of the five human malarias, with about 35% of the world's population being at risk. It infects 19–50 million people each year mostly in the Asia Pacific region, Latin America, and parts of Africa. It causes significant morbidity and can be associated with severe malaria and death. Clinically, *P. vivax* malaria presents as an acute debilitating illness that is characterized by recurrent paroxysmal fever and relapses from dormant liver stages (hypnozoites). These symptoms can occur even when blood parasite density is low. *P.* vivax can be present and be infectious to mosquito vectors, while infected persons show no symptoms. The liver stage of *P. vivax* can lie dormant for weeks to years after first infection before causing relapses of symptomatic malaria. Primaquine is the only licensed antimalarial drug that targets the liver stage of the lifecycle. It used to be thought *Plasmodium vivax* depended on the Duffy antigen to invade red blood cells and individuals who do not express the Duffy antigen were refractory to *P. vivax* infection. Reports of *P. vivax* infections in Duffy negative patients raise the possibility of an alternative invasion mechanism (Menard et al. 2010; Howes et al. 2016). The incubation period for *P.* vivax malaria ranges from 12 to 18 days.

P. vivax presents a particular challenge to malaria elimination for the following reasons: (1) It can survive in cooler climates hence its wider

geographical coverage; (2) it is more difficult to detect using current diagnostic techniques; (3) a single infection can give rise to multiple episodes of malaria; (4) treatment of liver-stage parasites requires a 14-day course of primaquine; and (5) primaquine treatment can produce serious side effects in persons with glucose-6-phosphate dehydrogenase (G6PD) deficiency (WHO 2015a; Baird et al. 2016).

Plasmodium malariae

Plasmodium malariae is a widely distributed *Plasmodium* species. It is endemic in parts of Africa, South America, Asia, and the Western Pacific, and is responsible for a mild form of malaria. Malaria caused by *P. malariae* is often referred to a benign, quartan malaria. This is because it rarely results in severe disease, and the associated fever tends to occur at three-day intervals unlike the others which are usually tertian (i.e. 2-day interval for the occurrence of fever). *P. malariae* has a tendency for low-dose chronic, asymptomatic infection, which when untreated can lead to nephrotic syndrome and albuminuria (Gilles and Hendrickse 1963; Ehrich and Eke 2007). There are no animal reservoirs for *P. malariae*. A large case series reported from southern Papua in 2015 shows that *P. malariae* is responsible for a minority (2.6%) of clinical malaria cases but has potential to cause a severer form of anaemia. The mean haemoglobin in patients with *P. malariae* infection was 0.3–0.6g/dl lower than the other locally prevalent Plasmodium species, with an associated 2.3-fold greater odds of severe anaemia compared to individuals without malaria (Langford et al. 2015). The incubation period for *P. malariae* malaria is highly variable and ranges from 16 to 59 days (Collins and Jeffery 2007). Late recrudescence may occur with *P. malariae* malaria.

Plasmodium ovale

Plasmodium ovale is primarily found in sub-Saharan Africa (Collins and Jeffery 2005). Molecular methods have led to the elucidation of two distinct sympatric species termed *P. ovale curtisi* and *P. ovale wallikeri*. *P. ovale* also causes mild (*benign*) malaria and is relatively unimportant as a cause of severe malaria morbidity and mortality. A systematic review of clinical presentation, treatment, and relapse characteristics of *P. ovale* malaria

reported in 2017 identified 22 severe cases, five fatalities, and two cases of congenital malaria. Most cases were from sub-Saharan Africa, Indonesia, Papua New Guinea, and India (Groger et al. 2017). Comparatively, *P. ovale* has received little attention in medical research and knowledge gaps exist in the optimal drug for its treatment. The incubation period ranges from 18 to 40 days.

Plasmodium knowlesi

Plasmodium knowlesi is a malaria parasite found in monkeys which can infect humans via mosquito bites (Moyes et al. 2014). Human infection was first reported in 1964. It was however not until 2004 that reports of a large focus of naturally acquired human infections in Sarawak, Malaysia brought this species to greater global attention (Singh et al. 2004). *P.* knowlesi causes life-threatening malaria yet it is grossly under-reported and often misreported as *P. malariae*. It is the most common cause of malaria in Malaysia. Cases have also been reported in Indonesia, Thailand, Vietnam, and Myanmar. Infection with *P. knowlesi* is associated with high levels of parasitaemia. The risk of severe disease in adults appears as high as that of *P.* falciparum. For many years, misdiagnoses were associated with delayed administration of treatment and high fatality rates. Increased awareness of pathogenic potential has led to improvement in treatment and reduction in case fatalities (Rajahram et al. 2012; Jeremiah et al. 2014). Local transmission of *P. knowlesi* in sub-Saharan Africa is unknown and this may be due to lack of a monkey reservoir. Intravenous artesunate is highly effective in severe knowlesi malaria while chloroquine and artemisinin-combination therapy (ACT) are highly effective for uncomplicated *P. knowlesi* malaria (Barber et al. 2017). There is uncertainty about human-to-human *P. knowlesi* infection.

Life cycles of the malaria parasite and vector

Two life cycles are important in discussing how the bite of an infected female Anopheles mosquito (vector) transmits *Plasmodium* (parasite) and causes malaria. These are the life cycles of the *Plasmodium* parasite, and of the female Anopheles mosquito. A good knowledge of the essential aspects of these life cycles is important for an appreciation of how preventive and

therapeutic interventions have emerged and how they have been applied to date, their limitations and prospect for the development of new tools (Acharya et al. 2017).

Life cycle of the *Plasmodium* parasite

Malaria infection is initiated when an infected female Anopheles mosquito bites a human host. It injects into the host saliva that contain anophelin, an anticoagulant. This material counteracts the host's haemostatic response and prevents the sucked blood from clotting. In the process, the female Anopheles mosquito ingests sporozoites of *Plasmodium* parasite into the blood stream of the victim. The stage of the parasite life cycle that is transmitted in the bite is the sporozoite. Within 30 to 60 minutes of ingestion, sporozoites migrate through the venous circulation to the liver. (https://www.ncbi.nlm.nih.gov/books/NBK215619/). While within liver cells, sporozoites undergoes a series of asexual multiplications that lead to the development of schizonts that contain the next stage of the parasite called merozoites. This process is called sporogonic schizogony and because it takes place in liver, it is also called the hepatic or pre-erythrocytic stage (Mota et al. 2002; Mota and Rodriguez 2002) (Fig. 8.15.2).

Upon their maturation, merozoites burst out of schizonts and into the bloodstream where they attack red blood cells (RBCs) to begin the erythrocytic phase of development. Within the RBCs, merozoites differentiate further into ring form called trophozoites. Trophozoites undergo further asexual multiplication and develop into schizonts. This process is called erythrocytic schizogony. Schizonts burst on maturation to release more merozoites into the bloodstream. The rupture of erythrocytic-stage schizonts out of RBCs coincides with the emergence of symptoms. While within RBCs, the developing parasite digests haemoglobin and converts the waste product into hemozoin (also called malaria pigment) which are packaged in vesicular compartments called digestive vacuoles. The burst of schizonts leads to the release of digestive vacuoles (DVs) into the bloodstream, a triggering of immune response and the emergence of symptoms. While DVs get phagocytosed, merozoite largely escape the attack of the immune system, attack more RBCs, and further aggravate the illness.

Typically, it takes 10–14 days from the time of sporozoite injection to the emergence of symptoms. This is called the incubation period. The cycles of

release from RBCs and DVs, attack on new cells, and further RBC destruction underline bouts of fever, chills, and other symptoms of the disease (Mueller et al. 2015; Tannous and Ghanem 2018).

This does not constitute its endorsement or recommendation by the U.S. Government, Department of Health and Human Services, or Centers for Disease Control and Prevention During the intraerythrocytic stage, some merozoites differentiate into male (microgametocytes) and female (macrogametocytes) gametocytes. Gametocytes are the sexual forms of the

parasite and they are the stage of development that can infect mosquitoes. During a blood meal, the female Anopheles mosquito ingests gametocytes and this reinitiates the sporogonic stage of parasite development. In the gut of the mosquito, male and female gametocytes develop into gametes which merge, and over 2 to 3 weeks develop into sporozoites in the salivary glands. Higher climatic temperatures accelerate parasite development within the mosquito (Afrane et al. 2012) (https://www.cdc.gov/malaria/about/biology/mosquitoes/). This is one of the anticipated effects of climate change on malaria.

While the aforementioned is the classical presentation of the life cycle of the *Plasmodium* parasite, it important to appreciate that important difference exist in the life cycles of the different *Plasmodia*. In the case of *P. vivax* and *P. ovale*, a dormant stage (hypnozoites) can persist in the liver and cause relapses by invading the bloodstream weeks, or even years later after infection (Olliaro et al. 2016). Once in the bloodstream, *P.* vivax tends to attack reticulocytes (young RBCs) and remain in the ring form. The ability of *P. vivax* to attack RBCs is due to the presence of Duffy blood group antigens on the red cells of susceptible populations. For many years, it was thought that the absence of this antigen is the reason populations in sub-Saharan Africa are less susceptible to *P. vivax* infection. This is now firmly disputed.

Generally, the level of parasitaemia with *P. vivax* infection is much lower than occurs with *P. falciparum* infection. Gametocytaemia also tends occur earlier in the course of *P. vivax* malaria. This makes patients infectious almost at the onset of symptoms.

The different stages in the life cycle of *plasmodium* present a range of antigenic challenges to the host immune system. Antigen expression has been implicated in the aetiology of severe malaria (Pal et al. 2016, 2017). An improved understanding of the nature of antigen expression, facilitated by emerging genetic technology, should lead to the development of new diagnostic and therapeutic options for the management and control of the disease.

Life cycle of the *Anopheles* mosquito

Anopheles is a vector that belongs to the class of mosquitoes named by J.W. Meigen in 1818. While over 100 of the *Anopheles* species can transmit human malaria, only 30–40 commonly do so. *Anopheles* gambiae is one of

the best studied because of its role in malaria transmission (Afrane et al. 2012).

The anopheline mosquito develops through four stages: egg, larva, pupa, and imago. This begins with the laying of eggs in fresh or stagnant water by the female anopheline mosquito. Cans, buckets, discarded tyres, clogged rain gutters that hold stagnant water are common sites for the laying of eggs. The eggs develop into larva which further develops into the pupa. All three stages are aquatic and last about 5 to 14 days. This length of time depends on the species of anopheline, the level of humidity and ambient temperature (Beck-Johnson et al. 2013).

The adult stage emerges from the pupa on the surface of the breeding water. Female anopheline mosquitoes seek blood meals to derive vitally needed nutrients to fertilize its eggs. In the process it acts as vector for malaria and transmits the parasite into man.

Although the adult female has the potential to live for up to a month, it typically lives for no more than two weeks. For malaria transmission to be possible therefore, the *Anopheles* mosquito needs to live long enough to enable the sporogonic stage of *Plasmodium* development to be completed. One of the postulated effect of global warming is that it will shorten the sporogonic phase of parasite development and enhance the ability of the mosquito to transmit malaria (Afrane et al. 2012; Caminade et al. 2014).

Pathogenesis of malaria

All the mechanisms through which infection with *P. falciparum* leads to malaria are associated with the erythrocytic stage of parasite development (Buffet et al. 2011; Sanyal et al. 2012). When RBCs are infected by malaria parasites, they (RBCs) undergo configurational changes. These include loss of the normal discoid shape, increased rigidity of the membrane, elevated permeability to a wide variety of ionic and other species and increased adhesiveness (Mohandas and An 2012).

Sticky RBCs more easily adhere to other normal RBCs (rosetting) and to the inside walls of capillaries (cytoadhesion). Clumping, rosetting, and cytoadhesion occur, blocking small vessels and causing ischaemic cell injury in several organs of the body (Moxon et al. 2011). Most notable are the lung, heart, brain, and kidney. This explains why malaria is a multisystem disease with wide range of unspecific clinical manifestations. The effect in the brain

forms the basis of cerebral malaria. The rupture of parasitized RBCs and clearance of deformed parasitized and unparasitized erythrocytes by cells of the immune system including the spleen is the principal cause of malarial anaemia (Autino et al. 2012; Safeukui et al. 2015; White 2017). The release of toxins (packaged as digestive vacuoles referred to earlier) from ruptured RBCs into the bloodstream leads to cytokine expression and unspecific symptoms like fever, headache, loss of appetite, and vomiting.

In pregnant women, parasitized RBCs adhere to chondroitin sulphate A in the placenta. The accumulation of RBCs compromises the efficiency of the placenta and this leads to clinical manifestations such as abortion, intrauterine growth retardation, low birth weight, and stillbirths.

Cells that are attacked by RBCs express antigen on the surfaces as part of activation of the immune system. It is the repeated triggering of the immune system through antigen expression that forms the basis of immunity and tolerance to malaria (Matuschewski 2017). It is the reason the severity of malaria generally declines with increasing age and gravidity (in the case of pregnancy) in persons who live in malaria-endemic countries (Mendonca and Barral-Netto 2015). It is also the reason why individuals who have lived in endemic settings loss some immunity when they move into non-endemic settings.

An important aspect of the immune response of the body is the mobilization of all possible capacity to destroy parasitized RBCs. The major organs in the body responsible for the destruction of parasitized and damaged RBCs are the spleen and liver. Hyperactivity due to repeated attacks leads to enlargement of these organs, most particularly the spleen. Community-based prevalence of palpable spleen enlargement was in the past used as a measure of the endemicity of malaria (Snow et al. 2012).

Clinical presentation

The clinical presentation of malaria is closely related to the stages in its pathogenesis as outlined earlier. The *liver phase* of the *malaria* lifecycle occurs without clinical symptoms**.** Symptoms emerge following invasion and rupture of RBCs. In an ‘interruptible’ continuum, there are two forms of clinical presentations. These are uncomplicated and complicated or severe malaria.

Uncomplicated malaria

Uncomplicated malaria is characterized by symptoms such as fever, headache, vomiting, and general malaise. In most high transmission settings, these symptoms often trigger suspicion of malaria and the initiation of treatment, when available. Unfortunately, the symptoms of uncomplicated malaria are so unspecific that they could as well be caused by other infections, particularly viral infections. In the absence of a test, the false diagnosis of malaria leads to treatment with antimalarials. If correctly diagnosed and effectively treated at this stage, good and complete recovery is nearly always assured. Most cases of malaria are uncomplicated and do not progress to severe or complicated malaria unless treatment is delayed or wrongfully administered.

Severe or complicated malaria

When treatment of malaria is delayed or ineffectively administered, a cascade of pathophysiological events leads to progression to severe or complicated malaria. For epidemiological and research purposes, severe malaria is defined as one or more of the conditions defined in Table 8.15.1, occurring in the absence of an identified alternative cause, and in the presence of *P. falciparum* asexual parasitaemia (WHO 2014) (Table 8.15.1).

Sustained RBC destruction and multiorgan damage leads to severe or complicated malaria. Although all organs of the body are affected, the most sensitively affected at early complicated stage is the brain. Brain involvement manifests a syndrome of presentations, the most common of which is cerebral malaria. Cerebral malaria refers to the syndrome in which altered consciousness is associated with a malarial infection, and cannot be attributed to convulsions, sedative drugs, or hypoglycaemia alone, or to a non-malarial cause. Commonly associated symptoms are severe loss of appetite, inability to tolerate oral feeds, repeated vomiting, disorientation, and convulsions.

Sustained red cell destruction results in severe weakness, pallor, jaundice (yellowing of the eyes and skin), and kidney failure. At this stage, urgent and effective treatment is needed to prevent death. The highest mortalities occur in children aged less than 5 years, pregnant women, and non-immune adults.

In these persons, malaria takes a rapid course from uncomplicated to complicated state. The state of consciousness commonly assessed in children

in sub-Saharan Africa with the Blantyre coma score (BCS) is a good indicator of prognosis.

In Gambia, a BCS of 2 or less was found in a review of 2,901 children with severe malaria to be the most sensitive and specific predictor of death or development of neurological sequelae (Jallow et al. 2012). Children who survive severe malaria may develop long-term neurological deficits that impact development and performance in school (Fernando et al. 2003; Brooker et al. 2008; Clarke et al. 2008; Gomes et al. 2009; Dondorp et al. 2010). Multiorgan failure including renal failure occurs more commonly in non-immune adults than in children in highly-endemic areas.

Table 8.15.1 Epidemiological and research definition of severe falciparum malaria

Impaired consciousness	A Glasgow Coma Score <11 in adults or a Blantyre coma score <3 in children
Acidosis	A base deficit of >8 meq/L or, if unavailable, a plasma bicarbonate of <15 mm or venous plasma lactate >5 mm. Severe acidosis manifests clinically as respiratory distress—rapid, deep, and laboured breathing
Hypoglycaemia	Blood or plasma glucose <2.2 mm (<40 mg/dl)
Severe malarial anaemia	A haemoglobin concentration <5 g/dl or a haematocrit of <15% in children <12 years of age (<7 g/dl and <20%, respectively, in adults) together with a parasite count >10 ,000/µl
Renal impairment (acute kidney injury)	Plasma or serum creatinine >265 µm (3 mg/dl) or blood urea >20 mm
Jaundice	Plasma or serum bilirubin >50 µm (3 mg/dl) together with a parasite count >100, 000/µl
Pulmonary oedema	Radiologically confirmed, or oxygen saturation <92% on room air with a respiratory rate >30/min, often with chest indrawing and crepitations on auscultation
Significant bleeding	Including recurrent or prolonged bleeding from nose gums or venipuncture sites; haematemesis or melaena
Shock	Compensated shock is defined as capillary refill ≥3 s or temperature gradient on leg (mid to proximal limb), but no hypotension. Decompensated shock is defined as systolic blood pressure <70 mm Hg in children or <80 mmHg in adults with evidence of impaired perfusion (cool peripheries or prolonged capillary refill)
Hyperparasitaemia	P. falciparum parasitaemia >10%

Malaria in pregnancy

Malaria in pregnancy is a major cause of maternal morbidity and perinatal mortality in high transmission countries. Up to 9.5 million pregnant women in sub-Saharan Africa are estimated to be at risk of *Plasmodium falciparum* infection. In the absence of interventions, malaria in pregnancy results in

900,000 (95% CI 530,000–1,240,000) babies who are born with low birth weight (Walker et al. 2014).

The state of pregnancy increases the risk of malaria infection and an estimated 125 million pregnant women get infected annually. The risk of severe malaria is particularly high in primigravidae in areas of higher transmission. The development of partial immunity leads to an attenuation of the risk in successive pregnancies. This pattern is less marked in areas of low transmission. The risk of malaria is highest in the second trimester. In the first trimester, malaria increases the risk of miscarriage by 60% and the rate of mortality from severe malaria in pregnancy can be as high as 50%. Younger women are particularly at risk of malaria during pregnancy (WHO 2015b; Tarning 2016).

Pathogenesis, clinical presentation, and diagnosis

The increased susceptibility of pregnant women to malaria is due to the sequestration of malaria-infected erythrocytes in the maternal placenta. This sequestration is highest with *P. falciparum* infections. The affinity of parasitized RBCs for placenta is mediated by the expression of the parasite-derived protein VAR2CSA on the surface of infected RBCs. These cells bind to chondroitin sulphate A (CSA) in the placenta and induce placental inflammation. This inflammatory process leads to the aggregation of monocytes in the placenta, with compromise to the efficiency of the placenta as a medium of feto-maternal transfer.

Parasite sequestration in the placenta can occur in early pregnancy and lead to poor placenta development. This is evident in poor villous vasculature and small placenta size. This early effect can lead to miscarriages, intrauterine growth retardation, and death. In high transmission settings, placenta parasite sequestration can occur in the absence of malaria symptoms during early pregnancy. Concurrent parasite sequestration in the brain however results in severe malaria with possible dire consequences.

A challenge to the diagnosis of malaria in pregnancy is the fact that it may present without symptoms and blood smear microscopy will be negative even in the presence of a high parasite load in the placenta (Geelhoed et al. 2001; Kakuru et al. 2016). The sensitivity of microscopy to detect malaria parasites in peripheral blood in pregnant women can be as low as 42%. The

use of antigen-based diagnosis and Polymerase Chain Reaction increases sensitivity to about 80% and 97%, respectively (Mockenhaupt et al. 2002).

Diagnosis of malaria

Practically considered, there are three approaches to the diagnosis of malaria. These are

The presumptive approach
Rapid diagnostic test
Blood smear microscopy

The presumptive approach

The presumptive approach relies on the clinical judgement of an attending clinician, and it is based on the symptoms and signs that a patient presents with. For many years, fever was used as proxy indicator of malaria infection in high transmission settings. This was justified because transmission was high and that made malaria either a direct or underlying cause of most fevers. It was also because it was impractical to have microscopy in many settings where malaria was treated and most of the antimalarials in common use at the time were also relatively inexpensive.

The symptoms of malaria are very unspecific, and they could be caused by virtually many other acute infectious diseases. The presumptive approach was therefore associated with considerable overdiagnosis, inappropriate use of antimalarials, and selection of resistance strains. The approach also led to delayed diagnosis and management of the definitive causes of fevers. A shift away from the presumptive approach only began in the late 2000s and this was made conceivable by the development, global validation, and deployment of rapid diagnostic test kits. Today the management of malaria solely based on symptoms and signs is frowned upon and considered inconsistent with the WHO recommended strategy of '*TEST-TREAT-TRACK*' (next). The presumptive approach should therefore be used only when parasitological testing is not available.

Rapid diagnostic test

The dipstick technology for the rapid diagnosis of malaria was developed in the early 1990s. It was however not until the 2000s that they came into widespread use (Bell et al. 2006a, 2006b; Baiden et al. 2012). Rapid diagnostic tests for malaria (mRDT) are a point-of-care device that can be used to confirm parasite infection in about 15 to 30 minutes (Perkins and Bell 2008). Their availability has revolutionized the diagnosis of malaria and improved the targeting of antimalarials. The technology depends on the detection of antigens produced by the plasmodium parasite. These are histidine-rich protein-2 (HRP-2), lactate dehydrogenase (LDH), and adolase. Whereas the LDH and aldolase are expressed by all *Plasmodium* species, HRPS-2 antigen is specific to *P. falciparum*. This has made it possible to develop RDTs that distinguish *P. falciparum* from non-*P. falciparum* infections.

Important advantages with the use of mRDTs include the fact that non-laboratory technicians can use it with minimal training. It can also be deployed in all settings irrespective of infrastructural capacity. A drawback to the use of mRDTs is the fact that it does not afford a quantitative measure of the degree of parasitaemia. Additionally, antigen persistence in the bloodstream means HRP-2-based mRDT positive results can remain positive for up to 3–4 weeks after successful treatment (Baiden et al. 2012; Mbabazi et al. 2015; de Oliveira et al. 2009). HRP-2-based mRDTs can therefore not be used to monitor therapeutic response and, therefore blood smear microscopy should be used in the diagnosis and management of severe malaria.

An emerging challenge is the deletion of *Plasmodium falciparum hrp2* and *hrp3* genes from the genome of some parasites. This can affect the performance of HRP2-based mRDTs. These have been reported in South America, India, Eritrea and Kenya and are likely to spread as parasites with *hrp2* and *hrp3* genes will escape detection during test (Nima et al. 2017). Although the prevalence of HRP2 gene deletions in most high transmission countries remains low, effective surveillance is needed (Gamboa et al. 2010; Beshir et al. 2017; WHO 2018a).

Blood smear microscopy

Microscopy has been the mainstay for the definitive diagnosis of malaria since the work of Alphone Laveran. It involves taking venous blood,

preparing a blood smear on a glass slide, processing it, and reading under a light microscope. A technically competent technician is required to read the slide. The process requires much sophistication in terms of infrastructure, logistics, and technical competence. In most parts of the malaria-endemic world, the capacity to perform malaria microscopy could not be sustained beyond regional and district levels. Even in facilities that have the capacity to perform malaria microscopy, results may become available after treatment has been initiated due to the time it takes to perform this test. In the hands of a well-trained microscopist, microscopy is the gold standard for the diagnosis of malaria.

A major advantage of microscopy is the fact that it affords species differentiation and quantification of parasite load. It can therefore be used to monitor parasite load as part of response to treatment. A major reason why the capacity for blood smear microscopy needs to be sustained is the fact that the possibility of diagnosis of other infectious diseases adds to the utility and cost-effectiveness of blood smear microscopy.

Polymerase chain reaction (PCR) in malaria diagnosis

Another approach to detecting malaria infection is the use of PCR-based assays. PCR-based assays for the detection of malaria parasites were developed in the 1990s. They have over a 100-fold greater sensitivity than microscopy for the detection of malaria parasitaemia. High cost and technical sophistication however limit its use as a point-of-care device. They are extremely useful for surveys in areas where malaria is approaching elimination and where low levels of parasitaemia make microscopy and mRDT less useful. A setting where PCR-based assays could be extremely useful is detecting malaria infection during pregnancy.

T3: Test-Treat-Track

On World Malaria Day 2012, WHO launched *T3: Test. Treat. Track*, with a call on malaria-endemic countries, donors, and the global malaria community to scale-up diagnostic testing, treatment, and surveillance for malaria. The T3 strategy was premised on the vastly improved availability of quality-assured mRDTs, the substantially reduced levels of malaria

transmission and the need for prudent use of the available range of antimalarials (WHO 2010, 2015b).

Consistent with the strategy, it is now required that all cases of suspected malaria be confirmed through parasitological testing before treatment is initiated. In various trials and operational research, this approach has been shown to lead to significant reduction in the use of antimalarials. Reductions of between 30% and 60% have been reported (Skarbinski et al. 2009; D'Acremont et al. 2010; Kyabayinze et al. 2010; Thiam et al. 2011; Yukich et al. 2012). In a trial in a high transmission setting in Ghana however, the reduction in antimalarial use was a rather modest 12%. It was found in this trial that relying on the results of mRDTs to manage under-5 children presenting with fever (compared with the presumptive approach) improved the targeted use of antimalarials without compromise to clinical outcomes (Baiden et al. 2016). The use of mRDTs in the management of uncomplicated malaria has also been found to be cost-effective in diverse transmission settings (Yukich et al. 2010; Tawiah et al. 2016).

Improved targeted use of antimalarials has come at some considerable cost. In the absence of tools to establish the aetiology of other fevers, there has been a shift towards increased presumptive use of antibiotics in the management of non-malaria febrile illnesses (Baiden et al. 2011; Iroh Tam et al. 2016). An improved understanding of the aetiology of fevers in malaria-endemic countries is needed if clinicians in sub-Saharan Africa are to be better-guided (Baiden et al. 2012; D'Acremont et al. 2014; Hopkins et al. 2017).

Treatment of malaria

The primary goals of malaria treatment are:

To achieve cure and complete recovery in patients
To reduce the risk of transmission of the infection to others, by reducing the infectious reservoir and
To prevent the emergence and spread of resistance to antimalarial medicines

The effectiveness and utility of antimalarials are assessed on their intrinsic potential to achieve these goals.

Antimalarial drugs

Artemisinins

The remarkable story of the discovery of artemisinin and the establishment of its antimalarial activity by Chinese scientists represents one of the great discoveries in medicine in the latter half of the twentieth century (Krishna et al. 2008). The artemisins are a class of antimalarials derived from the Chinese plant, *Artemisia anua*, or sweet wormwood.

It is a herb that has been part of traditional medicine in China for over 1,000 years. In 1972, Youyou Tu, a scientist at the China Academy of Traditional Chinese Medicine, extracted the artemisinin from *Artemisia anua* (Liu and Liu 2016). Today, treatments containing artemisinin derivatives are part of the standard treatment for malaria.

In 2015, Youyou Tu was awarded the Nobel Prize in Medicine for her pioneering work. The artemisinins and its semi-synthetic derivatives are described as a gift of Chinese traditional medicine to the world. The account about how the artemisinins have today emerged as the most important class of antimalarials is a classic in global health. It is one that calls for respect for oriental alternative and complementary medicine (Guo 2016; Ikram and Simonsen 2017).

Artemisinin is a sesquiterpene, lactone-containing a distinctive peroxide bridge that is hypothesized to be responsible for its antimalarial properties. Once in the bloodstream, artemisinin derivatives kill the majority of parasites within a few minutes while getting rapidly metabolized. The poor level of artemisinin bioavailability limits its effectiveness. Semi-synthetic derivatives have been developed to overcome this limitation. Dihydroartemisinin is the active metabolite of all the artemisinin compounds. It is now available as a drug in the form of dihydorartemisinin-piperaquine (Baiden et al. 2015; Adjei et al. 2016; Oduro et al. 2017). The side effects of the artemisinins are minor and include nausea, vomiting, persistent cough, and dizziness. Very little is known about the teratogenicity of the artemisinins. They are therefore not recommended for routine use in first trimester pregnancy. This is likely to change soon.

It was initially thought that the short half-lives of the artemisinins will limit the possibility of resistance development. Recent reports however confirm the emergence of artemisinin resistance in the Southeast Asia region. Artemisinin resistance is now a major global public health concern

(Mbengue et al. 2015; Woodrow and White 2017). Derivatives of the artemisinins that are in common use are artesunate, artemether, and arteether.

Artesunate is a water-soluble ester derivative of the artemisinin. It is used in combination with antimalarials like amodiaquine, sulphadoxine-pyrimethanine and mefloquine in the treatment of uncomplicated malaria. Artesunate in combination therapy is first-line drug for the treatment of uncomplicated malaria in many countries in sub-Saharan Africa and Southeast Asia. As monotherapy, it is administered intravenously or intramuscularly to treat severe malaria. In a series of clinical trials conducted among Asian and African populations, the superior efficacy of artesunate (compared to quinine and artemether) was established (Dondorp et al. 2005, 2010; Esu et al. 2014). Rectal artesunate is a particularly useful formulation for the home and community-level management of severe malaria in children who are so sick they cannot tolerate oral medications. Where reaching the nearest health facility is likely to be delayed because of remoteness, rectal artesunate has been demonstrated to reduce the risk of death and neurological sequelae in children less than five years of age (Gomes et al. 2009).

Artemeter is a semi-synthetic, lipid-soluble methyl ether of dihydroartemisinin. When administered intramuscularly, peak plasma concentration is achieved within 6 hours. Artemeter has very rapid schizontocidal activity against blood forms of *P.* falciparum and *P.* vivax. It is combined with lumefantrine in the popular antimalarial brand Coartem (Artemeter-Lumefantrine). It is also among the first-line drugs for the management of uncomplicated malaria in most malaria-endemic countries in sub-Saharan Africa. Intramuscular injection of Artemeter is used in the treatment of severe malaria.

Arteether comes in two forms: artemotil and alpha/beta arteether, both of which are given as an intramuscular injection once a day. It is the least commonly used among the artemisinin derivatives.

Artemisinin-combinations are the most effective antimalarial medicines available today. Five ACTs are currently recommended by WHO for use against *P.* falciparum malaria. Individual country choice of ACT should be based on the knowledge of the local strains of *P.* falciparum and ACT efficacy. Unfortunately, artemisinin is produced in small quantities and this leads to a shortage of global supply and increase in price (Peplow 2016; Ikram and Simonsen 2017).

Chloroquine

Chloroquine is a 4-aminiquinolone that was discovered in 1934 and had over 60 years of widespread use in the treatment of malaria. Chloroquine is administered through oral and intramuscular routes. A bitter taste and itching are its major side effects. Once in the bloodstream however, chloroquine kills asexual forms of the parasite. It has no activity against mature gametocytes and does not have effect on either sporozoites or hypnozoites of *Plasmodium vivax*. Its terminal elimination half-life is 45–55 days. Its major plasma metabolite desethylchloroquine has a longer half-life of 59–67 days. Chronic use (as in the treatment of skin conditions) can result in retinopathies. Ease of production, monotherapy and sustained presumptive use led to the emergence of parasite resistance which by the late 1990s had surpassed the WHO recommended threshold of 25% in many malaria-endemic countries (Abuaku et al. 2005; Oduro et al. 2005; Takala-Harrison and Laufer 2015).

The WHO no longer recommends chloroquine for the treatment of malaria in sub-Saharan Africa. It is however retained (in combination with primaquine) for treatment for *vivax* or *ovale* malaria in travellers that aim at radical cure. Recent reports however suggest chloroquine efficacy is re-establishing in some areas in sub-Saharan Africa where resistance was initially high, and where chloroquine has not been used for many years (Kublin et al. 2003; Frosch et al. 2014; Galatas et al. 2017; Ndam et al. 2017). It is possible that chloroquine will regain efficacy and be reintroduced for malaria prevention and treatment.

Amodiaquine

Amodiaquine is a 4-aminoquinolone that is similar in structure and activity to chloroquine. It has been used as an antimalarial since 1948 and remains active against many of the chloroquine-resistance strains of the parasite. It is considered safe for use in post-first trimester pregnancy although tolerability precludes its use in intermittent presumptive treatment (Clerk et al. 2008). In combination with artesunate, amodiaquine is among current first-line drugs for the treatment of malaria in some sub-Saharan African countries. Like chloroquine, amodiaquine can be produced synthetically and is considered an affordable antimalarial. It has a bitter taste and the main side effects are

headache, drowsiness, and visual disturbances. Cardiac arrest may occur with overdose (Olliaro and Mussano 2003).

Sulfadoxine-pyrimethamine

This is a combination drug that contains sulfadoxine (a sulfonamide) and pyrimethamine (an antiprotozoal). It has been used for decades in the treatment and prevention of malaria. The combination acts synergistically to inhibitor protozoan folate synthesis. While the sulfadoxine competes with p-aminobenzoic acid, pyrimethamine serves as selective inhibitor of dihydrofolate. For many years sulfadoxine-pyrimethamine was used in the treatment of uncomplicated malaria, and over a brief period in the early 2000s it was used in combination with artesunate for the treatment of uncomplicated malaria in India, and some countries in east and southern Africa. Growing parasite resistance has lowered the efficacy of sulfadoxine-pyrimethamine in many parts of sub-Saharan Africa. Currently sulfadoxine-pyrimethamine is almost exclusively used in intermittent preventive treatment (IPT) during pregnancy (Owusu-Boateng and Anto 2017). Its use for this indication is however threatened by resistance mutations in the parasite dhps gene. Hypersensitivity can result in Stevens–Johnson syndrome. Sulfadoxine-pyrimethamine is synthetically produced and is considered an affordable antimalarial.

Primaquine

Discovered in 1946, primaquine is an 8-aminoquinoline used in the treatment and prevention of malaria caused by *P. vivax* and *P. ovale*. Primaquine is recommended for primary prophylaxis prior to travel to *P.* vivax-endemic regions. In low transmission settings, a single dose of 0.25 mg/kg body weight of primaquine combined with ACT is recommended to patients with *P. falciparum* malaria except pregnant women, infants aged less than 6 months and women breastfeeding infants less than 6 months of age. This is intended to reduce the risk of transmission.

Until recently primaquine was the only antimalarial drug capable of eliminating hypnozoites, the dormant liver form of Plasmodium vivax. It was therefore used to prevent malaria relapse in persons who travel to *P.* vivax-endemic regions. Primaquine has rapid and potent ability to kill the gametocytes of *P. falciparum* and *P. vivax*. In early 2018, the Food and

Drugs Agency (FDA) of the United States of America approved *Krintafel* (tafenoquine), as a single dose antimalarial for radical cure (prevention of relapse) of *P. vivax* malaria. It is approved for use in patients aged older than 15 years and who are receiving appropriate antimalarial therapy for acute *P. vivax* infection.

Primaquine kills gametocytes and because of this, WHO in 2012 recommended that a single dose of 0.25 mg/kg primaquine be added to malaria treatment schedules in areas with artemisinin resistance and where the intent is to stop malaria transmission. The side effects of primaquine include nausea, vomiting, and stomach cramps. Primaquine is contraindicated in persons with glucose-6-phosphate dehydrogenase deficiency (G6PD). In such persons, primaquine cause dose-dependent oxidant haemolysis in individuals with glucose-6-phosphate dehydrogenase (G6PD) deficiency (Watson et al. 2018). It is similarly for this reason primaquine is contraindicated in pregnant women and lactating mothers. There is synthetic production of primaquine and it is considered an affordable antimalarial. A case report in 2018 has highlighted the important role CYP-4502D6 mutation plays in primaquine treatment failure (Dijanic et al. 2018).

Quinine

Quinine is a basic amine that was first isolated in 1820 from the bark of a cinchona tree and has remained an effective antimalarial drug to date. Prior to its laboratory isolation, the bark of the cinchona tree was used in the treatment of fever for well over a century. Quinine is hypothesized to act against *P. falciparum* by interfering with the parasite's ability to dissolve and metabolize haemoglobin in RBCs. Quinine in its various salts is administered orally, intravenously, and intramuscularly. Until recently, quinine was the drug of choice for the treatment of severe and complicated malaria. Although it remains among drugs listed in many national guidelines for the management of severe malaria, intramuscular artemether, intravenous and intramuscular artesunate are preferred (see next). The common side effects of quinine are headache, palpation, nausea, tinnitus, hearing impairment, dizziness, blurred vision, and disturbance in colour perception. An important side effect of intravenously administered quinine is the risk of hypoglycaemia. Quinine toxicity can lead to cardiac arrest. Although quinine

can be synthetically produced, the cinchona tree remains the most economically-viable source of it (Shanks 2016; Gachelin et al. 2017).

Treatment of malaria during pregnancy

Except in the first trimester, the drugs recommended for use in malaria in non-pregnancy adults can also be use pregnant women. This includes artemisinin-based derivatives. The use of the artemisinin-based derivatives in the first trimester however remains restricted to situations where the benefits of its use outweighs the risk or where safer options are not available. There are increasing calls on WHO to reverse the current restriction and recommend the use of artemisinin derivatives for the treatment of malaria during the first trimester (Moore et al. 2016). The antimalarial medicines considered safe in the first trimester of pregnancy are quinine, chloroquine, clindamycin, and proguanil. WHO recommends the combination of oral quinine and clindamycin for the treatment of malaria in the first trimester of pregnancy (Table 8.15.2).

Table 8.15.2 Effects of *P. falciparum* malaria in pregnancy and the drugs used in the management

	Adverse effects		Drug options for treatment	
	Pregnant woman	**Foetus and baby**	**Uncomplicated**	**Severe or complicated**
1st Trimester • Psychological effects of miscarriage • Anaemia	• Miscarriage • Intrauterine growth retardation	• Oral quinine + clindamycin • Oral quinine	• IV/IM Quinine • IV/IM Artesunate • IM Artemeter
2nd and 3rd Trimesters • Premature delivery • Anaemia • Hypoglycaemia (if on quinine) • Pulmonary oedema • Death • Increased risk of other infections	• Intrauterine growth retardation • *In utero* death	• Artesunate-amodiaquine • Artemeter-lumefantrine • Dihydroartemisinin-piperaquine	• IV/IM Artesunate • IM Artemeter • IV/IM Quinine
Delivery and postpartum • Premature labour • Bacterial infection	• Stillbirth • Low infant birth weight • Neonatal death		

Vector control

An important part of malaria control involves killing the mosquitoes and or destroying breeding sites. This approach is referred to as vector control. Vector control interventions that have proven to be efficacious and are in common use are sleeping under an insecticide-treated net (ITNs) and in-door residual spraying (IRS). Both interventions rely on the use of chemical insecticides (Alonso et al. 2011; Williams et al. 2018).

Insecticide-treated nets

Investigation into the efficacy of ITNs began in the late 1980s and early 1990s with series of studies in different parts of sub-Saharan Africa that assessed the effect of ITN use on morbidity and all-cause child mortality. ITN use has been demonstrated to reduce overall childhood mortality by between 17 and 33% (Alonso et al. 1991; D'Alessandro et al. 1995; Binka et al. 1996; Nevill et al. 1996; Habluetzel et al. 1997; Lengeler et al. 1998; Phillips-Howard et al. 2003; Binka and Akweongo 2006). The use of ITNs was subsequently shown to provide community-wide protection by reducing the number of infective mosquitoes in the vicinity where ITNs are used (Binka et al. 1998).

An important basis for the development of ITNs was the fact that most biting by the vector mosquitoes occurred at hours of the night when most people were in bed. The peak-biting activity of *Plasmodium*-transmitting mosquitoes in sub-Saharan Africa was known to be between 22.00 hrs and 05.00 hrs. Sleeping under an ITN therefore reduced the risk of bite and enhanced the killing of mosquitoes that are likely to transmit parasites. At about the mid-2000s however, evidence emerged of change in the biting pattern of *Anopheles funestus* following massive deployment of long-lasting insecticide nets (LLINs). Evidence is now firmly established, and this adaptive behaviour of the vector now poses a challenge to the use of ITN in malaria vector control and elimination.

Notwithstanding the aforementioned, sleeping under an ITN remains one of the most cost-effective interventions in malaria control. In rural northern Ghana, the estimated cost per discounted healthy life-year gained is US $73.5 (Binka et al. 1997). In other areas, the cost per death averted could be as high as US $1,449 (Yukich et al. 2009).

To promote widespread use of ITNs, free distribution is undertaken in several endemic countries. Between 2014 and 2016, a total of 582 million ITNs (505 million in sub-Saharan Africa) were delivered by manufacturers globally. In Africa 75% of ITNs were distributed through mass distribution campaigns. Household ownership of at least one ITN has increased from 50% in 2010 to 80% in 2016. More people at risk of malaria in Africa are sleeping under an ITN. In 2016, 54% of the population was protected by this intervention, an increase from 30% in 2010 (WHO 2018a). The scale-up in the distribution of ITNs is reported to account for the substantial reduction in malaria transmission, and related morbidity and mortality in sub-Saharan Africa (Bhatt et al. 2015).

Two major challenges confront the continued effectiveness of ITN use in malaria control. First is the emerging gap between ITN possession and use (Lengeler and Snow 1996). In rural northern Ghana, ITN use is found to depend on cost and time of the year (Binka and Adongo 1997). Free mass distribution of ITNs has overcome the problem of cost in many places and has led to high levels of household possession though there is still inadequate access to ITNs even in the household with these ITNs. These high levels of possession are however not matched with usage (Doda et al. 2018).

A second major challenge is the spread of insecticide resistance to the chemicals used to impregnate nets (Ranson and Lissenden 2016; Kisinza et al. 2017; Rakotoson et al. 2017). Pyrethroids are the most commonly used insecticides. Resistance to pyrethroids is now widespread in *An. Gambiae* and *An. Funestus* mosquitoes, the major malaria vectors. A breakthrough in efforts to overcome ITN insecticide resistance was recently reported in a trial led by the London School of Hygiene & Tropical Medicine. The trial involved 15,000 children in Tanzania and it found that compared with nets impregnated with pyrethroid, nets impregnated with piperonyl butoxide reduced malaria infections by 44% (Protopopoff et al. 2018). This finding has prompted WHO to revise its recommendations on ITN production and use. It now recommends the use of nets sprayed with piperonyl butoxide in areas in Africa where mosquitoes are pyrethroid-resistant. A trial that is evaluating the effects of using combinations of nets in currently underway in Burkina Faso.

Indoor residual spraying

IRS is one of the oldest interventions in malaria control and elimination. Literally put, it is a ‘recycled’ and ‘repackaged’ malaria control intervention. With dichlorodiphenyltrichloroethane (DDT) as insecticide, IRS was the principal method by which malaria was eliminated in many countries between the 1940s and 1960s. An estimated 700 million people mainly in Europe, Asia and Latin America were freed of the risk of malaria within a 20-year period (Mabaso et al. 2004; Africa WHOROf 2007). IRS involves spraying the inside walls of dwellings with insecticides. The technical basis is that the inner walls of dwellings retain doses of insecticide that are sufficiently lethal to kill mosquito that rest on these walls.

In the years that followed the WHO-led efforts in the 1940s through the 1960s, IRS got used sparingly amid concerns that DDT use in sub-Saharan Africa would cause damage to ecology and poisoning within the food chain. Eventually DDT was banned from use as an IRS insecticide. The development of pyrethroids as alternative re-ignited interest in IRS but this was short-lived as insecticide resistance reduced effectiveness. An epidemic of malaria in South Africa in 1999–2000 however compelled authorities in the country to obtain international exemption to use DDT in an IRS-based malaria elimination programme. The success of this programme re-ignited interest in the use of IRS and DDT in countries in the southern Africa region (Mabaso et al. 2004; Channa et al. 2012a, 2012b). Insecticides that are currently being used in IRS include DDT, pyrethroids (lambdacyahlothrin, deltamethrin, alphacypermethrin), organophosphates (malathion, pirimiphosmethyl) and carbamates (bendiocarb). In the southern Africa Region DDT remains effective and populations-at-risk in Botswana, Namibia, South Africa, and Swaziland are being protected with this intervention (Smith Gueye et al. 2016a, 2016b). Resistance to cheaper insecticides and the need to shift to more expensive chemicals is slowing IRS implementation in the rest of sub-Saharan Africa (WHO 2018a). According to the 2018 World Malaria Report, IRS protection declined from a peak of 5% in 2010 to 3% in 2017, with decreases seen across all WHO regions. In the WHO African Region, coverage dropped from 80 million people at risk in 2010 to 45 million in 2016 (WHO 2018a). The intervention is also particularly popular with households because it can be disruptive of normal life.

Larval source management

Larval source management (LSM) refers to the targeted management of mosquito breeding sites, with the objective of reducing the number of mosquito larvae and pupae. It is considered by WHO to be a supplementary measure in malaria vector control. The four types of LSM are:

Habitat modification, i.e. permanent alteration to the environment, e.g. land reclamation;
Habitat manipulation, i.e. a recurrent activity, e.g. flushing of streams;
Larviciding: the regular application of biological or chemical insecticides to water bodies;
Biological control: the introduction of natural predators into water bodies.

For reason that are not always clear, LSM receives very little mention in global malaria control and elimination. This is even though LSM was a major intervention in malaria eradication efforts in southern Europe in the early 1970s, Cuba, other parts of Latin America and parts of north Africa. Its effectiveness has been demonstrated in areas in Africa where it has been well-implemented. In 2009, the Governments of Cuba and Venezuela entered into agreement with countries in the Economic Community of West African States (ECOWAS), to expand larviciding activities through the provision of financial technical support, including the establishment of African based factories for larviciding products (Newman et al. 2013). Beyond the current efforts spearheaded by Cuba, there appears to be very little global interest in the implementation of LSM. There is only one mention of LSM in the 2018 World Malaria Report.

Chemoprophylaxis

Antimalarials play an important role in malaria control when they are used in chemoprophylaxis. This is targeted at the most vulnerable including non-immune travellers to malaria-endemic countries. Current major interventions in this regard are intermittent preventive treatment in pregnant women (IPTp) and seasonal malaria chemoprophylaxis (SMC).

Intermittent preventive treatment in pregnancy

The risk malaria poses to mother and child during pregnancy has always been appreciated and chemoprophylaxis has been part of the management of pregnancies in endemic countries for many years. In the era when chloroquine was effective, weekly subtherapeutic doses was recommended to prevent malaria during pregnancy (Geelhoed et al. 2001). The mass

presumptive use of subtherapeutic doses and limited adherence contributed to parasite resistance to chloroquine.

Trials conducted in the late 1990s to early 2000 to explore alternative drugs led to the choice of sulfadoxine-pyrimethamine (SP). In clinical trials, the use of SP in IPTp reduced the risk of moderate-to-severe anaemia, antenatal parasitaemia, placental parasitaemia, spontaneous abortions and low birthweight by 40%, 62%, 55%, 39%, and 19%, respectively (Wilson et al. 2011; Desai et al. 2018). Currently WHO recommends that in areas of moderate-to-high malaria transmission, IPTp with SP is given to all pregnant women at each scheduled antenatal care visit after the first trimester. The first IPTp-SP dose should be administered as early as 13 weeks' gestation and each subsequent dose should be at least one month apart. The last dose may be administered up to the time of delivery (WHO 2015b).

Logistic and other reasons continue to hamper effective implementation of ITPp-SP in many countries in sub-Saharan Africa. According to the 2018 World Malaria Report, an estimated 22% of eligible pregnant women received the recommended three or more doses of IPTp in 2017. This was up from 17% in 2015, 19% in 2016, and 0% in 2010. Coverage varies considerably by country. It is only Zambia that has coverage of the third ITPp dose (IPTp3) was 50% or more as at 2017 (WHO 2018a).

With continued concern about parasite resistance to SP, dihydroartemisinin-piperaquine looks the most promising as potential alternative or replacement antimalarial. Trials have demonstrated that it is well tolerated, effective, and acceptable, although it is also vulnerable to development of artemisinin resistance (Chico and Moss 2015; Kakuru et al. 2016; Tarning 2016; Rogerson et al. 2018).

Seasonal malaria chemoprevention

In many parts of the world where malaria is a major cause of morbidity and mortality, transmission is highly seasonal. This pattern offers the opportunity to implement interventions that are targeted at the time of the year when incidence of malaria is highest. This principle underlines SMC. This is an intervention in malaria control where young children are provided with a treatment course of an effective antimalarial combination at monthly intervals for 3 or 4 months during the peak period of malaria transmission.

In clinical trials, this approach reduced the incidence of uncomplicated malaria by 82% and of severe malaria by 82%. The WHO in 2012 recommended that SMC with SP and amodiaquine (AQ) be used in children aged ages 3–59 months in areas of sub-Saharan Africa where malaria transmission is highly seasonal, and parasites are sensitive to these drugs (Cairns et al. 2012; Matangila et al. 2015; Coldiron et al. 2017; Greenwood 2017) (Fig. 8.15.3). There is growing evidence of the need to extend this intervention to older children due to the benefits being shown in that particular age group and the observed increasing burden of malaria in children older than 5 years. A similar principle has been proposed for the deployment of malaria vaccines that have high initial efficacy, but which provide only a short period of protection. An on-going trial in Burkina Faso and Mali is exploring this hypothesis (Greenwood 2017; Greenwood et al. 2017).

Intermittent preventive treatment in infants

Intermittent preventive Treatment for Infants (IPTi) is the administration of a full therapeutic course of SP delivered through the Expanded Programme on Immunization at defined intervals corresponding to immunization schedules (usually at 10 weeks, 14 weeks, and nine months of age) to infants at risk of falciparum malaria in areas of high-to-medium transmission (Gosling et al. 2009).

IPTi reduces clinical malaria, anaemia, and severe malaria in the first year of life. Despite WHO recommending IPTi in 2009, only Sierra Leone has incorporated it into policy and implemented the intervention; albeit on a limited scale.

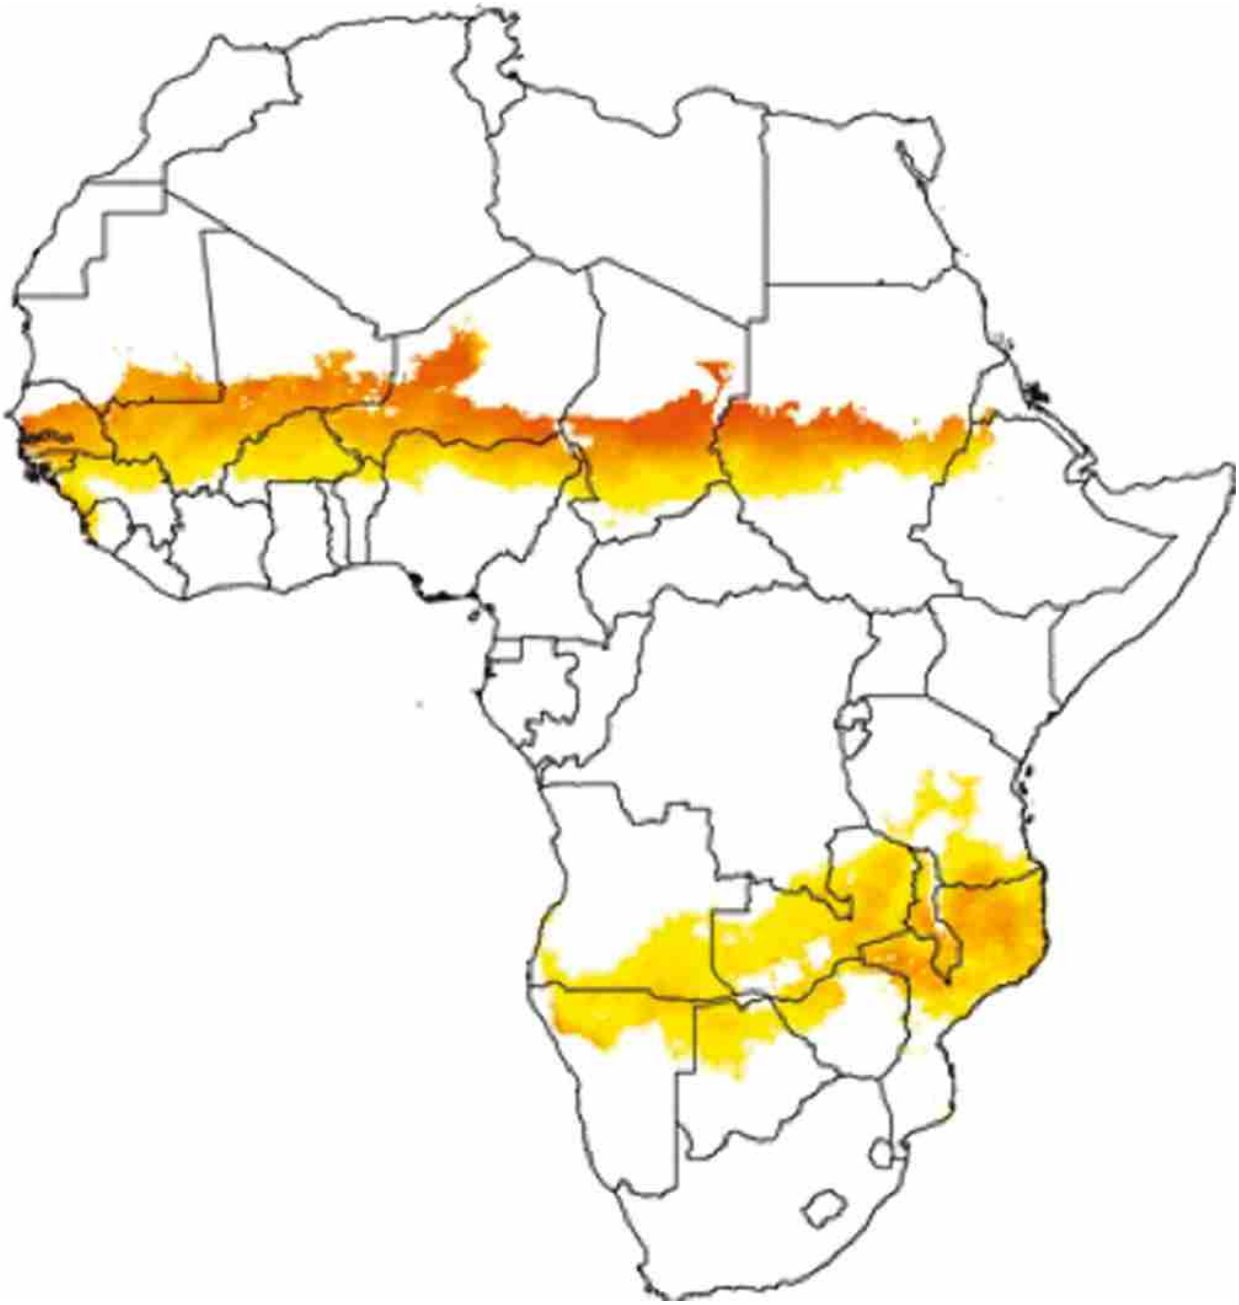

Fig. 8.15.3 A map of sub-Saharan Africa showing the areas where malaria transmission is likely to be highly seasonal.

Mass drug administration

Mass drug administration (MDA) consists in the administration of a full dose of antimalarial treatment, irrespective of the knowledge of symptoms or presence of infection, to an entire population in a given area, except those in whom the medicine is contraindicated. In the context of transmission reduction, MDA aims to provide therapeutic concentrations of antimalarial drugs to as large a proportion of the population as possible in order to cure asymptomatic infections and to prevent re-infection during the period of post-treatment prophylaxis. To impact on transmission, MDA requires high coverage of the target population which, in turn, demands a high level of community participation and engagement.

MDA has played an important role in the control and elimination of neglected tropical diseases (NTDs) such as trachoma, lymphatic filariasis, and onchocerciasis. WHO recommends MDA to achieve the following: (1) Interrupt falciparum malaria transmission in areas where elimination is the target; (2) To reduce the risk for spread of multidrug resistance in the Greater Mekong area; (3) Reduction in malaria burden during malaria epidemics and exceptional complex emergencies. Examples of exceptional complex emergencies was the MDA undertaken during the Ebola outbreak in West Africa (2014–2016) and the outbreak that followed in the Democratic Republic of Congo.

Malaria and travel medicine

There are 91 countries where international travellers may be at risk of malaria (WHO 2018a). For non-immune travellers to tropical regions, the risk of malaria is an ever-present danger. Non-immune here refers to persons who are ordinarily resident in temperate, non-malaria-endemic countries. Persons who were originally resident in malaria-endemic countries but have travelled and stayed out in a non-endemic country for more than six months are also considered as non-immune. For such persons, little or no immunity exist against malaria and they are at risk of malaria developing in the very severe forms. The disease can take a rapidly deteriorating course and may develop into cerebral malaria with a few hours to a day.

Non-immune travellers to tropical countries need to seek expert advice. They may be required to begin antimalarial chemoprophylaxis while at their countries of origin, continue during the period of stay in the tropical region and then for a period when they are back to their countries of regular

residence. *Malarone*, containing atovaquone and proguanil is one of the most commonly used antimalarial prophylaxis. Other antimalarials used in antimalarial prophylaxis are mefloquine and doxycycline. An emerging alternative to malaria chemoprophylaxis is 'standby emergency treatment' (SBET). This consist of providing travellers with emergency malaria treatment for self-administration in case of fever when no medical attention is available, or eventually for use under medical supervision after a confirmed malaria diagnosis (Genton and D'Acremont 2017).

As much as feasible pregnant women and children aged less than 5 years should put off non-essential travel to malaria-transmission areas. Where travel is unavoidable, appropriate advice should be sought on the best forms of malaria protection and chemoprophylaxis before, during and after travel (Irvine et al. 2011). This includes avoiding mosquito bites through the use of ITNs, protective clothes, and mosquito repellents.

Malaria vaccines

The current highly invigorated efforts to control, eliminate, and possibly eradicate malaria will have a greater likelihood of success if an effective vaccine were to become available to complement other interventions. The anticipation that this will be achieved has never been greater as gene technology is leading to identification of more target *plasmodium* antigens. The three main mechanisms being explored in malaria vaccine development are: (1) anti-infection; (2) transmission-blocking; and (3) antidisease. The most advanced malaria vaccine to date is the anti-infection RTS,S/AS01 vaccine developed by GlaxoSmithKline (GSK).

RTS,S/AS01 vaccine

The RTS,S/AS01 vaccine is an example of an anti-infective mechanism in malaria vaccine development. It is a monovalent recombinant protein vaccine that targets a fragment of the circumsporozoite protein parasite antigen. It has been evaluated in large phase 3 trials in 11 sites across Africa. These trials took place between 2009 and 2013 and showed the vaccine to offer partial protection against clinical malaria in the older age group (5–17 months). Efficacy in children who received three doses plus a booster on months 0, 1, 2, and 20 was 36.3% between month 0 and study end (median

48 months per child). This was a decline from 50.4% achieved 14 months from the first dose. No significant efficacy against severe malaria was noted in the 6–12 week age group; not even with a booster over the duration of the trial (Moorthy and Okwo-Bele 2015; Rts 2015). The RTS,S/AS01 vaccine has received a positive scientific opinion from the European Medicines Agency in July 2015 and WHO has recommended limited, pilot deployment in Ghana, Kenya, and Malawi. The deployment is being undertaken under the banner of the Malaria Vaccine Implementation Programme (MVIP) and is targeted at children who are at least 5 months of age. The objective is to assess the feasibility of administering the needed four doses of the vaccine in children, and whether administrative will be safe and effective in reducing the incidence of malaria among vaccinated populations. The programmes in Malawi and Ghana were launched in April 2019.

Transmission-blocking vaccines (TBV)

TBV are designed to target the sexual stages of parasite development in the mosquito. They utilize antigens expressed by gametocytes, gametes, zygotes and ookinetes to induce antibodies capable of attacking the parasite in the mosquito and impairing its viability and further development. TBVs that have reached human trials include Pfs25 and its Plasmodium vivax ortholog Pvs25, and Pfs230 (Ogobara et al. 2018).

The antigen Pfs25 has been the most evaluated. It is made up of a glycosylphosphatidylinositol-linked protein which is expressed on the surface of ookinetes. Its configuration is complex and eluding full elucidation. An improved understanding of the structural conformation of the antigen and the finding of a good matching adjuvants will likely make Pfs25 and other TBVs important additions to existing tools for malaria elimination and eradication.

Pre-erythrocytic vaccines

Pre-erythrocytic vaccines target the sporozoite and liver stages of Plasmodium and are designed to prevent disease and interrupt transmission. The leading approach in this mechanism is the vaccination using whole sporozoites which are genetically attenuated parasites, radiation attenuated sporozoites, and/or wild-type sporozoites administered in combination with

chemoprophylaxis. The principle of immune response following vaccination with whole sporozoites have been established (Coelho et al. 2017). As with the TBVs, the principal challenge is improving upon the level of immune response that is induced.

The PfSPZ is a non-replicating irradiated whole sporozoite vaccine which has entered human trials. In Mali, it proved to be efficacious against naturally transmitted parasites. A phase 3 programme is currently being developed.

It has been proposed that an imperfect malaria vaccine may still be useful if used in seasonal vaccination against malaria (Greenwood et al. 2017). While the findings of the RTS,S/AS01 vaccine moves the world closer to the goal of an effective enough malaria vaccine, the rapid waning of immunity and the lack of effect in children aged 6–12 weeks proved that it did not get the human immune system to do more than it will naturally do. Proving the principle is nevertheless a significant breakthrough and there is optimism that the world is not too far away from achieving the target of a truly effective and practical malaria vaccine.

Surveillance

Public health surveillance is the continuous, systematic collection, analysis, and interpretation of health-related data needed for the planning, implementation, and evaluation of public health practice. An effective surveillance aims to achieve the following:

Provide early warning for impending public health emergencies;
Benchmark set goals and track progress in the outcome of intervention(s); and
Accurately define the epidemiology of the health problem to enable priority-setting and informed public health policy and strategies.

The Global Technical Strategy (GTS) for Malaria 2016–2030 emphasizes the need for universal coverage of core malaria interventions for all populations at risk and highlights the importance of using high-quality surveillance data for decision-making. Surveillance is one of the three pillars of the GTS for Malaria 2016–2030, transformed from a routine activity of

the health system into a core intervention in all settings of malaria endemicity. The new 12 core principles of malaria surveillance are:

Accurate parasitological diagnosis of a malaria case should be the foundation of a malaria surveillance system.
Major components of a malaria surveillance system should be integrated within routine health management information systems (HMIS).
National standard operating procedures should be based on country needs and WHO recommendations.
Front-line staff involved in the detection, recording, and reporting of cases should be the first users of data from the malaria surveillance system.
Surveillance systems should address the within-country heterogeneity of malaria.
Necessary investments in surveillance and system transition in response to changing malaria burden should be made.
All malaria surveillance data should be linked to a decision at appropriate levels in the health system.
Concerted effort should be made to include data from all sectors, including the private sector.
Malaria surveillance may become the broad responsibility of general health services following the interruption of transmission. Malaria programme surveillance systems should however be supported to ensure monitoring.
Innovation and advances in technology should be incorporated in malaria surveillance based on empirical evidence of additional benefits, cost, and sustainability.
Malaria surveillance should incorporate regular monitoring of the efficacy of antimalarial drugs used in treatment.
Malaria surveillance systems should be assessed routinely for accuracy, reliability, completeness, precision, timeliness, integrity, and actions taken based on the results of surveillance.

The sources of data for malaria surveillance are be routine (health facility based and/or community based) or sentinel sites. Cases can be identified through an active or passive approach. The intensity of either or a mix of both is determined by the malaria transmission setting. Active approaches are increasingly adopted as transmission levels decline.

A set of 46 indicators have been recommended. These indicators consider varying levels of resources availability for malaria control (programme

financing, commodities), levels of service provision (intervention coverage), performance of systems for surveillance, monitoring, and evaluation; and trends in transmission, infection, and disease. Twelve (one for input, six for outcome, and five for impact) out of the 46 indicators are regarded as core. These are outlined in Table 8.15.3.

With surveillance a core malaria intervention, WHO in March 2018 published a thoroughly detailed reference manual for malaria surveillance, monitoring, and evaluation. This manual addresses the evidence-base for making malaria surveillance a core intervention, how malaria surveillance systems should be established, new concepts and practices of malaria surveillance, surveillance for antimalarial drug efficacy and drug resistance, approaches to entomological surveillance, and vector control monitoring and evaluation. It also addressed issues of malaria early warning, detection, and response to outbreaks, monitoring, and evaluation of national programmes. This manual is a highly-recommended text for all health professionals whose work impact the continuum of malaria control through elimination (WHO 2018b).

Table 8.15.3 The 12 recommended core indicators for monitoring malaria programmes and implementation of the Global Technical Strategy for malaria (2016–2030)

Indicator			Transmission intensity			Data source		
High	**Low and very low**	**Elimination or prevention of re-establishment**	**Routine reporting system**	**Health facility survey**	**Household survey**			
Inputs	Financing	Expenditure per capita for malaria control and elimination	**X**	**X**	**X**	**X**		
Outcome	Vector control	Proportion of population at risk sleeping under an ITN or living in house sprayed by IRS in the previous 12 months	**X**	**X**		**C**		**C**
	Chemoprevention	Proportion of pregnant women who received three or more doses of IPTp	**X**			**X**		**X**
	Case detection	Proportion of children <5 years with fever in the previous 2 weeks for whom advice or treatment was sought	**X**	**D**				**X**
	Diagnostic testing	Proportion of patients with suspected malaria who received a parasitological test	**X**	**X**		**X**	**X**	

Indicator			Transmission intensity			Data source		
High	Low and very low	Elimination or prevention of re-establishment	Routine reporting system	Health facility survey	Household survey			
	Treatment	Proportion of patients with confirmed malaria who received first-line antimalarial treatment according to national policy	**X**	**X**	**X**	**X**	**X**	
	Surveillance	Proportion of malaria cases detected by surveillance systems	**X**	**X**	**X**	**C**		**C**
Impact	Prevalence	Parasite prevalence: proportion of population with evidence of infection with malaria parasites	**X**	**D**				**X**
	Incidence	Malaria case incidence: number and rate per 1,000 people per year	**X**	**X**	**X**	**X**		
	Mortality	Malaria mortality: number and rate per 100,000 people per year	**X**	**D**	**D**	**X**		
	Elimination	Number of areas and countries that have eliminated malaria since 2015			**X**	**X**		

Indicator			Transmission intensity			Data source		
High	Low and very low	Elimination or prevention of re-establishment	Routine reporting system	Health facility survey	Household survey			
	Prevention of re-establishment	Number of areas and countries that were malaria-free in 2015 in which malaria has been re-established			**X**	**X**		

X Indicator highly relevant to the setting; **C** requires data from both routine systems and household surveys; **D** Indicator potentially relevant to the setting.

Measures of malaria frequency

The number of malaria cases per at-risk population (incidence) and the proportion of a population carrying malaria parasite in the blood (prevalence) are the most commonly used proxy indicators of the intensity of malaria endemicity. The advantage these two indicators have over other indicators are that they are relatively simple to compute and inexpensive to determine, and report within a short time. The input for the two indicators can be obtained from routine health information systems and population-based surveys. For reasons elaborated further in this section, both indicators are imprecise measures of malaria transmission (Oduro et al. 2011, 2016).

Incidence of malaria

Although absolute numbers of malaria cases, inpatients and deaths can be used to estimate trends over time and to identify places in which the problem of malaria is greatest, these are less useful for assessing which populations are at highest risk for acquiring malaria because of different population sizes. Incidence of malaria gives indication of risk of acquiring malaria and it is given by dividing the number of new cases of malaria over a given

period by the population at risk. The ascertainment of both measures has challenges in most malaria-endemic countries.

Coverage in diagnostic testing is still not universal and, in many places, there is a considerable mix of confirmed and unconfirmed cases counted among malaria cases. It is not always clear from routine health service records the number of cases of confirmed malaria and what proportion of unconfirmed cases could be estimated to be truly malaria. Another challenge is the so-called iceberg phenomenon. Access to health facilities remains a challenge in many rural and urban communities in malaria-endemic countries. Access is often limited by financial, geographical, and cultural constraints and only a fraction of people who fall sick seek care from health facilities. Health service data that are used to compute the incidence of malaria therefore tends to be biased towards underestimating the risk of disease.

To determine the population that is risk, WHO recommends the use of estimates of population size published by a relevant government department such as a statistics office, planning bureau, or census office. However, the breakdown in vital registration and the lack of systems for continuously tracking populations makes it difficult to report with certainty that figures obtained from such official sources truly represent at-risk populations. Despite these limitation, incidence of malaria when applied over a reasonable length of time and over large populations gives an accurate measure of the magnitude of risk of infection. Trend data also conveys a strong enough impression of the direction of risk.

Prevalence of malaria

The second measure of malaria frequency that is readily determined is the prevalence of parasitaemia in the population. Traditionally this represents the proportion of children aged 2–10 years who are found to have malaria parasites in their blood during surveys. National malaria programmes routinely use this to monitor the effect of interventions. The procedures have been incorporated into various demographic and health surveys, multiple indicators clusters surveys, and malaria indicator surveys. The determination of parasitemia is made at point-of-interview by trained, unskilled field workers, and the availability of mRDTs has made the procedures less cumbersome and less sophisticated.

A challenge with survey-determined malaria prevalence however is that it fails to adequately measure transmission and the burden of disease. In many high malaria transmission settings, a large proportion of children carry malaria parasites in their blood without being ill (White 2017). This phenomenon makes imprecise inferences between levels of parasitaemia and risk of disease. Another challenge is the inherent limitation in the use of mRDTs. The persistence of HRP2 antigen in the blood similarly undermines any inference that a positive mRDT connote risk of malaria. There have been attempts to establish modelling-based link between prevalence and infection rates. However, differences in model structure and calibration data has meant that no consensus yet exists on the optimal application in disease-burden estimation (Patil et al. 2009). With these caveats, the ease of application and ability to establish a trend through year-on-year consistency in procedures make the determination of parasite prevalence an attractive and pragmatic proxy measure of endemicity and impact of interventions.

Entomological surveillance indicators

The main entomological indicators are categorized into five groups:

Adult vector composition (species occurrence and density);
Adult vector behaviour (human blood index, human biting rate, biting time, biting location, resting location);
Adult vector resistance to insecticides (resistance frequency, status, intensity, and mechanisms);
Immature vector aquatic habitats (habitat availability and occupancy, larval density); and
Proxies for transmission (sporozoite rate, entomological inoculation rate (EIR), receptivity).

Two key indicators with direct implication on malaria transmission are the EIR and vectorial capacity.

Entomological inoculation rate

The most direct measure of malaria transmission is the EIR. The EIR measures the average number of infectious bites that a person receives per

year in a specified population. To compute it, two parameters need to be established. These are the human landing rate (HLR) and sporozoite carriage rate. Determining the HLR involves an elaborate process of capturing all mosquitoes that land on a person (human biting rate) throughout the night and expressing this per person per night. All captured mosquitoes are sent to the laboratory where the salivary glands of each is dissected to determine the proportion of mosquitoes that carry sporozoites (sporozoite rate—SR) (Morrow and Moss 2017). The EIR is the arithmetic product of HLR and SR. The process of determining the EIR in a given location is expensive and technically demanding. It is therefore not part of routine malaria surveillance in endemic countries. Often EIRs are only available in the context of research, or specific well-funded programmes. The day-biting characteristics of some species of the vector is becoming an increasing problem.

Vectorial capacity

Vectorial capacity (VC) is another basic indicator of malaria transmission. It is the number of new infections that the population of a given vector would induce per case per day at a given place and time, if the human population is and remains fully susceptible to malaria. It measures the rate of potentially infective contact and depends on mosquito longevity and susceptibility to *Plasmodium* infection.

It is critical for malaria transmission for the female *Anopheles* mosquito to live long enough to enable the sporogonic phase of the life cycle of the Plasmodium parasite to be completed and for sporozoites to be injected during a blood meal. Like EIR, VC provides a good measure of malaria transmission, but it is very technical to compute and therefore not routinely used.

Gametocytes carriage and its implications

The gametocyte is the stage in the life cycle of the Plasmodium parasite that is infective to the mosquito. Gametocytes are therefore vital to malaria transmission. However, because gametocyte carriage is asymptomatic (may be symptomatic in *P. vivax* malaria), this stage of arrested development in humans serves as reservoir for sustained malaria infection and re-infection. Developing antimalarial drugs that target gametocytes is an important part of

the agenda to eliminate malaria. Of recent interest is the gametocidal activity role of methylene blue (Lu et al. 2018). Adding a single dose of 0·25 mg/kg primaquine to amodiaquine and SP or 3 days of 15 mg/kg per day methylene blue to dihydroartemisinin-piperaquine has been found to prevent *P. falciparum* transmission (Dicko et al. 2018). The 'tolerant' existence of the gametocyte stage in human provides insight into how natural immunity evolves in malaria. It has been hypothesized that some level of gametocytaemia is required to sustain natural immunity (Stone et al. 2018).

Control, elimination, and eradication: the continuum

There are four distinct phases in the path towards country and global malaria-free status. These are control, pre-elimination, elimination, and prevention of reintroduction. A well-detailed process exists at WHO to define countries or regions as having transited from one phase into the other. This calls for clear, correct, and uniform use of the related descriptive terms. These have been supplied by WHO as follows:

Control: This is the reduction of disease incidence, prevalence, morbidity, or mortality to a locally acceptable level as a result of deliberate efforts. Continued intervention is required to sustain control.

Elimination: It is the interruption of local transmission (that is, reducing the rate of malaria cases to zero) of a specified parasite in a defined geographic area. Continued measures are required to prevent the re-establishment of transmission.

Eradication: It is the permanent reduction to zero of the worldwide incidences of infection caused by human malaria parasites as a result of deliberate efforts. Once eradication has been achieved, intervention measures would no longer be needed. The interchangeable use of the terms, elimination and eradication is no longer acceptable.

Malaria elimination

In 2016, WHO identified 21 countries (so-called E-2020 countries) with the potential to eliminate malaria by the year 2020 (Table 8.15.4). By 2018, 11 of these countries remained on track to achieve their elimination goals, while 10 had reported increases in indigenous malaria cases in 2017. Globally

however the elimination net keeps widening, with more countries moving towards zero indigenous cases. In 2017, 46 countries reported fewer than 10,000 such cases, up from 44 countries in 2016 and 37 countries in 2010. Between 2016 and mid-2019, the WHO Europe region, Paraguay, Algeria, and Argentina have been certified as malaria-free.

Table 8.15.4 Countries with the potential to eliminate local transmission of malaria by 2020, by WHO region (as at 2016)

WHO region	Countries
Africa region	Algeria, Botswana, Cabo Verde, Comoros, South Africa, Swaziland
Region of the Americas	Belize, Costa Rica, Ecuador, El Salvador, Mexico, Paraguay, Suriname
Eastern Mediterranean region	Iran (Islamic Republic of), Saudi Arabia
Southeast Asia region	Bhutan, Nepal, Timor-Leste
Western Pacific region	China, Malaysia, Republic of Korea

Certification

This is the WHO certification of a country as malaria-free. This certification is granted when local transmission of malaria by *Anopheles* mosquitoes has been halted for at least three consecutive years and an adequate system for preventing re-establishment of the disease has been established. The process of certification is managed at WHO by the Global Malaria Programme. It is a process that countries voluntarily submit to through application and providing the necessary proof. It is the WHO Director-General who grants the certification of malaria elimination (WHO 2016).

Malaria eradication

Over the past few years, discussions about malaria on the global scale has been dominated by issues related elimination and possible eradication, and

what it would take to achieve this feat. For many years after the failed attempt of the 1960s, the eradication of malaria was considered technically impossible. Of recent however, and particularly after the American billionaire-philanthropist Bill Gates declared eradication as a target of his foundation's malaria programme, a surge in momentum has brought back malaria eradication on the global agenda (Star 2015). Discussions have dramatically shifted from a blanket declaration of non-feasibility to which tools, if available, could make this target achievable. There is also a roll-back to an aspiration that malaria eradication can be achieved through elimination of the disease, country-by-country, region-by-region. This aspiration is given impetus in the vision of the GTS for Malaria 2016–2030, 'World-Free of Malaria'. The strategy targets elimination of malaria in 10, 20, and 35 countries by 2020, 2025, and 2030, respectively (WHO 2015c).

The Malaria Eradication Research Agenda (malERA) initiative has brought together some of the world's best malariologists to design a path in malaria research that is targeted at eradication. In the opinion of this group, malaria eradication is not feasible with current tools and state of knowledge (Alonso et al. 2011; Drugs mCGo 2011; Strategies mCGoI 2011). Among others, they advocate the need for drugs with the capacity to achieve Single Encounter Radical Cure and Prophylaxis (SERCaP). The target product profile (TPP) of such a drug should include radical cure, defined as elimination of all parasites (including the long-lived hypnozoites of *P. vivax* or *P. ovale* in the liver), suitability for mass administration (including administration to healthy subjects and the subsequent need of a very good safety profile), and prophylaxis for at least 1 month after treatment, to outlast the typical development period of *Plasmodia* parasites in anopheline mosquitoes. There is also the need to develop vaccines that will reduce and contribute to interruption of transmission, so-called TBVs. The vaccines in current development do not meet this standard as they aim at reducing morbidity and mortality, and not at blocking transmission (Drugs mCGo 2011; Vaccines mCGo 2011). To address in-country heterogenicity as the incidence of malaria declines will required new well-targeted tools for control and surveillance (Greenwood and Targett 2011). The drive towards malaria eradication is further buoyed by the formation of the Lancet Commission on Malaria Eradication in April 2018. This is a Commission of 24 experts from around the world, put together to develop a roadmap for malaria eradication (Chen et al. 2018).

Less-used terminologies

For many years, four levels of classification are used to describe malaria endemicity. These are holoendemic, hyperendemic, mesoendemic, and hypoendemic (coinciding with reducing levels of intensity and EIRs). Neither the 2018 World Malaria Report nor the WHO manual on malaria surveillance refers to this approach to classification. Currently, these terminologies are so much less-used that they are best to be avoided.

Global programme and strategy

Global Malaria Programme

The Global Malaria Programme (GMP) is WHO's lead agency in the fight against malaria. It is responsible for coordinating global efforts to control and eliminate malaria. The GMP supports Member States to achieve the GTS targets through:

Setting and disseminating global guidance and policies on malaria control and elimination;
Supporting countries as they adapt, adopt, and implement WHO global norms and standards for malaria control and elimination;
Assisting countries as they formulate national malaria strategic plans;
Helping countries develop robust malaria surveillance systems;
Responding to requests from countries to address biological and operational emergencies and bottleneck issues.

The GMP publishes the World Malaria Report each year. This is the most comprehensive report on the status of malaria in the world. It provides global and, country-by-country account of progress made to achieve set global targets. The GMP also produces a newsletter every two months that highlight latest news and developments in the work of the GMP. Subscription is available at https://www.who.int/malaria/news/sign_up_form/en/

Malaria Policy Advisory Committee

The Malaria Policy Advisory Committee (MPAC) was established in 2011 following an extensive review of the policy-setting process for malaria control and elimination, initiated by the WHO GMP (D'Souza and Newman 2012). It provides independent strategic advice to WHO on the following:

Appropriate malaria policies and standards based on data from malaria programme implementation by Member States and malaria control partners as well as reviews of the best available evidence;
Engagement of WHO in malaria-related initiatives;
Major issues and challenges to achieving global malaria goals; and
The identification of priority activities to address identified challenges.

The MPAC convenes twice a year in Geneva and is made of some of the world's foremost experts on malaria. It is supported by the GMP Guidelines Development Group and ad hoc Evidence Review Groups which support the policy making process. Among important policy and initiatives over which the MPAC has had profound influence has been those related to updated policy recommendations on the use of sulphadoxine-pyrimethamine for ITPp, as well as the use of single dose primaquine as a *Plasmodium falciparum* gametocytocide. It is on the recommendation of the MPAC that the current limited deployment of the RTS,S/AS01 malaria vaccine has been implemented in Ghana, Kenya, and Malawi.

GTS for Malaria 2016–2030

The GTS for Malaria 2016–2030 is a document produced by the GMP and adopted by the World Health Assembly in May 2015. It provides a comprehensive framework to guide countries and agencies in efforts to accelerate progress towards malaria elimination. The strategy has set the most ambitious targets for reductions in malaria cases and deaths since the malaria eradication era began. (Table 8.15.5) The timeline of 2016–2030 is aligned with the 2030 Agenda for Sustainable Development, endorsed in 2015 by all United Nations Member States. The path towards achieving these targets are anchored on three pillars and two supporting elements. The pillars are

Pillar 1. Ensure universal access to malaria prevention, diagnosis, and treatment
Pillar 2. Accelerate efforts towards elimination and attainment of malaria-free status
Pillar 3. Transform malaria surveillance into a core intervention

The two supporting elements of the GTS are (1) innovation and research and (2) a strong enabling environment.

Table 8.15.5 Goals, milestones, and targets of the Global Technical Strategy for malaria 2016–2030

Goals	Milestones		Targets
	2020	2025	2030
1. Reduce malaria mortality rates globally compared with 2015	>40%	>75%	>90%
2. Reduce malaria case incidence globally compared with 2015	>40%	>75%	>90%
3. Eliminate malaria from countries in which malaria is transmitted in 2015	At least 10 countries	At least 20 countries	At least 25 countries
4. Prevent re-establishment of malaria in all countries that are malaria-free	Re-establishment prevented	Re-establishment prevented	Re-establishment prevented

Viral alcoholic and fatty liver diseases

Ehud Zigmond and Daniel Shouval

Introduction

The burden of liver diseases continues to rise worldwide. The aetiology of acute and chronic liver disease (CLD) varies among continents. Viral hepatitis B and C comprise the main causes for CLD in Africa and Asia, while alcoholic and non-alcoholic fatty liver diseases (NAFLDs) dominate in Europe and the United states. However, the ongoing wave of immigrants from Asia and Africa towards European countries is expected to have an impact on the epidemiology of these liver diseases worldwide. Prevalence and mortality data suggest that the increasing numbers of patients with cirrhosis and HCC in Europe, the US, Africa and East Asia are linked to increase in alcohol consumption and fatty liver disease (in the Western hemisphere) and to chronic viral hepatitis C and B in Asia and Africa (El-Serag and Kanwal 2014; Gower et al. 2014; Beste et al. 2015; Pimpin et al. 2018; Williams et al. 2018). In the present chapter we will present the evolving information on the epidemiology, natural history, prevention, and treatment of these selected liver diseases.

Hepatitis B

Aetiologic agent

Hepatitis B virus (HBV) is a double-stranded, enveloped virus of the *Hepadnaviridae* family.

The hepatitis B virion consists of a surface and a core, which contains a DNA polymerase and the e antigen. The ~3,200 bp DNA structure is double-stranded and circular with four major genes: the S (surface), the C (core), the

P (polymerase), and the X (transcriptional transactivating)genes. The S gene consists of three regions: S, pre-S2, and pre-S1—that encode the small, middle, and large envelope proteins called in total the hepatitis B surface antigen (HBsAg). HBsAg is a lipoprotein of the viral envelope that circulates in the blood as spherical and tubular particles. The C gene is divided into two regions, the pre-core and the core, and codes for two different proteins, the core antigen (HBcAg) and the e antigen (HBeAg).

HBV strains are classified into ten genotypes designated A to J, based on divergence in nucleotide sequences of ≥8%, most of which have a characteristic geographical distribution (Cao 2009; Tanwar and Dusheiko 2012; Sunbul 2014). E.g. genotype A is highly prevalent in sub-Saharan Africa, Northern Europe, and Western Africa. Genotypes B and C are the major variants in South and South East Asia and the Pacific region. Genotype D is prevalent in Africa, Europe, the Mediterranean region, and India. Genotype E is restricted to West Africa. Genotype F is found in Central and South America. Genotype G has been reported in France, Germany, and the United States and genotype H is found in Central America (Kurbanov et al. 2010; Lin and Kao 2011). Genotypes A, B, C, D, and F have further been subdivided in up to four major subgenotypes and several minor genotypes, now identified by Arabic numerals. In recent years, massive immigration waves generate an impact on the geographic distribution of genotypes worldwide.

HBV infection is controlled by cellular and humoral immune responses (Tan et al. 2015; Corti et al. 2018). It can be tracked through serological detection of the viral antigens or the antibodies raised by the immune system to target the virus. The presence of antibodies to the hepatitis B surface and/or hepatitis B core antigens (anti-HBs and anti-HBc) in the absence of HBsAg is generally taken (with few exceptions) to indicate resolution of infection and provides evidence of previous HBV infection. Persistence of HBV infection (chronic carrier state) is diagnosed by the detection of HBsAg in the blood on two occasions, six months apart or through continuous detection of HBV DNA even in the absence of detectable HBsAg in patients with occult HBV infection (OBI) (Raimondo et al. 2013). HBeAg is a secretory protein processed from the pre-core gene and considered as a marker for high viral replication and infectivity. HBV DNA is used as an indicator for viral replication expressed as IU/ml. There is a clear association between serum hepatitis B viral load and prognosis. Thus, the cumulative

annual incidence of cirrhosis or HCC being 4.5 and 1.3%, respectively, in persons with DNA levels <50 IU/ml, while it is 36.2 and 14.9%, respectively, in persons with DNA levels of ≥ to 2 × 10^5 IU/ml). This relationship supports the rationale for treating patients with high levels of HBV DNA with antiviral agents (Chen et al. 2006).

Epidemiology and transmission

Globally, hepatitis B is one of the most common infectious diseases (MacLachlan et al. 2015; Schweitzer et al. 2015). There are however wide variations in published global estimates of persistent HBV infection ranging between 240 and 350 million HBsAg carriers (Basnayake and Easterbrook 2016), (up to ~3.5% of the world population). Estimates indicate that about 2 billion people (i.e. about 30% of the world population) have ever been infected with HBV worldwide (WHO 2012) residing mainly in Africa, Asia, and the Western Pacific regions. One recent burden estimate in 2015 proposed that 257 million people are living with chronic HBV infection while 2.7 million persons are co-infected with HBV and human immunodeficiency virus (HIV).

On the basis of sero-epidemiological surveys, the WHO classified countries into four levels of endemicity according to the prevalence of chronic HBsAg carriage. Thus, HBV prevalence can be defined as low (<2.0%), lower intermediate (2.0–4.99%), higher intermediate (5.0–7.99%), and high ≥8.0%) (Fig. 8.16.1).

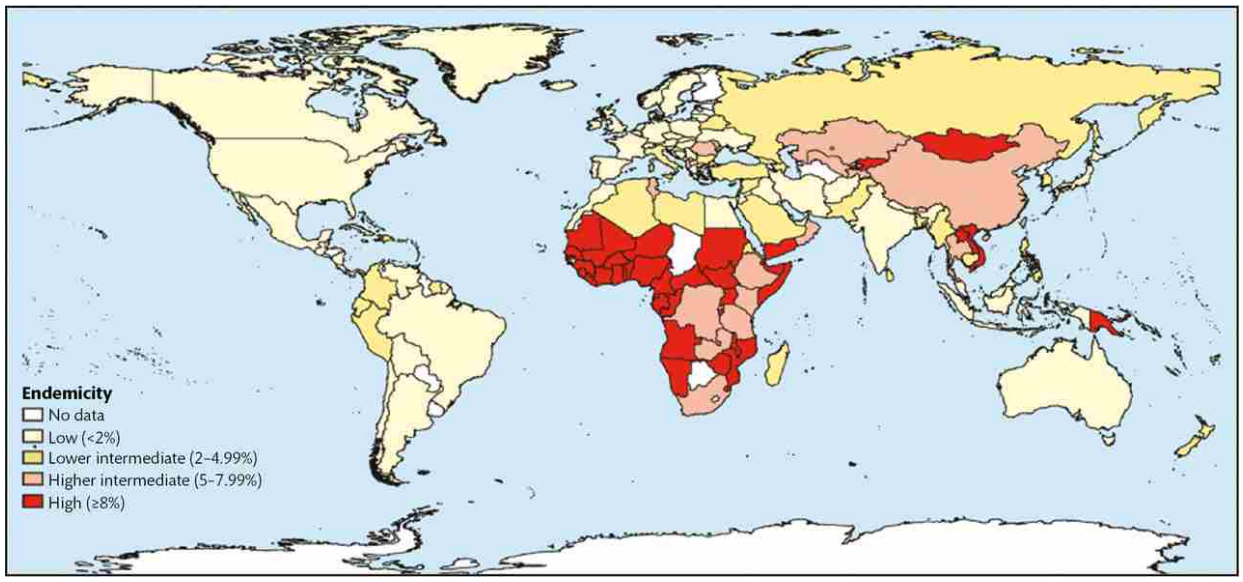

Fig. 8.16.1 Global HBsAg endemicity (1957–2013).
Reproduced from Schweitzer, A., Horn, J., Mikolajczyk, R.T., Krause, G., and Ott, J.J. (2015). Estimations of worldwide prevalence of chronic hepatitis B virus infection: a systematic review of data published between 1965 and 2013. *Lancet* 386, 1546–55, with permission from Elsevier.

HBV is transmitted by either percutaneous or mucous membrane contact with infected blood or other body fluid. The virus is found in highest concentrations in blood and serous exudates. The primary routes of transmission are vertical and perinatal, early childhood exposure (often called horizontal transmission), sexual contact, and percutaneous exposure to blood or infectious body fluids (i.e. injections, needle stick, blood transfusion, tattoos).

Most perinatal infections occur among infants of pregnant women with chronic-persistent HBV infection. The likelihood of an infant developing chronic HBV infection following vertical or horizontal transmission in the first year of life is 70–90% for those born to HBeAg-positive mothers (corresponding to high viral load) and less than 15% for those born to HBeAg-negative mothers. Most early childhood infections occur in households of persons with chronic HBV infection. The most probable mechanism involves unapparent percutaneous or permucosal contact with infectious body fluids (e.g. bites, breaks in the skin, dermatological lesions, skin ulcers). Sexual transmission has been estimated to account for 50% of new infections among adults in industrialized countries. The most common risk factors include multiple sex partners, men who have sex with men (MSM), history of a sexually transmitted infection and illicit drug injection.

Finally, unsafe injections and other unsafe percutaneous or permucosal procedures (such as cocaine snorting) are a major source of blood-borne pathogen transmission of HBV, hepatitis C virus (HCV), and HIV in many countries. The risk of HBV infection from needle stick exposure to HBsAg-positive blood (in patients and healthcare workers alike), is approximately 30% and worldwide unsafe injection practices account for approximately 8–16 million HBV infections each year.

In areas of high endemicity, the lifetime risk of HBV infection is more than 60%, and most infections occur during the perinatal period or during early childhood. In areas of intermediate endemicity, the lifetime risk of HBV infection varies between 20 and 60%, and infections occur in all age groups through the four modes of transmission, but primarily in infants and children. In areas of low endemicity, infection occurs primarily in adult life by sexual or parenteral transmission (e.g. through drug use). Acute infection is more often clinically overt in adults, while asymptomatic acute infection often remains unnoticed in young and older children. Infected infants and pre-school age children are at greatest risk of becoming chronic HBsAg carriers, thereby increasing the risk of cirrhosis and primary HCC later in life. The precise mechanism by which carrier rates are influenced by age of infection is unknown but probably relates to the effect of age on the immune system's ability to clear and eliminate the infection due to evolving immune tolerance to the virus.

Approximately 75% of the world's chronic HBV carriers live in Asian countries. In 2018, China ranks highest, with at least 87 million hepatitis B carriers, and India the second highest, with a carrier pool of 35 million (Tandon 1997; WHO Hepatitis Data and Statistics https://www.wpro.who.int/hepatitis/data/hepatitis_data_statistics/en/). Importantly, chronic carriers of HBV are not only at risk of developing long-term progression of the infection but also represent a significant source and reservoir of infection to others.

A model developed in 2005 estimated that for the year 2000, 620,000 persons died worldwide from HBV-related causes: 580,000 (94%) from chronic infection-related cirrhosis and HCC and 40,000 (6%) from acute HBV infection. Infections acquired during the perinatal period, in early childhood (<5 years old), and at 5 years of age and older accounted for 21%, 48%, and 31% of deaths, respectively (Goldstein et al. 2005).

Besides the acquired age of infection, some of the variation in outcome of HBV infection may be related to the genetic heterogeneity of the virus. Progression to chronic infection appears to occur more frequently following acute infection with genotypes A and D than with the other genotypes (Tanwar and Dusheiko 2012). Chronic infection with genotype A and B appears to have a better prognosis than genotype C and D which are often caused by pre-core mutations of HBV, most common in Asia, Mediterranean countries, and Southern Europe.

Clinical manifestations and immuno-pathogenesis of HBV infection

Acute hepatitis B has a long incubation period ranging from 15 to 180 days (90 days on average). Individual responses to the infection vary greatly. One-third of the individuals have subclinical infection; one-third experience a mild 'flu-like' illness without jaundice; and the remaining one-third develop jaundice with dark urine, extreme fatigue, anorexia, and abdominal pain. Jaundice usually peaks within 1–2 weeks and then gradually subsides. About 90–95% of infected adults and only 10–50% of infected newborns and babies recover spontaneously while the remaining subjects develop persistent HBV infection. Clinical recovery from acute infection is defined by normalization of ALT and AST associated with anti-HBs antibody seroconversion. Latent-occult HBV infection, also called OBI, manifested as intranuclear covalently closed circular (ccc) HBV DNA in the host hepatocytes, may persist for decades post so-called clinical recovery and anti-HBs antibody seroconversion (Rehermann et al. 1996). Such patients who may enter a dormant phase of persistent HBV infection are at risk for HBV reactivation when treated with immune-suppressive agents, including chemotherapy for malignant diseases or anti-inflammatory biologic agents, e.g. for inflammatory bowel disease, psoriasis, or rheumatoid arthritis (Shouval and Shibolet 2013). HBV reactivation rarely leads to immune clearance of HBV and more often to progression to cirrhosis and even fulminant liver failure. A small proportion (0.1–0.5%) of acutely infected adults develop fulminant hepatitis B, an exceptionally severe form of the disease which can be fatal requiring in two-thirds of cases an emergency liver transplant unless promptly treated with nucleos(t)ide analogue (Roche and Samuel 2014). About 5–10% of acutely infected adults and 50–90% of

newborns will become chronically infected and remain infectious (Kumar et al. 2007).

The immuno-pathogenesis of acute and chronic hepatitis B in infected newborns and babies as compared to adults may lead to different outcomes. Following acute infection, babies and young adults infected during the early years of life, often develop immune tolerance to HBV, associated with a high viral load and minimal liver injury. When immune tolerance to HBV is lost, the host immune system causes hepatocyte injury manifested by necro-inflammation and fibrosis, followed by an attempt at immune clearance of HBV, at a time when ALT levels often rise. A long-term, ongoing immune clearance phase causes more fibrosis and may lead to cirrhosis and compromised liver function. Once the host immune system is successful in inducing immune control against the virus, viral replication drops, and histologic evidence for liver injury may stabilize or resolve. However, resolution of the inflammatory process in the liver does not necessarily signifies cure since HBV DNA may still be present in the hepatocyte nucleus as cccHBV-DNA or undergo integration into the host hepatocyte genome. Thus persistent HBV infection is characterized by either overt viremia with detectable HBV DNA and HBsAg in serum or occult infection (OBI) extending to an inactive phase of the infection.

Extrahepatic manifestations of HBV infection

Extrahepatic manifestations following acute and chronic HBV infection occur in 10–20% of patients. These include serum sickness like syndrome, rash, arthralgia, glomerulopathies, and very rarely aplastic anaemia.

The natural history of chronic HBV infection can vary between individuals. Risk factors, which affect progression to chronic hepatitis, cirrhosis, and HCC include male gender, viral load, elevated alanine aminotransferase (ALT), genotype, and degree of fibrosis on liver biopsy. Patients with acute HBV infection are at risk for progression to a chronic carrier state. These patients, who may be still potentially infectious, may be asymptomatic with normal ALT and AST levels. A subgroup of HBsAg carriers may have clinically insignificant or minimal liver disease and never develop complications. Others will have clinically apparent chronic hepatitis with transition to cirrhosis and portal hypertension. Chronic infection with HBV can be either ‘replicative’ or ‘non-replicative’. The ‘replicative’ phase

or immune tolerance phase, characterized by positive HBeAg and high viral load (≥ 2000 IU/ml and often >10^6 IU/ml), is often present in newborns and children of HBsAg-positive mothers. In 'non-replicative' infection, the rate of viral replication in the liver is low, serum HBV DNA concentration is generally low, and HBeAg is not detected. In these inactive HBsAg carriers, reactivation of HBV and liver injury can occur either spontaneously or following reduction in dose of immune-suppressive agents (e.g. chemotherapy for malignant conditions) (Lalazar et al. 2007). Patients with chronic HBV and replicative infection generally have a worse prognosis and a greater chance of developing cirrhosis and/or HCC (Chen et al. 2006). In patients with HBV pre-core mutations, replicative infection can occur in the absence of detectable serum HBeAg. Finally, super or co-infection with the hepatitis delta virus (HDV) or HCV remain a constant threat for HBsAg-positive patients irrespective if they have an active inflammatory liver disease at time of exposure or not. (See later).

Treatment

Success in HBV treatment in CLD depends on the phase of chronic HBV infection. Viral replication by itself is not cythopathic and liver injury occurs only after the activation of host cellular and adoptive immune responses by the replicating virus, causing hepatocellular damage. Guidelines for treatment of chronic and acute HBV infection were developed by the American and European Associations for the Study of the Liver (European Association for the Study of the Liver 2017; Terrault et al. 2018). Treatment is indicated if ALT is elevated >X2 ULN, HBV DNA is ≥2,000 IU/ml or, if there are signs of moderate or severe liver fibrosis, or in case of treatment with chemotherapeutic or immune-suppressive agents.

The short-term goals of therapy for chronic HBV infection are suppression of viral replication and HBeAg seroconversion in HBeAg-positive patients or only viral suppression in anti-HBe positive patients. In some patients, HBsAg titres will drop or become undetectable by conventional assays but anti-HBs seroconversion, and loss of HBsAg which is an ultimate goal for therapy, is relatively rare. The long-term goals include prevention of cirrhosis and HCC. However, although control of inflammation and progression to cirrhosis are often attainable, complete resolution of infection with elimination of cccHBV-DNA is rarely achieved

in patients with persistent HBV infection. At present, treatment usually consists of a well-tolerated nucleos(t)ide analogue (p.o.) for an indefinite period and possibly lifelong. There are nowadays several licensed antiviral agents which are administered p.o., including lamivudine, telbivudine, entecavir, and tenofovir. Among these, entecavir and tenofovir are usually preferred, because of the higher genetic barrier (low probability of resistance) and higher potency. Treatment with the less tolerated interferon alpha by s.c. injections for about 48 weeks, is effective in inducing anti-HBe seroconversion in about a quarter of HBeAg-positive patients with chronic HBV; has the advantage of leading to prolonged suppression of viral replication when successful but is associated with significant adverse effects and still rare permanent resolution of infection. In summary, treatment of chronic HBV infections with oral antiviral agents is highly effective in suppression of viral replication and liver inflammation but rarely leads to anti-HBs seroconversion and complete resolution of infection. The recent detection of the sodium taurocholate co-transporting polypeptide (NTPC) which is an HBV receptor on the cell surface of hepatocytes is expected to trigger the development of new and more efficacious antiviral agents against HBV (Ni et al. 2014; Li 2015; Lin and Kao 2016).

Prevention

All major health authorities agree that the most effective approach to reducing the burden of HBV is primary prevention through universal vaccination as close to birth as possible and control of disease transmission. Interrupting the chain of infection requires knowledge of the mode of disease transmission and modification of behaviour through individual education to practice safe sex and good personal hygiene. Screening of all donated blood and maintenance of strict aseptic techniques with invasive health treatments using universal precaution measures, have reduced the likelihood of contracting HBV.

Safe and effective HBV vaccines have been available since the 1980s, and immunization with HBV vaccine remains the most effective means of preventing HBV disease and its consequences worldwide (Zanetti et al. 2008). Although the vaccine will not cure chronic hepatitis B, it is ~95% effective in preventing chronic infections, and is the first vaccine against a major human cancer.

After the development and licensure of plasma-derived vaccines in the 1980s, recombinant DNA technology has allowed the expression of HBsAg in bacteria, yeasts, mammalian cells and even plants (1986 and onwards). As a result, different manufacturers have successfully developed recombinant DNA vaccines against HBV, which are currently the backbone for most vaccination programmes worldwide (Shouval 2003).

Moreover, apart from monovalent vaccines against hepatitis B, a combination vaccine against hepatitis B and A as well as a broad range of combination penta and hexavalent vaccines that include an HBV component are available especially for vaccination during infancy and early childhood. Such vaccines, shown to be safe and immunogenic simultaneously, provide protection against a number of aetiologic agents including, diphtheria, tetanus, polio, pertussis (with either a whole-cell or an acellular component) and haemophilus influenza b.

More recently, the so-called third-generation hepatitis B vaccines—based on the S-, pre-S1-, and pre-S2-antigens, or using new adjuvants have been developed (Barry and Cooper 2007; Leroux-Roels 2015; Shouval et al. 2015). These vaccines generate a more robust humoral immune response against HBsAg as compared to conventional recombinant HBV vaccines leading to an enhanced immune response, especially in immune-compromised persons and non-responders to vaccination.

Immunization against hepatitis B requires the intramuscular administration of three doses of vaccine given at 0, 1, and 6 months. More rapid protection (i.e. for healthcare workers exposed to HBV or the susceptible sexual partner of a patient with acute hepatitis B) can be achieved through the adoption of an alternative schedule using three doses of vaccine administered at 0, 1, and 2 months followed by a booster dose given at 12 months. The extensive and long-term use of both plasma-derived and recombinant HBV vaccines has confirmed their excellent safety and tolerability. In 1998, several case reports from France raised concern that hepatitis B vaccination may lead to new cases or relapse of multiple sclerosis (MS) or other demyelinating diseases, including Guillain–Barré syndrome; however, no causal relation has been established (Duclos 2003). Hepatitis B vaccination is not contraindicated in pregnant or lactating women when absolute necessary.

Seroprotection against HBV infection is defined as having an anti-HBs level $\geq$10 IU/L after complete immunization (CDC 1987). Reviews on the

use of HBV vaccine in neonates and infants report seroprotective levels of anti-HBs antibodies at 1 month after the last vaccine dose for all schedules in 98–100% of vaccinees (Venters et al. 2004). While HBV vaccines generally induce an adequate immune response in over 95% of fully vaccinated healthy persons, a large interpersonal variability has been demonstrated in the anti-HBs immune response. The antibody response to hepatitis B vaccine has been shown to depend on the type, dosage, and schedule of vaccination used, as well as on the age, the gender, genetic factors, comorbidity, and the status of the immune system of the vaccinee (Hadler and Margolis 1992; Hollinger 1989). Immune-deficient patients i.e. with HIV, or those undergoing haemodialysis or immunosuppressant therapy, may require higher doses of vaccine and more injections (i.e. at months 0, 1, 2 and 6) to achieve an adequate and sustained immune response.

Follow-up studies have shown that vaccine-induced anti-HBs antibodies persist over periods of several decades and that duration of anti-HBs positivity is related to the antibody peak level achieved after primary vaccination (Jilg et al. 1988; Leuridan and Van Damme 2011). Follow-up of successfully vaccinated people has shown that the antibody concentrations usually decline over time, but clinically significant breakthrough infections are rare. Those who have lost antibody over time after a successful vaccination usually show a rapid anamnestic response when boosted with an additional dose of vaccine given several years after the primary course of vaccination or when exposed to the HBV. This means that the immunological memory for HBsAg can outlast the anti-HBs antibody detection, providing long-term protection against acute disease and the development of the HBsAg carrier state (Banatvala and Van Damme 2003). Hence, for immune-competent children and adults, the routine administration of booster doses of vaccine does not appear necessary to sustain long-term protection (Consensus-Group 2000). Such conclusions are based on data collected during the first 10–20 years of vaccination in countries of both high and low endemicity (Kao and Chen 2005; Zanetti et al. 2005).

Since the availability of hepatitis B vaccines in industrialized countries, early strategies for HBV control have stressed immunization of high-risk groups (e.g. MSM, healthcare workers, patients in sexually transmitted infection clinics, sex workers, IV drug users, people with multiple sex

partners, household contacts of chronically infected persons) and babies born to HBsAg-positive mothers. However, such vaccination strategies, directed at specific risk groups, had little impact on the overall burden of HBV in endemic countries and gradually were replaced by effective universal vaccination programmes of newborns.

In 1991, the WHO called for all children to receive the HBV vaccine. Substantial progress has been made in implementing this WHO recommendation: by the end of 2012, 179 countries had implemented or were planning to implement a universal HBV immunization programme for newborns, infants, and/or adolescents. In 2015, the global coverage with the third dose of hepatitis B vaccine reached 84%, which is not far from 90% goal, declared for the year 2020 by the WHO (WHO 2017). This high coverage leads to a major reduction in the incidence of chronic HBV infection in children below the age of 5 years worldwide as well as HCC. However, there are regional differences in coverage, especially in early administration of the birth dose of HBV vaccines in endemic countries. Thus, African, Eastern Mediterranean, and some European regions remain below the global average. Early vaccination within hours from birth, and high coverage with the primary vaccine series among infants had the greatest overall impact on the prevalence of chronic HBV infection in children (WHO 2004). According to model-based predictions, universal HBV infant immunization, (even without administration of a birth dose of vaccine to prevent perinatal HBV infection), would prevent up to 75% of global deaths from HBV-related causes, depending on the vaccination coverage for the complete series. Adding the birth dose would increase the proportion of deaths prevented up to 84% (Goldstein et al. 2005).

In countries with high or intermediate disease endemicity, the most effective strategy is to start immunization at birth (< 24 hours). In such regions a birth dose of a monovalent HBV vaccine is recommended even if vaccination protocols include later administration of combination vaccines, which also contain an HBV component. Countries with low HBV prevalence may consider immunization of children or adolescents as an alternative to newborn immunization (WHO 2004, 2006).

Indeed, the effectiveness of hepatitis B newborn and infant immunization programme has already been demonstrated in a variety of countries and settings (Andre and Zuckerman 1994; Lee 1997; WHO 2001). The results of effective implementation of universal hepatitis B programmes have become

apparent in terms of reduction not only in the incidence of acute hepatitis B infections, but also in the carrier rate in immunized cohorts and in hepatitis-B-related mortality from HCC and cirrhosis (Coursaget et al. 1994; Chang et al. 1997; Liaw 2013). In Taiwan, the HBsAg prevalence in children under 15 years of age decreased from 9.8% in 1984 to 0.7% in 1999 (Chan et al. 2004). In the Gambia, childhood HBsAg prevalence decreased from 10% to 0.6% since the introduction of the universal infant immunization programme (Viviani et al. 1999). Data in Hawaii show a 97% reduction in the prevalence of HBsAg since the start of the infant hepatitis B vaccination programme in 1991. The incidence of new acute hepatitis B infections in children and adults was reduced from 4.5/100,000 in 1990 to 0 in the period 2002–2004 (Perz et al. 2006b). In Bristol Bay, Alaska, 3.2% of children were HBsAg-positive before universal hepatitis B immunization; 10 years later, no child under 10 years of age was HBsAg-positive (Wainwright et al. 1997). Finally, surveillance data from Italy, where a universal programme was started in 1991 in infants as well as in adolescents, have shown that the incidence of acute hepatitis B progressively decreased from 1991 to 2005, with a 24-fold and 50-fold decrease in the 15–24-year and 0–14-year age groups, respectively (Mele et al. 2008).

Public health impact

HBV infection is a serious global health problem, which is under continuous surveillance by the WHO (WHO 2017). Prevention and elimination efforts of chronic HBV infection have utilized various estimates to assess the global burden of chronic HBV infection (Wiktor and Hutin 2016). Of the approximately 2 billion people who have been infected worldwide by 2012, more than 250 million are chronic carriers of HBV according to one estimate (WHO 2012). Approximately 15–40% of infected patients will develop cirrhosis, liver failure, or HCC. According to various estimates, HBV infection accounts for 600,000–900,000 deaths each year, mainly due to the consequences of chronic hepatitis, such as cirrhosis and liver cancer (Goldstein et al. 2005; Lavanchy 2004; Perz et al. 2006a; Schweitzer et al. 2015). Because these complications mainly occur in adults infected with HBV during childhood, most of the benefits of vaccination initiated 20–30 years ago have yet to be realized. Another consequence of persistent HBV

infection, which is often underestimated, is the stigma that HBV carries to the individual, in the family setting, as well as in social and professional life.

Hepatitis delta virus

HDV is a transmissible RNA pathogen that generally requires the help of a hepadnavirus like HBV for its own replication—similar to viroids or plant virus satellite RNAs (Hughes et al. 2011; Rizzetto 2015). Thus, in a natural setting, HDV is only found in patients who are also infected with persistent HBV since the HDV requires simultaneous presence of HBV for complete virion assembly and secretion. However, under rare circumstances, HDV may also replicate in immune suppressed, transplanted livers in the absence of overt HBV.

Aetiologic agent

The HDV genome is a small single-stranded RNA composed of approximately 1,680 bases with a unique circular conformation that is replicated using a host RNA polymerase. The HDV genome contains an open reading frame translated to HDV antigens—the small (S-HD) and large (L-HD) proteins which differ by 19 amino acids. The L-HD amino acid sequence is identical to S-HD with the addition of a carboxy-terminal extension of 19–20 amino acids following the editing of the S-HD stop codon during the viral RNA replication cycle. The S-HD is required for viral replication and might promote RNA polymerase II elongation of nascent HDV RNA, while L-HD is essential for HDV particle assembly (Tseng and Lai 2009).

Epidemiology and transmission

There are three types of HDV infection: simultaneous co-infection of HDV where HBV is transmitted by the same inoculum, super-infection of an HBV carrier with HDV (Rizzetto and Verme 1985) and isolated HDV infection without overt HBV re-infection (e.g. in immunosuppressed patients). A co-infection usually evolves into complete recovery, but the risk for severe acute hepatitis, even fulminant hepatitis, is higher than in the case of acute HBV mono-infection. A super-infection evolves towards chronicity in about

90% of cases. In isolated HDV infection, liver function tests are usually within normal range without significant histologic inflammatory activity.

According to the WHO, at least 5% of people with chronic HBV infection are co-infected with HDV, resulting in a total of 15–20 million persons infected with HDV worldwide (http://www.who.int/news-room/fact-sheets/detail/hepatitis-d) (Fig. 8.16.2).

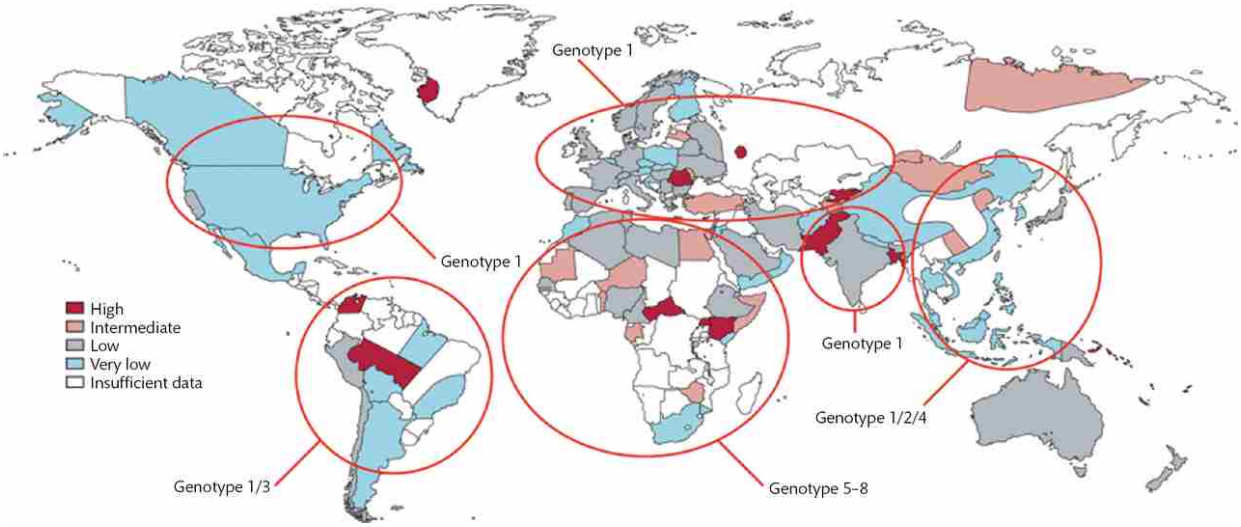

Fig. 8.16.2 Worldwide prevalence of HDV and the geographic distribution of its genotypes. Reproduced from Hughes, S.A., Wedemeyer, H., and Harrison, P.M. (2011). Hepatitis delta virus. *Lancet* 378, 73–85, with permission from Elsevier. Idilman, I.S., Keskin, O., Celik, A., Savas, B., Elhan, A.H., Idilman, R., and Karcaaltincaba, M. (2016).

However, this is a broad global estimate since many countries do not report the prevalence of HDV. Worldwide, the overall number of HDV infection has been declining since 1980s. This trend is mainly due to a successful control of transmission and more importantly, global HBV vaccination programmes. Eight HDV genotypes have been characterized to date on the basis of a small number of complete genome sequences with 19–38% divergence at the nucleotide level of complete genomes (Hughes et al. 2011). The most frequent genotypes are: genotype I (includes the European, North American, African, and some Asian HDV isolates), genotype II (found in Japan, Taiwan, and Eastern Europe), genotype III (found exclusively in South America), genotype IV (found mainly in West Africa) and genotype V (found in Central Africa). The global distribution of the

different genotypes of HBV and HDV is rather well known, although less is known on the types circulating among populations in remote areas. Little is also known on the viral transmission mechanisms driving the circulation of the endemic strains and epidemic outbreaks. Yet, on an individual basis, it appears that new and cell-to-cell transmission between hepatocytes is facilitated through the NTCP receptor.

In contrast to the US and Western Europe, the prevalence of HDV infection is relatively high in the equatorial subtropical and tropical zones, concentrating in certain population groups (Torres 1996). A putatively more severe form of HDV has been reported in Brazil and is, endemic in the Western Amazon states (Parana et al. 2008; Viana et al. 2005). HDV infection is also endemic in several Eastern European and Balkan countries as well as in Turkey. In Western Europe, HDV is becoming rare, affecting around 5% of chronic carriers (Rizzetto and Ciancio 2012). HDV infection is associated with an increased risk of developing advanced CLD, early cirrhosis development, and HCC (Farci 2003; Smedile and Bugianesi 2005).

In endemic areas, all HBV carriers should be tested for HDV. The diagnosis of HDV infection is based on serologic identification of anti-HDV (IgG) as evidence for previous or current exposure and anti-HDV(IgM) for identification of active /recent super or co-infection of an HBsAg carrier. Confirmation for delta virus viremia is obtained through HDV RNA testing by polymerase chain reaction (PCR), which may also be utilized quantitatively for evaluation of HDV treatment protocols.

Prevention and treatment

There is currently no vaccine for prevention of HDV. Consequently, it is imperative to prevent exposure of HBsAg carriers to contacts with HDV patients when applicable. Furthermore, no effective means are so far available for treatment of HDV infection. Long-term interferon alpha treatment may suppress HDV RNA in some patients and slow down progression of fibrosis but usually does not lead to resolution of HDV infection. The most effective means for controlling HDV infection is prevention of HBV infection through immunization. It is too early to judge if recently developed **e**xperimental pharmacologic agents against HDV i.e. blocking the NTCP receptor (Yurdaydin 2019), will reach licensure (Hughes et al. 2011; Yurdaydin 2019). Finally, for those patients with HDV co- or

super-infection who develop decompensation and liver failure, survival after liver transplantation is superior as compared to patients with HBV mono-infection (Roche and Samuel 2012).

Hepatitis C

Hepatitis C is a liver disease caused by the hepatitis C virus: the virus can cause both acute and chronic hepatitis infection, ranging in severity from an initially mild illness, lasting a few weeks to a lifelong illness with variable severity. Following acute HCV infection, 50–80% of patients will develop persistent infection and chronic hepatitis of variable severity, of whom ~20% will progress to cirrhosis with an annual risk for developing HCC of 4–5%.

Aetiologic agent

HCV is classified in the family *Flaviviridae*. Like other flaviviruses, HCV is an enveloped RNA virus with an inner nucleoprotein core. Its envelope contains two glycoproteins, E1 and E2, which form heterodimers (to form a functional subunit) at the surface of the virion (Dubuisson and Cosset 2014; Panel 2015). Efforts to identify the HCV succeeded by direct cloning and sequencing of its genome. Although the virus was identified almost three decades ago (Choo et al. 1989), its replication cycle is still only partially understood. An important feature of HCV is that the viral genome displays extensive genetic heterogeneity at an individual as well as the global level. Thus, even within the same host, the HCV genome population circulates as ‘quasispecies’ of closely related sequences. Worldwide, a high degree of genetic variation exists, resulting in at least six major genotypes and more than 100 distantly related subtypes (Forns and Bukh 1999). It has been reported that until recently, virus pathogenicity and sensitivity to current standards of treatment appear to vary with different subtypes (i.e. genotypes 2 and 3, responding better to interferon alpha treatment than genotype 1 and 4). This relative resistance to treatment with anti-viral drugs has practically been overcome through the development of new direct anti-viral agents.

Epidemiology and transmission

Estimates on the global prevalence of HCV and its consequences vary significantly (Alter 2007; WHO 2012; Basnayake and Easterbrook 2016; Polaris Observatory 2017). An extensive literature survey reports a wide range in estimates of the global prevalence of HCV carriers, ranging between 71 and 200 million of whom at least 2.28 million are co-infected with HIV (http://www.who.int/news-room/fact-sheets/detail/hepatitis). Yet reliable data from several countries remain unavailable. A review of the epidemiology and genotype distribution of HCV infection revealed a mean global prevalence of anti-HCV antibodies of 1.6% (range 1.3–2.1%) corresponding to 115 million past or present viraemic infections. Globally, genotype 1 was the most common variant (46%) followed by genotype 3 (22%). Genotype 4 is the most common genotype in African HCV patients. A significant number of those who are chronically infected will develop cirrhosis or liver cancer (Gower et al. 2014).

Figure 8.16.3 summarizes one estimate of the global prevalence of HCV. The highest prevalence of HCV has been reported from Egypt with a seroprevalence in the Nile delta ranging from 19% in the 10–19-year-old age group to 60% in the 30-year-old age group, and also associated with a high prevalence of liver cirrhosis. The high prevalence in the Nile delta is reported to be linked to parenteral anti-schistosomiasis therapy, which was carried out with inadequately sterilized injection material (Frank et al. 2000). Estimates in the United States reveal that 3.9 million Americans are chronically infected with HCV, with prevalence rates as high as 8–10% in African Americans (Smith et al. 2012). Haemodialysis patients, haemophiliacs, drug addicts, and people transfused with blood before 1990 are particularly affected by the disease. In Europe, 0.1–3.3% of the population has been infected, with the highest prevalence observed in Southern Europe (Italy) and Romania (Blachier et al. 2013).

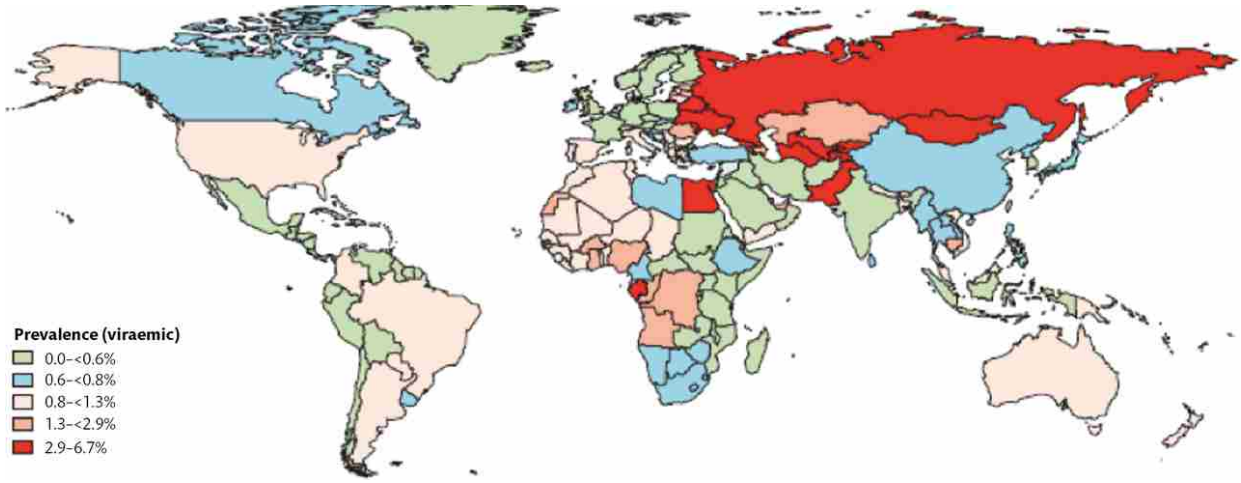

Fig. 8.16.3 Estimated prevalence of HCV.
Reproduced from Polaris Observatory, H.C.V.C. (2017). Global prevalence and genotype distribution of hepatitis C virus infection in 2015: a modelling study. *Lancet Gastroenterol Hepatol* 2, 161–76, with permission from Elsevier.

Despite infection control precautions, healthcare workers remain at risk for acquiring blood-borne HCV infections due to accidental exposure. Therapeutic injections are reported as accounting for 2 million new HCV infections each year. Many of these injections are performed in less than ideal conditions, often with reuse of needles or multidose vials and mainly, but not exclusively, in low- and middle-income countries. The residual risk of transmitting HCV through screened blood transfusions is very low in industrialized countries but safety of blood supply remains a major source of public concern in low- and middle-income countries.

Up to 60–70% of intravenous drug users living in urban areas are seropositive for HCV antibodies. The rate of infection depends on the length of drug use, with 25% of infections occurring during the first year of addiction, 50% after 5 years, and up to 90% after more than 5 years of intravenous drug use.

The global epidemic of HCV infection emerged in the second half of the twentieth century and has been attributed, at least in part, to the increasing use of parenteral therapies and blood transfusion during that period. In high-income countries, the rapid improvement of healthcare conditions and the introduction of anti-HCV screening for blood donors have led to a sharp decrease in the incidence of iatrogenic HCV (Prati 2006). Injectable drug use remains the main route of transmission, accounting for nearly 90% of new HCV infections. Mother-to-child transmission has been documented but is

lower as compared to HBV. The risk of perinatal infection in children from HCV-infected mothers ranges from 3% to 10% in different populations. Transmission is believed to occur *in utero*, as a consequence of a high viral load in the mother; in particular, from co-infected HIV positive mothers (Kato et al. 1994). There is no contraindication for infected mothers to breastfeed the newborn. Sexual transmission is thought to be relatively infrequent (up to 2–3%); as such, it is not recommended in monogamic and stable couples to use condoms. However, the large reservoir of HCV carriers provides multiple opportunities for exposure to potentially infected partners. Individuals with multiple sexual partners, MSM, prostitutes and their clients, patients with common sexually transmitted infections, and partners of HCV and HIV co-infected persons are at the highest risk of acquiring HCV sexually. In many cases of HCV infection, no recognizable transmission factor or route is identified (Memon and Memon 2002).

Clinical manifestations

The incubation period for hepatitis C before the onset of clinical symptoms ranges from 6 to 7 weeks on average. In acute infections, the most common symptoms are fatigue and jaundice; however, the majority of cases (between 60 and 70%), even those who develop chronic infection, are asymptomatic for years. Fulminant hepatitis C is very rarely observed. While most patients with acute HCV infection have mild symptoms or no symptoms, 50–85% of those infected develop chronic disease. Chronic disease is difficult to recognize because symptoms are mild and infection passes silently and insidiously from the acute to the chronic phase. Serological diagnosis of acute HCV infection is mainly based on recent HCV antibodies (anti-HCV) seroconversion. Persistence of HCV infection is diagnosed by the presence of HCV RNA in the blood for at least 6 months. The mechanisms leading to HCV persistence are currently unknown, although it is known that HCV chronicity develops despite humoral and cellular responses to HCV proteins (Park and Rehermann 2014). Factors associated with development of chronic disease appear to include older age at the time of infection, male gender, and an immunosuppressed state such as HIV infection (Lauer and Walker 2001).

Extrahepatic manifestations of hepatitis C

Hepatitis C virus infection provokes B-lymphocytes dysfunction with extrahepatic manifestations of autoimmunity. Several autoimmune and metabolic conditions and diseases have been associated with HCV infection: lichen planus, granuloma annulare, porphyria cutanea tarda, and psoriasis (Andrade et al. 2012). One important expression of autoimmunity in HCV carriers is HCV-related cryoglobulinaemia, which can cause purpura, vasculitis, glomerulonephritis, and peripheral neuropathy (Atta et al. 2010). Cryoglobulinaemia has been found in HCV carriers with lympho proliferative disorders, mainly B-cell non-Hodgkin lymphoma (Yu and Lin 2013). Furthermore, HCV infection has been associated with higher risk of insulin resistance and diabetes (Naing et al. 2013). On the other side, diabetes is a confirmed risk factor for the evolution to hepatocellular carcinoma.

The presence of non-organ specific autoantibodies is another expression of autoimmunity found in HCV carriers, which has been associated in some studies with advanced fibrosis and failure in the treatment of hepatitis C with the combined therapy of interferon-α plus ribavirin. Antibodies to self-antigens such as nucleoproteins (ANA), smooth muscle (SMA), liver–kidney microsomal type-1 antigen (LKM-1), immunoglobulin G (RF), neutrophil cytoplasm (ANCA), and phospholipids (APL), which are routinely used as biomarkers of autoimmune diseases, can be found in HCV carriers with varying prevalence. Their induction seems mainly to involve immune cross-reactions caused by molecular mimicry between HCV polyprotein and human auto antigens (Atta et al. 2010).

Treatment

The primary goals for treatment of HCV infection include eradication of infection as well as reduction of morbidity and mortality from CLD and HCC. Specifically, such effects are believed to occur through normalization of liver function tests such as ALT/AST, complete clearance of HCV, decline in disease progression leading to improved quality of life, and reducing the reservoir of chronic carriers, thereby controlling further transmission. In contrast to hepatitis B, chronic HCV infection is potentially completely curable. Virological cure or sustained viral response (SVR) is currently defined by undetectable HCV RNA for at least 24 weeks (SVR 24) after ending therapy (Gurusamy et al. 2013).

Treatment is recommended for HCV-infected patients who are at risk of developing cirrhosis or with potential harmful extrahepatic manifestations of HCV as well as for liver transplant recipients with graft re-infection of HCV.

In patients with cirrhosis, the benefits of therapy consist of reduction in of the risk of dying from a liver-related death including the risk of decompensation, liver failure, and development of HCC (Veldt et al. 2007).

Historically, and until 2011 effective SVR has been obtained in up to 50% of HCV patients with genotype 1 and 80% of patients with genotypes 2 or 3 who had received combined weekly pegylated interferon-based treatment with daily ribavirin for 24–48 weeks (Chevaliez and Pawlotsky 2007; Tan and Lok 2007). Following the development and licensure in 2011 of the first generation of direct antiviral protease inhibitors Telaprevir and Boceprevir, SVR rates in response to various combination protocols rose to 70–80%, in treatment naïve patients, albeit associated with significant adverse events (Kwo et al. 2010; Jacobson et al. 2011). Since 2014, several new, efficacious, safe, and well-tolerated direct antiviral agents (DAAs) have been developed and licensed worldwide for interferon free treatment of chronic HCV infection (i.e. various combinations of sofosbuvir, ledispasvir, simeprevir, daclatasvir, ritonavir-boosted paritaprevir, ombitasvir as well as dasabuvir, elbasvir and grazoprevir), leading to SVR rates >90% for the various genotypes treated for 8–12 weeks in treatment naïve patients (European Association for Study of the Liver 2015; Panel 2015; AASLD-IDSA Hepatitis C Guidelines, 2020).

The remarkable breakthrough in identification of HCV which lead to the development of efficacious anti-viral agents was recently acknowledged by the Swedish Nobel Prize committee. Thus the 2020 Nobel Prize in Physiology and Medicine was awarded to three scientists who have made the decisive contributions to the fight against blood-borne hepatitis, Harvey J. Alter, Michael Houghton and Charles M. Rice. Yet, the exceedingly high cost charged by the pharma industry for antiviral drugs has mellowed somewhat the excitement generated by the development of the new generation of DAAs. In spite of proven cost-effectiveness, low- and middle-income countries and even health insurers in the US and Europe face difficult challenges in coverage of the very high cost of curative treatment for the millions of patients around the globe (Chhatwal et al. 2015), (http://www.who.int/hepatitis/publications/hep-c-access-report/en/). The WHO is currently promoting an effort to simplify curative treatment

protocols for developing countries (http://www.who.int/hepatitis/news-events/hep-c-access-report-2018/en/).

Prevention

There is currently no licensed vaccine against HCV. The high mutation rates of the HCV genome complicate vaccine development and there is no consensus yet regarding the potential candidates for receiving such a vaccine once proven to be efficacious (Baumert et al. 2014; Mehta et al. 2014). Although 20–35% of patients with acute HCV infection clear the virus spontaneously, lack of knowledge of any effective protective immune response following HCV infection impedes vaccine research. Although some studies have shown the presence of virus-neutralizing antibodies, it is not fully clear whether and how the immune system is able to eliminate the virus. From a global perspective, an important impact on HCV disease burden will likely be achieved by a combination of efforts including public health measures as well as treatment of large cohorts of HCV carriers with the highly effective (but also very expensive) DAAs with a special emphasis on specific risk groups. It is imperative to continue and focus efforts on reducing the risk of HCV transmission from nosocomial exposures (e.g. screening of blood, rigorous implementation of infection control, reducing unsafe injection practices) and high-risk behaviours (e.g. injection drug use). Adherence to fundamental infection control principles, including safe injection practices and appropriate aseptic techniques, is essential to prevent transmission of blood-borne viruses in healthcare settings. Educational programmes aimed at the prevention of drug use and, for those already addicted, aimed at the prevention of shared needles and other equipment can decrease this source of infection. Some countries have established needle exchange programmes that provide easy access to sterile needles and syringes, accompanied by counselling and health education and instructions on the safe disposal of used syringes.

Public health impact

The WHO estimates that ~400,000 die each year from HCV infection and its complications; (http://www.who.int/news-room/fact-sheets/detail/hepatitis-c). It is estimated that 3–4 million persons are newly infected each year and

that ~20% of those infected with HCV progress to cirrhosis within the first 10 years after infection (Alter 2007; Gerberding and Henderson 1992). Although the prevalence of chronic HVC reached a peak in 2001 (according to a multiple cohort model) in the United States, the prevalence of hepatitis C cirrhosis and HCC is expected to continue to increase through the next decades (Davis et al. 2010). Furthermore, chronic HCV disease is the primary indication for liver transplantation in industrialized countries (Adam et al. 2012). In Europe the overall prevalence of chronic hepatitis C in the last decade was 0.13–3.26% and ~1% in countries of the European Union and Economic area (https://ecdc.europa.eu/en/hepatitis-c). It is of great concern that the majority of subjects infected with HCV and HBV globally are unaware of their status (Blachier et al. 2013).

Alcoholic liver disease

Alcoholic beverages have been used in human societies since the beginning of recorded history. In 2005, a study estimated that just over 40% of the world's adult population consumes alcohol and the average consumption per drinker is 17.1 L per year (Shield et al. 2013). The level of alcohol consumption worldwide in 2010 was estimated at 6.2 litres of pure alcohol per person aged 15 years and over (equivalent to 13.5 g of pure alcohol per day) (WHO 2014).

It has long been known that alcohol consumption is responsible for increased illness and death. Worldwide, alcohol causes ~3.3 million deaths each year (5.9% of all deaths), while liver cirrhosis and its complication accounts for 16.2% of the cases (WHO 2014). Furthermore, 139 million disability-adjusted life years (5.1% of the global burden of disease and injury), were attributable to alcohol consumption (WHO 2014). The burden is not equally distributed among countries. The highest disease load attributable to alcohol is found in the heavy-drinking countries of Eastern Europe and in Latin America (Figure 8.16.4). Of note, alcohol consumption over the last 20 years in the UK and Finland has increased significantly, while other countries such as France, Spain and Portugal were able to reduce the number of liver-related deaths (Sheron 2016; Williams et al. 2018).

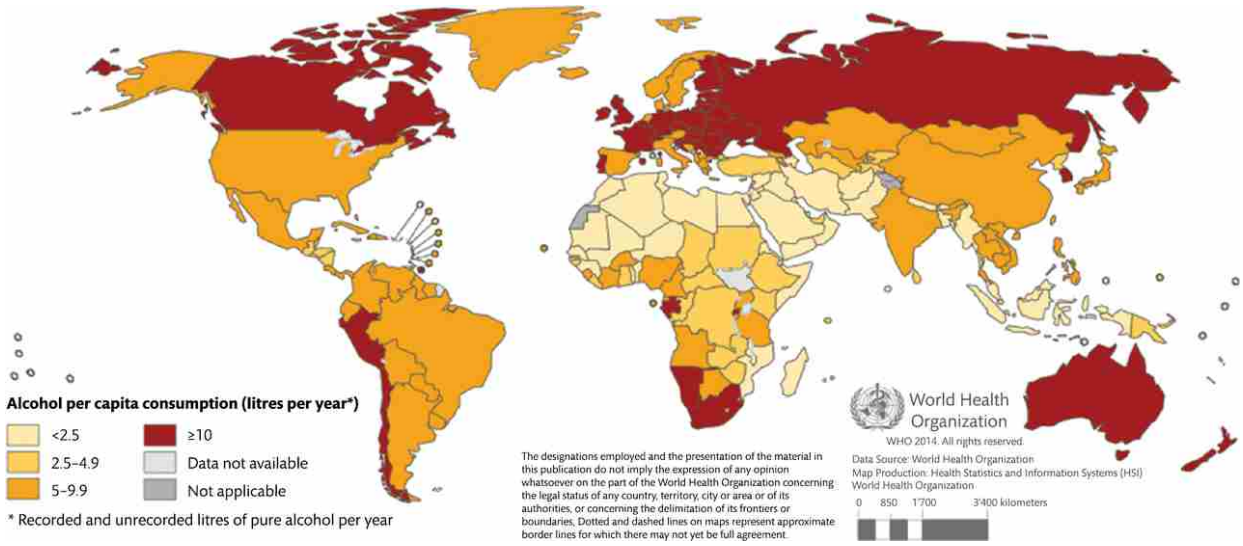

Fig. 8.16.4 Total (recorded and unrecorded) alcohol consumption per capita (aged 15 years and over), in litres of pure alcohol within a calendar year, by WHO region, projected estimates for 2012. Reproduced from WHO (2014) 'Global status report on noncommunicable diseases 2014' with permission from the World Health Organization.

Alcoholic liver disease constitutes the commonest reason for admitting patients with liver disease to a hospital and is responsible for at least 41% of the liver deaths in Europe (Sheron 2016). Between 2004 and 2013, the number of new liver transplants registrations for this aetiology in the US increased by 45% (Wong et al. 2015). In Europe, the proportion of patients transplanted for alcoholic liver disease increased by 8.3% between the time periods 1988–1995 and 1996–2000 (Burra et al. 2010). Alcohol (38%), viral hepatitis (43%), or both (6%) are the leading indications for liver transplantation following cirrhosis.

The costs to society from alcohol abuse cannot be overemphasized. In 2006, overall costs in the United States reached US$223.5 billion, out of which healthcare expenses accounted for 11%. Almost three-quarters of these costs were due to binge drinking (Bouchery et al. 2011). In Europe in 2003, alcohol consumption resulted in estimated costs of €125 billion, equivalent to 1.3% of gross domestic product, while the reported contribution of the alcohol industry to the European economy was about €9 billion (Rabinovich et al. 2009).

In 2010, 5.5% of the global burden of disease was attributable to alcohol, almost similar to the burden of tobacco-associated illness (6.3%) (Lim et al. 2012). Alcohol use is the leading risk factor for global disease burden in Eastern Europe, most of Latin America, and southern sub-Saharan Africa.

Morphology and natural history of alcoholic liver disease

Fatty liver (steatosis)

The first and most predictable hepatic change attributable to alcohol is the development of large droplet (macrovesicular) steatosis. This disorder usually resolves within 2 weeks if alcohol consumption is discontinued (Diehl 1997). Of note, about 5–15% of patients with alcohol-induced steatosis will develop cirrhosis during a 10-year follow-up period (Sorensen et al. 1984).

Alcoholic steatohepatitis

The spectrum of alcoholic steatohepatitis includes fatty infiltration of hepatocytes associated with hepatocellular injury including ballooning degeneration, Mallory bodies, inflammation with neutrophils and/or lymphocytes, and fibrosis with a perivenular, perisinusoidal, and pericellular disposition. These changes are present in 10–35% of all alcoholics. It is estimated that the probability of developing cirrhosis in patients with alcoholic liver disease is 10–20% per year and overall, 70% of patients with alcoholic hepatitis will eventually develop cirrhosis (Diehl 1997) and some will proceed to fatal liver decompensation.

Cirrhosis

In 2010, alcoholic cirrhosis accounted for 48% of cirrhosis-related deaths globally (Rehm et al. 2013). The long-term prognosis of alcoholic cirrhosis improves with abstinence. The 5-year survival in compensated cirrhosis patients who continue to drink is 70%, but can rise to 90% if patients abstain from further alcohol intake. In patients with decompensated cirrhosis, the 5-year survival drops to 30% in individuals who continue to drink, but is 60% in those who stay abstinent (Alexander et al. 1971; Diehl 1997).

Hepatocellular carcinoma

Alcohol is considered both as a primary cause of HCC as well as a co-factor for the malignant transformation. As hepatitis C is relatively frequent in alcoholics, the proportional contribution of alcohol in the reported HCC incidence rates in earlier studies is likely to be overestimated. Although the exact annual incidence rate of HCC in alcoholic cirrhosis is unknown, it is

clear that alcoholic cirrhosis is a significant risk factor for HCC, sufficient to warrant surveillance for HCC (Bruix et al. 2005).

Factors influencing the risk of alcoholic liver disease

Most authors agree that persons who drink heavily (50–60 g of ethanol daily) are at increased risk of developing liver disease (Becker et al. 2002). However, the absolute risk of acquiring alcoholic hepatitis or cirrhosis is relatively low (6.9% in the mentioned study) which suggests that genetic factors and/or environment may play a role in the pathogenesis.

Amount of alcohol

Excessive alcohol consumption is associated with an increased risk of cirrhosis. However, a specific dose–response relationship for cirrhosis has not been agreed upon. Evidence suggests that there is an increased risk for alcoholic liver disease with the ingestion of 60–80 g/day of alcohol in men and 20 g/day in women (Day 2000). 'Safe' limits of alcohol consumption for the liver are up to two drinks per day for women, and up to three drinks per day for men, with at least three alcohol-free days per week (Rehm et al. 2010; European Association for the Study of the Liver 2018).

Drinking behaviour

A survey of 30,630 persons from Denmark revealed that beer or spirits are more likely to promote liver disease than wine (Becker et al. 2002). At present, it is uncertain whether wine *per se* is responsible for this reduced risk of liver disease compared to the other alcoholic beverages, or whether it represents a surrogate for other healthy behaviours such as increased consumption of fruits/vegetables (Everhart 2003). Binge drinking, a mode of social behaviour nowadays, is the exaggerated form of non-mealtime drinking. It has been reported to increase the risk of alcoholic hepatitis fivefold (Barrio et al. 2004) and to increase the risk of all-cause mortality in men and women (Tolstrup et al. 2004). Importantly, a report from the OECD countries revealed that 30% of men and 12% of women binge-drink at least once per month (OECD 2017). Also drinking multiple types of alcohol has been shown to be related to the risk of cirrhosis and non-cirrhotic liver disease (Naveau et al. 1997). Nevertheless, there are still controversies

regarding the risks of binge drinking. A Danish survey of 55,000 participants showed that daily drinking was associated with the highest risk of liver cirrhosis (Askgaard et al. 2015), while a Finnish population-based health study of 6,366 subjects without baseline liver disease revealed that binge drinking was associated with an increased risk of liver disease independently of average alcohol intake (Aberg et al. 2017).

Gender

The proportion of global deaths attributable to alcohol differs based on gender, with 7.6% of deaths among males and 4.0% of deaths among females in 2012 (WHO 2014). Nevertheless, it is well recognized that women are more susceptible to alcohol-induced health disorders than men. Men and women have similar sized livers and similar metabolic rates when the rate of alcohol metabolism is normalized to liver mass. However, blood alcohol levels after comparable doses of alcohol will usually be higher in women than in men because of their lower body volume and the higher percentage of their body mass consisting of fat. Evidence from animal models has suggested that oestrogen increases the gut permeability to endotoxin and accordingly upregulates endotoxin receptors of Kupffer cells leading to an increased production of tumour necrosis factor alpha in response to endotoxin (Enomoto et al. 1999). It is also known that the gastric alcohol dehydrogenase activity can be different in men and women (Parlesak et al. 2002).

Comorbid conditions

Individuals with comorbid conditions affecting the liver exhibit a greater tendency to develop liver disease in response to alcohol consumption than persons being otherwise healthy (Fattovich et al. 2004). This was clearly demonstrated in the case of hepatitis C (Corrao and Arico 1998), hepatitis B, hereditary haemochromatosis (Fletcher et al. 2002), and obesity (Naveau et al. 1997), and most probably applies to other causes of chronic hepatitis.

Genetic polymorphisms

Strong epidemiological evidence suggests the existence of heritable susceptibility to alcoholic liver disease. This appears related to several gene

polymorphisms, some of which impact alcohol metabolism and others that influence hepatic immune responses.

Prevention

The overall management of alcoholism and of alcoholic liver disease and its complications is beyond the scope of this chapter. Nevertheless, general measures include alcohol withdrawal and providing nutritional support. A number of public health policies to reduce alcohol consumption have been shown to be helpful and cost-effective (Wagenaar et al. 2009; Wagenaar et al. 2010). Effective strategies include price based policies via taxation or by setting a minimum unit pricing, limitation of alcohol availability, restriction of marketing and advertising. Children are particularly sensitive to alcohol marketing shown to impact their drinking behaviour (Anderson et al. 2009). Setting a floor price for a unit of alcohol has been shown to be highly successful, reducing alcohol-related mortality by 32% in British Columbia (Stockwell et al. 2013). General practitioners have a pivotal role in screening for excessive alcohol ingestion and referral to a professional multidisciplinary team for withdrawal (European Association for the Study of the Liver 2018). Notably, there is good clinical evidence that cessation of drinking at any point in the natural history of the disease reduces the risks of disease progression and incidence of complications from cirrhosis (Masson et al. 2014).

Non-alcoholic fatty liver disease and non-alcoholic steatohepatitis

Definitions

Steatosis is defined as the accumulation of fat in the liver parenchymal cells or hepatocytes. A distinction is made between macrovesicular and microvesicular steatosis. Macrovesicular steatosis implies the presence of large fat vacuoles, containing predominantly triglycerides, and occupying a large part of the cell cytoplasm, displacing the nucleus towards the cell border. The hepatocytes may be enlarged by the presence of these fat vacuoles. Macrovesicular steatosis is graded according to the percentage of hepatocytes containing fat vacuoles: less than 5% is minimal or no steatosis;

5–30% is mild steatosis; over 30–60% is moderate; and greater than 60% is considered to be severe macrovesicular steatosis (D'Alessandro et al. 1991). In microvesicular steatosis, bipolar lipids are forming micelles, which are spread over the cytoplasm, and which do not displace the nucleus. The cells usually have normal dimensions. In many patients, both types of steatosis are present, called mixed type steatosis. In those cases, macrovesicular steatosis is usually predominant.

Individuals with fatty liver may present with a wide range of histological disease severity starting from pure steatosis without other abnormalities to steatosis accompanied by inflammation, tissue damage, liver fibrosis, and finally cirrhosis. The term *non-alcoholic fatty liver disease* (NAFLD) encompasses the entire spectrum of fatty liver diseases in individuals that lack secondary causes of hepatic fat accumulation such as significant alcohol consumption and use of steatogenic medications. Of note, NAFLD also implies the exclusion of other CLDs, including chronic viral hepatitis, toxic hepatitis (due to industrial toxins or solvents or to pharmacological agents), autoimmune liver disease, haemochromatosis, Wilson's disease, and some rare metabolic disorders. Hepatitis C, especially genotype 3, and Wilson's disease are two classical examples of liver diseases accompanied by steatosis, but they are not NAFLD.

NAFLD can be classified histologically into *non-alcoholic fatty liver (*NAFL) and *non-alcoholic steatoheatitis* (NASH). NAFL is defined as the presence of liver steatosis of more than 5% without evidence of hepatocellular injury or fibrosis. The risk of progression to liver cirrhosis in NAFL is considered minimal. NASH is defined as the presence of liver steatosis of more than 5% with inflammation and hepatocyte injury (especially ballooning of hepatocytes), with or without fibrosis. NASH might progress to cirrhosis, liver failure and hepatocellular carcinoma (Chalasani et al. 2018). The maximum daily alcohol consumption allowed for the definition of NAFLD is uncertain and inconsistent in the literature. As for eligibility for clinical trial, a consensus meeting recommended a limit of 21 and 14 standard drinks per week over a 2-year period in males and females, respectively (Sanyal et al. 2011). A standard alcoholic drink contains about 14 g of pure alcohol according to the National Institute of Alcohol Abuse and Alcoholism (NIAAA 2016). The diagnosis of alcohol consumption relies on thorough anamnesis and hetero-anamnesis, with a detailed 7-day diary of alcohol use. The diagnosis of the aspect of 'non-

alcoholic' therefore constitutes a first problem in the interpretation of any data on the prevalence and natural history of NAFLD.

Diagnosis

A first problem is the diagnosis of the aspect 'non-alcoholic' fatty liver. Patients may not accurately report the quantity of alcohol they consume. Laboratory tests, including elevation of AST (aspartate transaminase) more than ALT (alanine transaminase), and elevation of γ-GT (gamma-glutamyl transpeptidase) measurement may be helpful, but are inaccurate. Thorough anamnesis and hetero-anamnesis is the cornerstone of the diagnosis, which nevertheless may remain questionable.

A second problem is the distinction between steatosis and steatohepatitis. Abdominal ultrasound has a sensitivity of 70–75% and a specificity of 60–70% in diagnosing moderate to severe steatosis (Bellentani et al. 2000). Computed tomography scanning and magnetic resonance imaging are equally specific (100%) and sensitive (75%) in making the same distinction (Rinella et al. 2001). These non-invasive tools are thus not very sensitive, not able to accurately grade the steatosis, and not able to diagnose the presence of inflammation or fibrosis, and hence do not distinguish between NAFL and NASH.

Magnetic resonance imaging by spectroscopy or proton density fat fraction can accurately quantify the fat content of the liver, but the need for specific software and practical considerations limits its use to specific research centres (Heba et al. 2016; Idilman et al. 2016). Transient elastography based measurement of continuous attenuation parameters is a novel promising tool for quantifying hepatic fat in an ambulatory setting (de Ledinghen et al. 2016; Kwok et al. 2016). Yet, the utility of non-invasively quantifying steatosis in patients with NAFLD in routine clinical care is limited.

The diagnosis of steatohepatitis is even more complex. Laboratory tests, especially the elevation of aminotransferase levels, are inaccurate, although frequently regarded as a sign of liver cell damage and hence inflammation. Patients with abnormal liver tests may have pure steatosis without inflammation on liver biopsy, and 50% of the patients with biopsy-proven steatohepatitis have normal transaminases (Prati et al. 2002). The cut-off values for normal aminotransferase levels have been questioned, and

lowering the upper limit of normal ALT to 30 U/L in males and 19 U/L in females increases the sensitivity for the diagnosis of NASH from 42% to 74%, but specificity decreases from 80% to 42% (Kunde et al. 2005). Circulating levels of cytokeratin-18 fragments have been investigated as novel biomarkers for the presence of inflammation in patients with NAFLD (Chen et al. 2014; Cusi et al. 2014). However, this assay is currently not available in a clinical care setting. The gold standard for the diagnosis of steatohepatitis is still a liver biopsy. However, the invasive character of this procedure, limits its use on a larger scale.

Several well established non-invasive tool for assessment of advanced fibrosis in patients with NAFLD are currently available for clinicians. The NAFLD fibrosis score (NFS) is based on six readily available parameters (age, body mass index (BMI), hyperglycaemia, platelet count, albumin, and AST/ALT ratio). In a meta-analysis the NFS had an AUROC of 0.85 for predicting advanced fibrosis (Musso et al. 2011). FIB-4 index is an algorithm based on platelet count, age, AST, and ALT that offers dual cut-off values (patients with score <1.45 are unlikely, whereas patients with score >3.25 are likely to have advanced fibrosis) (Kaswala et al. 2016). The enhanced liver fibrosis (ELF) panel, that was recently approved for commercial use in Europe comprises of plasma levels of 3 matrix turnover proteins (hyaluronic acid, tissue inhibitor of metalloproteinase 1, and N-terminal procollagen III-peptide) had an AUROC of 0.87 with 89% sensitivity and 96% specificity for detecting advanced fibrosis (Rosenberg et al. 2004).

Vibration-controlled transient elastography (VCTE, FibroScan) is an ultrasound-based method to measures liver stiffness non-invasively, recently approved by the US FDA. Several studies examined the performance of VCTE in patients with suspected NAFLD. A study from the United States in 164 patients with biopsy-proven NAFLD (median BMI, 32.2 kg/m^2) showed sensitivity of 95% and specificity of 77% with AUROC of 93% for detection of advanced fibrosis. Interestingly, in 27% of the participants the VCTE yielded unreliable results (Tapper et al. 2016). In a similar Japanese study that included 142 patients with biopsy-proven NAFLD (mean BMI, 28.1 kg/m^2) the AUROC for identifying advanced fibrosis was 0.88 (Imajo et al. 2016). MR elastography is excellent for identifying varying degrees of fibrosis in patients with NAFLD (Kim et al. 2013; Loomba et al. 2014;

Imajo et al. 2016), however the availability of this tool beyond clinical trials and excellence research centres is currently limited.

Incidence and prevalence NAFLD

As already mentioned, the difficulty in diagnosing non-alcoholic steatosis, and the lack of accurate tools for the diagnosis of steatosis, constitute two major limitations in the acquisition of precise epidemiological data. Tissue sample selection (namely a liver biopsy) constitutes a third obstacle in reaching a diagnosis. Only a few studies evaluated the incidence of NAFLD over time. Two studies from Asia that followed subjects for 3–5 years with ultrasound or MRI reported an overall fatty liver incidence of 12–13.5% during the follow-up period (Sung et al. 2014; Wong et al. 2016), while a cohort study that followed 77,425 subjects free of NAFLD for an average of 4.5 years showed incidence rate of NAFLD documented by ultrasound of 29.7 per 1,000 person-years (Chang et al. 2016). A study from Israel stated an incidence rate of 28 per 1,000 person-years (Zelber-Sagi et al. 2012), and a similar incidence rate has been reported by an English study based on administrative ICD-10 coding (Whalley et al. 2007). A meta-analysis from 2016 approximated the pooled incidence of NAFLD to be 52 and 28 per 1,000 person-year in Asia and the West, respectively (Younossi et al. 2016).

The prevalence of NAFLD has been evaluated in several studies summarized in a 2016 meta-analysis that estimated the overall global prevalence of NAFLD diagnosed by imaging to be as high as 25% (Younossi et al. 2016). Regional variation exists with the highest prevalence of about 30–32% reported in South America and the Middle East and the lowest prevalence rate of about 13% reported from Africa (Younossi et al. 2016). Of note, the prevalence and the stage of liver disease increase with age (Frith et al. 2009; Koehler et al. 2012), and the prevalence in men is about two times higher than in women (Zelber-Sagi et al. 2006). Ethnic differences for NAFLD have been described (Masuoka and Chalasani 2013). These differences may be partially explained by the genetic variation related to the paratin-like phospholipase domain-containing protein 3 (PNPLA-3) gene (Dongiovanni et al. 2013).

Given that liver biopsy is the gold standard for the diagnosis of NASH and is not feasible in the general population, a direct assessment of NASH prevalence cannot be done. Yet, efforts to assess NASH prevalence indirectly were done. Fifty-nine per cent (59%) of NAFLD patients who

underwent a liver biopsy for a clinical indication were diagnosed with NASH. However, in NAFLD patients who had a liver biopsy without a specific clinical indication, NASH prevalence was estimated from 6.67 to 29.85%. Taking into account these numbers, the estimation of NASH in the general population ranges between 1.5 and 6.45% (Younossi et al. 2016).

NAFLD and NASH and the metabolic syndrome

The metabolic syndrome is defined by visceral overweight, dyslipidaemia, hyperinsulinemia or diabetes mellitus, and arterial hypertension, as proposed in the Third Report of the National Cholesterol Education Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel-ATP III) (Expert Panel on Detection and Treatment of High Blood Cholesterol 2001). This entity seems to be closely related with NAFLD and NASH. Some authors consider NAFLD and NASH as the hepatic manifestation of the metabolic syndrome. A number of epidemiological studies support a close relationship between the two entities. In patients with NAFLD, the metabolic syndrome, according to the criteria of the ATP III, is fully present in 30% of males and 60% of females. Visceral adiposity is present in 40% and 65% of males and females, respectively, and diabetes in 10% and 30%, respectively. These prevalence rates were significantly higher than in the control population. The metabolic syndrome is significantly more prevalent in patients with NASH compared to patients with simple steatosis (38% vs. 14%, $p = 0.004$) (Marchesini et al. 2003).

In patients with obesity, steatosis is present in 60–95%, according to the selection of patients and the procedure used for diagnosis (e.g. ultrasound or histology in a series of patients undergoing bariatric surgery). The BMI is an independent predictive factor for the accumulation of fat in the liver (Marchesini et al. 2003).

Globally, the prevalence of overweight and obesity has increased since 1980, and the increase has accelerated. The global age-standardized prevalence of obesity nearly doubled from 6.4% in 1980 to 12.0% in 2008 (Stevens et al. 2012). This increase of the prevalence of overweight in children and adolescents is of particular concern. The prevalence of diabetes is also increasing, and was estimated at around 9% worldwide in 2008 (Danaei et al. 2011). In the United States, 22% of the adult population fulfils the criteria of the metabolic syndrome (Lin and Pi-Sunyer 2007).

The natural history and outcome of NAFLD

Data on the natural history of NAFLD and NASH have the same three limitations as outlined for the prevalence data. In patients with NASH, 45% will exhibit fibrosis progression and 19% will ultimately develop cirrhosis (Fassio et al. 2004).

On the other hand, in a study that followed 109 NAFL patients (pure fatty liver without inflammation per biopsy) for a median follow-up time of 16.7 years, only one patient developed cirrhosis during the follow-up period, supporting the impression of a benign clinical course of this condition (Dam-Larsen et al. 2004). A long-term follow-up study (mean follow-up of 13.7 years) showed no increase in mortality in patients with elevated liver enzymes and pure steatosis on an initial biopsy. Patients with biopsy-proven NASH, on the other hand, had a higher risk of dying from cardiovascular disease (15.5% vs. 7.5%, $p = 0.04$) and from liver-related causes (2.8% vs. 0.2%, $p = 0.04$). Disease progression was, however, noted: 41% had fibrosis progression and 5.4% of patients developed cirrhosis, and this did not depend on features of inflammation on the initial biopsy (Ekstedt et al. 2006).

Patients with NAFLD have an increased overall mortality compared to matched control populations without NAFLD, with the most common cause of death being cardiovascular disease (Adams et al. 2005; Sayiner et al. 2017). Liver-related mortality is the second or third cause of death among patients with NAFLD while in the general population is only the twelfth leading cause (Younossi and Henry 2016).

In a recent meta-analysis, liver-specific mortality rates among NAFLD and NASH patients were determined to be 0.77 and 11.77 per 1,000 person-years respectively (Younossi et al. 2016). The most important histological factor of NAFLD associated with long-term mortality found to be the fibrosis stage (Younossi et al. 2011; Angulo et al. 2015).

Importantly, NASH is the second-most common cause for liver transplantation and will likely overtake viral hepatitis as the number one cause in the future, as more HCV patients are treated with effective antiviral regimens (Wong et al. 2015).

In patients with cryptogenic cirrhosis, more than 60% have features that might have been associated with NASH and in these patients, cirrhosis is believed to be an end stage of NASH (Ekstedt et al. 2006). Essentially,

cryptogenic cirrhosis accounts for 4% of the total indications for liver transplantation in Europe (Adam et al. 2012). Of note, NASH may recur after liver transplantation, further enforcing the concept of NASH as aetiology of cryptogenic cirrhosis (Maheshwari and Thuluvath 2006).

NAFLD is currently the third-most common cause of hepatocellular carcinoma (HCC) in the United States (Mohamad et al. 2016). NAFLD-related HCC incidence is growing by 9% annually, probably due to the increasing obesity and the metabolic syndrome (Younossi et al. 2015). In the Ekstedt series (Ekstedt et al. 2006), 2.3% developed HCC or 43% of those with documented cirrhosis. It is thus not clear whether the risk is comparable to the 10% cumulative risk usually reported in cirrhosis of any aetiology, but it might be higher (Smedile and Bugianesi 2005). Patients with NAFLD-related HCC are older, have a shorter survival time and are more likely to die from their primary liver cancer as compared to HCC patients of other aetiologies (Mohamad et al. 2016). Importantly, a Veteran Administration study reported that about 13% of HCC patients did not have cirrhosis, and having NAFLD was independently associated with HCC in the absence of cirrhosis. This study strengthens previous small studies reporting of HCC in NAFLD patients without cirrhosis (Mittal et al. 2016) and raise questions regarding the need to screen non-cirrhotic NASH patients for HCC development, although it is estimated that the risk for developing HCC in non-cirrhotic NAFLD patients is very low given the enormously large number of patients with NAFLD without cirrhosis within the general population (Younossi et al. 2015).

Risk factors reported to be associated with an increased risk of fibrosis are: age (40 or 50 years of age), the presence of diabetes, BMI 25 or 28 or 30, hypertriglyceridaemia, elevated transaminases two times the upper limit of normal, and AST/ALT ratio of 1 (Angulo et al. 1999; Adams et al. 2005). Patients with NAFLD and diabetes have a higher probability of cirrhosis and liver-related death, compared to NAFLD patients without diabetes (Abrams et al. 2004). In the Ekstedt series (Ekstedt et al. 2006), a 41% progression of fibrosis was associated with higher levels of ALT, a higher weight gain during follow-up, more severe insulin resistance, and more pronounced fatty infiltration. Of note, patients with NASH more frequently meet the criteria of the metabolic syndrome and are more likely to have visceral obesity compared to patients with simple steatosis. As it is believed that NASH is a subgroup of NAFLD at risk for progressive fibrosis, the metabolic syndrome

and its components clearly constitute a risk factor for fibrosis and cirrhosis, which will be a major burden of disease in view of the epidemic of obesity and diabetes and their related conditions.

Prevention and treatment

No specific treatment is clearly defined for NAFLD/NASH. There is however a consensus concerning implementation of behavioural and lifestyle change measures, as well as treating cases of advanced disease (Sourianarayanane et al. 2013). NASH treatment is driven by the stage of the disease and associated metabolic abnormalities such as overweight, hyperglycaemia, and hyperlipidaemia. In more advanced stages, drugs must be added to classical behavioural measures. Up to now, it is clear that patients with NASH benefit from physical exercise and balanced well oriented diets, probably through weight loss and decreased insulin resistance (Carulli et al. 2013).

In a meta-analysis of eight randomized controlled trials (RCT), patients who were able to lose at least 5% of body weight had improvement in hepatic steatosis, whereas 7% body weight reduction was associated also with improvement of the NAFLD activity score that includes steatosis, lobular inflammation, and ballooning (Musso et al. 2012). A recent prospective trial (including paired liver biopsies) in 261 patients, combining caloric restriction and physical activity, demonstrated a dose–response between weight loss and improvement in histopathology in NASH (Vilar-Gomez et al. 2015). Importantly, patients losing more than 5% body weight stabilized or improved fibrosis in 94% of the cases, however, only 50% of patients were able to achieve at least a 7% weight loss at 12 months in this trial (Vilar-Gomez et al. 2015).

Bariatric surgery is recommended in patients with a BMI greater than 40 kg/m^2 or BMI greater than 35 kg/m^2 and comorbidities. This procedure is highly effective and may be indicated even in patients with well-compensated cirrhosis, but it has high risk of morbidity if the patients have portal hypertension.

For patients who evolve towards advanced liver disease or HCC, liver transplantation can be indicated, although NASH relapse post transplantation is quite frequent.

Specific pharmacotherapy includes drugs used to treat the metabolic syndrome (e.g. statins, bezafibrate) and diabetes, as well as drugs with putative antioxidants effects. Two meta-analyses concluded that Metformin did not improve liver histology in patient with NAFLD and hence it not recommended for the treatment of NASH (Li et al. 2013). Pioglitazone, a ligand for the nuclear transcription factor peroxisome proliferator-activated receptor gamma, has been evaluated in several trial for the treatment of NASH and overall shown to improve liver histology. Of note, pioglitazone has been associated with potential harmful adverse events, such as weight gain and possibly bladder cancer (Aithal et al. 2008; Sanyal et al. 2010; Yau et al. 2013; Cusi et al. 2016; Tuccori et al. 2016). The American Association for the Study of Liver Disease (AASLD) practice guidelines recommend that this drug may be used to treat patients with biopsy-proven NASH, while the risks and benefits should be discussed with each patient before starting therapy (Chalasani et al. 2018).

Glucagon-like peptide-1 (GLP-1) analogues are used for the treatment of the metabolic syndrome and may be attractive option for NASH. A recent RCT evaluated treatment with liraglutide for 48 weeks in NASH patients and found improvement in resolution of steatohepatitis and decreased progression of fibrosis that was associated with weight loss (Armstrong et al. 2016).

Antioxidants are considered promising drugs for NASH, but the studies are considered preliminary. Among the putative antioxidant drugs, vitamin E has been evaluated as having the most consistent results, even with documented amelioration in liver pathology (Sanyal et al. 2010). On the other hand, prolonged use of vitamin E has been associated with adverse reactions such as risk of cerebral vascular haemorrhage, coagulation disturbance, and prostatic disorders.

Despite benefits observed in the aforementioned drug therapies, the long-term use of these drugs in NASH patients in terms of efficacy and safety remains unknown.

Overall conclusion

In spite of the availability of safe and effective vaccines and their proven effectiveness in reducing the chronic consequences of HBV infections, the current burden of disease associated with hepatitis B remains substantial. To

finally achieve the WHO goal of HBV elimination, continuous efforts will be required to keep prevention of hepatitis B on the agenda of public health officers worldwide, and to continue to improve treatment options for those already suffering chronic hepatitis B.

Even though the present burden of disease caused by HCV is somewhat lower as compared to HBV, the lack of an effective vaccine makes control of this global epidemic very challenging. Thus, the increased burden of CLD resulting from the high rates of HCV infection 20–30 years ago (the baby boomer generation, born 1946–1964), pose a substantial challenge to public health authorities. However, the recent introduction of highly efficient DAAs should contribute to the WHO goal of HCV elimination within the next decade on a global scale, provided the cost of treatment can be cut significantly.

Alcoholic liver disease remains a major cause of morbidity and mortality worldwide. Indeed, alcohol-related cirrhosis mortality rates have decreased in some countries during the past 30 years. However, rates are no longer declining in several other countries and are even increasing in low-and middle-income regions. Thus there is concern that, worldwide, the rate of alcoholic liver disease may increase in the next decades, especially in view of recent data which indicate that alcohol consumption is increasing in such low- and middle-income nations. In addition, rates of excessive alcohol intake appear to be rising in women and binge drinking has become a common pattern of excessive alcohol use.

Although data on the prevalence and natural history of NAFLD/NASH are scarce and suffer from multiple methodological problems, it is clear that, because of their association with the metabolic syndrome and its components, which are increasing to epidemic proportions in the Western population, NAFLD, NASH and HCC will constitute a major health problem in the near future. Moreover, recent data suggest that NAFLD may play a detrimental role in the outcome of COVID-19 infection (Portincasa et al. 2020). To cope with this challenge the pharma industry is involved in a major effort for development of new and effective anti-NASH agent(s) (Issa et al. 2018).

Key points

Liver cirrhosis and primary liver cancer are important public health problems worldwide, killing millions of people each year.
Viral hepatitis B and C, and alcoholic as well as non-alcoholic fatty liver disease, represent the major causes for CLDs worldwide, all of which have oncogenic potential.
Despite the availability and widespread use of effective and low cost hepatitis B vaccines, efforts will be required to keep the momentum of universal immunization programmes against HBV with special emphasis on administration of the birth dose of such a vaccine.
The new DAAs against HCV are highly efficacious in clearing chronic HCV infection. Equal access to the new antivirals is of the utmost importance.
As the development of a hepatitis C vaccine has not yet resulted in success, prevention and control measures form a major challenge to all those involved in public health.
Alcohol consumption remains a major health problem comprising ~6% of all deaths globally.
Fatty liver disease, steatohepatitis and CLDs associated with the metabolic syndrome, are rising to epidemic proportions globally.
New and efficient pharmacologic agents are urgently needed to cope with the rising number of patients with fatty liver disease.

ACKNOWLEDGEMENT

The authors of the present extensively revised edition of this chapter are indebted to the authors of the previous edition who developed the original template for this review.

Emerging and re-emerging infections

David L. Heymann and Vernon J.M. Lee

Introduction to emerging and re-emerging infections

The microbial world is complex, dynamic, and constantly evolving. Infectious organisms reproduce rapidly, mutate frequently, cross the species barrier between animal hosts and humans, and adapt with relative ease to their new environments. Because of these characteristics, many infectious organisms are able to alter their epidemiology, their virulence, and their susceptibility to anti-infective drugs.

When disease is caused by an organism that is newly identified and not known previously to infect humans, or has changed in susceptibility to an anti-infectious drug, it is commonly called an emerging infectious disease, or simply an emerging infection. When a disease is caused by and infectious organism that has re-entered human populations or changed in epidemiology, it is called a re-emerging infection. A report published by the United States Institute of Medicine in 1992 first called attention to emerging and re-emerging infectious diseases as evidence that the fight against infectious diseases was far from won, despite great advances in the development of anti-infective drugs and vaccines (Lederberg et al. 1992).

All forms of infectious organisms—bacteria, viruses, parasites, and prions—are able to emerge or re-emerge in human populations, and it is estimated that up to 70% or more of all emerging infections have a source in animals (zoonotic infections). Infected humans may become clinically ill or remain asymptomatic; human-to-human transmission may or may not occur; and virulence may remain the same, or increase or decrease. Changes in clinical expression, transmissibility and virulence can occur gradually through a process of adaptive mutation, or abruptly as the result of a sudden genetic exchange (reassortment) during reproduction and/or replication.

Epidemiology of emerging and re-emerging infections

In general, when an infectious organism emerges or re-emerges in human populations there are three potential outcomes. Some do not transmit from humans to other humans; some have limited human-to-human transmission, with the potential to re-emerge when the conditions are favourable; and others emerge, spread widely, and become endemic.

There are many factors that influence the transmission of an infectious organism to and among humans including the type of organism, the incubation period (time from exposure to the infectious organism to clinical disease and infectiousness), clinical outcomes, mutations, and human genetics. The following subsections describe some examples of common infections based on their ability to transmit among humans.

Infections that do not transmit from humans to other humans

Rabies is a zoonotic infection that commonly occurs after the bite of a rabid animal, and variant Creutzfeldt–Jakob disease (vCJD) is a zoonotic infection associated with beef and bovine spongiform encephalopathy (BSE) or ‘mad cow disease’. These infections cause illness in humans but cannot transmit from one human to another unless there is iatrogenic transmission through non-sterile medical procedures, blood transfusion, or organ transplant. In several instances, corneal transplantation from a person who died with undiagnosed rabies infection has caused rabies in transplant recipients. The identification of several humans with vCJD associated with blood transfusion demonstrates its potential to spread iatrogenically within the human population.

Infections with limited human-to-human transmission

Some zoonotic infections in humans are able to initially transmit from person to person, but then are unable to sustain transmissibility. Thought to have a rodent reservoir in the sub-Saharan rain forest, the monkeypox virus infects humans who come in contact with an infected animal. Transmission among humans is through direct contact with infected droplets, and it is thought that smallpox vaccination (vaccinia virus vaccine) protects against infection with the monkeypox virus. Most outbreaks of human monkeypox

cease spontaneously. As smallpox immunity continues to wane since the cessation of vaccination after the certification of smallpox eradication in 1980, the epidemiology of human monkeypox appears to be changing with longer chains of human-to-human transmission after re-emergence before outbreaks spontaneously cease (Pru Rimoin et al. 2010). The case fatality rate, that can approach 10% when infection becomes generalized, appears to remain the same as transmissibility declines.

The monkeypox virus caused a limited, multistate outbreak of non-generalized cutaneous infection in the United States, linked to Gambian giant rats imported from West Africa and distributed to pet shops as exotic pets. In the pet shops, prairie dogs, thought to have been the source of the outbreak, appear to have been infected with the monkeypox virus by the Gambian giant rats, and they then transmitted the virus onwards to humans (Guarner et al. 2004).

Another zoonotic infectious organism with limited human-to-human transmission is the Ebola virus. With a relatively short incubation period, infection leads to rapid progression to disease with a severe and often fatal outcome that limits the potential for contact of infected humans with others. Because of its high virulence and short incubation period, most epidemiologists believe that the Ebola virus cannot sustain prolonged transmission, and will therefore not become endemic in humans in its current form. The 2014 Ebola outbreak in West Africa spread more widely than previous outbreaks in part due to the lack of a robust emergency response when it was first identified. The same time-proven response measures together with adequate capacity to implement these measures can stop Ebola outbreaks: hospital infection control and protection of health workers; contact tracing with contacts placed under daily fever surveillance and isolation if Ebola symptoms develop; and community engagement with health education on transmission, safe burial practices, and prevention. The 2014 outbreak spread in an area where health systems were being rebuilt after years of civil strife and there was thus inadequate infection control, low access to healthcare, and great movement of populations. This led to the World Health Organization (WHO) declaration of a Public Health Emergency of International Concern (PHEIC), and the outbreak was finally contained after the input of substantial international aid resources over the prolonged outbreak period of more than 2 years (http://apps.who.int/ebola/ebola-situation-reports).

One common infectious organism that is able to sustain human-to-human transmission for varying periods of time—the influenza virus—demonstrates the great diversity of infectious organisms. The RNA viruses that cause seasonal human epidemics of influenza are highly unstable genetically and mutate frequently during replication. Mutation, or genetic drift, results in susceptibility of individuals regardless of their exposure to the viruses before drift, requiring annual antigenic modifications in seasonal influenza vaccines to ensure protection. The short incubation period, and the mild illness caused by the majority of infections, especially among pre-school and school-aged children, result in rapid transmission potential that leads to seasonal influenza epidemics.

Different subtypes of influenza viruses are found across a variety of avian species, and these occasionally infect humans directly from birds, or from intermediary animal populations that have been infected by birds. The H5N1 type A avian influenza virus that was first identified in Hong Kong as the cause of human infections in 1997 continues to cause occasional severe infections in humans. However, H5N1 remains a zoonotic disease and does not transmit easily from person to person. This virus, like many other avian influenza viruses, has the potential to mutate and gain the epidemiological characteristics that would permit it to spread easily among humans to cause an epidemic or a pandemic.

A novel A(H1N1) virus however, emerged in 2009 and unlike the H5N1 virus, spread easily among humans with sustained transmission around the world, resulting in a pandemic (http://www.who.int/csr/disease/swineflu/en/).

Pandemics are, by definition, infectious disease epidemics that spread to affect susceptible populations over much of the world, and they can in some cases lead to endemicity. The highly fatal 1918 influenza pandemic is thought to have originated from an avian influenza virus that may have undergone adaptive mutation in non-human mammals over time, attaining human transmissibility characteristics before crossing the animal/human species (Taubenberger and Morens 2006).

Other influenza pandemics in 1957, 1968, and 2009 are thought to have been caused by genetic reassortments during the intracellular replication process in an animal dually infected with viruses containing human and avian influenza genetic components (Guan et al. 2010; York and Donis 2012. The 2009 H1N1 pandemic influenza virus, for example, showed genes from

swine, avian, and human influenza. Although the 2009 pandemic virus is thought to have its human origins in the Americas, risk factors for emergence of influenza viruses in humans are thought to be highest in areas such as East and Southeast Asia, shown by the many other type A influenza viruses that have recently emerged there, where there are large populations of aquatic birds (the hosts of many different types of avian influenza viruses) and where humans live in close proximity to animals such as pigs and poultry that may be easily infected by these aquatic birds.

Finally, the Middle East Respiratory Syndrome Coronavirus (MERS Co-V) and the Nipah virus periodically cause zoonotic infections in humans that can lead to outbreaks of varying size, generally caused by iatrogenic transmission in health facilities with poor infection control (Cho et al. 2016; Hassan et al. 2018).

Infections with sustained transmission

Infection with the human immunodeficiency virus (HIV), thought to have emerged from a non-human primate sometime in the late nineteenth or early twentieth century, has a long incubation (latent) period during which it is difficult to detect clinically. Though amplification of transmission is thought to have begun during the 1970s through risky sexual behaviour, HIV escaped detection until the early 1980s by which time it had already spread throughout the world and caused a series of epidemics that led to its endemicity. During 2016, an estimated 36.7 million persons were living with HIV infections, and an estimated 1 million of them died from AIDS-related illness worldwide, placing HIV infection high on the list of causes of human morbidity and mortality (http://www.aidsdatahub.org/sites/default/files/publication/UNAIDS_Global_AIDS_Update_2017_Data_book_2017_en.pdf).

It is generally believed by most medical epidemiologists that most other endemic infectious diseases likewise had their origins as emerging infections at some time in the past when the conditions for emergence lined up in such a way that emergence across the species barrier occurred.

Geographic distribution of emerging and re-emerging infections

Emerging infections have the potential to occur in every country and on every continent (Fig. 8.17.1). Though the term emerging infections was introduced in the early 1990s, the previous 40 years had seen a panoply of newly identified infections in humans on every continent. The year 1976 was especially illustrative of this phenomenon with the identification of the 1976 swine flu virus (H1N1), thought to be a direct descendant of the virus that caused the pandemic of 1918, at a military base in Fort Dix (United States) (Sencer 2011); the identification of *Legionella pneumophila* as the cause of an outbreak of severe respiratory illness among a group of veterans staying at a hotel in downtown Philadelphia (United States), initially feared to be a human outbreak of swine influenza (H1N1) (Centers for Disease Control and Prevention (CDC) 2012a); and the identification of the Ebola virus as the cause of simultaneous outbreaks of haemorrhagic fever in Sudan and the Democratic Republic of Congo (then called Zaire) (CDC 2012b).

Nine years earlier, in 1967, the Marburg virus was identified for the first time in an outbreak in Germany that caused 25 primary infections and seven deaths among laboratory workers who were infected by handling monkeys from Uganda; and six secondary cases in health workers who took care of primary cases, with subsequent spread to family members (Slenczka and Klenk 2007). A member of the same filovirus family as Ebola, the Marburg virus has caused sporadic outbreaks in Africa since the 1970s, followed by the major West African outbreak from 2013 to 2015 (http://www.who.int/news-room/fact-sheets/detail/ebola-virus-disease).

Since the Marburg virus was first identified in 1967 there have been over 40 other newly identified infectious organisms in humans, an average of one per year. Some of the most recent emerging/re-emerging infections are MERS Co-V and Zika virus infections, the latter associated with microcephaly in children born to women who were infect during pregnancy (Heymann et al 2016).

Economic impact of emerging and re-emerging infections

Outbreaks caused by emerging and re-emerging infections are costly (Fig. 8.17.2). They consume healthcare resources and divert them from endemic disease problems, result in productivity loss, and decrease trade and tourism revenue. At times they economically devastate entire sectors. This has occurred after major outbreaks of emerging or re-emerging infections during

the past 20 years, with economic losses ranging from an estimated US$36 million after the re-emergence of cholera in Tanzania in 1998 (WHO 2007a, 2013), to approximately US$39 billion after the emergence of BSE in the United Kingdom during the period 1990–1998 (WHO 2007a). During 2009, after the pandemic of H1N1 had been initially identified in Mexico, the Mexican economy lost an estimated US$2 billion, mainly due to decreased trade and tourism, and the nosocomial outbreak of MERS Co-V in South Koreas has been unofficially estimated by some to have cost the economy a loss of revenue of up to US$ 10 billon (https://www.adb.org/news/features/middle-east-respiratory-syndrome-testing-asia-s-ability-address-emerging-diseases).

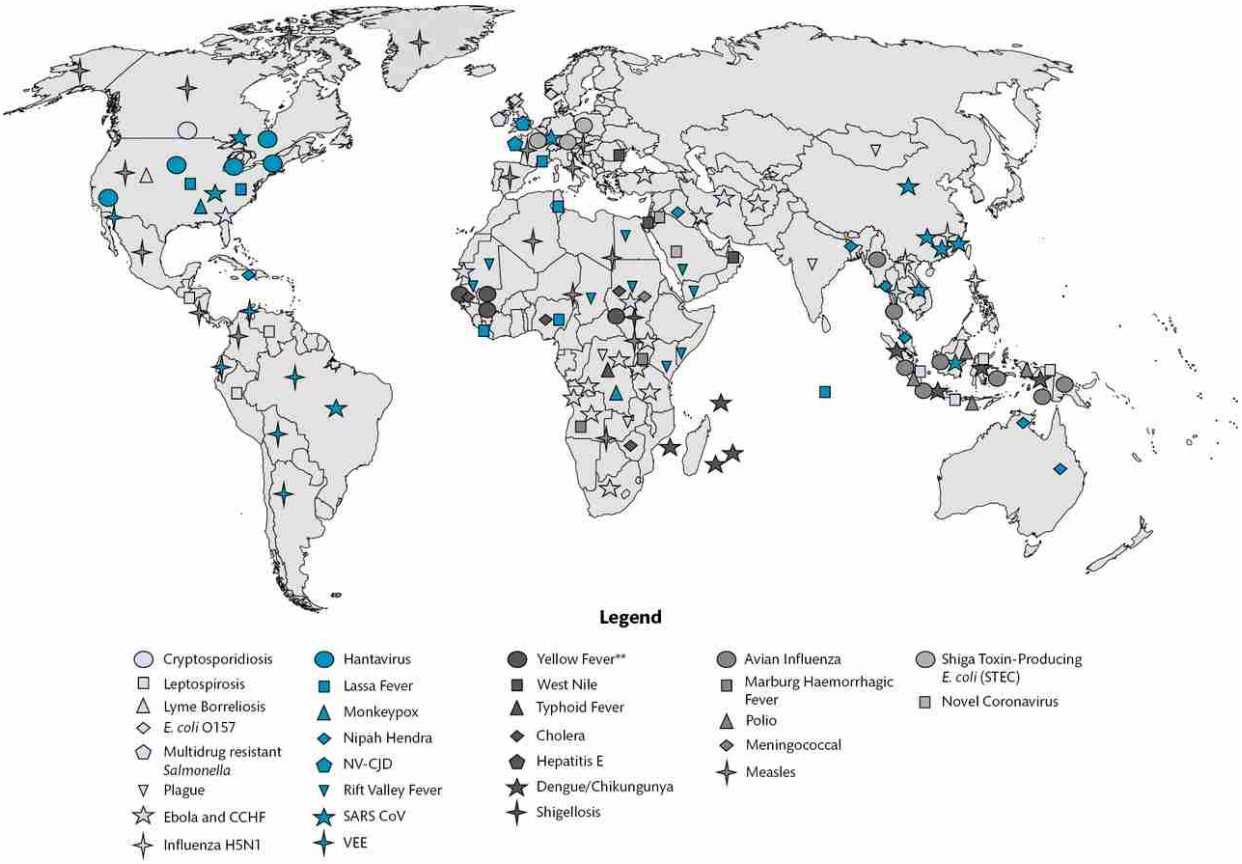

Fig. 8.17.1 Selected emerging and re-emerging infectious diseases, 1996–2012.
Source: data from World Health Organization (WHO), Global Alert and Response (GAR), Disease Outbreaks by Year, Copyright © WHO 2014, available from http://www.who.int/csr/don/archive/year/en/.

Costs from outbreaks can be direct, indirect, or intangible. The most apparent direct costs are those associated with medical care of patients. Indirect costs arise at the individual level from loss of work and caregiving by relatives, and through interventions aimed at reducing the impact of the outbreak such as quarantining of contacts or closure of schools. Indirect costs also arise at the macro-economic level because of their impact on travel, tourism, trade, and consumer confidence. Fear of transmission causes international tourists to choose alternative holiday locations, and local populations to avoid any perceived source of infection such as foods from animals that may have been implicated in the outbreak, restaurants, and other public leisure venues—sectors of the economy that are significant contributors to the gross domestic product (GDP) of many countries. Misinformed consumers avoided purchasing pork during the 2009 pandemic of H1N1 influenza even though it was not a continued source of human infection as clearly demonstrated by a 10% decrease in pork trade on the Chicago Mercantile Exchange during the month after news of the pandemic was first announced; and avoided fresh vegetables during the 2011 outbreak of *Escherichia coli* O104 in Europe when speculation occurred as to its cause. Finally, there are intangible costs such as the loss of life. Economists have attempted to estimate the economic cost of death, but fail to capture other non-economic and sociocultural changes that can be a consequence of a highly lethal outbreak.

The severe acute respiratory syndrome (SARS) was a good example of an emerging infection with severe indirect costs, as it was responsible for sizeable economic losses and insecurity in financial markets across Asia and worldwide. With fewer than 9,000 reported cases, the outbreak was estimated by the Asian Development Bank to have cost Asian countries an estimated US$18 billion in GDP terms for 2003, and up to US$60 billion of gross expenditure and business losses (Asian Development Bank 2003).

In 2008, the World Bank estimated that the cost of a severe influenza pandemic (which would apply to other pandemics of similar severity) could be up to US$2–3 trillion taking into account healthcare costs and impact on the economy (Burns et al. 2008). It is therefore important to prepare for and respond to infectious disease outbreaks in order to minimize their healthcare and economic impact. Though the economic impact of the 2009 pandemic of H1N1 did not reach these proportions, the avian influenza virus and other

novel flu viruses continues to circulate among poultry in Asia with potential to cause a highly lethal and costly pandemic in poultry and/or humans.

Factors influencing emergence and re-emergence

Many external factors may align in such a manner as to provide opportunities for the emergence or re-emergence of infectious diseases. They range from weakened public health infrastructure and failure of safety procedures/regulations to increases in population, anthropogenic activities,

or climate change, civil disturbance/human displacement, and human behaviour that varies from misperceptions about the seriousness of the risks that cause emerging infections and the use of anti-infective drugs, to the safety of public health interventions and the desire to deliberately cause terror and harm.

Weakened public health infrastructure

Weakening of public health infrastructure resulted in part from decreased investment in public health during the second half of the twentieth century. This is compounded by poverty in lower-resourced countries where there are competing priorities for development, and suboptimal access to healthcare and sanitation. Deficient infrastructure also leads to a lack of the robust public health practices that could prevent the emergence of infectious diseases, or prepare communities to respond to them should they emerge.

Aedes aegypti has now become well established in many large cities worldwide following the deterioration of mosquito control campaigns during the 1970s. The resurgence of the *Aedes* species has been confounded by the adoption of modern consumer habits in urban areas where discarded household appliances, tyres, plastic food containers, and jars create abundant mosquito breeding sites. With the increase in *Aedes* species there has been an increased risk of dengue outbreaks. Prior to 1970, nine countries, mainly in Latin America, reported outbreaks of dengue. In 1983, 13 countries in Latin America and Asia reported dengue outbreaks, and by 1998, 1.2 million cases were reported from 56 countries. During 2001, 69 countries reported dengue outbreaks, and it is now endemic in more than 100 countries in Africa, the Americas, the Eastern Mediterranean, South East Asia, and the Western Pacific. By 2010, reported dengue infections to WHO exceeded 2.2 million annually with more than 20,000 deaths, and estimates placed the actual number of infections worldwide at between 50–100 million (WHO 2012a). By 2015 reported cases of dengue had increased to 3.2 million, with major outbreaks in Brazil, Indonesia, Thailand, Vietnam, Bangladesh, India, Pakistan, and Cape Verde. During 2012, an unexpected outbreak of dengue occurred in Portugal, with 191 probable cases reported (WHO 2012b). Currently WHO estimates that there are approximately 400 million dengue infections each year, while reporting of cases by countries remains much lower (http://www.who.int/denguecontrol/epidemiology/en/).

In 2005, the Chikungunya virus, likewise transmitted by *Aedes* species, emerged and spread throughout several Indian Ocean islands. A total of 3,100 human infections were reported by a sentinel network on La Réunion within the first 6 months of the outbreak, leading to an estimate of over 204,000 human infections by March 2006. In 2007, the Chikungunya virus spread north to Europe, where it caused an outbreak with 292 suspected human infections in northern Italy, and during 2010–2011 Chikungunya epidemics occurred throughout southern India (WHO 2012c). During 2017 Chikungunya continued to cause outbreaks in Asia, Latin America, and Africa, and in 2017 Italy again reported an outbreak of Chikungunya with 183 reported cases (http://www.who.int/csr/don/29-september-2017-chikungunya-italy/en/).

During the twentieth century the Zika virus spread from Africa to Asia, then in 2013 was first identified in island nations in the Pacific, and subsequently spread to the Americas. A major outbreak of Zika virus infection in South and Central America in 2015 caused concern because of the association between Zika virus infection and microcephaly and other neurologic defects among newborns to mothers who were infected with Zika, and Guillain Barre syndrome in adults (Heymann et al 2016). As there is no vaccine for Zika, vector control and personal protection against mosquito bites were recommended, but the outbreak subsided in Brazil and other Latin American and Caribbean countries by the end of 2016 (http://www.who.int/emergencies/zika-virus/situation-report/en/).

A major outbreak of yellow fever was first reported by Angola in late 2015, and yellow fever then spread to neighbouring urban areas in the Democratic Republic of Congo, and by unvaccinated Chinese guest workers to China who returned while still in the incubation period. Major vaccination campaigns were held, resulting in a worldwide shortage of yellow fever vaccine and the successful use of fractional doses of existing vaccine supplies (http://www.who.int/emergencies/yellow-fever/mediacentre/qa-fractional-dosing/en/). In 2017, Brazil reported major yellow fever outbreaks throughout the country, and as in Africa, major vaccination campaigns were conducted using fractional doses of yellow fever vaccine because of the continued worldwide shortage of vaccine.

Lapses in routine childhood immunization coverage due to weakened childhood immunization programmes in Russia resulted in the re-emergence of diphtheria, with major epidemics in the early 1990s. Reported cases of

diphtheria in the Russian Federation increased from just over 1,200 in 1990 to over 5,000 in 1993. In 2017 there were major diphtheria outbreaks in Bangladesh and Yemen among the children of displaced persons who had poor access to vaccines (http://www.who.int/csr/don/22-december-2017-diphtheria-yemen/en/; http://www.who.int/csr/don/13-december-2017-diphtheria-bangladesh/en/).

Lapses in routine yellow fever vaccination programmes in sub-Saharan Africa since the 1950s had likewise left large susceptible populations in both rural and urban areas of the region, with sporadic urban outbreaks in cities in Côte d'Ivoire (2001), Senegal and Guinea (2002), and Burkina Faso (2004) (Jamison et al. 2006), prior to the major outbreak in Angola in 2015. This is in contrast to the successful smallpox eradication programme that achieved sustained investment and close links between policy and political support, research, and field programmes that contributed to its success. Progress in the eradication of polio that has decreased the annual number of children paralysed from an estimated 1 000 children per day in 1988 to fewer than 100 in 2017 worldwide (http://polioeradication.org/polio-today); and the decrease in measles mortality by 74% (2007) after intensified efforts at measles mortality reduction were begun during 2000 (WHO 2008a). By 2016, there were 89,780 measles deaths reported globally—marking the first year that measles deaths had fallen below 100,000 per year (http://www.who.int/immunization/diseases/measles/en/).

Surveillance systems are critical in the early detection of outbreaks and during their containment, and to monitor progress. Setting up of surveillance systems requires substantial investment in infrastructure and manpower, and the commitment to sustain these systems in the long term. Most epidemiologists recognize that it was in part because of substandard surveillance systems in developing countries that HIV rapidly spread during the late 1970s, and was not detected until it was first identified in the United States in the early 1980s.

Failure of safety procedures/regulations

Substandard universal precautions and hospital regulations during the 1980s led to breaches in sterile injection practices and nosocomial infections of HIV in the former USSR and Romania, together infecting over 250 children, accompanied by high levels of hepatitis B in both patients and health

workers (Matic et al. 2006). Likewise substandard universal precautions led to nosocomial outbreaks of Ebola haemorrhagic fever in the Democratic Republic of Congo in 1976 and 1995, where syringes and/or failed barrier nursing amplified the transmission to patients, health workers, and the community (CDC 2012b). Continued lapses in universal precautions led to the amplification of recent outbreaks of Ebola infection in the Democratic Republic of Congo, Uganda, Sierra Leone, Liberia, and Guinea; and contributed to nosocomial transmission of SARS in hospitals in China, Hong Kong, Taiwan, Singapore, Vietnam, and Canada. Outbreaks then spread to family members of infected health workers, and then into the communities in which they lived. In 2015 the MERS coronavirus, thought to be transmitted to humans directly from camels, was first identified in humans in the Kingdom of Saudi Arabia in 2012, and has since caused nosocomial outbreaks in hospitals in the Middle East, and a major nosocomial outbreak in South Korea after a 68 year old male developed severe respiratory symptoms after returning from the Middle East. Nosocomial spread occurred to at least 15 hospitals in South Korea before transmission was finally interrupted (Oh et al. 2018).

Blood transfusions are another potential source of infection, especially for emerging infections that are not yet known and therefore impossible to detect by screening. A substantial proportion of HIV cases in the early phases of the epidemic were transmitted by blood transfusion (Curran et al. 1984). Although most countries now test banked blood for HIV and many other known infectious organisms, many resource-poor countries struggle to bank blood and ensure that transfusions are safe (Goodnough et al. 2003).

Changes in the process of rendering the carcasses of ruminant animals for the preparation of bone meal, which was fed to other ruminant animals, are thought to have been the cause of the outbreak of BSE in cattle that also led, in May 1995, to the death of a 19-year-male in the United Kingdom, the first human death from what is now known to be variant vCJD or human bovine spongiform encephalopathy (hBSE) (Trevitt and Singh 2003). The BSE and hBSE outbreaks demonstrate the health consequences of regulations for rendering that had changed over a 10-year period prior to 1995, inadvertently permitting rendered parts of cattle infected with the BSE-causing prion to contaminate bone meal used for livestock feed. The most likely source of human infection is thought to be through the preparation or consumption of contaminated meat and/or beef products. The BSE and

hBSE outbreaks led to the recognition of the need for stronger government intervention along the entire ‘feed to food’ continuum to better ensure the safety of foodstuffs for human consumption.

Major food borne outbreaks have also been related to contamination of the food chain with organisms such as *E coli* and *Salmonella* species. A major outbreak of bloody diarrhoea, with a high frequency of complications and death occurred in Germany in 2011, for example, linked to *E coli O104:H4* —contaminated fenugreek seeds imported from Egypt (Buchholz et al. 2011); and major outbreaks in North America in 2017 have been caused by *E.coli*, *Salmonella* species, listeria, and norovirus (CDC 2012a–d).

Population shifts including rapid increase and uncontrolled urbanization

Population shifts can lead to the emergence, re-emergence, and transmission of infectious diseases. Classic examples are the plague epidemics in Europe in the fourteenth century thought to have originated in Asia and spread first along the Silk Road, then by trade on merchant ships sailing the Mediterranean; and smallpox that is thought to have arrived in the Americas from Europe during the years of exploration and colonization that began in the fifteenth century. These epidemics incited fear and killed many who became infected, threatening to bring down entire civilizations. The world is much more easily travelled and interconnected since then, with large numbers of people moving from continent to continent every day. This has facilitated the international spread of emerging diseases as illustrated by the SARS epidemic that spread from a medical doctor who had treated patients with a severe atypical pneumonia in Guangdong Province, China. He became ill, but travelled to Hong Kong for a wedding and spent a night in a hotel where he passed the infection to tourists and other travellers who then seeded outbreaks in Vietnam, Singapore, Canada, and other parts of the world within days.

Population growth can result in increased disease transmission, especially where the infrastructure is unable to cope. The world’s population more than doubled in the second half of the twentieth century, accelerating most rapidly in the developing countries of the tropics and subtropics. Rural–urban migration has resulted in crowded living conditions, and inadequacy of water and sanitation systems, and other basic infrastructure. In 1950, there

were two urban areas in the world with populations greater than 7 million; by 1990, this number had risen to 23. As of 2017, as urban migration continues, there are 47 megacities, each with more than 10 million people, some of which have not been able to keep up with the development of infrastructure that will prevent major outbreaks related to water and sanitation.

Population increases in Latin America resulted in breakdowns in sanitation and water systems in large coastal cities. In 1991, when cholera re-emerged in Peru after having been quiescent for approximately 100 years, it rapidly spread throughout other urban areas in Latin America. Thought to have originated from contaminated seafood on the Peruvian coast, the disease caused nearly 400,000 reported cases and over 4,000 deaths in 16 South American countries that year. By 1995, there were more than 700,000 reported cases and just over 6,000 deaths in the Americas, and in 2012, cholera remains endemic in many areas (Delgado et al. 2011). A cholera outbreak in Haiti that began in 2010 after a major earthquake that destroyed Haitian infrastructure, caused by a strain of *V cholera* imported from Nepal, had resulted in approximately 10,000 deaths by 2017, and is now endemic in Haiti causing occasional outbreaks; while in 2017 a major outbreak of cholera began in Yemen among displaced populations, and has continued during the first half of 2018 (http://www.who.int/gho/epidemic_diseases/cholera/cases/en/).

Uncontrolled urbanization, with overcrowding and substandard living conditions in slum areas of Asia and Africa, has likewise contributed to the re-emergence of tuberculosis (TB) and plague (WHO 2011). HIV infection, also concentrated in urban areas, has facilitated the re-emergence of TB, showing the sometimes dynamic interaction among infectious agents. An outbreak of plague occurred in five states in India in 1994, where almost 700 suspected bubonic or pneumonic plague cases and 56 deaths were reported; a smaller outbreak of 16 persons with pneumonic plague was reported from northern India in 2002 (Gupta and Sharma 2007). In 2016 an outbreak of pulmonic and bubonic plague was reported from rural Madagascar with over 2,000 cases, and it rapidly spread to urban areas in just under 50% of all administrative areas in the country (http://www.who.int/news-room/fact-sheets/detail/plague/).

Anthropogenic activities or climate change

Deforestation that disrupts natural habitats of animals, and forces animals, searching for food, into closer contact with humans has been linked to the emergence and re-emergence of Lassa Fever in West Africa, and sine nombre virus in North America. First identified in 1969 when two nurses died with a haemorrhagic fever syndrome in Nigeria, the Lassa Fever virus is now known to be transmitted to humans from human food supplies and/or the household environment contaminated by urine and/or other excreta of infected rodents (Fichet-Calvet and Rogers 2009; Senior 2009). A major Lassa Fever outbreak began in 2018 in Nigeria, with approximately 1,800 suspected cases during the first 3 months of the year, occurred in areas where low levels of rainfall are thought to have forced rodents to move closer to humans in search of food (http://www.who.int/csr/don/01-march-2018-lassa-fever-nigeria/en/).

In many instances, rats invade human living spaces in search of food because rainforests, a natural habitat, have been destroyed. Sin nombre virus is a hantavirus, first identified in an outbreak in the southwestern United States in 1993. It is now known to spread from infected rodents to humans through aerosolized excreta found in dust of homes that have been invaded by rodents (CDC 2012c).

The Nipah virus outbreaks in Malaysia and Singapore in 1998–1999 are another example where evidence suggests that anthropogenic activities, including clearing of forests for agricultural purposes, encroached on the natural reservoir for the Nipah virus, the fruit bat. The virus, excreted in bat guano, is thought to have infected pigs that were farmed in areas that had penetrated the forests. The virus subsequently spread to humans in close contact with the infected pigs, and resulted in outbreaks with approximately 250 human infections and 100 deaths from Nipah-caused viral encephalitis. Additional outbreaks of the Nipah virus from 2001 to 2009 in Bangladesh suggested indirect transmission from bats to humans through palm sap collected from palm trees where fruit bats are known to feed, and nosocomial human-to-human transmission in hospitals (Epstein et al. 2006, Ref Islam NS); and an outbreak occurred among health workers in southern India in 2018 (http://www.who.int/csr/disease/nipah/en/).

Another virus thought to be carried by bats, the Ebola Reston virus, infected pigs in the Philippines in 2009, and the virus spread from pigs to pig farmers and workers in slaughterhouses causing asymptomatic infection (Miranda and Miranda 2011).

In Latin America, Chagas disease re-emerged as an important human disease after deforestation caused triatomine populations to move from their wild natural hosts to involve humans and domestic animals in the transmission cycle, eventually transforming the disease into an urban infection that can also be transmitted by blood transfusion. Other emerging infections influenced by changing habitats of animals include Lyme borreliosis in Europe and North America, transmitted to humans who come into contact with ticks that normally feed on rodents and deer, the natural reservoir of *Borrelia burgdorferi*.

Climatic changes, both anthropogenic and from natural variations, also influence the development of epidemics. The narrow band of desert in sub-Saharan Arica, in which epidemic *Neisseria meningitides* infections traditionally occur, has enlarged as drought spread south to involve Uganda and Tanzania. Climate extremes, whether involving excessive rainfall or drought, can likewise displace animal species and bring them into closer contact with human settlements, or increase vector breeding sites. A 1998 outbreak of Japanese encephalitis in Papua New Guinea has been linked to extensive drought, which led to increased breeding sites for the *Culex* mosquito as rivers dried into stagnant pools (Erlanger et al. 2009). It is thought that mosquitoes then transmitted the Japanese encephalitis virus from infected pigs and/or wild birds to humans. The Japanese encephalitis virus is now widespread in Southern Asia from India and Thailand to Malaysia, and as far north as Korea and Japan.

Above-normal rainfall associated with the occurrence of the warm phase of the El Niño Southern Oscillation phenomenon is thought to have been the cause of extensive flooding in East Africa from December 1997 to March 1998, increasing the breeding sites for *Aedes* mosquitoes. Mosquitoes then facilitated the transfer of the Rift Valley fever (RVF) virus from infected cattle, sheep, and/or goats to humans who had been forced to live in close proximity to animals on islands of dry land surrounded by flood water. During this period, the largest RVF outbreak ever reported in East Africa occurred in Kenya, Somalia, and Tanzania. The total number of human infections in northern Kenya and southern Somalia alone was estimated at 89,000 with an estimated 478 deaths. During 2006 and 2007, RVF caused outbreaks with approximately 250 human infections and 130 deaths in Kenya, Somalia, and Sudan; and an outbreak of 172 cases and 15 deaths occurred in 2010 in South Africa (Hightower et al. 2012). Outbreaks have

also occurred in Mauritania (2012) and Niger (2016), demonstrating the board geographic range of this infection first identified in East Africa in 1931 (http://www.who.int/emergencies/diseases/rift-valley-fever/en/).

Public health consequences of civil disturbance, human displacement, and natural disasters

Human population movements on a large scale as a result of war, conflict, or natural catastrophe often result in crowded, unhygienic, and impoverished living conditions. This in turn heightens the risk of emergence and re-emergence of infectious diseases. In the aftermath of civil disturbance in Rwanda in 1994, over 48,000 cases of cholera and 23,800 deaths were reported within 1 month among Rwandans who had been displaced to refugee camps in Goma, Democratic Republic of Congo (Goma Epidemiology Group, 1995).

A collateral impact of war, conflict, or natural catastrophe such as earthquakes is the destruction or weakening of health systems with diminished capacity to detect, prevent, and respond to infectious disease outbreaks. One consequence of the 27-year civil war in Angola was the outbreak of Marburg haemorrhagic fever in 2004 that spread to more than 200 humans, 90% of whom died. Emergence of the Marburg virus was detected late and transmission was amplified in overcrowded and understaffed health facilities where lack of investment during the war had resulted in substandard infection control. Another large outbreak of Marburg virus infection was identified in late 1998 in the Democratic Republic of Congo, also a conflict-ravaged country. This emergence resulted in sporadic cases with small chains of transmission over a 2-year period in a remote area where civil war had interrupted supply lines and communication to health facilities in the region (Bausch et al. 2006).

In addition to cholera outbreaks among those displaced by war and conflict in Yemen, polio outbreaks, caused by the wild polio virus, thought to have been imported from Pakistan, occurred among children w Syria in 2013 and 2014 who had been unvaccinated, the first reported polio since 1999. Another polio outbreak occurred in in Syria in 2017, caused by a circulating vaccine derived polio virus type 2, again among unvaccinated children displaced by the civil war (http://polioeradication.org/where-we-work/syrian-arab-republic/).

Natural disasters can also create conditions that facilitate the direct or indirect spread of infectious disease. Flooding commonly disrupts clean water supplies, and in 2009 in the Philippines, where leptospirosis is endemic, more than 2000 reported human infections, with an estimated case fatality rate of 10%, were associated with flooding caused by a major typhoon (Amilasan et al. 2012). The deterioration of clean water supplies and health services in Haiti after the earthquake in 2010, discussed previously, served as fertile ground for the cholera importation that has led to the continued outbreaks occurring throughout the country (CDC 2012d; Piarroux and Faucher 2012).

Human behaviour

Occupation

Throughout history, some human occupations have been associated with infectious disease. Anthrax has been called wool-sorters' disease because of transmission of its spores from infected animals to humans who shear sheep and other wool-producing animals, or whose occupation leads to exposure to their hides. It has also been associated with butchers who come into contact with infected animals at the time of slaughter or during preparation of meat for markets. Anthrax spores infect humans either intradermally, causing cutaneous anthrax, or by ingestion or inhalation, causing enteric or pulmonary/inhalation anthrax.

Though intensive research has failed to confirm the origins of Ebola haemorrhagic fever outbreaks, infection is thought to occur as humans encounter animal sources, possibly infected bats and/or non-human primates infected by bats, somewhere in the transmission cycle. An outbreak of Ebola haemorrhagic fever in humans in 1995 was linked to a woodsman, who worked deep within the tropical rainforest making charcoal, where he was believed to have become infected with the Ebola virus that he then carried back to his home village. An outbreak of Ebola in Gabon in 1996 is thought to have had a point source in a chimpanzee that was killed and butchered by a group of young hunters; and in 1994 a Swiss researcher infected with the Ebola virus in a forest reserve in West Africa was thought to have become infected while conducting chimpanzee autopsies in search of the cause of a major die-out of the animals (Daszak 2006). More recent outbreaks of Ebola in Uganda (2008) and Guinea (2013) have been associated with exposure to

bat guano in gold mines and in the rainforest, respectively (Food and Agricultural Organisation 2011, http://www.who.int/csr/disease/ebola/one-year-report/virus-origin/en/).

In 2003, a veterinarian in the Netherlands became infected with the influenza A (H7N7) virus during an investigation of influenza outbreaks in poultry and later died from acute respiratory failure. A total of 89 humans, including the veterinarian, were confirmed to have H7N7 influenza virus infection linked to this poultry outbreak and no further deaths occurred. The majority of human infections are thought to have occurred as a result of direct contact with infected poultry; but there were three possible instances of transmission of infection from poultry workers to family members (Jong et al. 2009). The H5N1 influenza virus has caused major lethal epidemics of influenza among poultry in many Asian countries, and exposure of children or adults to infected poultry being raised in backyards or industrial poultry farms has resulted in periodic human infections. By August 2012, a total of 608 sporadic infections had been reported to the WHO with an estimated case fatality rate of approximately 59% (WHO 2012e), and sporadic human infections have continued to be reported every year since then. Several countries have reported small clusters of persons infected with H5N1 infection that do not sustain transmission, usually occurring in family members or others who have close contact with an infected person. Other avian influenza viruses including H7N9 and other subtypes, continue to cause human infection among persons who are in close contact with poultry in China (http://www.who.int/influenza/en/),

demonstrating the diversity of this family of RNA viruses.

Healthcare workers are exposed to emerging and re-emerging infections on two fronts. Laboratory and health workers are at especially high risk of emerging and re-emerging infections, and can themselves be conduits of transmission. In the 1995 outbreak of Ebola haemorrhagic fever in Kikwit (Democratic Republic of Congo), almost one-third of those infected were health workers, and in the Ebola outbreak in West Africa from 2013 to 2015 up to 40% of all deaths have been estimated to have occurred among health workers (https://www.cdc.gov/vhf/ebola/history/2014-2016-outbreak/index.html), while in the 2003 SARS outbreak in Singapore, ten health workers were thought to have been infected while treating an infected health worker colleague who is also thought to have infected her husband, three other patients, and seven visitors to the hospital (Wilder-Smith et al.

2005). These examples show the potential for health workers to become infected, and in some instances to sustain and amplify transmission in hospitals, and through their patients and family members, to the community. Laboratory workers are also at risk of infection: the last human case of smallpox was caused by a laboratory accident in the United Kingdom, and the last-known human cases of SARS occurred in laboratory accidents in Singapore and China.

Mistrust and misinformation

During 2003, unsubstantiated rumours circulated in northern Nigeria that the oral polio vaccine (OPV) was unsafe and vaccination of young children could cause infertility. Mistrust and misinformation that followed led to the government-ordered suspension of polio immunization in two northern states and substantial reductions in polio immunization coverage in those states, and a large number of others (Larson and Heymann 2010). The result was a polio outbreak across northern Nigeria that then spread to, and re-emerged in, previously polio-free areas in sub-Saharan Africa, the Middle East, and as far as Indonesia. Over 70% of all children worldwide who were paralysed by polio during the following year, 2004, were living in Nigeria—or in other parts of sub-Saharan Africa that had been re-infected by polio virus genetically linked to viruses that had a Nigerian origin (United Nations Children's Fund 2006; Modlin 2010).

Misinformation about the safety of vaccines against pertussis, measles, and hepatitis B has likewise led to decreases in vaccine uptake among children, and in some instances industrialized country outbreaks of pertussis and measles. An example is a decrease in uptake of the measles, mumps and rubella (MMR) vaccine in the United Kingdom from a coverage of 92% at the time of a falsified publication in 1998 that suggested a link between MMR and autism, to a low of 79% during 2003 (Pearce et al. 2008). Persistent low coverage has led to measles outbreaks in England and Wales during the following years, with the outbreak still ongoing during the first six months of 2018 (https://www.gov.uk/government/news/measles-outbreaks-confirmed-in-leeds-liverpool-and-birmingham). To ensure vaccine uptake is maximized, public confidence in the benefit, safety, and effectiveness of vaccines must be upheld, which in turn, relies on a comprehensive evidence base underpinning vaccination strategies (Larson et al. 2011).

Deliberate use to cause terror and harm

Infectious organisms have been deliberately used to cause terror and harm throughout history, with accounts of the use of highly infectious and lethal organisms such as smallpox to kill or weaken the opposition during wars in the eighteenth century (Riedel 2005), and this has continued into the twenty-first century. It was graphically illustrated in 1979 in an outbreak of inhalation anthrax in Sverdlovsk, 1,400 km east of Moscow, in the then Soviet Union. Attributed at first by government officials to the consumption of contaminated meat, it was later shown to have been caused by the unintentional release of anthrax spores from a Soviet military microbiology facility. It is estimated that up to 358 humans were infected and that between 45 and 199 died (Meselson et al. 1994) (see Chapter 8.18).

In the United States in 1984, salad bars in restaurants in Oregon were deliberately contaminated with *Salmonella enterica* by a group of followers of a spiritual leader in order to cause illness at the same time as county elections. The result was food poisoning of over 750 persons (https://www.cdc.gov/phlp/docs/forensic_epidemiology/Additional%20Materials/Articles/Torok%20et%20al.pdf).

In late September 2001, the deliberate dissemination of anthrax spores in four known letters sent through the United States Postal Service caused massive disruption of postal services in the United States, and in many other countries around the world. The anthrax letters—dated 11 September 2001, and postmarked 7 days later—caused huge public alarm and prompted a massive public health response. A total of 22 persons are thought to have been infected by anthrax spores sent through the postal system; 11 developed cutaneous anthrax and the remaining 11 developed inhalation anthrax, of whom five died. Twenty of the 22 patients were exposed to work sites that were found to be contaminated with anthrax spores. Nine of them had worked in mail processing facilities through which the anthrax letters had passed (Bouzianas 2009).

Other bacteria, viruses, mycotic organisms, and biological toxins are also considered to have the potential for deliberate use to cause harm to humans. Great concern has been expressed by many countries about the potential health consequences that could be caused by the deliberate introduction of infectious organisms such as the variola virus into a human population where smallpox vaccination is no longer practised, or the plague bacillus that could potentially cause an outbreak of pneumonic plague. Stockpiles for

vaccines against infections such as smallpox and anthrax are currently being maintained, at great expense, as part of emergency contingency planning in some countries.

In addition to the deliberate use of existing infectious agents, new laboratory research can result in the creation of novel agents that have the potential for human spread. One example is the laboratory research on H5N1 influenza viruses to determine the mutations that will facilitate human spread. While the research was performed to understand the determinants of transmission in an academic setting, if these more transmissible viruses were to fall into the wrong hands, it could result in a pandemic of unprecedented proportions. This has resulted in much debate among the scientific and regulatory communities on the merits of research with potential dual uses.

Antimicrobial drug resistance—susceptibility of infectious organisms to anti-infective drugs

Bacteria, viruses, and parasites all have the potential to develop resistance to anti-infective drugs by spontaneous mutation and natural selection, or through the exchange of genetic material between strains and species. These resistant organisms can then transmit from human to human, replacing more susceptible organisms with resistant strains. Soon after development of the first antibiotics, warning signs of microbial resilience began to appear. By the end of the 1940s, resistance of hospital strains of *Staphylococcus aureus* to penicillin emerged in the United Kingdom with levels as high as 14%, and by the end of the 1990s, levels had risen to of 95% or greater. Resistance has also developed to semi-synthetic penicillin derivatives as *S. aureus* has acquired genes encoding resistance to methicillin and other narrow-spectrum beta-lactamase-resistant antibiotics. Methicillin-resistant *S. aureus* (MRSA), first identified in the United Kingdom in 1961 within a year of the introduction of methicillin, is now widespread in hospital-acquired infections in the United Kingdom and throughout the world (Johnson 2011).

The bacterial and viral infections that contribute most to human disease are also those in which antimicrobial resistance is rapidly emerging: diarrhoeal diseases such as dysentery; respiratory tract infections, including pneumococcal pneumonia and TB; sexually transmitted infections such as gonorrhoea and HIV; and infectious organisms that have now accumulated

resistance genes to virtually all currently available anti-infective drugs such as extremely drug-resistant TB (XDR-TB).

Since 2008, Gram-negative Enterobacteriaceae have been shown to be resistant to a broad range of beta-lactam antibiotics including carbapenems that are widely used for their treatment. Carbapenem-resistant bacterial infections have been identified in many countries across the world with emergence thought to have occurred somewhere in Asia (Kumarasamy et al. 2010).

The causes of antimicrobial drug resistance (AMR) are complex, and involve both the human and animal health sectors, and others such as plant and fish agriculture. AMR is a major global public health issue because it threatens the effectiveness of antimicrobials in combating infection, which has been one of the most important advances in clinical medicine. A lack of effective antimicrobials could lead the world back to the pre-antimicrobial era where simple infections often led to severe outcomes, and where effective measures to control the spread of disease, especially those for which there are no vaccines, would be lost. AMR also increases healthcare and other indirect costs as more expensive treatments are required, and illnesses may be prolonged.

Use of anti-infective drugs in human health

Behaviours such as over- or underprescribing of antibiotics by health workers, excessive demand for antibiotics by the general population, or the use of substandard drugs with inferior anti-infective drug content, have had a remarkable impact on the selection and survival of resistant microbes, rapidly increasing levels of microbial resistance.

In Thailand, among 307 hospitalized patients in the late 1980s, 36% of persons who were treated with anti-infective drugs did not have an infectious disease (Aswapokee et al. 1990). Overprescribing of anti-infective drugs occurs in most other countries as well. In Canada, it has been estimated of the more than 26 million people treated with anti-infective drugs, up to 50% were treated inappropriately (Kondro 1997). This has also led to community-based resistance where otherwise healthy individuals may be carrying resistant microbes which can result in transmission or infection. Findings from community surveys of *Escherichia coli* in the stool samples of healthy children in China, Venezuela, and the United States suggest that although

multiresistant strains were present in each country, they were more widespread in Venezuela and China, countries where less control is maintained over antibiotic prescribing and sales (Lester et al. 1990).

The availability of multiple drugs to treat TB since the 1940s has reduced death rates from TB substantially. Resistant organisms have emerged, however, facilitated by inappropriate prescribing and poor adherence to treatment regimes. Multidrug-resistant TB (MDR-TB) has now become widespread, especially in prison settings in Eastern Europe, and resistant organisms are now being transmitted to healthy populations throughout the world. During 2016 WHO estimates that there were a total of 490,000, over 50% of them in China, India, and the Russian Federation (http://www.who.int/tb/publications/global_report/Exec_Summary_13Nov2017.pdf?ua=1).

In 2006, an outbreak of extremely drug-resistant TB (XDR-TB), against which almost all TB drugs are ineffective, occurred in South Africa (WHO 2012f), and all XDR-TB cases that were tested for HIV were found to be HIV-positive as well. WHO has estimated that up to 9% of the 490,000 MDR MDR-TB cases that occurred in 2016 were XDR-TB, and with HIV infection endemic, the world provides continued fertile ground for the transmission of all forms of TB, including MDR- and XDR-TB (http://apps.who.int/iris/bitstream/handle/10665/259366/9789241565516-eng.pdf?sequence=1).

Carbapenem-resistant Enterobacteriaceae (CRE) are carbapenemase-producing Enterobacteriaceae (CPE) that have become resistant to the carbapenem class of antibiotics. Resistance has spread from country to country in persons infected during medical procedures or in the community, and treatment of resistant infections requires prolonged hospitalization and attempts to cure with various antibiotic combinations (Tängdén 2015)

Malaria is another major infection with high mortality that has been reduced substantially with the introduction of antimalarial drugs. By 1976, however, chloroquine-resistant *Plasmodium falciparum* malaria had developed and was highly prevalent in South East Asia. Ten years later, chloroquine-resistant malaria was found worldwide, as was high-level resistance to two second-line drugs, sulphadoxine/pyrimethamine and mefloquine. Subsequently, use of artemisinin combination therapy is now recommended by the WHO to ensure effective treatment, but since 2009 there are reports of artemisinin resistance in South East Asia, threatening to

derail efforts to control malaria in Asia, and worldwide (Nayyar et al. 2012). Multidrug-resistant malaria has now emerged and spread in Cambodia, Laos, Thailand, and Vietnam (Takala-Harrison and Jacob 2015). Surveillance and monitoring for resistance continues both in Asia where efforts are being made to contain its spread to other continents including Africa.

Prevention and control of resistant infections such as MRSA and *Clostridium difficile* in healthcare facilities is an important key to reducing the spread of AMR, and control of such hospital-acquired infections must be a priority.

Use of anti-infective drugs in animal husbandry and agriculture

Large quantities of anti-infective drugs are indiscriminately added to animal feed in some countries to promote animal growth, resulting in the selection of resistant bacterial strains in animals. Antibiotics are also used in agriculture for spraying of fruit trees, rice paddies, and flowers to avoid bacterial blights.

Some of the organisms that infect animals freely circulate between animals and humans, providing opportunities for zoonotic infection with resistant organisms, and for swapping or exchanging resistant genes, thus increasing the speed with which anti-infective resistance evolves in both agriculture and human populations. Alternative approaches can reduce such antibiotic use as in Norway, where the introduction of effective vaccines in farmed salmon and trout, and improved health management, reduced the annual anti-infective use in farmed fish by 98% from 1987 to 2004 (WHO 2012g). Similar outcomes have occurred in North America as well, where vaccines are also used intensively in salmon farming in the Pacific Northwest. During the 1990s, Norway and other countries throughout Europe banned the non-discriminate use of antibiotics for growth promotion in animal feed; and in the United States in 2017 a voluntary ban on use for growth promotion of those antibiotics used in humans was put into place by the Food and Drug Administration.

The weakness of surveillance and monitoring systems for antimicrobial resistance, partially the result of the lack of easy-to-use surveillance tools, makes it difficult to understand the extent and evolution of the AMR

problem globally. The lack of financial investment for research into new antimicrobials and vaccines is also a major global problem. Many of the anti-infective drugs currently in use were developed decades ago and the lack of drugs that target non-similar areas on microbes limits treatment modalities available to combat infections. Mechanisms are beginning to be put in place in an attempt to increase the development of new antibiotics and vaccines with additional funding or research and development, and de-linkage of marketing from research and development is seen as a potential means of prolonging new antibiotic life by decreasing the marketing pressure that inevitably occurs as companies attempt to rapidly recuperate their investment.

The WHO proposed a five-pronged containment strategy for AMR (Fig. 8.17.3) through activities set up around a World Health Day in 2011(WHO 2012h), and a report on AMR in 2012. In 2015 a Global Action Plan on Antimicrobial Resistance was launched. Underpinning this strategy is the need for national commitments for sufficient and sustainable resources to be made available to combat AMR, and for countries to developing national action plans (http://www.who.int/antimicrobial-resistance/global-action-plan/en/).

In 2016, at the United National General Assembly, Member States recognized AMR as a global problem and adopted a declaration of the high-level meeting on AMR. The United Nations also established an Interagency Coordination Group on AMR, to provide guidance on approaches to ensure sustained effective global action on AMR.

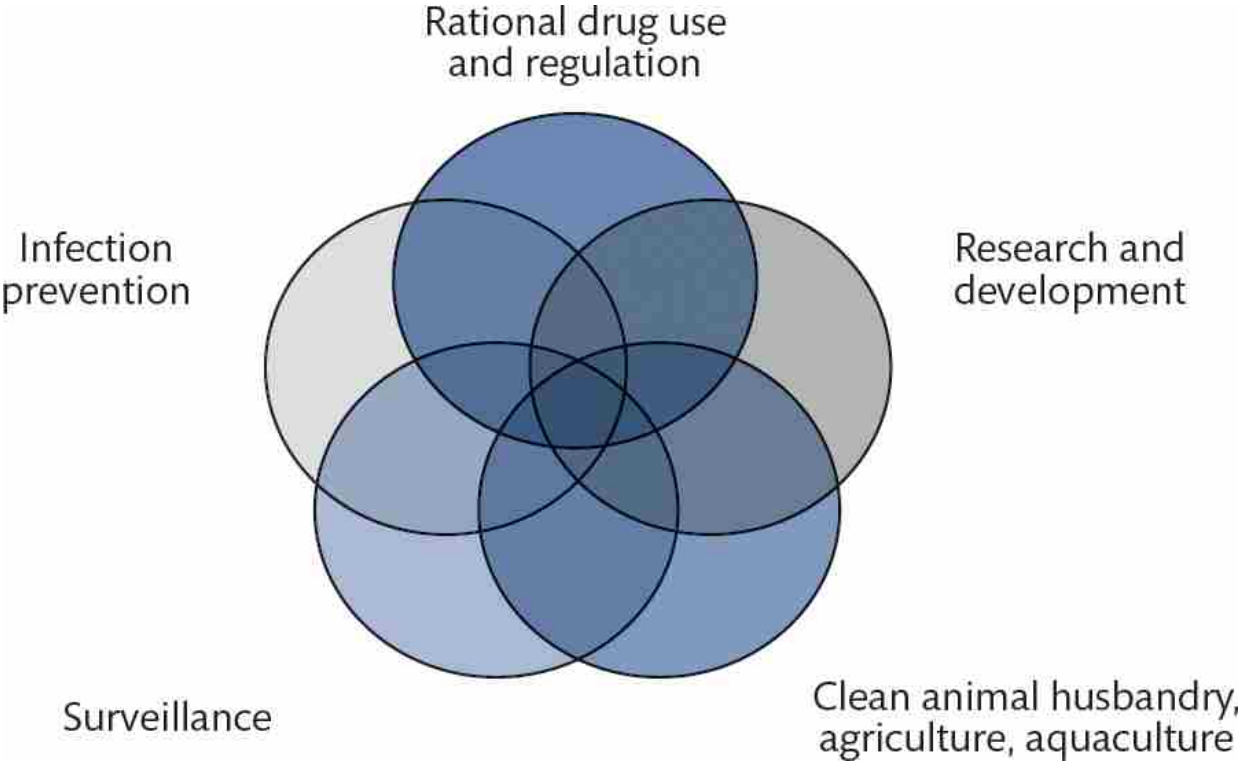

Fig. 8.17.3 The five key areas for containment of antimicrobial resistance.

Public health security: globalization and emerging/re-emerging infectious disease organisms

Our world of increased human mobility and interdependence facilitates the transfer of infectious organisms from country to country, and across continents. Infectious organisms efficiently travel in humans, insects, food, and animals, and can spread around the globe and emerge in new geographic areas with ease and speed. Some are transported by migratory birds. Others, such as disease-carrying mosquitoes, travel in the passenger cabin or luggage hold of jets, to cause tropical infections in temperate countries when they feed on airport workers or those who live nearby. They thus threaten public health security—our collective vulnerability to acute infectious disease outbreaks across international borders (Heymann 2003).

In 2000, among 312 athletes participating in an international triathlon held in Malaysia, 33 became infected with leptospirosis and returned to their

home countries during the incubation period. While leptospirosis lacks human transmissibility and therefore did not set up local foci or transmission, the outbreak of SARS in 2003 clearly did, and demonstrates the full potential of emerging infectious organisms to spread internationally. From a medical doctor infected in Guangdong Province of China, who unknowingly carried the new infectious organism to a Hong Kong hotel, SARS spread in individual chains of transmission from infected hotel guests to 8,422 reported cases in North and South America, the Middle East, Europe, and Asia with a case fatality rate of approximately 11% (WHO 2003).

During the years 1969–2003, 18 instances of airport malaria were reported to the WHO—malaria infections in workers at airports or in persons who live nearby who had not travelled to malaria-endemic countries (WHO 2007b). Their infection originated from malaria-infected *Anopheles* mosquitoes that had travelled from countries with endemic malaria and took a blood meal from airport workers or other persons upon landing. In 2003, a seven-person outbreak of malaria among persons in Florida who had not previously travelled to malarious areas demonstrated the potential for imported malaria to set up local foci of transmission if the *Anopheles* mosquito is present (Morbidity and Mortality Weekly Report 2004). In 2013, 4 cases of malaria were reported in persons living within a 2 km radius of the Tunis International Airport who had no history of international travel, the first malaria reported in Tunisia since 1980 (Siala and Gamara 2015), and ‘airport malaria’ continues to regularly reported from industrialized countries, demonstrating that malaria remains a risk in countries where there is no endemic malaria transmission.

Livestock, animal products, and food can also carry infectious organisms that emerge or re-emerge in non-endemic countries. VCJD, identified in persons in 11 countries, most of whom had not previously travelled to the United Kingdom (Diack et al. 2012), clearly demonstrates the ability of infections to travel in animals or animal products. RVF emerged in humans in Yemen and Saudi Arabia in 2000, 2 years after a major outbreak of RVF in East Africa. Infection has since become endemic in livestock in the Arabian Peninsula, and is thought to have been imported from East Africa in livestock traded across the Red Sea (Balkhy and Memish 2003). In 2000, imported raspberries contaminated with *Cyclospora* caused an outbreak in the United States. It is hypothesized that the raspberries imported from

Guatemala were contaminated when surface water was used to spray them with fungicide before harvest (Ho et al. 2002). In 2011, the German outbreak caused by *Escherichia coli* O104 linked to sprouts grown from imported beans resulted in over 3,000 infections and 31 deaths from haemolytic uramic syndrome (WHO 2006; European Food Safety Authority 2012).

Concerns about the international spread of emerging and re-emerging infections and the need for strong public health security are not new. By the fourteenth century, governments had recognized the capacity for international disease transmission and legislated preventive measures, as reflected in the establishment of quarantine in the city-state of Venice. Arriving ships were not permitted to dock for 40 days, and people at land borders were held in isolation for 40 days in the hope of keeping plague from entering.

Many European leaders of the mid-nineteenth century, worried by the cholera pandemic of the time, threats of plague, and the weakness of quarantine measures, began to recognize that controlling the spread of infectious diseases from one nation to another required cooperation between those nations. International conventions were organized and draft covenants signed, almost all of which related to some type of quarantine regulations.

From 1851 to 1897, ten international sanitary conferences were held among a group of 12 European countries, focusing exclusively on the containment of epidemics in their territories. The inaugural 1851 conference in Paris lasted 6 months and was followed in 1892 by the first International Sanitary Convention that dealt with cholera. Five years later, at the 10th International Sanitary Conference, a similar convention that focused on plague was signed.

New policies then emerged in the late nineteenth century, such as the obligatory telegraphic notification of first cases of cholera and plague, a model that a small group of South American nations followed when they signed the first set of international public health agreements in the Americas during the 1880s. In addition to cholera and plague, often carried by immigrants arriving from Europe, the agreements in the Americas covered yellow fever that was endemic in much of the American region at that time, and that from time to time caused major urban epidemics.

During the following decade, 12 countries attended the First International Sanitary Convention of the American Republics in Washington, DC, leading to the creation of the Pan American Sanitary Bureau (now called the Pan

American Health Organization) in 1902. Its counterpart in Europe was the Office International d'Hygiène Publique (OIHP), established in 1907, and based in Paris.

In 1951, 3 years after its founding, the WHO adopted a revised version of the International Sanitary Regulations (1892) that remained focused on the control of cholera, plague, and yellow fever and was rooted firmly in the preceding agreements of the nineteenth and twentieth centuries.

The International Health Regulations

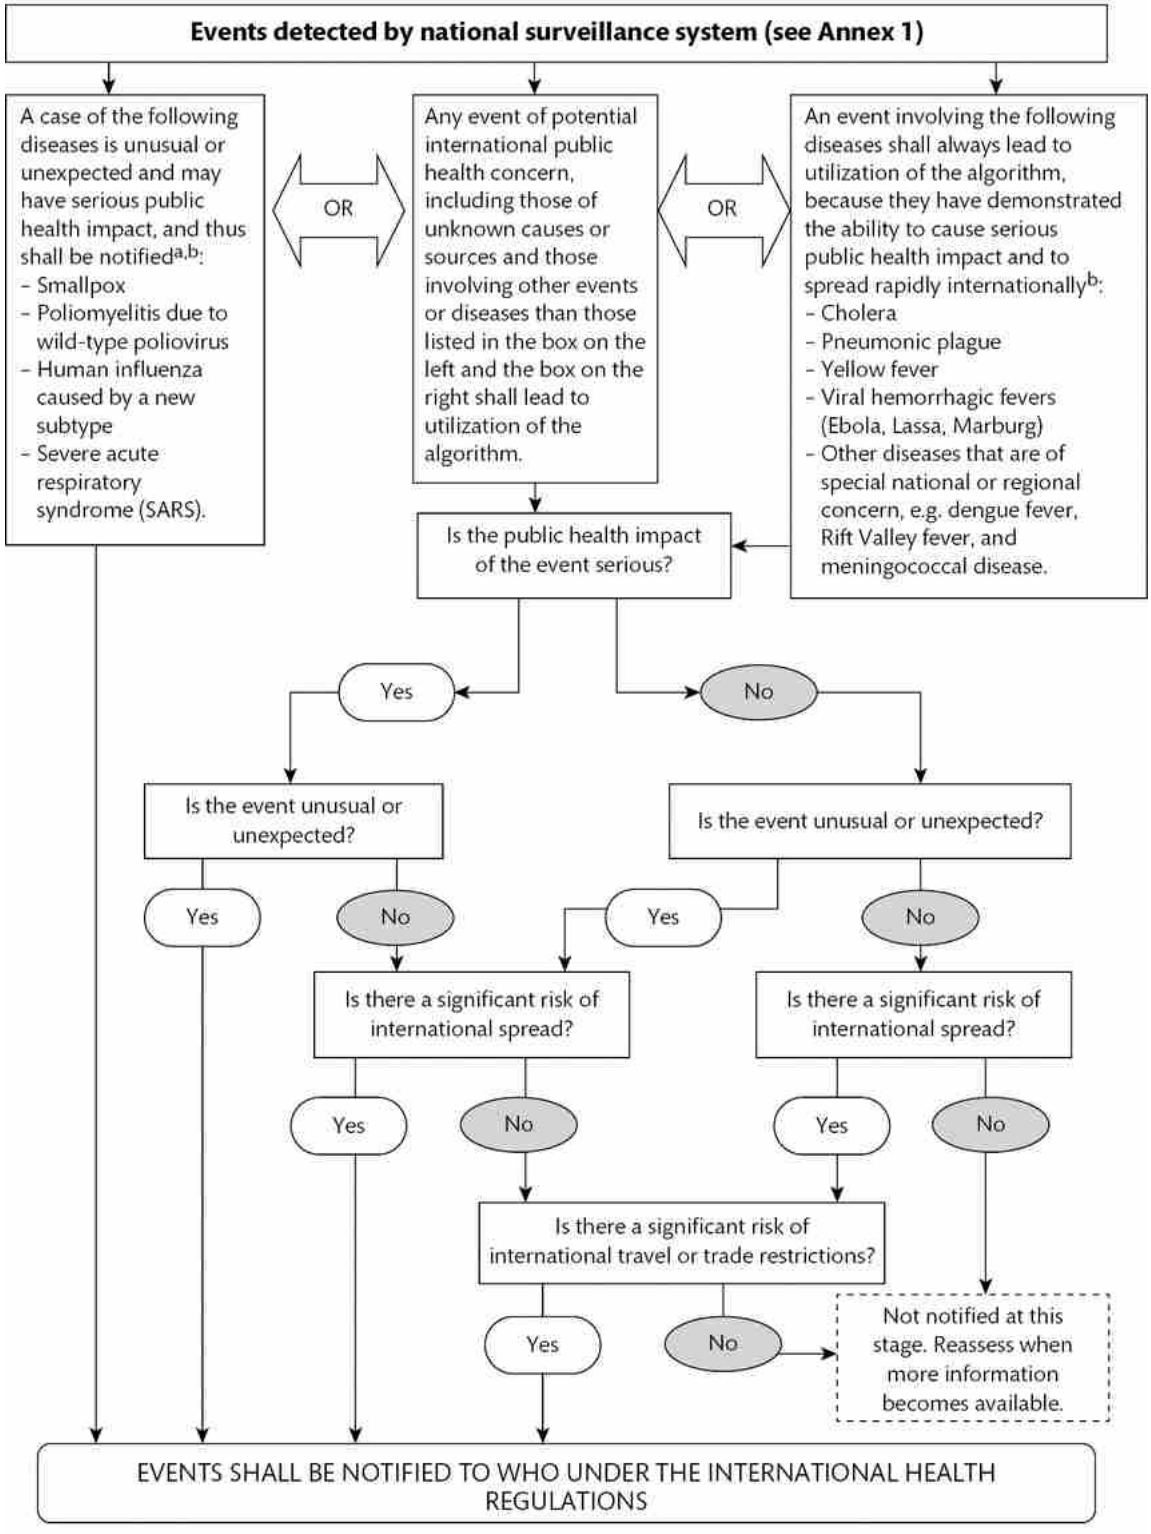
In 1969, the Member States of the WHO agreed to a new set of international sanitary regulations—the International Health Regulations (IHR)—aimed at better ensuring public health security with minimal interruption in travel and trade. In addition to requiring reporting of four infectious diseases—cholera, plague, yellow fever, and smallpox—the IHR were aimed at stopping the spread of disease by pre-established control measures at international borders. They included reporting requirements for these four diseases, and described appropriate responses such as yellow fever and smallpox vaccination for passengers arriving from countries where yellow fever or smallpox outbreaks had been reported. The IHR provided a legal framework for global surveillance and control of spread of infectious diseases.

By 1996, it had become clear, however, that the IHR were not able to ensure public health security as had been envisioned. Over the previous 30 years, border posts proved inadequate to stopping the international spread of infectious diseases which often crossed borders while still in the incubation period in humans, or silently in non-human hosts—insects, animals, food, and agriculture goods. At the same time, countries reported the occurrence of cholera, plague, and yellow fever late or not at all because of fear of stigmatization and economic repercussions (smallpox had been removed from the list when it was certified eradicated in 1980). The IHR also did not meet the challenges caused by other emerging and re-emerging infectious disease and their rapid transit round the globe.

From 1996 until 2005, WHO Member States therefore undertook a process to examine and revise the IHR. The result—the IHR (2005) (WHO 2008b)—provided a more up-to-date legal framework requiring reporting of any PHEIC, and the use of real-time evidence to recommend measures to stop their international spread. A PHEIC is defined as an extraordinary event

that could spread internationally or might require a coordinated international response (WHO 2012i). Under the IHR (2005) an event is evaluated for its potential to become a PHEIC by the country in which it is occurring even though reporting might legitimately come from elsewhere, using a decision tree instrument developed for this purpose (Fig. 8.17.4). If the criteria for a PHEIC are met, an official notification must be provided to the WHO. Notification is also required for even a single occurrence of a disease that would always threaten global public health security—smallpox, poliomyelitis caused by a wild-type poliovirus, human influenza caused by a new virus subtype, and SARS. In addition, there is a second list that includes diseases of documented—but not inevitable—international impact. An event involving a disease on this second list, which includes cholera, pneumonic plague, yellow fever, Ebola, and the other haemorrhagic fevers, still requires the use of the decision tree instrument to determine if it is a PHEIC. Thus, two safeguards create a baseline of public health security by requiring countries to respond, in designated ways, to well-known threats.

ANNEX 2
DECISION INSTRUMENT FOR THE ASSESSMENT AND NOTIFICATION OF EVENTS THAT MAY CONSTITUTE A PUBLIC HEALTH EMERGENCY OF INTERNATIONAL CONCERN



[a] As per WHO case definitions.
[b] The disease list shall be used only for the purpose of these Regulations.

Fig. 8.17.4 Decision tree for assessment of a potential public health event of international concern. Reproduced with permission from World Health Organization (WHO), International Health Regulations, Second edition, Copyright © WHO 2005, available from: http://www.who.int/ihr/publications/9789241596664/en/.

In contrast to previous regulations, the IHR (2005) also introduced a set of core capacity requirements for surveillance and response. All countries were to meet these requirements during the first years of implementation of the IHR (2005) in order to rapidly detect, assess, notify, report, and contain the events covered by the regulations so that their potential for international spread and negative economic impact would be minimized. The IHR (2005) likewise require collective action by all WHO Member States in the event that an emerging or re-emerging infectious disease threatens to spread internationally, and the free sharing of information pertaining to this threat. They thus provide a safety net against the international spread of emerging or re-emerging infections, requiring collaboration between all states to ensure the timely availability of surveillance information and technical resources that better guarantee international public health security.

Other international frameworks have also been developed to contain and curtail the international spread of emerging infections. Among them is the WHO Global Action Plan on Antimicrobial Resistance (WHO 2015) described earlier in this chapter (see ‘Use of anti-infective drugs in animal husbandry and agriculture’). Though not legally binding, this framework calls on countries to work across the human health, animal health, agricultural, and trade sectors to ensure more rational use of anti-infective drugs in order to limit the factors that accelerate the selection and proliferation of anti-infective drug-resistant microbes.

Recommendations for the future

National and international systems for addressing the threat of infectious diseases

To enable the world to deal effectively with the threat of emerging and re-emerging diseases, there is the need for countries to follow the international frameworks laid out by such agreements as the IHR (2005) and the WHO Action Plan on Amtimicrobial Resistance (2015); and also by the United Nations Framework Convention on Climate Change, still under negotiation.

These international agreements call for action at the global, national, and subnational levels that will decrease the risks factors that influence emergence and re-emergence of infectious diseases. At the same time, if followed they will result in better detection and response where and when emerging and re-emerging public health events occur, be they at the animal/human interface or in other situations where a series of risk factors align in such a way as to permit their occurrence. Effectively preventing, or rapidly detecting, assessing, and responding to infectious disease outbreaks will save lives and protect economies.

The link between health and overall human development is also important, as many factors such as poverty, lack of education, and basic community infrastructure play a role in emergence and re-emergence. As concluded by the WHO Commission on Macroeconomics and Health (2001b), health considerations must be placed squarely at the centre of economic development, and all sectors of society must work together to achieve this goal, as it is not the sole purview of the health sector alone.

A better understanding of our ecosystem and causative factors will enable preventive actions that reduce the likelihood of disease emergence, especially infections at the animal/human interface. One example is safe and healthy market programmes to encourage proper handling and distribution of livestock and maintenance of strict sanitation in markets where animals or animal products are sold that could be a source of infection. This fits with the one health agenda that calls for joint collaborative activities between the animal and human health sectors in such areas as surveillance and response, and risk assessment.

For emerging and re-emerging infections that are able to transmit from person to person, the window of opportunity for effective intervention often closes quickly. The most important defence against their international spread is robust surveillance and preparedness, response protocols, and mitigation systems. Infectious disease outbreaks must be detected rapidly and the response must be timely and effective. This includes highly sensitive national surveillance systems, public health laboratories that can rapidly detect such outbreaks, and mechanisms for timely outbreak containment and mitigation. It also necessitates good communications systems, and risk communication and health education programmes, to enable coordinated preparedness and response by all stakeholders. These are the core capacities required by the IHR (2005), and it is clear that the same systems that detect

and contain naturally occurring outbreaks also permit detection and initial response to deliberately caused outbreaks of infectious disease.

The requirement of the IHR for core capacity development is key to effective prevention and control of emerging and re-emerging infections—it will equip countries with the ability to detect and respond when and where outbreaks occur, preventing their spread across borders. The collaborative action required by IHR (2005) when emerging or re-emerging infections threaten to spread internationally provides a safety net of global surveillance and response that can be called into action if and when outbreaks begin to spread internationally. The IHR (2005) explicitly acknowledge that non-state sources of information about outbreaks often precede official notification, especially when countries may be reluctant to reveal an event in their territories. Collaboration among countries for public health security in the face of emerging and re-emerging infections is vital. If an outbreak of emerging or re-emerging infectious disease occurs in a country that requires international assistance to help in containment activities, as agreed by the WHO and the affected country after confidential and pro-active consultation, other countries are obligated to provide the technical expertise required to the country through WHO or bilaterally. To this end, global databases of professionals with expertise in specific diseases or epidemiological techniques are maintained as part of the requirement of the IHR (2005), together with non-governmental organizations present in countries and in a position to reach remote areas. Such mechanisms, which are further supported by the WHO network of Collaborating Centres (national laboratories and institutes throughout the world serving as international reference centres), help optimize the use of global expertise and resources. The IHR (2005) were instrumental in the coordination of the international response to the H1N1 influenza pandemic in 2009. Upon the recommendation of the IHR Emergency Committee set up by the Director General of the WHO, the pandemic was declared as a PHEIC within weeks of its onset, and triggered a series of obligations for collaboration among countries under the IHR (2005). Since then PHEICs have been declared by the Director General for polio, Ebola, and Zika virus infections.

At the same time operational protocols that had been developed as part of pandemic planning and preparedness activities in countries around the world were implemented, together with coordinated actions under the IHR (2005).

Another platform that supports disease response is the Global Outbreak Alert and Response Network (GOARN). GOARN was formed in 2000 by WHO together with partner institutions, organizations, and networks with interests in global epidemic surveillance and response. GOARN contributes to outbreaks response, to providing technical assistance to affected states rapidly, and to long-term preparedness and capacity building. GOARN brings together resources for rapid identification, confirmation, and response to outbreaks of international importance. During outbreaks, WHO coordinates international outbreak response using resources from GOARN partners that volunteer their services, to ensure that the right expertise and provided where and when they are needed most.

The 2020 SARS-CoV2 pandemic

In 2020 the world is experiencing the worst rapidly-spreading pandemic since the 1917–18 H1N1 Influenza pandemic. As of this writing, April 2020, almost 200 million cases and 120,000 deaths have been reported from countries on every continent, and the pandemic continues to spread.

On 21 December 2019, it is understood that an ophthalmologist and several other clinicians in Wuhan, Hubei Province, China began reporting to their colleagues cases of an unusual respiratory disease with pneumonia. By 27 December local public health officials reported the occurrence of this unusual disease to the Jianghan Centers for Disease Control. It was thought that the Huanan fish and wild animal market was the source of the first cases of the new disease, and it was closed on 31 December. On this same date an epidemiologic alert was sent to the China Centers for Disease Control in Beijing which then forwarded the alert to the WHO and to other countries. On 5 January the WHO published in its Disease Outbreak News a description of the clusters of pneumonia, an assessment of its seriousness, and provided advice based on the reports coming from Beijing. By 12 January the causative agent had been identified with a genetic sequence closely related to two other mutated coronaviruses which had caused epidemics of SARS and Middle Eastern Respiratory Syndrome, and the genetic sequence was shared publicly. The new agent was designated as Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) and the disease labelled as COVID-19. A genetic similarity to bat coronaviruses was noted suggesting that a bat virus had been transmitted to an animal

intermediary from which it emerged to cause human infection and disease. As of this writing an animal intermediary host has not been confirmed, and based on further analysis of the genetic sequence, it is hypothesized that the virus emerged several weeks earlier than originally thought.

The magnitude of the epidemic in China, as confirmed by polymerase chain reaction (PCR) testing, and the infectious nature of the virus prompted a strict lockdown of Wuhan City 23 January and subsequently further lockdown of an additional 15 other cities from 24 to 27 January. The tight lockdown of the major cities in China ultimately achieved the goal of slowing the epidemic in China and decreasing its international spread, and by mid-April Wuhan and other Chinese cities had pulled back on the intensity of the lockdown. By the time of this writing, China was reporting more imported cases than were occurring domestically (Wu et al. 2020a, 2020b, 2020c).

On 30 January 2020, the WHO declared the epidemic a PHEIC, and in March declared SARS-CoV2 a global pandemic with cases reported from other Asian countries, and countries around the world including reports of severe epidemics by Italy, Spain, and other parts of Europe where outbreaks were overwhelming demand on hospital systems. The United States, as of the time of writing, has reported more cases and more deaths than any other country in the world including China. Singapore, Germany, Taiwan, South Korea, and Hong Kong, which have kept the reproductive number less than 1 by implementing strong outbreak containment measures including patient identification and isolation, and contact tracing with rigorous daily follow-up.

Other countries have implemented these measures less consistently, and all countries are attempting to limit population exposure by issuing personal self-protective policies that include frequent hand washing and physical distancing, and social distancing measures such as closing schools and non-essential businesses, and the cancelling large gatherings of people for concerts, sports, and other events. The wearing of a face mask or other means of protecting the spread of droplets from potentially infected persons has become policy for the general public in some countries, and all are recommending the use of face mask for persons who have cough, fever, or other symptoms, or who are unable to physically distance such as workers in homes for the elderly. At the same time hospitals in all countries are

increasing their infection prevention and control measures to prevent infection of health facility workers and nosocomial transmission.

Despite early examples of outbreak control in Asian countries, many other countries did not heed the warning, and the different experiences in dealing with the pandemic underscore the importance of stronger preparedness of basic public health strategies such as alert systems, containment strategies including patient isolation and rigorous contact tracing, surge capacity in health systems, and application of quarantine measures when required based on continuing risk assessment. It is also generally acknowledged that in the future there must be stronger surveillance and risk assessment at the human-animal interface.

In the majority of persons infected with SARS-CoV2 disease manifestations are mainly those of mild respiratory illness, but in the elderly, and in those with underlying medical conditions such as diabetes, hypertension, cardiac disease, and chronic pulmonary disease, there is a risk of severe disease and death. Severe disease and death have also been observed in other age groups and in persons with no known underling medical conditions, but at the time of writing they have not been clearly quantified, nor is the percentage of infections that remain asymptomatic fully understood. The case fatality ratio has ranged from under 1% to as high as 13–14% depending on the case definition used, which has usually been for severe disease and therefore does not include persons with less severe illness in the calculation; and the capacity of hospitals to support those who require intensive care is also a factor that contributes to mortality. Common symptoms of illness include low-grade fever, dry cough which can become continuous, shortness of breath which can progress to respiratory failure, and extreme fatigue. The incubation period from exposure to development of symptoms is thought to range from 1 to 14 days, and transmission has been observed from individuals who subsequently developed symptoms one or two days after they had been exposed to persons who later developed infection. The role of earlier transmission from asymptomatic persons is currently not completely understood, nor is the immune response. Antibody testing facilitates determination of the prevalence of disease and may be helpful in understanding the proportion of infections that are asymptomatic, but at the time of writing it is not known whether the antibodies detected are protective, and if so for how long; and the sensitivity and specificity of these tests is not yet understood, with validation continuing. It is known, however,

that immunity to some of the common coronaviruses in humans is not long-lived.

The impact of the on the global economy of forced physical distancing through the lockdown of certain economic sectors has been severe. Stock markets have fallen, jobless rates have increased as restaurants and other small businesses have closed, and the socioeconomic gap between the wealthy and poorer population groups is feared to be widening in all countries. It is also feared that an excess of deaths will occur in persons not infected with SARS-CoV2 because of restricted access to routine medical care. In some countries forced physical distancing measures have resulted in tension between public health leaders and business leaders about how long to continue the strict lockdown policies, and recovery, once the pandemic has been controlled, is anticipated to take several years or longer. Though the destiny of this virus is not yet fully understood and cannot be predicted with accuracy, some epidemiological modellers suggest that it could continue to cause waves of transmission for years to come, and others are predicting a decrease in transmission at certain times of the year.

The future

The vision embraced by the IHR (2005) is of a world alert and ready to respond collectively to the threat of emerging and re-emerging infections that represent an acute threat to public health security. This requires an unbroken line of defence within countries and globally, using the most up-to-date technologies of surveillance and response.

The IHR (2005) require adherence to new norms and standards for reporting and responding to emerging and re-emerging infections despite the economic consequences that may result. Their full achievement will provide the highest level of public health security possible. National core capacities as described in the IHR (2005) must be put in place within the national public health system that can detect, investigate, communicate, and contain events that threaten public health security as soon as they appear. An interconnected system must be operating at the national and international levels, engaged in specific threat and risk assessment and management activities that minimize collective vulnerability to public health events.

The newly established and voluntary WHO joint external evaluation (JEE) process provides countries with the platform to help them assess their core

capacities in public health, followed by an action plan and budget that permits them to mobilize resources (https://www.jeealliance.org/). At the same time, development agencies are gearing up to provide resources for such capacity strengthening through their global health security efforts.

Countries must sustain and/or increase their resources to strengthen core capacity in public health. In today's mobile, interdependent, and interconnected world, threats arising from emerging and epidemic-prone diseases affect all countries. Such threats reinforce the need for shared responsibility and collective action in the face of universal vulnerability, in sectors that go well beyond health.

Bioterrorism

Peter Katona

Introduction

Whether from a natural pandemic, antibiotic resistance, a biological accident, or an act of terrorism, deadly disease can be a threat to all of us and to our national security as the fine line between natural and man-made infection is getting thinner. With earth's 7.4 billion people, 20 billion chickens, and 400 million pigs, we have the ideal scenario for creating and spreading deadly microbes between humans, animals, and even to and from plants. Trade and travel connect points of the globe in a matter of hours not days or weeks as in the past. Tens of millions of people are living in the microbe rich and sanitation poor mega-city slums or markets of the developing world such as Lagos or Mexico City or Wuhan where a small outbreak can spread into a pandemic with or without a terrorist's help. Add to this a sophisticated bioterrorist using a microbe on an unprecedented scale with today's advancing weaponization technology and one can further understand our need for preparedness.

The evolution, risk, and relevance of biological weapons

Biological agents are living organisms that may or may not have disease or transmissibility properties. Biological weapons are living biological agents or their toxins that are intentionally used to cause harm to humans, plants, or animals. More specifically, the draft Model State Emergency Health Powers Act of 2001 defined bioterrorism as 'the intentional use of any microorganism, virus, infectious substance, or biological product that may be engineered as a result of biotechnology, or any naturally occurring or

bioengineered component of any such microorganism, virus, infectious substance, or biological product, to cause death, disease, or other biological malfunction in a human, an animal, a plant, or another living organism in order to influence the conduct of government or to intimidate or coerce a civilian population'. These organisms may be easily obtained, and, with the right equipment and technical skills, grown and disseminated relatively easily. If weaponized, they can infect a large number of hosts with a small quantity of product. They can be contagious or non-contagious from person to person.

If disseminated efficiently, biological weapons can cause high morbidity and mortality. Whether weaponized or naturally occurring, they can be seen as part of a larger group of evolving emerging and re-emerging biological agents. This evolution is caused or aggravated by a number of factors including climate change, antibiotic resistance, the overuse or misuse of antibiotics, new or changing disease vectors, new habitats, advancing, mostly genetic, technology, or a terrorist act. Microbial agents may be harmful or beneficial to society as shown in Table 8.18.1.

Table 8.18.1 Microbial agents

Dr Jekyll	Mr. Hyde
• Antibiotics and vaccines • Fungi that eat plastic, provide clean fuels, and clean up radiation polluted areas • Better understanding of the genome, proteome, and microbiome	• Isolated infections • Outbreaks, epidemics, and pandemics • Biological control byproducts • Emerging and re-emerging agents • Biological weapons • Increasing resistance

Biological weaponization is key to intentionally causing significant morbidity and mortality to large numbers of people, animals, or plants. The process of making a biologic agent weaponized first involves achieving a particle size of 1–5 microns. Also important is the chemical coating, the absence of an electrostatic charge, the non-hydrophobic non-self-adhering or 'flowability' properties, virulence, the viability of the agent within each

particle, antibiotic resistance, and ease of milling to remove clumps and to stabilize the particle.

There are several types of serious intentional biological events. They can be biological crimes targeted against individuals, acts of bioterrorism making a violent political statement against a target audience between or by nations (see Fig. 8.18.1), or agroterrorism directed against animals or crops. There have also been accidental laboratory releases. A bioattack may be a high impact low probability event such as Nissan Talib's low probability high impact 'black swan', or Donald Rumsfeld's unanticipated 'unknown unknown'. All may constitute public health emergencies.

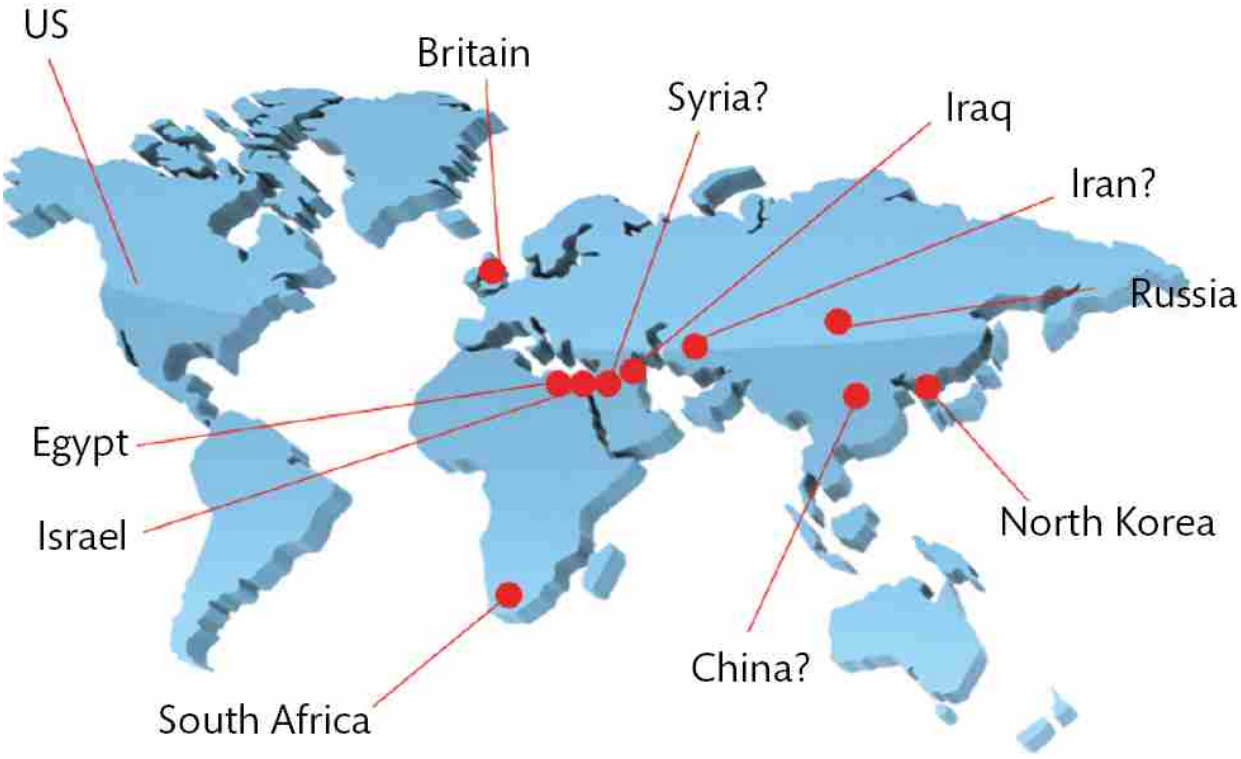

Fig. 8.18.1 Biowarfare programmes.

The risk of a biological attack is loosely defined as its probability times its consequences. This takes into account prevention, mitigation, resilience, preparedness, avoidance, post-event emergency response with detection, containment, treatment, and recovery. The term 'dual use' is important in that care is needed in not letting a terrorist get the upper hand with peacetime technology that could later be converted into a weapon (dual use). Other

factors promoting bioweapons are the low cost, the compensation for military inferiority, the attribution difficulty, and the fact that it enables hyperempowered individual(s) to achieve a nefarious and more significant goal. Ultimately, for a bioterror attack to be successful there needs to be a critical system breach, a widespread mechanism, and a prevention or mitigation failure.

Treaties, initiatives, directives, and legislation

Bill Gates warned world leaders that terrorist use of a genetically engineered virus could kill more people than a nuclear weapon when he delivered a chilling address at the 2017 Munich Security Conference. His concern was supported by US and British intelligence agencies, which felt that 'scientific terrorists' have access to the necessary tools to design biological weapons of mass destruction capability. In the face of this knowledge, he said that governments around the world remain complacent and neither prepared nor equipped to respond. Gates suggested preparing for epidemics 'the way the military prepares for war' with more exercises and training (Gates 2017).

Gates specifically mentioned organizations like the Coalition for Epidemic Preparedness Innovations, a public-private coalition that aims to derail epidemics by speeding up the development of vaccines, much like what the federal government is doing with programmes like the Biomedical Advanced Research and Development Authority (BARDA), but with less paperwork. Research was needed, he said, to dramatically reduce the time to develop vaccines. He added that there needs to be adequate laboratory resources to identify and monitor suspect pathogens, as well as trained medical personnel, germ games, and other preparedness exercises.

Post 9/11 US presidents have also shown an interest. In 2002 President George W. Bush said: 'Bioterrorism is a real threat to our country. It's a threat to every nation that loves freedom. Terrorist groups seek biological weapons; we know some rogue states already have them … It's important that we confront these real threats to our country and prepare for future emergencies.' Many programmes addressing this were started under his administration.

The Public Health Security and Bioterrorism Preparedness and Response Act of 2002 was critical. It established preparation procedures for bioterrorism and public health emergencies. It created the National Disaster

Medical System, and security risk assessment of all individuals who have access to select agents and toxins, especially from the CDC Category A list mentioned later.

National Security and Presidential Directives HSPD 10 in 2001 and NSPD 33 in 2004 addressed ‘Biodefense for the 21st Century’ for threat awareness, prevention, and protection, surveillance and protection, as well as response and recovery in an attempted comprehensive way. The National Security Preparedness Memorandem of 2018 (NCPM-14) emphasized that biothreats are persistent, originate from multiple sources, and don’t respect borders. Biothreats require multisectoral cooperation for prevention and response, and need science and technology to advance globally.

There were many developments regarding biopreparedness following the events of 9/11. Congress established a Senate Subcommittee on Bioterrorism and Public Health Preparedness (SSBPHP). The House established the House Subcommittee on Emergency Preparedness, Response and Communications (HSEPRC). There was even a position created for a Special Assistant to the President for Biodefense (ASPR).

President Obama spoke of the need to ‘come together to prevent, detect and fight every kind of biological danger, whether it’s a pandemic like H1N1, or a terrorist threat’. His mention of bioterrorism in the 2010 State of the Union address, and his issuance of several executive orders increased congressional attention (Obama Administration Gets an ‘F’ for Bioterrorism Defense 2010). The absence of a comprehensive US capability to rapidly recognize, respond to, and recover from a disease-based attack was, he claimed, the most ‘significant failure’ identified by the Commission on the Prevention of Weapons of Mass Destruction Proliferation and Terrorism.

In 2018 President Trump spoke of establishing a Biodefense Steering Committee (BSC), led by the Health and Human Services (HHS) Secretary, to coordinate biodefense efforts across the federal government. He would also task the National Security Adviser with reviewing threats and updating preparations on an annual basis. He claimed that his administration was focused on strengthening our nation’s defences against the full range of threats to our health and security, including those of a biological nature. The planning, he said, was meant to counter both man-made biological weapons and naturally occurring diseases like Ebola.

With threats to food, water, agriculture as well as to humans there have been many federal initiatives addressing weapons of mass destruction

(WMD) in general, and bioterrorism specifically. USDA, HHS, and the Department of Homeland Security (DHS) are tasked with initiatives inside the US, while the Department of Defense (DoD), the Department of State (DoS) and the intelligence community are tasked to the foreign side. Prevention was placed under DoS, the Department of Justice (DoJ), DHS, HHS, and the intelligence services.

Many HHS efforts are housed within the Centers for Disease Control and Prevention (CDC), which supervises the Bio-Intelligence Center, the Strategic National Stockpile (SNS) of countermeasures available on short notice from distribution centres strategically placed around the country. CDC also manages the Cities Readiness Initiative (CRI) programme designed to enhance biopreparedness in the nation's largest population centres, where nearly 60% of the population resides. The purpose was to effectively respond to large-scale public health emergencies needing life-saving medicines and medical supplies. HHS, like DHS, also funds regional Centers of Excellence to lead and coordinate research on defences against both bioterrorism and emerging infectious diseases. CDC has a unit dedicated to emergency preparedness and response and has also published numerous guidelines (e.g. Emergency Preparedness and Response 2018).

The Pandemic and All-Hazards Preparedness Act (PAHPA) of 2006, reaffirmed by the 2013 Pandemic and All-Hazards Preparedness Reauthorization Act (PAHPRA) established the HHS Assistant Secretary for Preparedness and Response (ASPR) as the principal adviser to the HHS Secretary. They were responsible for providing integrated policy coordination and strategic direction for all matters related to public health, medical preparedness, and deployment of the federal response for public health emergencies and incidents. Most of these initiatives are housed under HHS' Science and Technology Directorate.

PAHPA transferred the National Bioterrorism Hospital Preparedness Program (NBHPP) from the Health Resources and Services Administration (HRSA) to ASPR. The focus was now all-hazard preparedness from the original focus on bioterrorism. The purpose of the now renamed Hospital Preparedness Program (HPP) was to enhance the ability of hospitals and healthcare systems to prepare for and respond to bioterrorism and other public health emergencies. Programme priority areas included interoperable communication systems, National Incident Medical System compliance and training, bed tracking, personnel management, mass fatality management

planning, and hospital evacuation and shelter in place planning. During the past 5 years, HPP funds have also improved medical surge capacity and resources, decontamination capabilities, isolation capacity, pharmaceutical supplies, training, and education drills and exercises. Much of this responsibility has more recently been transferred to regional healthcare coalitions across the country.

Louisiana State University's National Center for Biomedical Research and Training (NCBRT) is a member of the National Domestic Preparedness Consortium (NDPC), a partnership of public and private organizations, the majority academic, and is committed to serving emergency first responders by providing quality, cost-effective counterterrorism training. The goal is to provide a focused threat responsive, long-term national capability to execute and sustain comprehensive and coordinated domestic WMD emergency responder education courses, and is specifically tasked with educating first responders about biological terrorism and community disaster preparedness.

Established in 2016, The National Biodefense Analysis and Countermeasures Center (NBACC) is a national biodefense research laboratory created by DHS. It supports intelligence assessments, preparedness planning, response, emerging threat characterization and bioforensic analyses. It was the first national laboratory created by DHS.

NBACC is comprised of two sections: The National Bioforensic Analysis Center (NBFAC) and the National Biological Threat Characterization Center, the lead federal facility to conduct and facilitate the technical forensic analysis and interpretation of materials recovered following a biological attack in support of the appropriate lead federal agencies like the FBI. It supports federal law enforcement conducting experiments to better understand biological vulnerabilities and hazards. The NBFAC provides the FBI with bioforensic analysis and testing of suspected biothreat samples and has supported over 100 federal cases. The Center is partnered in the National Interagency Confederation for Biological Research at Fort Detrick and has laboratories with biosafety levels 1 2,3, and 4. Having the highest level of safety and experimental capabilities this enables research on pathogens that do not have a treatment or vaccine. Currently, there are only 13 BSL-4 laboratories in the US. NBACC works with the DoD and National Institutes of Health to organize and conduct research with the goal of addressing the gaps and needs of biodefense.

DHS's National Biosurveillance Integration Center (NBIC) looks at the biothreat awareness, detection, and information sharing needed to respond to incidents that may cascade into a nationally significant event. This includes bioterrorism attacks, disease outbreaks, and environmental catastrophes as well as data on medical intervention, food safety, travel, and wildlife health. By tapping into all of these databases, their centralized system would be able to track, map, and predict national patterns and outbreaks. With enough data across so many sources and sectors, they hope to eventually generate predictive algorithms using artificial intelligence.

DHS surveillance and communication systems such as BioWatch are used to detect the release of biopathogens into the air as part of a terrorist attack on major American cities. It was created in 2001 in response to the increased threat of bioterrorism on postal facilities sparked by the 2001 anthrax attacks, and was announced in President George W. Bush's State of the Union Address of 2003. The programme, described as 'the nation's first early warning network of sensors to detect biological attack', operates via a system of filters located within existing Environmental Protection Agency (EPA) air filters that monitor air quality. The CDC analyses results from these filters and passes any significant results to the FBI. Unfortunately, the system also had generated more than 50 false alarms between 2003 and 2008. State and local health officials have never ordered evacuations or distributed emergency medicines in response to a false positive reading from the system.

BioSense, also operated by the CDC, has near real-time electronic connectivity with 32 hospital emergency departments in 10 cities. It is designed to give federal and local health officials an immediate indication of a bioterrorism or deadly infectious disease outbreak via syndromic surveillance of symptoms.

An overview of these agencies and laws is highlighted in Table 8.18.2.

Table 8.18.2 Bio acronyms mentioned in the text

DHHS	DHS	DOD	Laws	Directives

The CDC-defined agents

There are many factors that make biological terrorism appealing. Biothreat agents can be cheap and—with proper expertise—relatively easy to handle as production recipes have been available on the Internet. There is an incubation period between contact with the agent and the development of symptoms, which can range from a day for plague to a few weeks for smallpox. Perpetrators may be halfway around the world before any symptoms are recognized. Detection is difficult as they are tasteless and odourless. Most important is that they can be efficiently disseminated by aerosol especially in large closed spaces.

Since there have been very few large-scale bioterrorist incidents, CDC had to rely on a panel of experts to decide which agents were most important to prepare for. They classified agents into categories A, B, or C based on their ease of transmission, severity of morbidity and mortality, and likelihood of use. Category A agents can be easily disseminated or transmitted from person to person, result in high mortality rates and have the potential for major public health impact. They might cause public panic and social disruption and require special action from public health authorities. Most Category A agents are considered especially dangerous due to the potential for airborne transmission. They are shown on Box 8.18.1

Box 8.18.1 CDC Category A agents

Variola major (smallpox)*
Bacillus anthracis (anthrax)
Yersinia pestis (plague)*
Clostridium botulinum toxin (botulism)
Francisella tularensis (tularemia)
Filoviruses Ebola and Marburg*
Arenaviruses Lassa (Lassa fever), Junin (Argentine), and related viruses*

* contagious from person to person including only the pneumonic form of plague.

CDC Category B agents are moderately easy to disseminate, result in moderate morbidity and low mortality, and require CDC's diagnostic capacity and enhanced disease surveillance. They include Coxiella burnetti (Q fever); Brucella species (brucellosis); Burkholderia mallei (glanders); Rickettsia prowazekii (Typhus fever); alphaviruses Venezuelan, Eastern, and Western equine encephalitis; Ricinus communis (ricin toxin from castor beans); epsilon toxin of Clostridium perfringens; and Staphylococcus enterotoxin B. The CDC list also contains a group of Category B agents loosely defined as 'food- or waterborne pathogens'. These include Salmonella species, Shigella dysenteriae, *Escherichia coli* O157:H7, Vibrio cholera, Cryptosporidium, and Noroviruses.

Category C agents are emerging pathogens that could be engineered for mass dissemination because of their availability, ease of production and dissemination, potential for morbidity and mortality, and major health impact being less significant than Category A and B agents. This includes Nipah virus, hantaviruses, tick-borne haemorrhagic fever viruses, tick-borne encephalitis viruses, yellow fever, and multidrug-resistant tuberculosis.

Although clinical symptoms of these agents may vary from diarrhoea to a skin rash, a commonality of virtually all of these biothreats agents is a 'flu-like illness' consisting of fever, chills, and body aches. Contagiousness is important but not necessary. Pandemic influenza and coronaviruses were not even on this list.

There are many possible routes of exposure to a biologic agent. There is ingestion, where the agent enters when the host eats, drinks, or puts contaminated fingers or other objects into his or her mouth. An example is the Salmonella salad bar attack by the Rajneesh. There is absorption, where

the agent enters the host through mucosal surfaces such as eyes, nose, or throat. Intact skin is hard to breech except by T2 mycotoxin, a fungal byproduct. There is injection, where the organism enters the host through the skin via a vector such as animal bites, hypodermic needles, any sharp object, or defects in the skin surface as in the Markov ricin incident. The most effective route is inhalation, where the agent enters when the host takes a breath. This occurred with the anthrax letters. The optimal particle size, as mentioned, is 1–5 microns, so the agent can easily establish itself in the lungs, cause local disease, or even enter the bloodstream. Inhalation exposure can occur with slowly descending aerial bombs or bomblets, spray tanks, carefully designed ballistic missile warheads, or, as we now know, letters.

Clinical recognition indicators of an intentional bioattack may include unusual time of year or locale for a particular set of common flu-like symptoms. There may be an unusual or unexpected number of sick or dying people or animals. There may be an unscheduled or unusual dissemination of sprayed material such as mosquito sprayers or crop dusters. We may even find abandoned sprayer dispersion devices.

Initial detection may be from a ‘sentinel’ case where an astute physician has diagnosed the disease in a patient. There may be arrival in large numbers overwhelming emergency rooms. There may be gradual recognition by the medical community, an indicator from a public health or animal or syndromic surveillance system, a lab report, or the opening of a suspicious letter. The best-case scenario is prevention by infiltration into a terrorist organization from good intelligence gathering. The worst-case scenario is after mass chaos has occurred.

Like nuclear weapons, to optimize the dissemination of a weaponized biothreat agent ideally one needs to do experiments, which the US military originally did in the 1950s. Both liquid agents, preferred by the Soviets, and dry powder, preferred by the US, were tested. Testing was done in Alaska to assess the influence of extreme cold weather (it was not a factor). In Texas, an experiment was done utilizing flying aircraft to assess if there was sufficient energy to deliver a respiratory sized particle aerosol using liquid agent (there was). In New York City, experiments were done to see if subway cars generated sufficient wind currents to disseminate a dry powder product (they did). In San Francisco Bay experiments assessed the influence

of weather conditions. They found that outdoor dissemination of an agent is very dependent on inversions, air temperature, wind speed, and humidity.

More recently there is an EPA and DHS project designed to help develop the tools and techniques necessary for the rapid return of service to a subway system after it had been contaminated with a biological organism. In one experiment they wrapped a subway car in cellophane to assess how quickly they could decontaminate it. All told here were three field studies done since 2013.

Indoor release has fewer potential liabilities. Researchers concluded that a well-planned weaponized aerosol agent disseminated through the air can have far-reaching consequences, especially in large enclosed spaces such as closed stadiums, subway systems, and convention halls. All this information has been available to terrorists.

There were also functional WMD management exercises, the most prominent being TOPOFF and Dark Winter. TOPOFF consisted of four WMD scenarios played out every other year by ‘top officials’. The first TOPOFF exercise was held in 2000 in Denver, Colorado, and Portsmouth, New Hampshire where participants faced a simulated attack with plague. TOPOFF 3, held in 2005, involved a biological attack in New Jersey, also with plague. Operation Dark Winter was a senior-level bioterrorist attack simulation conducted in 2001. It was designed to carry out a covert and widespread smallpox attack on Oklahoma City with additional attacks in Georgia and Pennsylvania. Organized by DoJ and FEMA, it was specifically designed to spiral out of control. The purpose was to assess the nation’s crisis and consequence management capability by local, state, and federal responses to geographically dispersed terrorist threats and acts.

History: from nations to cults to lone wolves to unknown perpetrators

There have been large-scale national programmes, cults, individuals, and unknown perpetrators involved in intentional bioattacks. There were also accidental releases. While early biowarfare started by contaminating a city’s reservoir with a dead horse going back thousands of years, we will start with an incident in the 14th century.

During the 1346 battle of Caffa the Tartar army hurled the corpses of plague victims over the walls of the city, a seaport on the Crimean coast. Gabriel de Mussis, a notary, saw the Tatar attack on this well-fortified Genoese-controlled seaport in modern Ukraine. He described how the plague-weakened aggressors catapulted dead victims of plague over the walls into the town. He wrote: '[The Tatars], fatigued by such a plague and pestiferous disease, stupefied and amazed, observing themselves dying without hope of health, ordered cadavers placed on their hurling machines (catapults) and thrown into the city of Caffa, so that by means of these intolerable passengers the defenders died widely.' An epidemic of plague within the walls of the city followed, forcing a retreat of the Genoese forces. The exported disease continued to spread in Europe. Some speculate that this may have set off the 2nd European Black Death plague pandemic of the Middle Ages that resulted in 30–40 million deaths, half the worldwide population. This was repeated in 1710, when the Russians, besieging Swedish forces at Reval in Estonia, also catapulted bodies of people who had died from plague.

The French and Indian Wars were not spared from acts of biological terrorism. British forces used smallpox-tainted clothing as a weapon in the 1785 siege of La Calle. Earlier, British officers such as Sir Jeffrey Amherst had plans to intentionally transmit smallpox to Native Americans during Pontiac's Rebellion near Fort Pitt (present-day Pittsburgh) in 1763. It is not clear whether they actually carried out these plans. But, from whatever its source, smallpox did spread rapidly among susceptible Native Americans in the area during and after that rebellion, killing off as many as 50% of the Indian population.

Japan's infamous Unit 731 operated between 1937 and 1945. Unit 731 was a biowarfare unit masquerading as a water purification facility with a 150-building complex just outside of Harbin, Manchuria, with another related site at Changchun named Unit 100. In one experiment plague-infected fleas were dropped with grain from airplanes using uniquely designed fragmentation bomblets over Manchuria. The grain attracted rats, and the rats became infected from the fleas. This brought the disease deep into the human population. All told they field-tested biological weapons on the Chinese, on prisoners of war and on other civilians. Tens of thousands died as a result of these plague, cholera, and anthrax experiments.

In their facilities the Soviet Union produced biological agents in unconscionable quantities., including greater than 1,000 metric tonnes of anthrax and plague, and 100 metric tonnes of smallpox. Produced in Biopreparat and other facilities, this was enough bioagent to eradicate every living thing on the entire galaxy. But there were also problems. In 1979 the Soviet Union had an anthrax accident at Sverdlovsk, a Soviet military compound. The accident resulted in 77 anthrax cases with 66 deaths, all downwind from the facility that had failed to replace a defective filter, and all from less than 1 gm of weaponized anthrax spores. Cases occurred within the known incubation period of 4 to 45 days. The Russians, originally stating that this was naturally occurring intestinal anthrax, did not admit this was from a military accident until many decades later. Biopreparat employed 60,000 people in the production of offensive biological weapons. Russia may well still be experimenting with bioweapons in other facilities.

During World War I, the German Army developed anthrax, glanders, cholera, and a wheat fungus, specifically for use as biological weapons. They allegedly spread plague in St. Petersburg, Russia, infected mules with glanders in Mesopotamia, and attempted to do the same with the horses of the French Cavalry.

The US also had a programme housed at the US Army Medical Research Institute for Infectious Disease (USAMRIID), which stopped offensive bioweapons experiments in 1969, but has continued studying defensive technology, studying agents that had a vaccine or therapy. National biowarfare programmes are shown on the graphic.

With the defection of Iraqi General Hussein Kamal Hassan in 1995, evidence was found that the Iraqi biological warfare programme was more advanced than previously believed. Iraq had both biological and chemical weapons in the 1990s. Inspectors found that they produced 19,000 litres of botulinum toxin, 2,200 litres of aflatoxin, and 8,500 litres of anthrax. They filled 25 missiles and 166 bombs with anthrax and botulinum toxin. They also had delivery systems using SCUD missiles, bombs, and even a remote-controlled MIG-21 equipped with a 500-gallon sprayer. The reason these agents were not used in Gulf War I remains unclear.

In 1978 Bulgarian exile Georgi Markov, while in London, was injected in the leg with a steel ball impregnated with ricin via a specially constructed umbrella. He felt immediate pain at the injection site and within 5 hours became weak and dizzy. Fifteen to 24 hours later, Markov developed a fever,

became nauseated, and was admitted into a hospital. He eventually died. The reason for the area of induration and redness on his leg was unknown until the autopsy. Markov represents, in recent history, the first example of state-supported bioterrorism. The assassination was carried out by the communist Bulgarian government with technology supplied by the Soviet Union. The platinum-iridium pellet was the size of the head of a pin and cross-drilled with 0.016-inch holes to contain the toxin.

Only 10 days earlier, a similar assassination attempt was made against another dissident, Vladimir Kostov, in Paris. In this case only heavy clothing prevented the steel ball from entering any farther than Kostov's subcutaneous tissue. After he learned of his comrade's death, he went in for an examination and the pellet was found before any of the toxin was absorbed. Forty years later a similar presumed Russian attack using the chemical agent novichok occurred just outside of London.

Aum Shinrikyo was a religious cult based primarily in Japan. During the morning of March 12, 1995 they unleashed the chemical agent sarin in the Tokyo subway. The five simultaneous attacks resulted in 5,000 injuries and 12 deaths in a very poorly executed attack consisting of punching holes into plastic bags containing liquid sarin with an umbrella. Less well-known were eight unsuccessful anthrax attacks the group tried. They had purchased a 48,000-acre farm in Australia to test biological agents on livestock. They went to Africa for Ebola samples, had two biologic research centres, and had $300 million, $80 million of which was earmarked for biological weapons. Fortunately they lacked the expertise to successfully carry out an attack.

The 2001 letters laden with weaponized anthrax resulted in 22 cases, including five deaths. Initially, the letters were sent to NBC News, the New York Post, and AMI, a newspaper publishing firm. Three weeks later two more letters were sent to Senators Tom Daschle and Patrick Leahy, each bearing the handwritten return address of a non-existent 'Greendale School' in Franklin Park, New Jersey. Dr Steven Hatfill was the FBI's first 'person of interest', but eventually USAMRID researcher Bruce Ivins became the focus of the FBI investigation until his suicide just days before his arrest. The anthrax letters had many consequences: the largest investigation in law enforcement history, very high cost, numerous reports, commissions, meetings, books, articles, a building frenzy of BSL-4 labs, many dead ends, and many new federal programmes.

What's the possible role of ISIS and other current terrorist actors in bioterrorism? In 2014 an ISIS laptop was recovered containing a 19-page document on how to develop biological weapons, and in 2017 Kenyan authorities disrupted an anthrax plot by a medical student and associates affiliated with ISIS. In 2018 South Korea raised concerns that North Korea possessed biological weapons and could use drones to carry out attacks. A North Korean defector also showed evidence of anthrax exposure by antibody studies.

Although the nature of the 'next 9/11' was factored well into preparedness, worry over the unpredictable domestic lone wolf seems to dominate. With minimal resources the harm they inflict may be limited, but the inspiration from groups such as ISIS and the Taliban will continue to be problematic. Using airplanes as weapons was unpredictable as was using cars and trucks to run over pedestrians. Would drones or something else be next?

Connecting the agent, the perpetrator, the victim, and the target

For a successful bioattack you need an effective terrorist group or perpetrator(s) and a target population—which may not be the victim. The selected biological agent has to be available in large enough quantities, weaponized, with an effective dissemination method. The target should be 'soft' or vulnerable.

A biological attack will have three main phases (Fig. 8.18.2). First, there's the pre-exposure planning phase where drug prophylaxis, immunization, and training are done. Second is the incubation phase, which may range from a few hours for toxins, or days to several weeks for bacteria or viruses. This is the period between acquisition of infection and manifestation of disease. Finally, there is the period of overt disease where diagnosis, treatment, and multidisciplinary communication become increasingly important. The 'window period' between the onset of illness in the first few cases and confirmation of the agent is very important. Vital decisions will have to be made during this brief period of time (hours to a few days) with limited data on hand. The longer-term implications of these decisions are going to be

important regarding resource allocation and public statements. Afterwards there is the post-recovery or resilience phase.

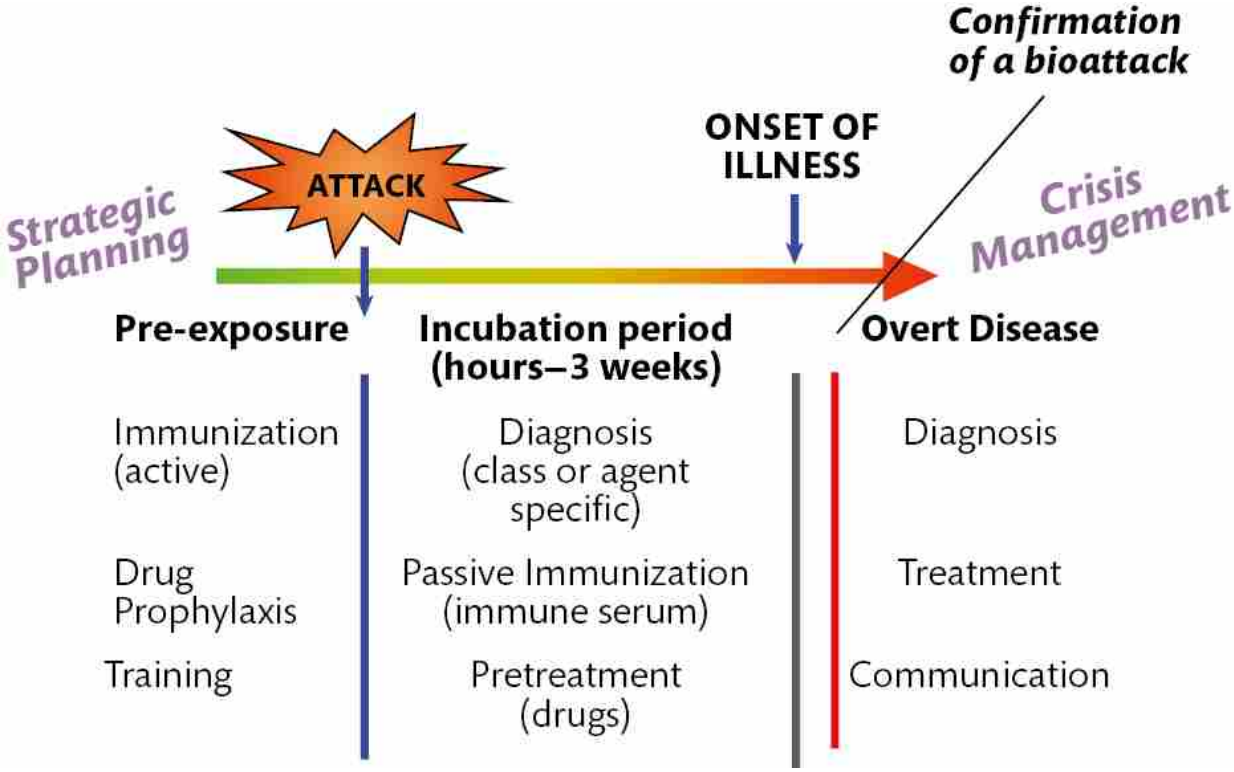

Fig. 8.18.2 Sequence of events.

Preparedness, disease management, and resilience

A few basic questions: How prepared are we for a biological attack? How prepared do we need to be? In a perfect world, how prepared can we be? What type and distribution of training should be made available to optimize preparedness and response? Irwin Redlener, Director of the Earth Institute at Columbia University, said that preparedness is the right place on the continuum between mindless complacency and all-consuming paranoia. In normal times we look for medical affordability, quality, and accessibility (Redlener 2006). We plan for dual use and maintain stockpiles or caches. Disasters, especially biologic ones, require a different approach, including functional resilience, the ability to surge, having access to stockpiles,

avoiding panic, and understanding that, with limited resources, we're dealing with a new type of mass casualty ethics.

At all levels there are four components of disaster preparedness and response that come into play with a biodisaster. They are public health, delivery of healthcare, public safety, and emergency management.

Public health deals with the distribution of countermeasures, leading the epidemiologic investigation in conjunction with the criminal investigation, public relations messaging to the public, and setting up quarantine, isolation and 'cordon sanitaire' procedures. CDC, with broad resources and jurisdiction, does, on a national level, what health departments do on local and state levels. Public health will have the best biological expertise.

In the US healthcare is a complex mosaic including very large health systems, single physician practices, public and private payers, research institutions, medical device developers, software companies, and a diverse patient population. Today's hospital system is the key ingredient, and in some ways is like independent fire stations without agreements for multiple alarm fires. There is no broad incident command (ICS) structure. The hospital ICS, or HICS, is a good start for facilities, but it is internal to each facility usually without shared resources with other hospitals. Preparedness exercises are not practised enough. Electronic medical records, if used wisely, can help. There will be patient confidentiality considerations. Large hospital systems devote more resources and thus seem to be better prepared. A contagious agent might present more complex problems. Healthcare providers have the needed medical expertise.

Public safety includes law enforcement and fire. Law enforcement has many jurisdictions including local city police, county Sheriff, state Highway Patrol, federal Marshals, and FBI, all with different roles in a biodisaster. They deal with the criminal investigation as well as enforcing quarantines. The FBI will ultimately be the lead agency. Public safety provides security expertise and emergency medical services.

All disasters are local, and emergency management is the public entity that leads coordination in a unified command structure at the local level. The emergency manager leads mitigation, planning, response, and recovery efforts for natural, technological, and man-made disasters, including acts of bioterrorism. Is their access to data and the ability to quickly analyse and coordinate it the new source of authority? Emergency management provides the crisis management component. See Figure 8.13.3.

Fig. 8.18.3 Healthcare planning and recovery.

Surveillance is paramount to preparedness, and falls into several categories: general routine, syndromic, non-specific (i.e. drug sales, absenteeism, animal disease), and targeted surveillance that is intensified once we know that an outbreak has started. But surveillance methodologies are changing. There are now prediction models, social networking, Google Trends, integrated diverse human and non-human systems, as well as big data mining and complex analytics.

Global concerns and interactions

The World Health Organization (WHO) lacks adequate appropriations and was slow to recognize the 2014 Ebola as a 'Disease of International Concern'. CDC, the lead US domestic public health agency, has assets and capabilities that reach well into both domestic and international communities. A review of WHO's Blueprint list of priority diseases occurred 6–7 February 2018. Given their potential to cause a public health emergency

and the absence of efficacious medical countermeasures, there was an urgent need for accelerated research and development for agents shown in Box 8.18.2.

Box 8.18.2 WHO blueprint agents

Crimean-Congo haemorrhagic fever (CCHF)
Ebola virus disease and Marburg virus disease
Lassa fever
Middle East respiratory syndrome coronavirus (MERS-CoV)
Severe acute respiratory syndrome (SARS)
Nipah and Henipa viruses
Rift Valley fever (RVF)
Zika
Disease X

Disease X represents the knowledge that a serious international epidemic could be caused by a pathogen currently unknown to cause human disease, and so the R&D Blueprint explicitly seeks to enable crosscutting R&D preparedness that is also relevant for an unknown 'Disease X' as far as possible. Note that only Ebola from the CDC A List was mentioned, and influenza was not mentioned at all.

There have been a number of international bioweapons agreements. The Geneva Protocol of 1925 was signed by 108 nations. This was the first multilateral agreement that extended prohibition of chemical agents to biological agents. In 1972 the US became a signatory to the United Nations Convention on the Prohibition of the Development, Production and Stockpiling of Bacteriological and Toxin Weapons and or Their Destruction (usually called the Biological and Toxin Weapons Convention or BTWC) By November 2001, there were 162 signatories with 144 countries ratifying the convention. Unfortunately, without established verification procedures in place, dual use, and lack of inspections, many nations such as the North Korea, Iran, Soviet Union, and Iraq didn't abide by its terms. This preceded President Ronald Reagan's 'Trust but verify' comment. The UN Security Council has also held sessions devoted to preventing the proliferation of chemical, biological, and nuclear weapons, although not much has come out of these meetings.

The future

Will offensive technology outgrow defensive technology? Will risk change significantly over time as we feel (often falsely) complacent? From the sociological perspective there will always be enemies. And if these enemies have the capability and desire to attack with a biological weapon they will do so.

The historian Yuval Harari noted that we are uneasily poised at the conjuncture of standard history and science fiction, of sober analysis and mad prophecy, of nightmare and Utopia. With different backgrounds terrorists are prone to do different things. Osama bin Laden studied economics and used airplanes as weapons. He was in the construction business.

Should we be preparing for a conventional weaponized agent, or an exotic new threat such as mixes of spores, bacteria, toxins, and viruses; altered antigenicity agents for vaccine evasion; antibiotic resistant organisms; chimera or fusion agents? Probably not, but there is worrisome technology out there regarding altering genetics with technologies such as CRISPR. Gene drives and CRISPR technology have enormous implications for genetic manipulation. Cheap and simple CRISPR kits are now available on the Internet, allowing almost anyone to edit the genes of bacteria and viruses making them more virulent and/or transmissible. Eventually, there is the nightmarish prospect of engineered targeted diseases to targeted individuals. There's also the combination of a civilian, military, and/or cyber targeted attack in conjunction with a biological attack. Wirth this in mind, can we actually prepare for the 'unknown unknown'?

There are examples of genetic manipulation. The highly pathogenic H5N1 influenza virus kills most of the people it infects, and has artificially acquired the ability to transmit easily. This wasn't the naturally occurring strain, but one created in research laboratories in Holland and the US with the best of scientific intentions. Scientists had created a deadly strain of avian influenza virus that transmits easily in ferrets, which have a remarkably similar immune response to humans. Pressured not to publish the entire genetic blueprint, this heated up the debate about where you draw the publishing line. CDC and WHO committees disagreed about harm versus benefit of publishing this research. The argument was that while no one wants bioterrorists to get hold of such a recipe, if researchers cannot pool

their knowledge then we hamper their ability to give us the best chance of averting or surviving a flu pandemic with a such high kill rate. The results were eventually published.

Another example: Australian and American researchers inserted into a mousepox virus a gene that creates large quantities of interleukin-4. Shockingly, this totally suppressed the 'cell-mediated response'—the arm of the immune system that combats viral infections. The engineered virus also appeared unnaturally resistant to attempts to vaccinate the mice. Could superviruses created in laboratories inspire terrorists to create their own deadly diseases? Where is all this leading us? Both optimistic and pessimistic scenarios for the future are shown on Table 8.18.3.

Table 8.18.3 Optimism vs. pessimism

An optimistic scenario	A pessimistic scenario
• Defensive technology dominates • Violent extremism recedes • Weaponization becomes harder to achieve • Antibiotic resistance recedes • We don't let our guard down psychologically • US appropriations and global health pandemic preparedness spending and interest increases	• Offensive technology dominates • Violent extremism expands as social media and slick advertising keeps pushing people to extremes • Weaponization technology gets easier to access • Antibiotic resistance grows as we run out of effective antibiotics • We don't remain vigilant • Appropriations diminish for both global and domestic health pandemic preparedness and management

Walter Laquer wrote in 'No End to War' that a disproportionate number of doctors are terrorist leaders. Ayman al-Zawahiri is the leader of al Qaeda, George Habash founded the Popular Front for the Liberation of Palestine; Dr Fathi Shikaki was a founder of Palestinian Islamic Jihad, Dr Kefah Basheer Hussein was both an ISIS Minister and a rheumatologist. Seven of the eight suspects in an attempted car bombing in London and Glasgow were doctors. With so many doctors involved in terrorist leadership, could use of a biological agent be more appealing?

Finding and stopping disease outbreaks at the earliest possible moment no matter where they emerge is important to reduce illness and death, increase

national security, and maintain the economic gains made over the previous decades. Disease threats, after all, require only the smallest opening to take root and spread. In today's tightly connected world a disease can be transported from an isolated, rural village to any major city in as little as 36 hours.

How much damage can a weaponized biological agent actually do? Can it wipe out humanity or wipe out much of our infrastructure? Can it cause massive direct and indirect damage to civil society with rampant disease, civil unrest, anarchy, and a greater need to trade freedom for security? Is biological terrorism an existential risk, a catastrophic threat, a weapon of mass disruption, or a WMD? Is it a 'black swan' low-probability high-consequence event, or merely a weapon that temporarily overwhelms local and regional resources and responses, but then quickly recovers? It's hard to know since this has never happened on a large enough scale in modern history.

In today's complex world we need to minimize biological risk. There needs to be continued vigilant multisource pre-event intelligence on terrorist countries, groups, and individuals that have potential biocapabilities. Effective disease recognition surveillance systems, and use of big data and artificial intelligence are needed. Intelligence driven analytical threat mitigation, as well as good predictive modelling is essential.

We need to keep countermeasures such as vaccines, antitoxins, and antibiotics in the pipeline. Development of better rapid on the scene (point of care) diagnostics needs to be encouraged. Continued multidisciplinary exercises, training, cooperation, and communication are important. We need more effective well thought out laws and treaties with appropriations that back them up. Public–private partnerships in biomedical and interdisciplinary research and collaboration should be encouraged. In the event of an attack, public health needs to work well with clinical medicine, public safety, and disaster management. Programmes like SNS, BARDA, and BioWatch need to continue.

Expert opinions differ on the plausibility or risk of a large-scale bioattack. The US Office of the Director of National Intelligence stated in 2008 that bioterrorism is a more likely threat than nuclear terrorism. That same year, Director Mike McConnell stated that of all WMD, biological weapons were his personal greatest worry. Other defence experts and scientists insist that the possibility of any attack, especially a large-scale one, is small, given the

immense challenges to obtaining, weaponizing, and deploying biological agents. Regardless, most biosecurity experts acknowledge that the potential of an attack should not be ignored. Moreover, specific preparations will likely benefit the response to other types of public health emergencies.

Genetic epidemiology

Elizabeth H. Young and Manjinder S. Sandhu

Introduction to genetic epidemiology

What is genetic epidemiology?

Classical epidemiology asks whether, across a study population, a measured exposure is consistently associated with an observed disease or trait. Similarly, *genetic* epidemiology in its simplest paradigm asks whether a *genetic* exposure is associated with a disease or health outcome in a given population. To expand on this, genetic epidemiology can be defined as population-based research that focuses on the aetiological role of genes in the occurrence of disease, in order to provide insights into disease biology and mechanism by unpicking the causal pathway from genes to disease.

Over the last decade there has been an extraordinary pace of change in genetic epidemiology driven by rapid advances in technology. These changes have revolutionized the scope and scale of what can be done, ranging from studies of single gene variants measured in small samples through to the emergence of high-throughput genotyping, genome-wide association studies (GWAS), and next-generation whole genome sequencing technologies which produce information on millions of genetic variants in thousands of individuals. In parallel, as these genomic technologies provide new opportunities to better understand disease and develop targeted therapeutics for patients, it is becoming increasingly apparent that a knowledge of genomic medicine will be essential for public health practitioners in meeting the public's future healthcare needs.

Genetic epidemiology and public health practice

Ultimately, the goal of genetic epidemiology lies in the application of research findings to clinical care and improved health for the population. The discovery and confirmation of genetic variants associated with diseases and traits may have translational implications—such as advances in treatment and genetic risk prediction. First, the identification of genetic determinants of traits, together with a better understanding of the underlying physiology and regulation, should help inform drug development and improve therapeutic effectiveness. Secondly, in relation to risk prediction, as more disease loci are identified it may be useful to assess whether genetic testing could improve risk prediction of disease beyond traditional risk factors. Additionally, use of genetic data makes risk stratification possible at a young age, when signs and symptoms of disease are not yet present—the clinical and ethical implications of this must be carefully considered. Thus, in this twenty-first-century era of genetic epidemiology and genomic science, public health practitioners cannot overlook the impact of genetic epidemiology on our understanding of models of disease, individualized medicine, and the relationship between individuals and populations, treatment, and prevention strategies.

Heredity, genetics, and disease

DNA, RNA, and proteins: the structure and function of genes

The human genome carries the chemical information that allows the exact transmission of genetic information from one cell to its daughter cells and from one generation to the next. Our genome is made up of deoxyribonucleic acid (DNA), which consists of a long sequence of nucleotide bases of four types: adenosine (A), cytosine (C), guanine (G), and thymine (T). Strong covalent bonds bind the bases together along a single strand, and weaker hydrogen bonds pair A with T, and C with G, between the two strands in their double-helix form. The double-stranded DNA acts as a template for its own replication: separation of the two strands, and construction of a new complementary strand for each, results in two identical copies of the original.

DNA also acts as a template for its transcription and translation into proteins. The precise order (the ‘sequence’) in which nucleotide bases are arranged along the DNA strand determines the amino acid sequences of the

proteins. First, a single strand of DNA can act as a template for a complementary strand of ribonucleic acid (RNA), through the process of *transcription*. Importantly, in certain regions of DNA, which can be called genes, the transcribed RNA encodes instructions that tell the cell how to assemble amino acids to make proteins through a process known as *translation*. Thus, just as DNA directs the sequence of RNA, so RNA directs the sequence of amino acids and proteins. Only 1–2% of these RNA transcripts encode for protein; the vast majority are transcribed as non-coding RNA which has important biological functions that influence gene expression through a variety of mechanisms (Amaral and Mattick 2008; Kaikkonen et al. 2011).

At its simplest, a *gene* can be thought of as a length of DNA containing the code for the amino acid sequence of a protein. However, few genes exist as continuous coding sequences; rather, most genes contain one or more non-coding regions, called introns, that interrupt the coding regions, or exons. It was previously assumed that non-coding regions of DNA had no biological function. However, we now know that many types of non-coding DNA sequences may have active roles in the regulation of protein-coding sequences and gene modulation (The ENCODE Project Consortium 2011).

The complete human DNA sequence is the human genome, and contains around 3 billion DNA base pairs. The human genome is distributed among 46 chromosomes, composed of 23 pairs: 22 homologous pairs of autosomes, and one pair of sex chromosomes (X and Y). In each pair of autosomes, one chromosome is inherited from the mother and the other from the father. Chromosomal DNA will contain many genes, with DNA segments of varying length between them. A given gene may exist in alternative forms, differing in DNA sequence, known as *alleles*. The *genotype* of an individual refers to the combination of two alleles inherited (one inherited maternally, the other paternally) at a specific locus—for example, AA, AG, TC, GG, etc. If the alleles are the same, the genotype is homozygous; if different, heterozygous.

Generating genetic diversity

The DNA of the human genome is subject to a variety of different types of genetic variation, defined as any change in the nucleotide sequence or arrangement of DNA. Some genetic variants may have no phenotypic effect

and, therefore, no clinical consequences. Other variants will profoundly alter disease susceptibility or, in extreme instances, be incompatible with life.

Genetic variants can be inherited from a parent, or acquired during a person's lifetime (somatic). They may be caused by radiation, viruses, and mutagenic chemicals, as well as errors that occur during meiosis (cell division) or DNA replication, or induced by cellular processes within an organism. Globally, human populations show structured genetic diversity as a result of geographical dispersion, selection and drift (Campbell and Tishkoff 2008; McCarthy et al. 2008; Novembre and Ramachandran 2011). Understanding this genomic variation can provide insights into our human origins and the evolutionary processes that shape variation in phenotypic traits and disease risk.

In the context of genetic epidemiology, we are concerned with understanding how disease susceptibility may be conferred by different kinds of genetic variation. Within an individual, genetic variation can occur at three levels:

Genome variation: changes that affect the number of intact chromosomes in the cell.
Chromosome variation: changes that alter the structure of individual chromosomes.
Genetic variation: changes that alter the sequence of nucleotide bases in a length of DNA.

Genetic variants

Gene variants are alterations in DNA sequence. Different versions of a particular DNA sequence at one specific chromosomal location (locus) are called alleles. When a particular allele is rare—conventionally, with a frequency of less than 1% in the general population—it is known as a *rare variant* or *mutation*. By contrast, where an allele is found in more than 1% of the population it is called a *genetic polymorphism* (literally, 'many forms') or *common variant*. There are many different types of DNA sequence variants, that can range from a change in a single nucleotide base to a change in many thousands of base pairs (Bochud 2012).

The most studied class of variant is the *single nucleotide polymorphism* (SNP, pronounced 'snip'; also known as a point mutation), where the DNA sequence varies in a single base—for example, A is present instead of T, C is

present instead of G. SNPs are the most common type of variant; as of March 2018, there are at least 113 million known SNPs in the human genome (NCBI dbSNP Build 151). SNPs lying in protein-coding regions of the gene can alter the code for an amino acid sequence and may (or may not) in turn affect the function or availability of a protein and cause disease. Non-coding SNPs, occurring in intronic (non-coding sequence of a gene) or intergenic (sequence of DNA between genes) regions of the genome can also cause disease, by affecting gene transcription and function. In addition to SNPs, there are also other types of structural variations in the human genome such as variable number tandem repeats (VNTRs), insertions and deletions of DNA bases, and copy number variants (CNVs), which have been used successfully to identify disease genes (Bochud 2012).

Patterns of inheritance, genotypes, and phenotypes

An individual's *genotype* can be understood as the combination of alleles present at a specific position (known as a locus) occupied by a gene on a chromosome. A *phenotype* is an observable, measurable characteristic or trait (biochemical, physiological, morphological, or behavioural) of an individual, other than its genotype. A phenotype could be a quantitative characteristic (such as systolic blood pressure) or a binary disease state (presence or absence of hypertension).

Many variations at the genotype level result in little or no observable variation in phenotype. If, however, a phenotype is present in individuals with just one copy of an abnormal allele, the allele is dominant. By contrast, if the phenotype is only expressed in the presence of two abnormal alleles, the allele is said to be recessive.

Reduced penetrance and variable expressivity are additional factors that influence the phenotypic expression of a particular genetic change. The *penetrance*, or positive predictive value, of a given genotype is the percentage of people with a disease-associated genotype who develop the disease. In cases where all individuals with a particular genotype develop the disease, the gene shows 100% penetrance. In contrast to this, some phenotypes are not expressed in all genotypically predisposed individuals; here, the gene is said to show *reduced penetrance*.

The concept of penetrance is often confused with *variable expressivity*, which is the variation in the severity of expression of a phenotype. Although

some genetic disorders exhibit little variation, most have signs and symptoms that differ among affected individuals, in some instances ranging from mild symptoms through to life-threatening complications. Variable expressivity refers to the range of severity of clinical features that occur in different people who have the same genotype.

Single-gene disorders

Single-gene, or monogenic, disorders run in families and are caused by a single mutated gene. Single-gene disorders are often called ‘Mendelian’ because they display obvious and characteristic patterns of inheritance as described by the nineteenth-century scientist Gregor Mendel, in his study of how traits were passed from one generation of garden peas to the next. Mendelian disorders are usually characterized by extreme phenotypes in rare patient subgroups that are linked to causal genes with rare mutations. These disorders, while individually rare and not contributing substantially to the global burden of disease, might collectively cause significant disease and death in a population. They can also provide invaluable insights into the underlying biology of disease and help to inform the search for susceptibility genes for more common diseases and traits.

Complex multifactorial diseases

Familial aggregation

In contrast to monogenic disorders, genetic disorders may also be complex (also known as multifactorial, or polygenic or non-Mendelian), meaning they are likely to be associated with the effects of multiple genes in combination with lifestyle and environmental factors, with no clear mode of inheritance. Multifactorial disorders include many common diseases such as cancers, heart disease, and diabetes, and quantitative traits such as height, weight, blood pressure, and blood chemistries. Patterns of inheritance for complex disorders do not fit simple patterns as with Mendelian diseases. This makes it difficult to determine a person’s risk of inheriting or passing on these disorders. Complex disorders are also difficult to study and treat because the specific factors that cause most of these disorders have not yet been identified.

However, this does not mean that the genes cannot eventually be located and studied. Because relatives share a greater proportion of their genes with one another than with unrelated individuals in the population, a primary feature of diseases or traits with a genetic basis is that affected individuals tend to cluster in families. Of course, familial aggregation does not necessarily mean there must be a genetic contribution; family members may develop a disease or trait simply by chance alone, particularly if it is common in the general population, or as a result of a shared environmental exposure. Given this, a helpful measure of familial aggregation is the *recurrence risk ratio* (λ_r), which takes into account the population prevalence of a disease. λ_r estimates the ratio of the risk of developing disease when a relative already has the disease compared with the risk in the general population (i.e. background prevalence).

The correlation of a trait or disease among relatives provides another useful estimate of genetic influence, on the assumption that the degree of similarity in the values of trait (e.g. body mass index (BMI)) measured among relatives is proportional to the number of alleles they share at the loci for that trait. Based on this premise, the more closely related the individuals are in a family the more likely they are to share alleles at loci and—in this instance—the more strongly correlated will be their BMI values. Thus a tendency for BMI to be more similar among relatives than among the general population is further evidence for a genetic aetiology. Familial correlations can also be used to calculate the *heritability* (h_2) of a trait, a measure that quantifies the percentage of phenotypic variation in a trait that is attributable specifically to genotypic differences. The higher the heritability, the greater the contribution of genetic variation among people in causing the variability of a trait for a given population.

Twin studies

To help disentangle the relative contributions of genes and environment in the aetiology of disease, twin and adoption studies are used (Boomsma et al. 2002). Comparison of disease concordance rates in identical (monozygotic (MZ)) and non-identical (dizygotic (DZ)) twins helps to assess the genetic influences on a disease. MZ twins are genetically identical, sharing the same alleles at every locus. DZ twins, on the other hand, share on average half the alleles at all loci, like all siblings. MZ twins provide an opportunity to study

disease occurrence when genetic factors are held constant, by measuring concordance in relatives with identical genotypes who may or may not be reared together in the same environment. Concordance in MZ twins in early life can be the result of genes or a shared environment. However, in later life most twins live apart and concordance at that stage may suggest a genetic component to the disease. Concordance less than 100% in MZ twins is strong evidence that non-genetic factors are involved in disease aetiology.

DZ twins reared together provide an opportunity to study disease occurrence when genetic differences are present but environmental factors are shared. Greater concordance in MZ versus DZ twins is strong evidence of a genetic component to the disease. Comparison of concordance rates in MZ versus DZ twins can be used to estimate the heritability of a disease.

As with family studies, twin studies are not without their limitations. First, despite being referred to as ‘identical’, MZ twins do not have identical gene expression of their identical genotypes; for example, somatic rearrangements will differ between MZ twins, which may give rise to phenotypic discordance and differences in disease susceptibility. Secondly, environmental exposures may not be the same for twins; even the intrauterine environment may differ within a twin pair (e.g. differential placental blood supply in MZ twins). Furthermore, studies comparing MZ to DZ twins are based on the assumption that they differ only by the number of genes they share and that within each pair the exposure to environment factors is identical; yet it is likely that MZ twins share more of their environment than DZ twins (particularly compared with opposite-sex DZ twins). Ascertainment bias poses an additional limitation, where twins who are very alike will tend to participate in studies more than twins who are very discordant for a phenotype. Studies of twins reared apart are easier to conduct than adoption studies, and similarly are an effective way of investigating the influence of shared genes and different environments. However, even with MZ twins separated at birth, intrauterine environmental influences cannot be distinguished from genetic influences.

Adoption studies

Adoption studies provide another valuable source of information about the genetic component of a disease. In this study design, a disease or trait is identified in adoptees and then studied in both their adoptive family (shared environmental factors only) and biological family (shared genetic factors

only). While undoubtedly providing the best way of separating out genetic and environmental influences, adoption studies carry obvious difficulties: information may be lacking about the biological family, compounded by their wish not to be identified and approached for details. In addition, relatively small sample sizes for which both adoptive and biological parents are available have limited the use of these studies.

The results of family studies must be interpreted with care. Importantly, familial aggregation of a continuous trait or discrete disease—however measured—does not indicate that genes are wholly responsible. Families share many factors besides their genes, such as common environmental exposures, cultural attitudes, and behaviours. This means that family studies are likely to overestimate the genetic component of a disease, and the strong environmental component to many complex, multifactorial diseases must not be overlooked.

Role of the environment and gene–environment interactions

Nearly all human diseases originate in large part from a complex interplay between genetic susceptibility factors and modifiable environmental exposures (including chemical, physical, infectious, nutritional, and behavioural factors). Therefore, in understanding the aetiology of disease and assessing the role of susceptibility alleles in disease risk, it is important to examine genetic factors *and* environmental factors and—importantly—the relation between the two: so-called gene–environment interactions.

Studies of gene–environment interactions present a number of methodological challenges (Hunter 2005). The assessment of the relation between genes and environment requires information on both components. Gene–environment interaction may be measured by the different effects of an environmental exposure on disease risk among individuals with different genotypes, or by the different effects of a genotype on disease risk among individuals with different environmental exposures (Yang and Khoury 1997). However, the power of studies to detect statistically relevant interactions is highly dependent on the precision with which genetic and non-genetic exposures are measured. As discussed elsewhere in this chapter, with the advent of next-generation genotyping and sequencing technologies, it is now possible and affordable to generate massive genomic datasets. By contrast, a challenge still remains to achieve accurate and objective measures

of environmental exposures such as dietary intake or physical activity that are feasible to collect in a large-scale epidemiological context.

In addition, the need for suitably large sample sizes is a major obstacle to overcome in the design of interaction studies (Hunter 2005). The sample size required to detect the joint effect of two variables is much larger than the size required to evaluate the main effect of each variable; given that many epidemiological studies are underpowered to detect main effects, these studies will be substantially underpowered to detect interactions. Careful consideration of study design, and the accurate and detailed assessment of genetic factors, environmental exposures, and disease phenotypes, is therefore crucial for planning interaction studies that will yield meaningful results.

Determining the details of gene–environment interactions will help us to understand the aetiology of disease and might lead to opportunities for targeted prevention strategies for some high-risk individuals (Hunter 2005; Khoury et al. 2005). Indeed, there may be significant public health benefits in using genetic information to improve existing approaches to identify and modify environmental risk factors, including stratifying the allocation of environmental interventions that prevent disease (Khoury et al. 2005). It may be, for example, that individuals with a certain genotype are particularly susceptible to the negative consequences of specific lifestyle behaviours, and that they would have most to gain from a targeted preventive intervention programme. Understanding how to detect these individuals and which environmental factors a programme should attempt to manipulate is a major goal of studies that attempt to unravel gene–environment interactions.

Finding disease genes: methods in genetic epidemiology

From monogenic to multifactorial disease

A number of strategies have been used to try and uncover genes involved in the aetiology of common, multifactorial disease (Table 8.19.1). Non-Mendelian disorders may depend on the interplay of common variants—polymorphisms—in several susceptibility genes together with a variable contribution from the environment. These genetic variants are presumed to have only modest effects accounting for a small percentage of variation in a trait, at least when examined individually; however, they may play a more

important role through interaction with other gene variants and be responsible for significant population attributable risk for disease.

Table 8.19.1 Common strategies for finding disease genes

Study design	Participants	Strengths	Limitations
Linkage studies	Relatives: large pedigrees, affected sib-pairs, or discordant sib-pairs	Can study multiple genetic markers simultaneously Good for rare traits	Only defines a locus or region, not specific genes
Family-based association studies	Parent–child trios, siblings	Less prone to population stratification Provides a rich context for evaluating shared genetic and environmental influences	Difficult to separate genetic from environmental influences Challenging for outcomes of older age: finding families with more than one affected generation will be difficult Findings may not be applicable to general population
Candidate gene association studies	Unrelated individuals	Powerful study design for common traits	Led by the state of current knowledge: success depends on selecting the right candidate gene
Genome-wide association studies	Unrelated individuals	Genotyping platforms developed to simultaneously examine hundreds of thousands of genetic variants	Lots of false positives; association does not equate to causation Replication of initial results is a challenge
Sequencing studies	Unrelated individuals	Good for identifying rare variants	Limited by costs and existing technological capabilities

Linkage studies, fine mapping through mutation screening, and case–control and cohort-based association studies of patients—combined with data from animal models—have uncovered the genes causing many Mendelian, or monogenic, disorders. In turn, a knowledge of the genetic basis of these Mendelian disorders has helped further our understanding of human physiology and played a vital part in establishing the causal role for disease risk factors and in the development of drug targets. In recent years

there has been considerable progress in mapping—that is, identifying and localizing—loci that influence susceptibility to common human diseases.

Genetic linkage scans

Linkage analysis is often the first stage in the genetic investigation of a trait, since it can be used to identify broad chromosomal regions of the genome (as opposed to specific alleles) that might contain a disease gene (Teare and Barrett 2005; Altshuler et al. 2008). Genetic linkage is the tendency of genes that are located close to each other on a chromosome to be transmitted together to offspring. Genes that are positioned nearer to each other are less likely to be separated onto different parts of the chromosome during *genetic recombination* (the breakage and rejoining of DNA strands to produce new combinations of alleles, encoding a novel set of genetic information) and are therefore said to be genetically linked. On this basis, susceptibility or causal genes can be localized by searching for genetic markers that co-segregate with the disease trait; if an allele of gene A causes disease, but is otherwise undetectable, whereas the allele of gene B can be easily detected and distinguished, gene B can be used as a marker of the inherited disease. Linkage studies use DNA from family members to identify areas of the genome that show evidence of containing the unknown disease-related genetic variant on the basis of correlation with DNA variation. Polymorphic markers positioned across the genome are genotyped in families, followed by calculating the degree of linkage of the marker to a disease trait. An advantage of linkage analysis is that this approach attempts to map genes purely by position and does not presume any a priori hypotheses about their location, biological function, or number.

Linkage analyses have proved highly successful for finding genes causing Mendelian disorders. However, linkage studies only work well if the phenotype of interest is caused by variation in the same gene region, and have generally been unsuccessful at identifying genes for common disorders where multiple genes are implicated (Hirschhorn and Gajdos 2011). Linkage analyses can only identify large regions and, while a very strong candidate gene might exist within the linkage region, such regions may contain hundreds of genes, many of which are biologically plausible candidates. To refine any association may require extensive genotyping—both time-

consuming and expensive—and potentially produce many false positive results.

Association studies

Genetic association studies provide an alternative approach to finding disease genes, which overcome some of the limitations of linkage studies. Genetic association studies aim to detect an association between an allele and trait (unlike linkage studies, which focus on a genetic locus as the unit of analysis regardless of the alleles present at that locus). Association differs from linkage in that the same allele (or alleles) is associated with the trait in a similar manner across the whole population, while linkage allows different alleles to be associated with the trait in different families. Whereas linkage studies can only be conducted using family data, association analyses can be done using unrelated and/or related people. Association studies can be conducted at the level of a candidate gene (candidate gene association study), or at the level of the entire genome (GWAS).

Candidate gene association studies

The candidate gene approach has many parallels with identifying and ranking risk factors in an epidemiological study (Tabor et al. 2002): from a large number of potential factors, researchers must pick those factors that are most likely to be associated with the outcome of interest. The selection of candidate genes focuses the search onto specific susceptibility genes that are identified a priori on the basis of their presumed biological relevance to the disease or trait of interest. Once a candidate has been selected, common variants—usually SNPs—in the gene are then identified (either *de novo* from sequencing/mutation screening, or based on previously published work). The SNPs are then genotyped and tested for association with the outcome of interest. In the case of a binary outcome, SNPs will be genotyped in cases and controls to assess whether the variants are associated with the phenotype of interest; where the outcome of interest is a quantitative trait, SNPs are typed in population cohorts. A strength of this gene-centric method is that it is a highly efficient way of identifying susceptibility genes if biological plausibility is high. Conversely, a drawback of the method is that it is, by definition, limited by the state of current knowledge. Thus countless genes may be overlooked because biological candidacy has not yet been

established. Issues of multiple testing and false positives remain limitations of the candidate gene approach.

Genome-wide association studies

GWAS have recently emerged as a powerful new tool for identifying the genetic variants related to common, complex diseases by effectively combining the association and linkage approaches to gene identification (McCarthy et al. 2008; Hirschhorn and Gajdos 2011). The basic paradigm of GWAS is to catalogue thousands of very common SNP markers located throughout the human genome, and then to genotype them in large numbers of unrelated humans who have already been carefully characterized for a wide variety of common diseases and traits. The GWAS approach affords the possibility of exploring the whole genome without any a priori knowledge of underlying disease biology. This allows for hypothesis-free testing of a substantial fraction of common genetic variation for a role in determining disease risk, and potentially enables the discovery of unexpected genetic factors or pathways for common diseases.

A central factor in the development of GWAS is having a comprehensive map of carefully selected SNPs (Box 8.19.1). Over the last two decades, a number of international efforts have successfully done this, creating denser and denser genetic maps. As these have emerged, it has become apparent that many SNPs are strongly correlated (Palmer and Cardon 2005). Consequently, if the pattern of allelic association can be described, direct assay of all existing polymorphisms is unnecessary, because genotypes of common SNPs may be inferred from knowledge of only a few representative SNPs. This is the principle underlying the tagging-SNP method: that it is possible to select the maximally informative set of polymorphisms (tagSNPs) to genotype in an association study such that all known SNPs are either directly genotyped or exceed a threshold level of association with a tagSNP. Given the practical limitations on genotyping, selection of tagging SNPs can usefully decrease the amount of genotyping required and thus improve the cost-effectiveness of studies. Inevitably, there is a trade-off between this improved efficiency and the loss of power that occurs when SNPs are discarded. However, by specifying various parameters (e.g. the level of allelic correlation, and the likelihood of genetic linkage) it is possible to try and maximize efficiency while maintaining statistical power.

Box 8.19.1 International scientific efforts to describe common human genetic diversity

The Human Genome Project, the SNP Consortium, the International HapMap Project, and the 1000 Genomes Project have collectively identified around 10 million common genetic variants in humans. Knowledge of these SNPs and their patterns of correlation have enabled GWAS which have successfully identified hundreds of novel disease genes (Donnelly 2008; International HapMap 3 Consortium 2010).

Completed in 2003, the Human Genome Project was an international collaborative research programme whose goal was to discover all the estimated 20,000–25,000 human genes and map the complete sequence of the 3 billion DNA bases (International Human Genome Mapping Consortium 2001; International Human Genome Sequencing Consortium 2001; International SNP Map Working Group 2001; Roberts et al. 2001; Collins et al. 2003). The official Human Genome Project was meant to have been a 15-year project spanning 1990–2005, but progress was faster than expected. Conducted on an industrial scale at a few large genome centres across the world, genetic maps were developed ahead of the original schedule, and the final stage of large-scale DNA sequencing was facilitated by developments in automated high-throughput sequencing techniques. The need to manage and store the huge amounts of sequencing data that were being produced led to the development of large electronic databases. Importantly, a key aim of this endeavour was to make these genomic data publicly available and accessible to the scientific community at large.

The SNP Consortium was established in 1999 as public–private partnership of several companies and institutions to produce a public resource of SNPs in the human genome (Kruglyak 2008). The initial goal was to discover 300,000 SNPs in 2 years, but the final results exceeded this, as 1.4 million SNPs had been released into the public domain at the end of 2001.

The SNP Consortium subsequently joined forces with the International HapMap Project. Launched in 2002, the HapMap Project is a global consortium of scientists and researchers with the aim of providing a public resource to inform and accelerate genetic medical research. Specifically, the project set out to describe the common patterns of human DNA sequence variation across the human genome in order to find genes affecting health, disease, and responses to drugs and environmental factors. Whereas the SNP Consortium was concerned with individual SNPs, the HapMap Project focused on examining combinations of SNPs that are inherited together, known as haplotypes. By 2007, the project had genotyped more than 3 million SNPs which captured the majority of all common variants with frequencies above 5% (International HapMap Consortium 2007). In its current phase, ‘HapMap 3’, the project is expanding its scope to identify rarer genetic variants that may be implicated in human disease and achieve a higher resolution map of human genetic variation (International HapMap 3 Consortium 2010).

The 1000 Genomes Project (1000 G) was launched in 2008 as an extension of the HapMap Project. Its aim is to create a public reference database containing an even more detailed characterization of the human genome by extending the catalogue of human genetic variants to include 95% of rarer variants, occurring at frequency of 1–5% (The 1000 Genomes Project Consortium 2010). As of November 2012, using a combination of whole genome sequencing and exome sequencing, the architecture and functional spectrum of human genetic variation has now been characterized in the genomes of 1,092 individuals from 14 populations (The 1000 Genomes Project Consortium 2012).

In 2007, the Wellcome Trust Case Control Consortium (WTCCC) set the benchmark for GWAS of common disease on an unparalleled scope and scale. Representing a UK-wide collaboration of more than 50 research groups and 200 scientists in the field of human genetics, the WTCCC genotyped over 500,000 SNPs in DNA samples from 17,000 people across the United Kingdom. Over 2 years, they analysed almost 10 billion pieces of genetic information, and substantially increased the number of genes known to play a role in the development of some of our most common diseases such as heart disease, hypertension, Crohn's disease, and diabetes. Many of these genes that have been found are in areas of the genome not previously thought to have been related to the diseases (Wellcome Trust Case Control Consortium 2007). More recently, advances from commercial companies such as Affymetrix and Illumina in the availability of dense genotyping chips with approximately 5 million SNPs are making even larger GWAS both cost-effective and feasible, and there has been considerable progress in the search for disease-related loci and genetic variants using the GWAS approach.

Searching for rare variants

GWAS have now been completed for many common human diseases and related traits, identifying a wealth of common gene variants. However, GWAS have a number of limitations: first, their scope is defined by the current knowledge of existing genetic variants that are included on a specific genotype chip. Second, most of the disease-associated SNPs found in GWAS have very small effect sizes, and explain only a modest fraction of the genetic component of human disease. This is to be expected if much of the missing heritability is due to gene variants that are less common or too rare to be detected by GWAS and have relatively modest effect sizes (Cirulli and Goldstein 2010). On this basis, gene discovery efforts have in recent years expanded to search for rare genetic variants.

To capture such rare variants, it will be necessary to use large samples sizes (thousands of individuals) and sequence entire genomes, rather than genotype a catalogue of variants. Until recently, this was technically unfeasible. However, the technological advances of the last couple of years (so-called next-generation sequencing technology) have made this possible (Metzker 2010; Zhang et al. 2011): now, billions of DNA bases can be

sequenced in a matter of days. The most complete study of rare disease variants will require *whole genome sequencing* in large sample sizes of human participants. Recent initiatives such as the 100,000 Genomes Project in the UK, which aims to sequence 100,000 genomes from around 70,000 individuals, show that with the rapid pace of technological development and the precipitant fall in the costs, such a shift to whole genome sequencing association studies on a massive scale is becoming more feasible.

In the meantime, *targeted sequencing* and *exome sequencing* offer more affordable strategies for finding rare genetic variants. Targeted sequencing is focused on genomic regions of specific interest—rather than the whole genome—and enables a systematic assessment of the full spectrum of genetic variation, including common and rare variants, for high-throughput sequencing at a lower cost per sample. Similarly, selectively sequencing only the exome constitutes a powerful and efficient alternative to whole genome sequencing (Bamshad et al. 2011). Approximately 85% of all disease-causing variants in humans can typically be found in the subset of the human genome that is protein coding—known as the exome. With the availability of next-generation sequencing technology, exome sequencing has become a cost-effective method for the identification of rare sequence variants (Choi et al. 2009; Ng et al. 2009; Pussegoda 2010). This strategy (also known as targeted exome capture) has been used successfully to identify disease-causing variants for a number of rare Mendelian disorders (Choi et al. 2009; Ng et al. 2010; Bamshad et al. 2011) and is an effective technique to detect causal variants associated with disease even when few individuals with disease are sequenced (Cirulli and Goldstein 2010). Although this method has been predominantly used in the study of Mendelian disorders, these studies provide the framework for applying this method to complex diseases (Cirulli and Goldstein 2010); for example, recent whole exome sequencing studies have identified genetic variants associated with low-density lipoprotein (LDL) cholesterol and risk of myocardial infarction and coronary heart disease (Bomba et al. 2017).

Generating genomic data: analytical issues

At present GWAS typically generate information on several million genetic variants, on many thousands of individuals. Many computational and analytical steps are required to translate massive raw genomic data into

usable, high-quality data, and may include techniques for genotype imputation. Imputation is the term used to describe the substitution of some value for missing data. In relation to GWAS data, genotype imputation is the process of predicting or imputing genotypes that are not directly assayed in a study sample of individuals, based on reference panels of SNPs (Li et al. 2009). These *in silico* genotypes can then be used to increase the total number of SNPs that can be analysed for association, thus improving the statistical power of the study. Handling such vast datasets, and identifying the few true association signals among the masses of false positive signals, requires extensive computing and storage infrastructure, and advances in computational resources and statistical techniques for processing, analysis, and interpretation (Hunter and Kraft 2007). In this context, cloud computing —with its advantages such as virtualized resources, parallel processing, and data service integration with scalable data storage—has become a powerful tool to perform massive-scale and complex computing with big data (Hashem et al. 2015; Langmead and Nellore 2018).

A key determinant of the quality in any association study—genetic or non-genetic—is its sample size (Ioannidis et al. 2003). This is particularly pertinent in genetic studies, which must be powered to detect variants that have only modest associations with the outcome of interest. Small initial studies rarely find the correct result and, even when they do, are likely to overestimate the true effect size (Ioannidis et al. 2003; Lohmueller et al. 2003; Wacholder et al. 2004). An implication of looking at modest effect sizes of genetic variants is the need for sufficiently large sample sizes to avoid underpowered studies with false negative results (Lohmueller et al. 2003; Ioannidis et al. 2006). In addition to ensuring adequate samples sizes, care must be taken to ensure optimal ascertainment of cases and controls, to improve study power—for example, by selecting cases with minimal phenotypic heterogeneity, or focusing on extreme phenotypes such as early-onset severe disease in order to enrich for disease-causing alleles (Hattersley and McCarthy 2005).

Multiple testing is also an issue for these large datasets: when testing so many SNP–disease associations simultaneously, the probability of a nominally significant result from within the entire experiment occurring by chance is higher than the individual *p*-value associated with that result, because of random variation in the data and the large number of tests that are performed (Thomas and Clayton 2004). In other words, there is an increased

chance of false positives, and one cannot be certain at the outset whether there are any true associations to be found at all. Consequently, the individual *p*-values of the tests may not be an appropriate guide to actual statistical significance.

There are several statistical techniques which may be used to correct for multiple testing, including a reduction in the number of tests, or the setting of a more stringent *p*-value, or permutation testing (Hirschhorn and Daly 2005). When adjusting for multiple testing, larger samples will be required so that if an initial association is statistically significant, it will remain significant after correction (Benjamini and Hochberg 1995; Hirschhorn and Daly 2005). Where GWAS findings indicate an association between a genetic variant and a trait or disease, validation and replication studies are essential to determine whether the result of the initial study represents a true reproducible association with genome-wide statistical significance (McCarthy et al. 2008; Ioannidis et al. 2009).

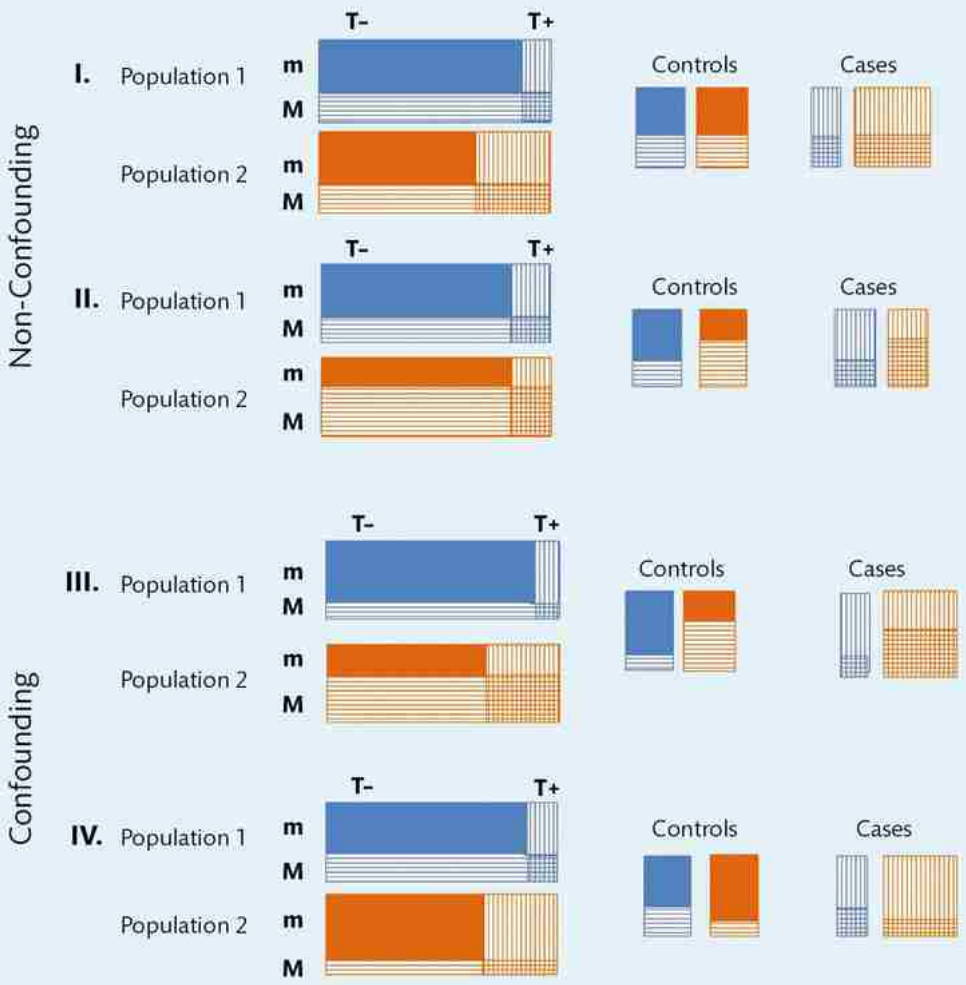
Causal inference

In observational epidemiological studies, causal inferences are potentially susceptible to problems of bias and confounding that, in addition to chance, provide alternative explanations for an observed association between an exposure and a disease. Likewise, the assessment of causality in gene–disease associations is vulnerable to possible other explanations (Geneletti et al. 2011). The role of *bias* must be considered in any observed gene–disease association. In contrast to studies of non-genetic exposures, which are potentially prone to recall bias, an individual's genotype is an exposure that is fixed at conception—thus the association between genetic variants and disease outcomes will not usually be biased in this way. However, a key potential bias in genetic association studies is the differential genotyping of cases and controls. Wherever possible this can be minimized by randomly allocating cases and controls in the genotyping process, so that systematic genotyping errors affecting solely cases or controls are unlikely to occur. Selection bias due to non-comparable cases and controls may also explain the observed associations. Bias, though, need not necessarily be a problem: it can also be used positively to enhance a study. For instance, one might deliberately select cases enriched for genetic variants (e.g. based on their

family history of a disease or trait), in order to improve the power of a study to detect a statistically significant association.

In the context of genetic association studies, classical *confounding* variables such as age and sex are not usually relevant. This is because in order to confound the association between genotype and phenotype, these characteristics would need to be associated with both the genotype and the specific outcome. In the case of genetic association studies this is not applicable, based on the assumption of random assortment—that is, during gamete formation alleles are allocated arbitrarily from parent to offspring independently of other traits. This results in population distributions of genetic variants that are generally independent of behavioural and environmental factors that typically confound epidemiological associations between risk factors and disease.

Nevertheless, we cannot ignore confounding as a result of *undetected population stratification* due to ethnic admixture, which can mimic the signal of association and give rise to false positives and produce associations of disease with genotype at loci that are not linked to any locus that affects disease susceptibility (Hoggart et al. 2003; Freedman et al. 2004; Marchini et al. 2004). Ethnic admixture refers to the presence of multiple subgroups within a larger population, caused by non-random mating, which have differing allele frequencies. This can have implications for studies of gene–disease association if the subgroups have different genotypic distributions (Fig. 8.19.1). If cases and controls are drawn differentially from two or more subpopulations in which marker allele frequencies *and* disease prevalence differ across subpopulations, this will result in an over-representation of one or more genetic subgroups among individuals chosen as disease cases in an association study. In this instance, any SNP with allele proportions that differ between the subgroup and the general population will be associated with disease status. Although the association is real from a statistical point of view, it is regarded as spurious since it does not yield any information about the biology of the phenotype or about the genomic location of the disease-modifying locus; rather, the association between the allele and the disease is confounded by the existence of genetic heterogeneous subpopulations (Wacholder et al. 2000; Ziv and Burchard 2003).



Rectangles on the left of each panel represent two subpopulations from which cases and controls are selected. The rectangles on the right represent the sample of cases and controls, sampled without regard to membership in genetic subpopulations. The horizontal lines represent the proportion of the population with the candidate allele, **M**. The vertical lines represent the proportion of the population with the trait of interest, **T+**. In each population on the left, there is no association between M and T+

I. The frequency of the trait is higher in population 2, but because the M allele frequency is the same in both populations, the frequency of M is the same in both cases and controls. Therefore, while cases are over-represented by population 2, there will be no spurious association as the trait is equally likely to be associated with the M allele in both populations.

II. The prevalence of the trait is the same in both populations, but the frequency of M is greater in population 2. Because the frequency of M is the same for both controls and cases (a control and a case are equally likely to have allele M), there is no spurious association.

III. Both the prevalence of the trait and the frequency of M is higher in population 2. This will result in a positive confounding association because as a larger number of cases will be sampled from population 2, cases will have a disproportionately high frequency of M compared with controls, resulting in a false-positive association between allele M and trait T+

IV. The trait prevalence is higher and the allele frequency of M is lower in population 2 compared with population 1. This will result in a negative confounding association because as a larger number of cases will be sampled from population 2, cases will have a disproportionately low frequency of M, resulting in a false-negative association between allele M and trait T+

Fig. 8.19.1 Spurious associations as result of population stratification.
Reproduced from Ziv E, and Burchard EG. (2003) Human population structure and genetic association studies, Pharmacogenomics, Volume 4, pp. 431–41, with permission from Future Medicine.

There are a number of different ways of addressing population stratification, such as matching cases and controls according to ethnicity and geographical origin. This matching can be difficult to achieve, and several different control populations might have to be used in any given study. To address this problem, a variety of statistical methods that infer genetic ancestry may be used to control for confounding by population stratification (Cordell and Clayton 2005; Balding 2006; Price et al. 2010). A commonly used statistical method for controlling population stratification is *genomic control*, in which the test statistic is corrected using an inflation factor (lambda, λ). To do this, associations between marker loci across the genome and traits or diseases are used to assess population structure and determine an average effect of population structure across the whole genome. The residual effects of stratification for all investigated markers are then adjusted by a uniform λ. Thus the further λ deviates from the value 1, the greater the correction, and the more evidence for presence of population stratification or other biases; conversely, the closer λ is to 1, the more unlikely it is that stratification is present.

An alternative method is to use *principal components analysis* (PCA) to correct for stratification, which can be carried out using software such as EIGENSTRAT. PCA explicitly models ancestry differences between cases and controls. The resulting genomic correction factor, λ, is specific to a candidate marker's variation in frequency across ancestral populations, minimizing spurious associations while maintaining power to detect true associations. Other approaches include family-based tests such as the transmission disequilibrium test, and mixed models—the latter having the additional advantage of simultaneously addressing population stratification along with other systematic differences, such as family structure or relatedness, that may be present in the data (Price et al. 2010).

Even after many convincing replications of a SNP–disease association, causality may not be inferred; the causal variant may still need to be identified. In this instance, the parallels with classic epidemiology are clear: an association between a SNP and trait might exist if: (1) the SNP with the observed association has a causal role; (2) the SNP has no causal role but is highly correlated (associated) with the true causal variant. It is also possible

that the currently identified SNPs might not fully describe genetic diversity, as a result of *incomplete capture of genetic variation*. One therefore cannot exclude the possibility that the unidentified and untyped variants might have shown statistically significant associations with disease and might include among them the true causal variant. Ultimately, to refine the association signal at a locus of interest requires knowledge of the SNP correlations in that region which, in turn, depends on the genetic variation in the region being fully characterized (Ioannidis et al. 2009).

The need for functional validation

For conclusive evidence of causality, the epidemiological approaches just described need to be complemented by efforts to establish which regions of the human genome sequence truly have a biological function and thus may be relevant to disease mechanism and human health. The recent discoveries from genome-wide studies represent a significant advance in our unravelling of the genetic basis of common human disease (Kruglyak 2008). Despite the large number of loci and the robustness of their associations with diseases or disease traits, these loci tend to have small individual effects on phenotype, and even collectively tend to explain only a small fraction of the heritable component. Moreover, it is not yet clear what most of the causal variants or even the causal genes are at these loci. Thus, whether the GWAS approach can yield biologically relevant insights into human physiology remains to be established.

A next step is to identify and validate functional variants through studies of gene expression, in order to elucidate the biological role of proteins or other gene products encoded by specific genomic regions and to understand the clinical and phenotypic consequences of genome sequence variation; an example of this is the ENCODE project (Box 8.19.2).

Problematically, some genes may only be expressed locally—for example, in specific brain nuclei—and so attaining samples for physiological studies may prove unfeasible. *In vitro* studies of gene activity, as well as *in vivo* overexpression and knockout studies in experimental animal models, will continue to play an important role in elucidating the specific molecular pathways that are relevant to human physiology and validating GWAS results. Promisingly, recent developments in cellular and functional genomics, including CRISPR-Cas9 gene-editing technology, are increasingly

being used to help clarify molecular and biological mechanisms at GWAS loci for disease traits (Klann et al. 2018; Roman and Mohlke 2018). If functional studies can confirm a causal role for genetic variants, these results may help identify potential new drug targets.

Using genetic epidemiology to identify new environmental exposures

A key challenge of classical epidemiology is establishing whether an association between an exposure and a disease outcome is causal or not. Given the observational nature of epidemiological research, an association may also be completely explained by confounding. In this scenario, the relationship is explained by a third factor that is associated with both the exposure and disease risk; the exposure is not independently or causally linked to disease risk. Epidemiological approaches generally use multivariable statistical analysis to reduce confounding. However, because of residual confounding (as a result of measurement error) and unknown confounders, standard observational epidemiology cannot resolve whether an observed association has a causal basis. The conceptual ambiguity of any disease mechanism (specifically, defining mediators and confounders) also limits statistical modelling to reduce confounding. Furthermore, the observed association may be due to reverse association/causation—that is, the relationship between biomarker and disease could be the result of undiagnosed or early disease rather than the risk factor, and thus a consequence of disease rather than a cause.

Box 8.19.2 The ENCODE project: identifying functional properties of the human genome sequence

ENCODE, the Encyclopedia of DNA Elements, is an international collective effort to interpret the human genome sequence and make this information available for medical and scientific communities to apply it to understand disease biology and improve human health (The ENCODE Project Consortium 2011). The project aims to define and annotate the functional elements encoded in the human genome sequence, such as those regions that regulate transcription from DNA into RNA, or regulate the expression of genes. In its initial pilot phase in 2003–2007, the ENCODE investigators set out to annotate functional elements in a defined 1% of the human genome. In 2007, the ENCODE project was expanded to study the entire human genome, to locate and describe discrete regions of the genome with a specific biological function. All data and derived results are readily available

through a freely accessible public database. In September 2012, the project released an extensive set of results, in 30 papers published simultaneously in several journals, including *Nature*, *Genome Biology*, and *Genome Research*. As part of ENCODE's expansion, a subproject named GENCODE was launched, run by an international team led by the Wellcome Trust Sanger Institute, specifically to annotate the genes within the human genome with even higher accuracy (Harrow et al. 2012).

Establishing the causal inference of environmental risk factors can be strengthened by the *Mendelian randomization* approach, in which the biology underpinning genetic epidemiology can be exploited to make causal inferences and establish aetiological associations (Davey Smith and Ebrahim 2003; Lawlor et al. 2008; Sandhu et al. 2008, 2010). The assignment of alleles from parents to offspring that occurs during gamete formation and conception tends to be random, and not correlated either with environmental exposures or with alleles at other loci. This means that the inheritance of one trait is independent of (that is, randomized with respect to) the inheritance of other traits, and characteristics that may confound any association between an exposure and disease are equally distributed among the relevant genetic variants. Thus the association between a disease and a genetic variant is generally much less susceptible to reverse causation or confounding by classical or environmental risk factors.

Given this, a comparison of groups of individuals defined by a genetic variant, based on a Mendelian randomization design, is equivalent to a randomized comparison, with only the relevant exposure differing across the relevant genetic variant. Examining the relationship between variants in the genome that show unequivocal associations with the relevant exposure and disease risk is therefore a potential method of assessing whether an exposure might be causally linked to disease (Fig. 8.19.2).

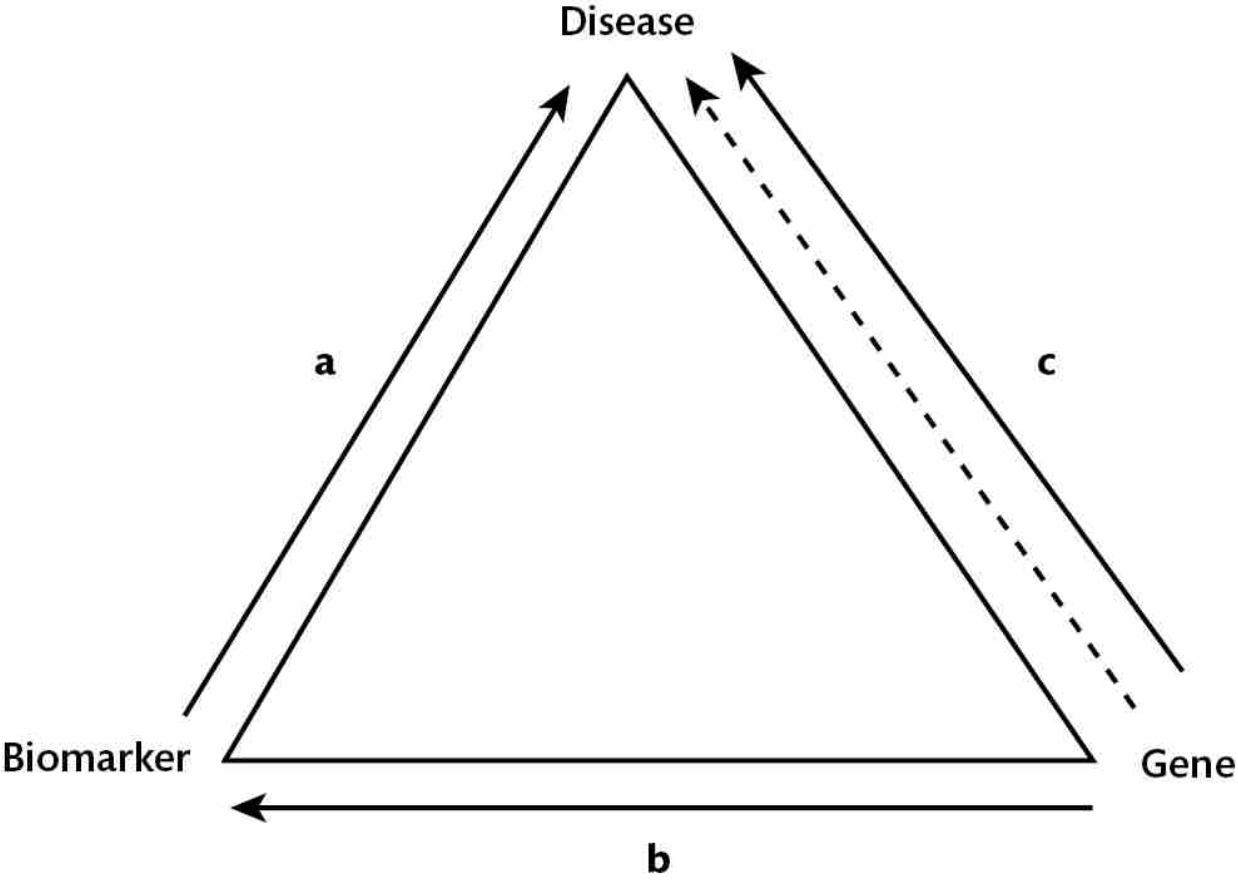


Fig. 8.19.2 Mendelian randomization. The Mendelian randomization design provides a strategy to help clarify whether there is a causal relation between an exposure and disease. Information on the magnitude of the association between the exposure and disease (a), combined with information on the magnitude of the association between the genetic variant and the exposure, (b), is used to estimate the expected magnitude of the association between the genetic variant and disease risk (dashed line in (c)). Based on several assumptions, including a linear association between the exposure and disease, the direct assessment of (c) (indicated by the solid line) provides an unconfounded assessment of the association between the exposure and disease risk, (a).

Reprinted from Springer, *Diabetologia*, Volume 51, Issue 2, 2008, pp. 211–13, Mendelian randomisation studies of type 2 diabetes: future prospects, Sandhu MS et al, Figure 1.

One example of the success of the Mendelian randomization approach is its role in providing evidence of a causal association between lipoprotein(a) and coronary heart disease. Lipoprotein(a) is a composite particle comprising LDL cholesterol linked to apolipoprotein(a) and has long been studied as a possible cardiovascular risk factor. Despite large-scale meta-analyses previously demonstrating an association between lipoprotein(a) and disease risk (Emerging Risk Factors Collaboration et al. 2009), it remained unclear whether the observed association reflected a causal relationship or simply an unexplained correlation. However, a Mendelian randomization

study of around 40,000 participants demonstrated that the magnitude of heart attack risk associated with genetically raised concentrations of lipoprotein(a) was consistent with that associated with an equivalent difference in measured lipoprotein(a) levels (Danesh and Erqou 2009; Kamstrup et al. 2009). These findings are consistent with a causal association between lipoprotein(a) and increased risk of heart disease, and highlight lipoprotein(a) as a potential therapeutic target for the management of cardiovascular disease risk. Mendelian randomization analyses have since been used to investigate a number of biomarkers of coronary heart disease—for example, to provide evidence that genetic variants underlying triglycerides are likely to be causal and, conversely, to refute a causal role for high-density lipoprotein (HDL) cholesterol in coronary heart disease (Triglyceride Coronary Disease Genetics Consortium and Emerging Risk Factors Collaboration et al. 2010; Voight et al. 2012).

As with all genetic epidemiology studies, there are problems associated with the need for large sample sizes (Ebrahim and Davey Smith 2008). Mendelian randomization studies, like other genetic epidemiological studies, require reliable identification of statistical associations between genetic variants and biomarkers and disease risk. Importantly, the principal requirement is the ability of Mendelian randomization studies to detect an association of equivalent magnitude to that predicted by a proportional change in the relevant trait or risk factor. Given that individual genetic variants are likely to explain only a very small proportion of the variation in a biomarker trait or risk factor, these assessments will require very large sample sizes. Mendelian randomization findings may also be limited by the effects of biological compensation (also known as canalization) and pleiotropy (Davey Smith and Ebrahim 2003; Lawlor et al. 2008). Canalization refers to the process by which potentially disruptive influences on normal development from genetic variations are buffered by compensatory developmental and physiological adaptations. This developmental compensation can lead to inconsistencies in the magnitude of the triangulated associations. Furthermore, the pleiotropic nature (multiple biological and phenotypic effects) of some genetic variants may produce confounded associations between genetic variants and phenotypes. Despite these limitations, Mendelian randomization provides a potential research framework using genetic variants to make causal inferences about modifiable (non-genetic) risk factors for disease and health-related

outcomes. These studies, when correctly performed, will provide insights into aetiological mechanisms and causality, informing potential therapeutic and preventive strategies.

Why is genetic epidemiology important for public health?

Genetics has increasingly become an essential part of the epidemiology paradigm. As we have seen, the integration of epidemiological methods with genome-wide technologies has provided unprecedented insights into the aetiology of complex traits and diseases in human populations and has made substantial and independent contributions to the identification of genetic loci associated with a broad range of complex traits and diseases, including diabetes, heart disease and cancer (Visscher et al. 2012). In parallel, there has been increasing speculation and expectation over how these findings may translate into practical applications for improving human health and lead to public health benefit.

The integration of human genomics discoveries into clinical and public health practice raises a number of questions. Public health is, by its very definition, concerned with improving health from a population perspective (Khoury et al. 2011a, 2011b). How does genomic discovery translate into population health benefit and provide new tools for achieving public health goals? After all, public health prevention and health promotion initiatives have, conventionally, focused on risk factors that are modifiable whereas genetic risk factors are unmodifiable. As we make the case in this section, the discovery and confirmation of genetic variants associated with diseases and traits may have translational implications and major impacts on both individual and population health: first, through elucidation of underlying disease biology and advances in therapeutics and, second, through risk prediction and personalized medicine. In addition, *genetic testing*—undertaken in order to diagnose an inherited disease that is caused by a specific genetic mutation—represents another application of genomic medicine, and is briefly mentioned here for completeness; for a full discussion of the topic, see Chapter 2.5.

Drug discovery and development

The aetiological mechanisms underpinning complex disorders almost certainly involve a combination of many factors: multiple susceptibility genes of modest effect, gene–gene interactions, gene–environment interactions, and heterogeneity of genetic and environmental exposures. The most beneficial application of genetic association studies is likely to be in unravelling the complex biological mechanisms of disease and providing novel insights into disease pathways. In turn, a better understanding of human biology may offer new possibilities for treatment and prevention at the population level (Kingsmore et al. 2008; McCarthy et al. 2008).

Clinical advances in novel therapeutic targets

First, the identification of susceptibility genes for common diseases and traits, together with a better understanding of their underlying functional properties and advances in knowledge of human physiology, should help inform drug development and help determine whether changes in gene activity have pharmacological potential. This is likely to have broad application at the population level (Table 8.19.2). For example, if overexpression of a variant gene product was protective against hypercholesterolaemia, then—even if the effect size was small among carriers—a drug which mimicked and inflated the biological effect of the causal variant might be an effective therapy for treatment of raised blood cholesterol. Such a drug could confer clinical benefit across the cholesterol range, and could be used in the general population irrespective of a person's genotype. Such translational opportunities present very real benefits for public health, although expectation must be tempered with realism: the time from gene discovery to an approved and marketable drug takes, on average, at least 10 years. Thus while the greatest impact of genomic medicine is likely to result from its application to novel biological pathways and new therapies, the full success of this will only be appreciable in decades to come (Hirschhorn and Gajdos 2011).

Table 8.19.2 Examples of matches between GWAS traits and drugs licensed for clinical use

Drug name or class	Gene	Drug indication	GWAS trait
Immunosuppressants and immunomodulators	*IL2RA*	Relapsing-remitting multiple sclerosis	Multiple sclerosis
Antidiabetic drugs	*KCNJ11*	Type 2 diabetes	Type 2 diabetes
Statins	*HMGCR*	Hypercholesterolaemia	LDL cholesterol
Lipid-regulating drugs	*LPL*	Hyperlipidaemia	HDL cholesterol
Gonadotrophins	*FSHR*	Female infertility	Polycystic ovary syndrome

Source: data from *Nature Biotechnology*, Volume 30, Issue 4, pp. 317–20, Sanseau P et al, Use of genome-wide association studies for drug repositioning.

Improved responses to existing drug treatments

A second, and more immediate, application of genomic data may be for drug repositioning—that is, the identification or refining of clinical indications for existing drugs (Sanseau et al. 2012). To do this, a first step would be to identify genes that are already being pursued as drug targets and the diseases that these drugs are currently being used to treat. Next, by utilizing data from GWAS, one can see whether those genes may be associated with additional traits or disease, which in turn could be explored as new potential drug indications. As an illustration, denosumab is a drug currently licensed for the treatment of osteoporosis, bone metastases, and rheumatoid arthritis. It acts by targeting the gene *TNFSF11*. In GWAS, the *TNFSF11* gene has been associated with Crohn's disease and thus it is reasonable to speculate that denosumab may have a therapeutic role in the management of Crohn's disease (Sanseau et al. 2012). Taking this approach thus affords translational opportunities for repositioning existing drugs for many common diseases with widespread benefit to public health.

Pharmacogenomics

Patients can vary in their response to prescribed drugs; some patients do not respond at all to certain drug treatments, and for other drugs the dose required to achieve a therapeutic effect can vary (Daly 2010). Personalized

treatment for diseases according to genotype might be feasible where risk alleles predict an individual's response to treatment or susceptibility to adverse drug reactions—for example, those genes that influence the effect of coumarin anticoagulant drugs such as warfarin. Warfarin is widely prescribed to reduce blood clotting and is used to protect high-risk patients from stroke, pulmonary embolism, and thrombosis. However, there is a large variation in the dose required to achieve safe yet effective anticoagulation; thus, reducing the uncertainty in establishing the therapeutic dose for individual patients would improve the safety and efficacy of anticoagulation therapy and potentially avoid the clinical complications associated with under- or overcoagulation. Warfarin is metabolized by the hepatic cytochrome P450 enzyme expressed by the *CYP2C9* gene. Its anticoagulant effect is mediated by the enzyme VKORC1, which is the target enzyme inhibited by warfarin. Among Caucasians, warfarin dosing is more strongly correlated with genetic variation in the *VKORC1* and *CYP2C9* genes than other patient-related factors (Cooper et al. 2008; Takeuchi et al. 2009; Teichert et al. 2009; Jorgensen et al. 2012). Common variants in *CYP2C9* are associated with slower metabolism of warfarin, higher warfarin concentrations, decreased dose requirements, and susceptibility to bleeding. Polymorphisms in *VKORC1* lead to hypocoagulable states, and necessitate lower dosage.

The translational applications of these observations are not yet fully established. In principle, an individual's genotype could, potentially, be used as a predictor of warfarin dosage. Indeed, several studies have suggested that combining genetic information on variants in *VKORC1* and *CYP2C9* together with clinical data of a patient may help better predict the warfarin dosage—both for initiation of therapy and for maintenance—required to achieve satisfactory anticoagulation (Hatch et al. 2008; International Warfarin Pharmacogenetics Consortium et al. 2009; Horne et al. 2012; Tatarunas et al. 2012). To date, though, genotype-guided dosing algorithms are not widely used, as they have not yet been shown to be cost-effective in preventing adverse events. However, a number of large clinical trials are now underway, designed specifically to assess whether using genetic data to inform warfarin dosing will improve outcomes for patients being treated with warfarin.

Another example of how genomic information has been successfully applied to understanding drug responses is in the treatment of chronic

hepatitis C infection. Standard therapy for the last decade has been a combination of pegylated interferon and ribavirin. It has been well documented that treatment response has only limited efficacy, even for more responsive viral genotypes. However, there is increasing evidence that marked variation in prognosis and response to hepatitis C treatment may be due to differences in human genome diversity; in particular, polymorphisms at the *IL28B* gene locus, encoding interferon-λ-3 (IFN-λ-3), predict response to interferon with genome-wide significance (Ge et al. 2009; Thomas et al. 2009).

A number of other GWAS on pharmacogenomics have identified several novel genetic variants that may affect drug responses or reactions, although many of these associations have failed to reach statistical significance probably due to insufficient sample sizes (Daly 2010). Nevertheless, these findings potentially could be used to develop genetic tests to determine the most appropriate drug for treatment or the optimum dose to prescribe. While it is too early to say if this is of clinical relevance in terms of predicting the trajectory of disease, the prospect of individually tailored treatment in the future raises exciting possibilities—see later for further discussion. Genotype-based randomized controlled clinical trials will be needed to formally evaluate the potential utility of genotype-specific treatment (Manolio et al. 2009; Marteau et al. 2010b).

Genomic medicine

The emergence of genomic medicine represents a shift from traditional medical genetics—with its focus on rare genetic diseases—towards improved risk prediction and, potentially, greater personalization in the practice of medicine and prevention of common diseases.

Risk prediction

Complex diseases and traits—including coronary heart disease, diabetes, hypertension, and most cancers—are caused by multiple genetic and environmental factors. For such conditions, individual risk assessment is an important component of clinical decision-making, potentially identifying people who might benefit from earlier or more intensive interventions. However, individual risk assessment is multifaceted, involving an evaluation

of risks and benefits to the individual and to society (British Medical Association Board of Science 2005; Grosse and Khoury 2006). It is also complicated by the debate over statistical methods to assess the utility of risk factors (including genetic variants) for disease risk prediction (Fig. 8.19.3) (Wood and Greenland 2009; Romanens et al. 2010; Talmud et al. 2010). Ultimately—and crucially—the utility of predictive models depends on their ability to alter clinical management which in turn relies on the availability of clinical interventions that are universally indicated but might be beneficial or cost-effective for higher-risk patient subgroups (Hirschhorn and Gajdos 2011).

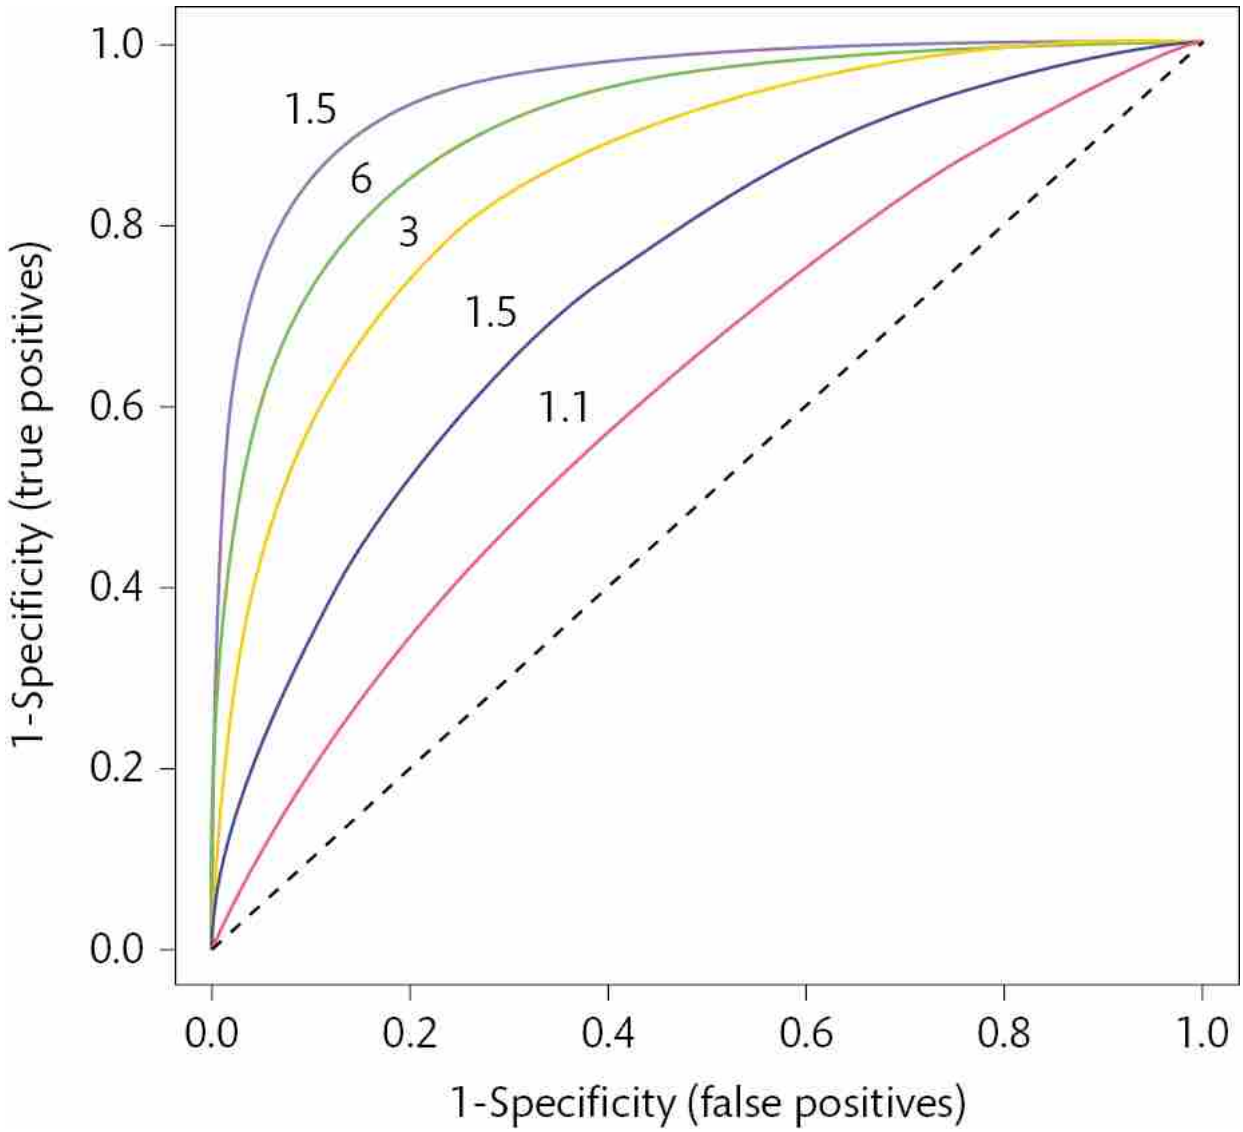

Fig. 8.19.3 Genomic risk prediction and personalized medicine. (a) Individual disease risk prediction from theoretical ROC curves for familial relative risk. Measures of risk discrimination include the sensitivity (the proportion of people who develop disease who were correctly categorized as having a high risk of disease) and specificity (the proportion of people who do not go on to develop disease who were correctly categorized as having a low risk of disease) of the test. These metrics are usually presented in a receiver operator characteristic (ROC) curve, and an overall assessment is given by the area under the ROC curve. This area is equal to the probability that a random person with disease has a higher value of predicted risk than a random person without disease; thus the larger the area, the better the test.

These metrics can be used to determine the positive predictive value—the proportion of people categorized as high risk that go on to develop disease. The figure shows ROC curves for various values of FRR. For a given disease prevalence, when the FRR is high (for example, FRR=15), the curve rises steeply, indicating the test has a relatively high sensitivity and specificity; the corresponding area under the ROC curve increases. As the FRR drops, sensitivity and specificity fall and the area under the curve decreases. For lower FRRs (for example, FRR = 1.1), the curve approaches the diagonal dotted line, indicating a test with only 50% probability of correctly predicting

risk of disease. (c) The spectrum of genomic medicine. In practice the three elements of risk prediction, stratified medicine, and personalized medicine, are not distinct but form a continuum of patient management. Genomic risk prediction involves identifying genetic variants that predict disease risk within a population. Further along the spectrum lies stratified medicine, which potentially allows targeting of treatments to specific disease pathways, identification of treatments effective for particular groups of patients, and development of diagnostics to ensure the right patient gets the right treatment at the right time. In the context of genomic medicine, individuals with disease are tested for a genetic marker which indicates whether a patient is likely to show a response to therapy. A further refinement of this approach takes us to personalized (individualized) medicine, where patients receive custom-made treatment.

Reproduced from *The Lancet*, Volume 376, Issue 9750, Sandhu M. et al., Genomic risk prediction, pp. 1366–67, with permission from Elsevier.

The identification of several genetic variants, each independently impacting on disease risk, has led to a reassessment of whether these variants improve risk prediction. To date, genetic variants identified for complex diseases explain only a small proportion of the total variation in disease risk. Accordingly, currently identified genetic susceptibility loci do not have the discriminatory power to substantially improve disease risk prediction (Kraft et al. 2009). However, with large-scale studies and new genomic sequencing technologies, there is the potential to identify new susceptibility loci. Could these variants improve clinical risk prediction? Data indicate that the variation in disease risk explained by many of these unidentified genetic variants may be very small; their detection may always be beyond the resolution of genomic research strategies and available sample sizes. Hence, a small proportion of the heritability of a disease may not be identified (Clayton 2009; Wray et al. 2010).

At the population level, the familial relative risk (FRR) represents the risk prediction achievable if all relevant loci were identified—assuming that the magnitude of the FRR is accurate and that it primarily reflects shared genetic variants rather than environments (Xu et al. 2009; Wray et al. 2010). With these caveats, for rare or common diseases with greater heritability the discovery of all disease susceptibility variants might provide opportunities to more reliably identify people at greater risk of disease (Fig. 8.19.3). However, for common diseases, such as type 2 diabetes, heart disease, and some cancers, with relatively small FRRs, it is unlikely that the discovery of all susceptibility loci will achieve the necessary predictive accuracy to provide clinically useful information (Wald et al. 1999; Ware 2006; Park et al. 2010).

The ultimate utility of genomic risk prediction in the context of complete genome sequencing will depend on the underlying genetic architecture, the

proportion of the variation in disease attributable to genetic factors, and the disease prevalence. Population-wide, it seems unlikely that genomic risk prediction alone will attain the discriminatory resolution to predict individual disease risk for many common diseases with only modest heritability. However, the use of genomic factors for individual disease risk prediction in conjunction with conventional risk factors, or for identifying subgroups for screening, remains unclear (Pharoah et al. 2008; Xu et al. 2009). While at present we lack the ability to provide clinically useful risk prediction, as more disease loci are identified it may be beneficial to re-assess whether genetic testing could improve risk prediction of common disease beyond traditional risk factors.

Stratified medicine and the emergence of personalized medicine

In addition to risk prediction and a better understanding of disease aetiology, genetic data may be increasingly used in the field of stratified medicine (Fig. 8.19.3). Patient response to drug treatments and therapeutic interventions varies markedly across the population as a result of differing underlying mechanisms of disease and patient responses to both disease and treatment. Stratified medicine can be described as identifying the different strata within a disease using a biomarker or genotype, in order to identify a patient subpopulation which is more likely to benefit or experience an adverse reaction in response to a given therapy. This approach—with patients better matched to therapies—is anticipated to have a major effect on both clinical practice and the development of new drugs and diagnostics (Trusheim et al. 2007). At the extreme of this patient matching are ‘personalized’ medicines, which by definition vary for each individual’s unique genetic make-up, such as customized stem-cell based therapies. However, the logistical, clinical, and ethical implications of this must be carefully considered.

Integrating genomics into electronic health records

As outlined earlier, personalized, or precision, medicine has the potential to transform medicine by tailoring treatment to individuals and subpopulations. In this context, large-scale integration of genetic data and prospective health data is vital for translating genetic discovery into direct clinical applications. If applied appropriately, such resources could revolutionize our

understanding of genetic risk of disease susceptibility and severity, as well as our understanding of drug response and adverse events in the clinical setting. Electronic health record (EHR) frameworks provide a unique platform to do this. EHR data can provide important information for the development of predictive algorithms, to help target screening and management interventions at specific individuals, and help target interventions required for certain diseases. Integrating genetics into predictive analytics has been shown to inform clinical interventions, and produce algorithms that can materially improve prediction of patient outcomes, response to drug, and the probability of adverse events with specific medication.

Importantly, the value—clinically and economically—of integrating genetic data into routine clinical care has not been evaluated; providing clear evidence for the utility of such initiatives will be a critical first step to realizing the full potential of genomics at population health scale.

Limitations and challenges of genetic epidemiology

Human genetics has advanced at an extraordinary pace during the last 20 years. The number of, and the ease with which, genetic markers of disease are being discovered has gone from dozens to millions. As we enter the era of next-generation high-throughput genotyping and sequencing, it is important to remember the limitations of this knowledge in order to have realistic expectations of what it can, and cannot, deliver and to apply it appropriately and responsibly.

Ethical, legal, and social implications

The generation of genetic information has contributed greatly to our understanding of the molecular basis of disease and, increasingly, to the development of effective treatments. In parallel, there are concerns about the ethical, legal, and social implications of this knowledge on the well-being of individuals and populations (Box 8.19.3).

Box 8.19.3 Examples of some of the ethical, legal, and social implications of genetic epidemiology

Genetic discrimination

A primary concern is that genetic information could be harmful and could lead to discrimination such as: (1) denial of health insurance or employment, based on genetic susceptibility; and (2) stigmatization of a specific ethnic group.

Genetic determinism

This stems from a misconception about the causal relationship between genetics and behaviour, and the erroneous belief that genetic information is somehow more predictive and certain than other types of health information because ‘you cannot change your genes’. This can lead to an unhelpful and inaccurate sense of inevitability and the use of genetic determinism to explain health disparities.

Data protection

The generation of vast amounts of genetic data, and its potential identifiability of individuals, raises significant issues around the storage of genetic data, data processing, data access, and confidentiality. Additional concerns exist around sharing sensitive data with other family members, such as in the context of reproductive choice.

Return of individual research findings (including incidental findings)

Disclosing study results and presenting clinical risk information can have important effects on health outcomes and health behaviours among study participants. Understanding probability information about disease risk and the benefits of intervention is a vital component of an individual’s decision-making capacity. The obligation of the health professional to return genetic findings—particularly when the clinical validity and utility is unclear—needs to be considered. Additionally, disclosing results for which treatments may be unavailable or prohibitively expensive raises particular ethical issues.

Informed consent

National and international research guidelines agree that valid consent to participate in research must be consent that is informed in a manner that is linguistically and culturally appropriate and is understood by the study participant. This can be particularly challenging in the context of genomics research, which is complex and often difficult to understand, and where the implications of research findings are largely unknown (including incidental findings which are not relevant to the original research question but may have clinical significance). An additional challenge is to resolve issues around individual consent versus family consent, including the right ‘not to know’ the findings of genetic studies.

Fair distribution of benefits from research

As with all fields of research, particular individuals, groups, or communities should neither bear an unfair share of the direct burdens of participating in research, nor should they be unfairly excluded from the potential benefits of research participation. This is particularly pertinent when genetic research is conducted in countries where genetic services are not available or may not be readily accessed. Inclusiveness in genetic research and fair distribution of benefits and burdens should be important considerations for researchers, research ethics boards, and sponsors. Issues of fair and equitable treatment arise in deciding whether and how to include individuals, groups or communities in research, and the basis for the exclusion of some.

Accounting for unexplained variation

Despite the success of GWAS in identifying disease genes, a substantial proportion of the heritability of disease traits remains unexplained (Manolio et al. 2009). So far, loci shown to be associated with disease only account for a small fraction of the total genetic contribution; the great majority of susceptibility loci remain to be identified. How do we account for this remaining variation? Unexplained heritability may be due to unknown common variants of small effect, or rare variants with larger effects, or influences by environmental factors. To better understand the missing heritability of disease traits, larger-scale studies are required, using denser SNP arrays. In addition, exome sequencing, whole genome sequencing, or whole genome association studies in large populations will be needed to identify all potential variants within a gene or locus. Sequencing candidate genes in individuals at the extremes of a quantitative trait (e.g. the extremes of lipid levels) may identify new variants, common or rare, and help further our understanding of disease biology and prevention.

Genetic epidemiology in low- and middle-income countries

To date, most human genomics research has been done in populations of European ancestry, and has successfully provided new insights into the biology of chronic diseases and their risk factors in these populations. However, the relevance of many recent genomic findings to populations in low- and middle-income countries (LMICs) is not known. It may be difficult to meaningfully apply the findings from Western populations to LMIC populations, where both genetic and non-genetic susceptibility may be different.

To fully appreciate the impact of a genetic variant on disease risk it will be important to establish whether the findings from one population apply to other populations of different ancestry. Globally, human populations show structured genetic diversity as a result of geographical dispersion, selection and drift (Campbell and Tishkoff 2008; Novembre and Ramachandran 2011). Accordingly, among many populations in LMICs there is marked genomic diversity—in particular, among populations of African descent, where there is more human genetic diversity than anywhere else (Tishkoff et al. 2009). Given this, understanding the genomic basis of common diseases and their risk factors in LMICs is likely to provide additional insights into

disease aetiology and potential therapeutic strategies (Hill 2006; Campbell and Tishkoff 2008; Novembre and Ramachandran 2011); an example of this is the African Genome Variation Project (AGVP). Representing the most comprehensive characterization of African diversity to date, the AGVP highlighted the utility of genomic information from African populations for identifying genes related to disease susceptibility and resistance and facilitating medical genetics in Africa (Gurdansani et al. 2015). Now, in addition to genotyping resources such as the AGVP, sequencing efforts are increasingly underway to significantly advance the comprehensive catalogue of human genetic variation in Africa, providing a mechanism to evaluate the clinical relevance of genetic diversity both in African populations and globally.

Thus the value of GWAS will be enhanced further by including populations with greater genetic diversity and less correlation between variants, and will benefit from more precise characterization of phenotypes and environmental exposures (Manolio et al. 2009). Ultimately, large-scale international collaborations will facilitate studies in different global populations and help to determine whether loci identified in initial GWAS (usually done in populations of European ancestry) are relevant in non-European individuals. As a result of such studies, our ability to treat disease and reduce risk will be much more complete.

In addition to studies of the human genome, techniques from genetic epidemiology can also be used to examine pathogen genomes, yielding important applications for human health—for example, in helping to understand the causes of resistance to malaria treatment. First-line treatment for uncomplicated falciparum malaria is artemisinin-based combination therapy (ACT), which has been highly effective in treating this disease. However, in recent years, resistance to artemisinin has become increasingly prevalent in Cambodia and Thailand, characterized by slow parasite clearance from the blood (Uhlemann and Fidock 2012). Antimalarial drug resistance hinders malaria control and is a major public health threat to global initiatives to control and eliminate the disease. Using a variety of techniques, including targeted association studies of candidate genes for ACT and genotyping of variants across the malaria genome, a number of studies have identified that resistance to artemisinins is, in part, genetically determined by variants in the malaria-parasite genome and conclude that parasite genetics have a central role in determining parasite clearance rates

(Cheeseman et al. 2012; Phyo et al. 2012). Furthermore, these studies report that the heritability (h_2)—that is, the contribution of parasite genetics that explains the variation in parasite clearance—has increased from 30% in 2001–2004 to 66% in 2007–2010 (Phyo et al. 2012). The mechanisms underlying the reported associations are not yet known, but understanding these biological processes could potentially inform new approaches for effective malaria treatment in the future.

The application of genetic epidemiology and genomic research to public health practice merits specific discussion in the context of LMICs—where the global burden of infectious and chronic, complex diseases is greatest. Additionally, in LMICs healthcare is often severely constrained by limited financial and human resources and a lack of appropriate infrastructure (Burke et al. 2010). It would be simplistic to suggest that because of the great health needs of LMICs—overwhelmingly determined by economic and social factors—genomics is an irrelevance and has no role to play in improving health. Rather, to omit genomic discoveries from the healthcare agenda of LMICs would serve only to promote existing inequities between rich and poor, between economically advantaged and disadvantaged. Public health professionals have an essential role to play in leading the response to genomic medicine in LMICs, ensuring that healthcare providers and policymakers are informed by a strong evidence base for the effectiveness of genomic approaches in improving population health.

Improving phenotypic characterization and classification of disease

Associations between genetic variants and phenotypes are limited by the accuracy with which each is measured. The ability to measure genotypes now far exceeds our ability to measure phenotypes (Altshuler et al. 2008). We need to match this with more detailed, and more accurate, assessments of clinical phenotypes. Indeed, carefully designed GWAS with thorough phenotypic characterization have the potential to redefine disease classification (Kingsmore et al. 2008). In some cases, it will become increasingly possible to unpick the phenotypic complexity of diseases that involve several pathological processes and allow us to establish whether genetic factors distinctly contribute to different phenotypes of the condition. An example of this is in the area of coronary artery disease (CAD), where

GWAS have successfully discriminated genetic variants for distinct CAD phenotypes—suggestive of distinct underlying pathological mechanisms (Reilly et al. 2011). This opens up avenues for patient stratification and personalized treatments.

Conversely, for other complex diseases that have previously been regarded as distinct clinical entities, GWAS findings may point to common underlying disease processes and a shared pathogenesis. To illustrate, a GWAS of Crohn's disease and ulcerative colitis found a sizeable overlap in susceptibility loci for the two diseases. With such a degree of sharing of genetic risk, it seems likely that many of the biological mechanisms involved in one disease have some other role in the other (Jostins et al. 2012). These studies provide a rich source of clues to the biological mechanism underlying complex disease. However, the translation of such GWAS discoveries into prognostic and therapeutic benefit will need greater insights into the relation between each loci and the different phenotypes.

Risk communication

The extent to which genetic information will play a role in 'personalized medicine' will depend not only on whether predictive accuracy beyond conventional measure can be attained, but also on whether there are interventions whose effectiveness is improved by knowledge of a genetic result. A key challenge will therefore be to find effective ways to communicate information on small incremental risk increases conferred by genetic markers for disease risk, in order to prompt changes in lifestyle that will ultimately confer health gain to individuals. At present, it is not clear if personal genomic information is likely to beneficially impact public health through motivation of lifestyle behavioural change. Risk perception and risk communication are complex processes, and are shaped by social and cultural values, assumptions, and beliefs held at the individual and societal level.

An individual's ability to make sense of genetic information will involve an understanding of the concepts of genes, genetics, ancestry, and heritability, in a manner that is culturally relevant and acceptable. Most of the information we have on genetic susceptibility to disease is, at best, incomplete as discussed earlier in this chapter; health professionals' advice to people will have to change as more robust evidence on risk factors comes

to light, sometimes seeming to conflict with, or even to contradict, previous knowledge. Conveying this uncertainty is a difficult and challenging task.

The creation of personal genomic risk profiles, that predict an individual's lifetime risk of various common diseases, raises the possibility that public health promotion could potentially be directed at susceptible individuals/groups of people in the population based on their genomic risk profile. This marks a departure from conventional public health practice which has tended to focus on social and environmental determinants of disease and health, and allows a focus on preventing disease, disability, and mortality among people with specific genotypes that increase their disease risk. It is tempting to think that knowledge of individual risk of a given disease, as predicted by genome-wide profiling, will motivate individuals to change their behaviour and promote greater adherence to a healthy lifestyle or treatment regimen in order to reduce their risk; however, human behaviour is complex and risk estimates are difficult to communicate meaningfully to patients (Loos 2011). Recent studies, including a Cochrane review, seem to indicate that genetic testing may not result in individuals changing their behaviour in any significant or sustained way (Marteau et al. 2010a; Bloss et al. 2011).

Conclusions

It is clear that public health practice cannot ignore the impact of genetic epidemiology and the knowledge derived from genomics research. The results from genetic epidemiological research have two broad translational applications which have the potential to contribute to population health and well-being. First, as our understanding of disease aetiology and its underlying biological mechanisms increases, there is the potential for new drug development and improved therapeutic strategies to manage disease. Second, in parallel, there is growing interest in the use of these genetic variants to predict individual disease risk over and above classical risk factors, and to develop stratified and personalized approaches to diagnosis and disease management. The public health community has a central leadership role to play in critically and systematically evaluating these discoveries for their potential use in disease prediction, prevention, and treatment response. Furthermore, public health practice must ensure that the benefits of genomics are applied with equity across the population.

As our understanding of the molecular basis of disease increases, there is a need for public health practitioners to have a degree of knowledge about genetic susceptibility and to understand the scientific basis of genetic epidemiology and the benefits it can afford, as well as to be aware of the limitations of this knowledge. The ultimate goal of public health is to promote and improve the health and well-being of the population. A public health approach to genetic epidemiology should assess the contribution of genomics to health in the context of wider determinants of disease and health, and provide a robust evidence base to inform patients, healthcare policymakers, health service commissioners, and providers.

Introduction to tobacco use

Please respond to the following statements before reading further:

About 1 out of 20 smokers (i.e. 5% or less), if they continue to smoke, will eventually be killed by smoking.
To reduce deaths caused by smoking, preventing young people from smoking is the most important action.

Response: strongly agree/agree/disagree/strongly disagree.

Most people will choose agree or strongly agree for these two statements. However, in fact, smoking kills one in two smokers and quitting smoking prevents more deaths more quickly.

Tobacco is the world's most important and most avoidable public health problem. Tobacco killed 100 million people in the last century, mostly in developed countries, and could kill 1 billion this century, mostly in low- and middle-income countries (LMICs) especially China. Currently, tobacco kills 5.4 million people every year. Unless urgent action is taken, tobacco will kill 8 million per year by 2030, 80% of whom will be in developing countries. 'Of the more than 1 billion smokers alive today, around 500 million will be killed by tobacco' (WHO 2008). But millions of lives have been saved since the 1960s, mostly in developed countries (notably the United States and United Kingdom) which have progressively and successfully implemented effective tobacco control policies.

Tobacco control is the most remarkable example of global public health actions against non-communicable diseases (NCDs). It is unique in having an international public health treaty, the World Health Organization (WHO) Framework Convention on Tobacco Control (FCTC), which has been

ratified by 176 parties covering 88% of the world's population (as of 30 November 2012). It is one of the most rapidly ratified United Nations (UN) treaties of all time but two of the world's largest countries have not ratified the FCTC, namely the United States and Indonesia (WHO 2012a).

In the September 2011 Political Declaration of the UN on NCDs, tobacco use tops the list of four major risk factors that also include the harmful use of alcohol, unhealthy diet, and physical inactivity (UN 2011).

Globally, the epidemic of tobacco-induced diseases, mortality, and related social and economic burden is still expanding. Using the host–agent–vector model of infectious diseases, the tobacco epidemic is an epidemic of the agent, that is, tobacco. It is sometimes also described as an epidemic of smoking and its harms to others. These two descriptions tend to blame the agent (tobacco) and the host (smokers) or focus on the victims (passive smokers).

However, some might also consider that the tobacco epidemic is really a tobacco industry epidemic. The agent is produced massively, its use by the host is heavily promoted, and control measures are aggressively obstructed by the vector, the tobacco industry. There will be no tobacco epidemic without the tobacco industry. Tobacco control must therefore target the vector. Helping the hosts, that is, smokers, to quit smoking and preventing non-smokers, especially young people and women, from starting smoking are also important, but the impact will be limited to those who can be and are being helped effectively. Smoking cessation campaigns and services cannot produce substantial public health benefits when the tobacco industry is not under strict control. The success of tobacco industry control and other control measures will lead to more quitting, less relapse, and less uptake of smoking.

Effective control measures are stated in the FCTC and translated into six policies of WHO's MPOWER package as follows (WHO 2008):

Monitor tobacco use and prevention policies.
Protect people from tobacco smoke.
Offer help to quit tobacco use.
Warn about the dangers of tobacco use.
Enforce comprehensive restrictions on tobacco advertising, promotion, and sponsorship.
Raise taxes on tobacco.

Note that these six policies are not ranked, and all six are needed as a comprehensive approach against the tobacco industry and tobacco use. However, their implementation varies greatly even among countries that have ratified and are parties of the FCTC. WHO evaluates the progress and publishes global status reports regularly, which is part of the M (‘monitor’) under MPOWER.

Tobacco kills up to two in three smokers

At least one in two smokers killed

It is important to understand and warn about the dangers of tobacco use: first, the absolute risk of death from all causes combined, and second, the large number of resultant deaths globally, regionally, and locally. This absolute risk, that a smoker will have a 50% chance of being killed by tobacco, is easy to understand and more relevant to individuals than relative risks (RRs) or number of deaths. RRs only tell the exposed people that they have higher risks than those who are unexposed, but not the exact probability of harm, the absolute risk. Large RRs do not mean large absolute risks if the incidence rate in the unexposed is low. Telling smokers that millions have died from tobacco elsewhere might be alarming to some, but difficult to comprehend to others.

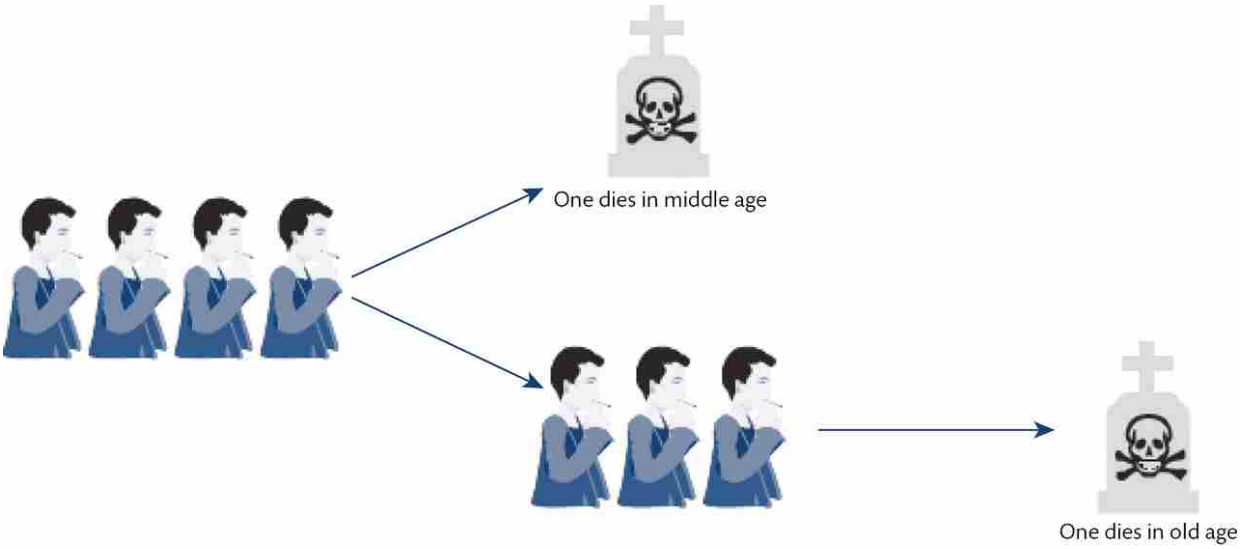

Fig. 9.1.1 One in two smokers will be killed by smoking.

The WHO statement ‘Tobacco kills up to one in every two users’ (WHO 2008) is derived from Peto, who stated ‘about half of teenagers who keep smoking steadily will eventually be killed by tobacco (about a quarter in old age plus a quarter in middle age)’ (Peto 1994) (see Fig. 9.1.1). This was based on the translation of the RR of two in the prospective British Doctors Study by Doll and Peto with 40 years of follow-up (Doll et al. 1994). This is a unique example of how an RR can be translated into absolute risk for public health actions and communication of risks.

From relative risk to absolute risk

The RR is the absolute risk of disease or mortality in the exposed group (smokers) divided by that in the unexposed (non-smokers). Translating the RR into an absolute risk in the exposed without knowing the absolute risk in the unexposed is only feasible for total or all-cause mortality. This is based on the attributable fraction (AF) in the exposed (AF = (RR − 1)/RR). With an RR of two for total mortality in smokers compared with non-smokers, the AF in smokers is (2 − 1)/2 = 0.5. That means of all smokers who died, half were due to smoking. Because all smokers will eventually die, the denominator of all smoker deaths can be turned into all current smokers who are alive, and hence of all current smokers, 50% or one in two will eventually be killed by smoking (Lam 2012).

Up to two in three smokers killed

Previously reported RRs could have been underestimated. The RR is based on a comparison of mortality rates of current smokers and non-smokers after some years of follow-up. Current smokers recruited at baseline are survivors as their weaker counterparts might have died. Non-smokers can be either never smokers or former smokers. The latter could have quit smoking while still being healthy (healthy quitters), or they had to quit because of ill health (ill quitters). Hence, RR can be underestimated as current smokers tend to be healthier (lower mortality rate in the numerator), and non-smokers can include some ill quitters (greater mortality rate in the denominator). This bias is particularly strong when a cohort includes older people.

Another bias could be due to insufficient duration of follow-up, especially for diseases that take many years to develop. A longer follow-up would yield more deaths and allow subgroup analysis. The results from Doll and Peto's study, after 50 years of follow-up, showed that if smoking started at a young age, two in three smokers (RR of 3) will be killed by smoking (Doll et al. 2004). That two in three very young smokers will be killed by smoking is particularly relevant for controlling smoking in children and youth, but this statement has not yet been publicized widely. Latest findings based on large contemporary cohorts in the United States and United Kingdom also revealed all-cause mortality RRs approaching 3 in male and female current smokers compared with never smokers (Jha et al. 2013; Pirie et al. 2013; Thun et al. 2013).

Not many cohort studies, especially those from LMICs, have been followed up for as long as the British doctor cohort studies and hence, their RRs of mortality due to smoking tend to be underestimated. In a small cohort of 1,696 people followed up for 20 years, Lam et al. (1997) found an RR of about 2, which is similar to that from Doll and Peto but greater than those of earlier (Yuan et al. 1996) and more recent cohort studies from China (Elliott et al. 2009) with shorter duration of follow-up.

The total exposure to tobacco in smokers varies by countries and cohort studies. Another explanation for the smaller RRs of cohort studies in China and other LMICs at an earlier stage of the tobacco epidemic is that their exposure to tobacco could be lower. Smokers in these cohort studies tended to have started smoking at an older age and could not afford to smoke as much as those in high-income countries.

A recent meta-analysis by Gellert et al. (2012) on smoking and all-cause mortality focused on elderly people (aged 60 or above). Based on 17 cohort studies from seven countries, the RR was 1.85 in current smokers. This means that the one in two deaths is still applicable to older smokers.

Public health applications

Such epidemiological findings can be used for more effective public health advocacy, education, and publicity campaigns. The AF of 50% can be translated into the number of people in a specific population who will be killed by smoking. If there are 4 million adults, and the prevalence of smoking is 50%, the number of people to be killed is 4 million × 0.5 × 0.5 = 1 million. The same can be applied to children and young people. A statement that among today's 4 million children in our country/city/district, about 1 million will be killed by tobacco, if the current prevalence of smoking is not reduced, is more striking. On the other hand, such figures can be used positively, saying that prevention of smoking and promotion of quitting can save millions of lives. As there is a trend of increased smoking in children and youth in many LMICs, if the RR of 3 is used, the estimates will be even more alarming.

For unknown reasons, the 'one in two deaths' message is not used in many websites that help smokers quit, including the US Centers for Disease Control and Prevention (CDC) website. The US Surgeon General's (USSG's) report (US Department of Health and Human Services (2004) does not include total mortality. Existing pictorial warnings in cigarette packs of more than 50 jurisdictions also do not show or highlight this risk. Even recent warnings in Canada and Australia in plain packaging do not have it (Physicians for a Smoke-Free Canada n.d.). The 'one in two risk' has seldom been used as a key campaign message until recently. In 2011, Ireland was the first country to use it for a major social marketing campaign resulting in wide media coverage and great increases in calls to the quitline and demand for smoking cessation services (Howell and HSE Social Marketing Working Group on Tobacco 2012). The Hong Kong Council on Smoking and Health launched a campaign on 'one in two' with a video for TV in October 2012. For public health information and education, the mortality risk of 'one in two' to 'two in three' should be highlighted consistently and widely (Lam 2012). For randomized controlled trials on smoking cessation advice or

counselling, there is also no report about using such absolute risk warning, and new trials are warranted.

Clinical applications

The AF of 50% can also be used to motivate clinicians or other healthcare professionals (HCPs) to be more active in helping smokers to quit. If they can help two smokers to quit, they would have saved one life. However, the AF does not tell when the smokers will be killed by smoking. The message to the smokers can be simple: 'If you and your good friend continue to smoke, one of you will be killed by smoking prematurely. We cannot predict who and when, but the premature death can come quickly and suddenly, and when it comes, it will be too late. Quit smoking now.'

Note that AF in the exposed can be used in clinical epidemiology for individuals with a disease and is exposed to the risk (causal) factor of the disease. If the RR of lung cancer due to smoking is 20 (Aubin et al. 2011), AF in the exposed is (20 − 1)/20 = 95%. Clinically, one can tell the smoker who has lung cancer that the probability that his lung cancer is due to his smoking is about 95%. This probability will be greater if the smoker has smoked heavily for a long duration, as the RR refers to an 'average' smoker, and there is a dose–response relation between RR and the amount of exposure (i.e. pack-years).

Specific harms of tobacco: active smoking

Causation versus association

Of the four major risk factors, tobacco use is the one confirmed to be a causal factor of the largest number of diseases. Hence, the term 'cause' or 'causal factor' should be used for smoking instead of risk factor, which implies association rather than causation. Similarly, the terms 'tobacco-induced diseases' or 'tobacco-caused diseases' are clearer than terms such as 'tobacco-related' or 'smoking-related' diseases. The USSG reports are the longest and most comprehensive series of reviews, with the latest on active smoking published in 2004 (US Department of Health and Human Services 2004). Updated reports are published regularly often with new harms added to the previous lists. Globally, different review panels use quite similar

criteria for causal inference. Despite the remarkable consensus on many diseases, disagreements remain as to whether the evidence is sufficient (or only suggestive) to reach a conclusion on causation for some diseases. More evidence to prove or confirm causation of additional diseases is of scientific interest and can add to the total disease burden estimates, but is not essential for tobacco control.

International Agency for Research on Cancer

The International Agency for Research on Cancer (IARC), a WHO agency, is the world authority in the evaluation of carcinogenic risks to humans. The 1986 and 2002 IARC monographs classify tobacco smoking and tobacco smoke as a Group 1 carcinogen, meaning that there is sufficient evidence that it can cause cancer in human. The most updated and comprehensive reviews released by IARC in 2009 conclude that tobacco smoking is the single largest cause of cancer worldwide, and 'Tobacco smoking causes cancers of the lung, oral cavity, naso-, oro- and hypopharynx, nasal cavity and accessory sinuses, larynx, oesophagus, stomach, pancreas, colorectum, liver, kidney (body and pelvis), ureter, urinary bladder, uterine cervix and ovary (mucinous), and myeloid leukaemia. Also, a positive association has been observed between tobacco smoking and cancer of the female breast. For cancers of the endometrium (post-menopausal) and of the thyroid, there is evidence suggesting lack of carcinogenicity' (IARC 2012). Note that two important cancers are added, that is, cancer of the colon and ovary, for which the evidence is now considered sufficient, but that for breast cancer is still limited (Secretan et al. 2009; IARC 2012). The report also concludes that bidi (hand-rolled cigarette commonly used in South Asia) smoking increases the risk for cancers of the oral cavity, oropharynx, hypopharynx, larynx, lung, oesophagus, and stomach, and smokeless tobacco causes cancer of the oral cavity, oesophagus, and pancreas.

The 2010 USSG report

The 2010 USSG report focused on mechanisms rather than causal inference. The major conclusions are: (1) no risk-free exposure level; (2) tobacco smoke causes adverse health outcomes through DNA damage, inflammation, and oxidative stress; (3) risk is related to the duration and level of exposure;

(4) exposures are due to powerful nicotine addiction in the brain; (5) low levels of exposure, including second-hand smoking, lead to rapid and sharp increases in endothelial dysfunction and inflammation, which are implicated in acute cardiovascular events and thrombosis; and (6) evidence is insufficient that modifications in tobacco production can reduce risks. Moreover, it has important new conclusions that cigarette smoking produces insulin resistance and chronic inflammation, which can accelerate macro- and microvascular complications. Hence, for diabetes: (1) smoking increases the risk of type 2 diabetes; (2) people with diabetes need more insulin; and (3) smokers with diabetes have more complications including heart and kidney disease, amputation, retinopathy, and peripheral neuropathy. The report has a very readable booklet for the public that is highly recommended (Centers for Disease Control and Prevention 2010).

Discrepancies and potential confusions

The conclusions on causal relations for cancers from the IARC are mostly similar to the 2004 USSG report. The most notable exceptions are that the 2002 IARC publication has included liver, nasal cavities and nasal sinuses, and nasopharyngeal cancer as causally related to smoking and cancers of the *tongue and lip* are specifically stated under oral cavity. The 2004 USSG report, which appeared later, does not. The 2012 IARC report has now added that smoking causes colon and ovarian cancer. Another notable discrepancy is that although the statement that smoking can cause erectile dysfunction (ED) is often shown in pictorial or other health warnings on cigarette packs, the 2004 USSG report considers that the evidence for causation is only suggestive but not sufficient.

Important new results

Since the 2004 USSG report, there has been no new meta-analysis or systematic review on ED. New results based on cross-sectional surveys have shown a consistent association between smoking and ED in Australia (Millett et al. 2006), Boston (Kupelian et al. 2007), Hong Kong (Lam et al. 2006), and China (He et al. 2007), and a Swiss survey showed that smoking was associated directly with premature ejaculation and indirectly with ED in young men (Mialon et al. 2012). Results from a randomized controlled trial

showed that quitting smoking improved ED (Chan et al. 2010). A smoking cessation clinic study showed that quitters had better erectile function than those who relapsed (Harte and Meston 2012). All three meta-analyses in 2007 concluded that smoking is associated with an increased risk of active tuberculosis (TB) disease and mortality (mostly due to reactivation of previous TB infection) and the evidence is strong and consistent (Bates et al. 2007; Lin et al. 2007; Slama et al. 2007). A mathematical model predicted that 'smoking would produce an excess of 18 million tuberculosis cases and 40 million deaths from tuberculosis between 2010 and 2050, if smoking trends continued along current trajectories. The effect of smoking was anticipated to increase the number of tuberculosis cases by 7% (274 million v 256 million) and deaths by 66% (101 million v 61 million), compared with model predictions that did not account for smoking' (Basu et al. 2011). The causal relation also suggests that tobacco control must be integrated with TB control in TB endemic countries. Public health advocacy has to be based on precise and sometimes conservative estimates of disease burden. With new results, systematic reviews by different authorities will come up with revised or updated conclusions. Public health professionals need to keep updated and critically appraise the original sources of information.

Specific harms of tobacco: passive smoking

Numerous reviews

No other substance like second-hand smoke (SHS) has been subject to so many systematic reviews within such a short period since the first two reports of an association with lung cancer were published in 1981 (Hirayama 1981; Trichopoulos et al. 1981). The massive and aggressive criticisms from the tobacco industry and its scientists were also unprecedented.

The 2006 USSG report

The 2006 USSG report is the most comprehensive review focusing on SHS (US Department of Health and Human Services 2006). It concludes that the evidence is sufficient that SHS causes: (1) premature death and disease in children and adults who do not smoke; (2) sudden infant death syndrome, acute respiratory infections, ear problems and more severe asthma in

children, and smoking by parents causes respiratory symptoms and slows lung growth in their children; and (3) immediate adverse effects on the cardiovascular system, coronary heart disease (CHD) (25–30% increased risk) and lung cancer (20–30% increased risk) in adults. The conclusions that have great public health implications are: (1) there is no risk-free level of exposure to SHS; (2) many millions of children and adults are still exposed; and (3) eliminating smoking in indoor spaces fully protects non-smokers from SHS, but separating smokers from non-smokers and cleaning the air and ventilating buildings cannot eliminate exposure. The list of diseases with suggestive but insufficient evidence is much longer, and most notably includes childhood cancer (leukaemia, lymphoma, and brain tumour), onset of childhood asthma, and adult-onset asthma, breast cancer, nasal sinus cancer, stroke, atherosclerosis, and chronic obstructive pulmonary disease (COPD).

The 2002 IARC monograph

The 2002 IARC monograph concludes that involuntary smoking is a Group 1 carcinogen based on more than 50 studies in many countries, causing lung cancer with excess risk from spousal exposure of 20% for women and 30% for men (Aubin et al. 2011). Excess risk from workplace exposure is 16–19%. The US Cal/EPA 2006 report concludes that SHS can induce asthma and can cause premenopausal breast cancer with an excess risk of 80–120% and these are different from the 2006 USSG report. The 2009 IARC report has added that parental smoking can cause hepatoblastoma in offspring, that there is limited evidence for cancer of larynx and pharynx, and the evidence for female breast cancer remains inconclusive.

The estimation of deaths from SHS is less straightforward. It depends on what diseases are to be included, and what criteria (sufficient or suggestive evidence for causation) or reviews or meta-analyses are being used. Reliable SHS exposure data are not available in many places, and definitions of exposure vary in different surveys, which may not be based on a sample representative of a whole country. The WHO Global Burden of Disease Study estimates that SHS has caused 603,000 premature deaths in never smokers in 2004, including 166,000 from lower respiratory infections, 1,100 from asthma in children, 35,800 from asthma, 21,000 from lung cancer, and 379,000 from ischaemic heart disease in adults. Of all deaths from SHS,

28% occur in children and 47% in women. The report notes that current smokers may be especially susceptible because of high and close exposure or existing smoking-caused diseases (Oberg et al. 2011).

National or local estimates of mortality in non-smokers due to SHS are critically important for advocacy for legislation to ban smoking completely. The 2006 USSG report estimates that in 2005, SHS killed over 3,000 Americans from lung cancer, 46,000 from CHD, and 430 newborns from sudden infant death syndrome. The 2007 China Tobacco Control report estimates that SHS killed more than 100,000 Chinese non-smokers. In Hong Kong, the results that SHS killed 150 catering workers from lung cancer and CHD (Hedley et al. 2006), and 1,324 people (from stroke, heart disease, chronic lung disease, and lung cancer) each year (McGhee et al. 2005), had been used successfully in campaigns leading to the 2006 law amendments extending the total ban of smoking to all indoor workplaces, restaurants and bars, and many other public places. New results on SHS will contribute important new evidence for causal inference for asthma in children (Burke et al. 2012), stroke (Oono et al. 2011), TB disease (Lin et al. 2007; Slama et al. 2007; Leung et al. 2010), COPD (Yin et al. 2007; He et al. 2012), and acute respiratory symptoms (Monto and Ross 1978). The uncertainty about SHS and breast cancer remains (Pirie et al. 2008).

Adverse effects of SHS in current smokers

There is a paucity of data on the adverse effects from SHS in current smokers, mainly because of the exclusion of current smokers in most, if not all, studies on SHS. In Hong Kong, SHS exposure was reported to be strongly associated with increased acute respiratory symptoms and recent outpatient service use in adult current smokers (Lam et al. 2005) and to be associated with increased risks for persistent respiratory symptoms among adolescent current smokers (Lai et al. 2009). The main purpose of banning smoking completely in indoor workplaces is to protect workers, which is an occupational health issue. Opponents and the tobacco industry have advocated for smoking areas or smoking rooms, but workers who need to serve or clean inside smoking rooms are heavily exposed to SHS. A further argument is that smoker-employees can be deployed to work in smoking areas. Results on additional harms of SHS to active smokers can be used as a counterargument. Also, both adult and youth smokers should be warned to

avoid SHS, which may motivate some to support a totally smoke-free legislation and to quit smoking.

Chemicals and carcinogens

Tobacco smoke

Tobacco smoke is a very complex mixture containing more than 7,000 chemical compounds (Rodgman and Perfetti 2009). Hundreds of these compounds are toxic and at least 69 are carcinogens. The list is expected to further increase. Also new additives have been and will continue to be added to cigarettes by the tobacco industry. These include various flavours (including menthol and fruits), and herbs or herbal medicine to attract special groups of smokers, such as children and youth, and people who believe in herbal medicine (Eriksen et al. 2012). The effectiveness of using such information to warn about the harm of smoking needs to be evaluated. The main problem is that smokers do not feel any acute toxic effects from such chemicals because the level of exposure to each compound is low.

Second-hand smoke

SHS is a complex mixture of mainstream smoke (smoke inhaled and exhaled by the smoker) and side-stream smoke (from the burning end of the cigarette). Many of the toxic substances have a higher concentration in side-stream smoke than mainstream smoke, and it has often been mistakenly publicized that SHS is more harmful than active smoking. In terms of toxicity, this is not true because the toxic substances in SHS are greatly diluted by the ambient air before inhalation by the non-smokers. Hence, the exposure level of various compounds from SHS in a non-smoker is much lower than that in a smoker. In terms of the number of people affected to varying extents from mild irritation to deaths due to lung cancer or CHD, this statement can be true because of the widespread SHS exposure in non-smokers, and the absolute number of non-smokers, including children, is always greater than the number of smokers. Public health professionals should be mindful that messages are based on strong evidence and are effective.

Third-hand smoke

Third-hand smoke (THS) refers to the residual tobacco smoke pollutants on dust, surfaces, clothes, and human body after SHS has cleared. It can be re-emitted as gases as well as react with other pollutants such as nitrous acid to form tobacco-specific nitrosamines, some of which are carcinogenic (Burton 2011). Although the phenomenon of smelling residual smoke is not new, the coining of THS (Winickoff et al. 2009) has triggered much research and public interest. THS is accumulated with each cigarette smoked and remains for weeks. Young children are particularly at risk of exposure as they explore their home environment. However, no studies have linked THS exposure to physical harm and more studies on the chemistry and health risk of THS are warranted (Matt et al. 2011).

Risk perception of the public

The risk perception and tolerance of the public is often irrational and their resulting actions are not proportional to the magnitude of risks. Most people have zero tolerance to fewer toxic contaminants in foods, such as malachite green in fish, but relatively few are aware of the chemicals and carcinogens in tobacco smoke. More awareness of the harms of SHS has led to the rapid decline in tolerance to SHS. Non-smokers take various actions to avoid exposure and to complain about smokers who smoke near them. The past few decades have witnessed a change from total acceptance of smoking to zero tolerance among many non-smokers, especially in countries with comprehensive smoking bans.

The protection of innocent non-smokers, including children and women and employees, has been the major driver for smoke-free legislation. In China and many LMICs, awareness is low and even non-smoking physicians are not concerned about their own exposure to SHS (Lam et al. 2011). Tobacco control advocates need to learn from successful experiences in using SHS and in comparing the risk of tobacco smoke with other toxic compounds to change risk perception and motivate actions from non-smokers.

Although the harm of THS has yet to be shown, parents who are aware of that potential risk are more likely to adopt home smoking bans (Winickoff et al. 2009). This represents an opportunity to promote a totally smoke-free

environment in the private home, the last frontier in the battle of tobacco control.

Warn about the dangers

Numerous surveys reveal that the knowledge about tobacco harms is often superficial. The earliest health warning required by governments or law was mostly a small and inconspicuous statement that smoking is harmful to health on tobacco advertisements (started in 1971 in the United States) or cigarette packs. Unfortunately, this is still the situation in many countries such as China.

Canada was the first country to require pictorial health warnings by law on cigarette packs in 2001. Its success has spurred many countries to follow suit. The Canadian Cancer Society 2012 report showed that 63 countries or jurisdictions and territories, covering 40% of the world's population, require pictorial warnings (Canadian Cancer Society 2012).

The FCTC Article 11 requires that health warnings 'should be 50% or more of the principal display areas but shall be no less than 30%' (WHO 2003) and may be in the form of, or include, picture warnings. Many countries have done more than this minimum, with Australia having some of the largest warnings in the world at 75% of the package front and 90% of the back. From December 2012, Australia has also implemented plain packaging (Fig. 9.1.2) to prohibit tobacco company colours, logos, and design elements on the brand part of the package, and to standardize the shape and format of the package. The Constitutional challenges launched by the tobacco companies against the Australian Government have been rejected by the High Court of Australia. The United Kingdom was the second country to implement these measures in 2016. Not all governments have the political will or the legal and other resources to defend against these. Nevertheless, the Australian success has served as a role model and the Australian court ruling will help governments, at least in common law countries, to defend and fight against new legal challenges.

Strong and increasing evidence shows that pictorial warnings are highly cost-effective in raising awareness and reducing tobacco use. The bigger the size of the warnings, the more effective they are. Some countries have also switched to the use of shocking images of diseased or damaged organs or dead bodies, including dead foetuses or babies. It is also important to start

using the most striking pictures, have a set of more warnings (Australia has now a set of 14 for plain packaging), and to require frequent rotations, with the printing costs totally borne by the tobacco companies and with minimal delay (as tobacco companies will produce many more packs before the law is passed and argue that they need many months or years to print new packs). The law should provide the health ministry the authority to change or update the pictures and warnings without having to amend the law. The warnings must be based on evidence that is considered sufficient for causation by most authorities. Information on pictorial warnings from all countries can be obtained from the Tobacco Labelling Resource Centre (n.d.) and the WHO warnings database (n.d.).

The tobacco industry has been fighting strongly in every country against such warnings, citing comments from smokers that they will take no notice of such warnings, and argues that printing such warnings increases production costs and affects the tobacco companies' rights to use their intellectual property to show their brand names and logos, jeopardizing freedom of trade and expression. In the United States, despite the Food and Drug Administration Rule in June 2011 requiring pictorial warnings to cover 50% of the package front and back as from September 2012, the implementation is on hold due to the successful legal challenge of the tobacco industry. The outcome of future legal proceedings is uncertain.

FCTC Article 11 (a) requires parties to ensure that 'tobacco product packaging and labelling do not promote a tobacco product by any means that are false, misleading, deceptive or likely to create an erroneous impression', and that 'These may include terms such as "low tar," "light," "ultra-light," or "mild" '(WHO 2003). Many countries still have tobacco products not complying with this article. The development and promotion of Chinese-style cigarettes as safer and healthier by the Chinese tobacco industry is particularly objectionable.

Although research has shown clearly that there is no completely safe form of tobacco, the tobacco industry continues to promote 'safer' cigarettes. There is evidence to show that such efforts have gained traction. The Global Adult Tobacco Survey in China (Chinese Center for Diseases Control and Prevention 2012) shows that more professionals and those with higher education believe that 'light' or 'low tar' cigarettes are safer. Because of the traditional belief in herbal medicine, adding such substances into cigarettes has been a major new effort by the Chinese tobacco industry to promote safer Chinese-style cigarettes.

Media campaigns

Mass media campaigns can be highly effective to raise awareness, motivate smokers to quit, and prevent young people from starting smoking. The effectiveness increases with the intensity of the campaigns, as well as the content and messages. Well-planned and sustained TV campaigns can reach most people, resulting in behavioural changes. Many antismoking videos have been systematically evaluated and confirmed to be effective in developed countries. However, the *WHO Report on the Global Tobacco Epidemic, 2011* showed a paucity of mass media campaigns against tobacco in many countries, especially in LMICs (Eriksen et al. 2012). The high costs of producing videos and broadcasting them on TV may be a factor, but could be overcome through global sharing of videos that have been shown to be effective, and by using alternative media such as YouTube and mobile phones. Further research, development, and evaluation are warranted.

Media campaigns are also needed to solicit public support for legislation and other government actions. Even when there is majority support for tax increases and smoke-free areas, objections from a small percentage of the population, sometimes leveraged on by the tobacco industry, can put great pressures on governments and legislators. Media campaigns to solicit public support need to be justified strongly by warnings that emphasize how many people, especially young people, will be killed by smoking, and such justification can further raise awareness.

Alternative ways to collaborate with the media should also be explored. Press conferences on local study results usually attract much media coverage, free of charge. The WHO's World No Tobacco Day is an annual event that can be linked to other broad-based activities that can garner substantial media reporting and commentaries. International news, for example, on important findings from medical journals, or on resolutions from the WHO or the FCTC can trigger the interest of local mass media. Public health advocates need to learn what the media want and how to work with them. For sustained effects, media campaigns need to be well-planned and repeated, with updated results and new activities.

Monitoring tobacco use and prevention

Prevalence of smoking

Globally, about 20% of all adults smoke cigarettes, consuming 5.9 trillion cigarettes in 2009. Even if smoking prevalence remains the same, tobacco consumption as a whole will increase due to the rising world population, especially in LMICs. China is the world's largest producer and consumer of cigarettes, accounting for 38% of global consumption. Because of its huge population and high smoking prevalence, China has the largest number of smokers (adults and youth) and smoking-induced deaths. The second to fifth highest cigarette-consuming countries are the Russian Federation, United States, Indonesia, and Japan.

Monitoring tobacco use is fundamental to our understanding of the extent of the epidemic, assessing the current and projecting the future burden of disease, and evaluating the effectiveness of prevention polices. The *Tobacco Atlas*, 4th edition (Eriksen et al. 2012), shows comprehensive world tables including prevalence in men and women, and in boys and girls. Sex-specific data are important since males and females have great differences in tobacco use. Time-trend data will become available for more countries. Interpretation of trend data where available should take into account variations in survey methods over time, and sampling errors.

In 1998, the WHO, US CDC, and Canadian Public Health Association initiated the Global Tobacco Surveillance System (GTSS) (Warren et al. 2009a) to help countries monitor tobacco use, using standardized methods in school-based and household surveys. The Global Youth Tobacco Survey (GYTS), Global School Personnel Survey (GSPS), Global Health Professions Student Survey (GHPSS), and Global Adult Tobacco Survey (GATS) started in 1999, 2000, 2007, and 2007 respectively (Warren et al. 2009b). The surveys are in progress, with greatest coverage for the GYTS as it started early. The GATS is a nationally representative household survey of men and women aged 15 or older. It includes: (1) tobacco use; (2) knowledge attitudes and perceptions; (3) cessation; (4) SHS exposure; (5) economics; (6) media; and (7) background characteristics. These surveys also provide essential data for monitoring prevention policies.

Other tobacco use

The tobacco epidemic started in the United Kingdom and United States with the invention of machines (in 1881 in the United States) for mass production of cigarettes, and the aggressive advertising and promotion of cigarettes by

the tobacco companies, before the serious health hazards were widely known. Tobacco use, however, also includes kreteks (Indonesia), roll-your-own cigarettes (Europe and New Zealand), bidis (South Asia, mainly India), pipes (worldwide), sticks (Papua New Guinea), water pipes (North Africa, the Mediterranean region, and parts of Asia), cigars (worldwide), and various forms of smokeless tobacco, including chewing tobacco (worldwide), moist snuff (Scandinavia and United States), dissolvable smokeless tobacco products (high-income countries), and dry snuff (Europe) (Eriksen et al. 2012). Since the mid-2010s, e-cigarettes or vaping has become increasingly prevalent, with 41 million users worldwide in 2018, up from 7 million in 2011. The long-term effects on health are currently uncertain.

The International Tobacco Control Policy Evaluation Project

The International Tobacco Control (ITC) Project is the first international cohort study on the psychosocial and behavioural impact of key national level policies of the FCTC (International Tobacco Control Policy Evaluation Project n.d.). ITC includes 20 countries with 50% of the world's population and 70% of the world's tobacco users and covers:

Health warning labels and package descriptors
Smoke-free legislation
Pricing and taxation of tobacco products
Communication and education
Cessation
Tobacco advertising and promotion.

Stages of tobacco epidemic

The patterns of smoking and tobacco-induced diseases, particularly lung cancer, vary greatly in different countries. Lopez et al. (1994) defined four stages of the tobacco epidemic, based on developed countries like the United Kingdom, United States, and Australia. Smoking prevalence rose rapidly since the 1900s, first in men peaking in the 1950s, followed by women about two decades later reaching a lower peak, and then declined since the 1960–1970s, after large numbers of smokers stopped. Tobacco deaths in men lagged this, peaking about three decades later in the 1980s and then declined

as a result of increased cessation, whereas in women, tobacco deaths continued to increase or plateau into the present century. This four-stage model highlights the long delay (about three decades) between widespread smoking and its full effects on mortality. It has been applied to other countries or regions, with sub-Saharan Africa in Stage 1, Latin America in Stage 2, Eastern Europe in Stage 3, and the United Kingdom in Stage 4.

A recent review of the model after two decades showed that in developed countries, the prevalence of smoking has continued to decline in both sexes and the proportion of deaths due to smoking has declined in men and continues to increase or plateau in women (Thun et al. 2012). Latest findings also support that tobacco deaths in the United States have plateaued in men but continue to rise in women (Thun et al. 2013). The model generally applies to men in developing countries but cannot predict when (or if) women will begin smoking in large numbers. Thus, modified criteria and separate models are needed to describe the epidemic entirely for men and women in developing countries. The long lag between peak tobacco deaths and peak tobacco consumption is a key reason for the lack of urgent action among governments and politicians.

Smoking in women

A limitation of this model is that it does not take into account the history and timing of tobacco control measures. Data from Hong Kong (Lai 2012) show that its downward male smoking trend (from 39.7% in 1982 to 19.9% in 2010) appears to be similar to Australia and the United States, but its female trend from 5.6% to 3.0% does not follow the model. About three decades ago, tobacco control advocates in Hong Kong predicted a great rise in female smoking prevalence, which did not happen. This could be due, at least partly, to the early introduction of tobacco control measures including a 300% increase in tobacco tax in 1983 (and 100% in 1991), and legislation restricting (1982, 1990, 1992, 1998, 1999, and 2007) and eventually banning tobacco advertising (2008).

Enforce bans on tobacco advertising

It is recognized that a comprehensive ban on advertising, promotion, and sponsorship would reduce the consumption of tobacco products. Before

restrictions on tobacco advertising in the mid-1960s, many high-income countries, such as the United Kingdom and United States, witnessed aggressive advertising especially targeting women. Now, 103 countries have some restrictions on tobacco marketing, but only 24 countries (10% of the world population) have banned all forms of direct and indirect advertising (WHO 2013a).

Partial restrictions are ineffective as the tobacco industry has many ways to bypass them. In Hong Kong, where all forms of tobacco advertising are banned but the display of cigarettes at retailing shops and newspaper stands is allowed, the tobacco companies pay large sums of money to expand the display area with spotlights on individual cigarette packs. The government has difficulty prosecuting this as newspaper stand and shop owners will protest such actions. LMICs should aim to move directly to a total ban. Some African countries have done so before the multinational tobacco companies have gained a foothold. Other countries like Thailand have banned the display of cigarettes.

Banning of indirect advertising is very difficult as some cigarettes share the same brand as non-tobacco products (brand stretching). In China, a famous and very expensive cigarette brand from Shanghai was named, many decades ago, ‘Zhong Hua’ meaning China. The tobacco company launched a campaign of ‘I love Zhong Hua’, featuring two Chinese characters in the same format as the cigarette logo. Some Chinese brands are named after a famous place or an animal (such as Panda). Bypassing advertising bans in this manner is increasing, but many governments have no experience or resources to prosecute them or the confidence that they will win in court.

Banning of sponsorship is the most difficult of all. The FCTC defines this as ‘any form of contribution to any event, activity, or individual with the aim, effect or likely effect of promoting a tobacco product or tobacco use either directly or indirectly’ (WHO 2003). Victoria in Australia was the first to use tobacco tax proceeds to establish a health foundation in 1987 to replace tobacco sponsorship. This successful example has been cited by tobacco control advocates in many countries, but few have succeeded (such as Thailand). Many organizations’ events and activities, politicians, legislators, researchers, and other individuals are receiving tobacco sponsorships/money. They are unlikely to support stringent tobacco control measures, and may join the tobacco alliance directly or indirectly. Governments need to ban offering and receipt of all forms of tobacco

sponsorships. Interim measures could include legislation requiring disclosure and policies forbidding such sponsorships. To help implement and enforce comprehensive bans on tobacco advertising, promotion, and sponsorship, the WHO has developed a 3-day training workshop for LMICs (World Health Organization and International Union Against Tuberculosis and Lung Disease 2011).

Protect people from tobacco smoke

A major breakthrough in tobacco control was the designation of smoke-free areas to protect people from SHS, and the related non-smokers' rights movement starting in the 1980s in the United States. Banning of smoking in public places by law has been introduced, often progressively from a partial to total ban, and is expanding to include all public places (from indoor to outdoor) and all indoor workplaces (public and private). Further bans were introduced in outdoor areas in some countries, such as busy streets in Japan. With overwhelming public support, Singapore has recently extended the smoking bans to the common areas of residential buildings, covered walkways, pedestrian bridges, a 5-metre radius from the edge of bus stops, and outdoor compounds of hospitals. The number of people protected by comprehensive smoke-free laws has doubled from 2008 to 2010, but 89% of the world's population remain unprotected (Eriksen et al. 2012).

Public support is strong only in countries where awareness of the harms of SHS is high together with strong political will of governments. The tobacco industry has worked to oppose this, building alliances with smokers' rights groups and others who may be adversely affected, such as the hotel and catering industry. Some restaurant workers or their unions are mobilized by their employers, with support from tobacco companies, to protest. The tobacco industry will lobby governments and legislators and repeatedly argue that banning smoking in restaurants and bars will result in loss of customers, revenue, and jobs. However, in all jurisdictions, implementation of smoke-free laws has mostly resulted in no changes or increased restaurant sales, and savings in cleaning costs and reduction of fire risks.

A total ban is needed to eliminate SHS exposure. However, the tobacco industry is often successful in exploiting loopholes in such laws (such as no legal liability or penalty for venue owners or managers if they allow smoking in their statutory smoke-free areas in Hong Kong). Many restaurant

owners still believe that their business will suffer from total smoking bans, particularly in LMICs. Public health advocates must distinguish between the tobacco companies and venue owners even when they form an alliance. Mass media and other campaigns, such as motivating students and other non-smokers to demand smoke-free dining areas, are effective ways to change the minds of some restaurant owners and workers. Some will never be convinced but all will want a level playing field such that any new laws should equally apply to all venues; allowing some restaurants to have smoking areas but not others will not work.

A national smoke-free law is needed but in China, only some major cities have started to introduce local smoke-free legislation. However, enforcement is weak, penalties for violation low, and compliance is expectedly unsatisfactory. Mass media campaigns are needed before the implementation of the new law. Initial law enforcement with substantial penalties is essential to convince the public and venue owners about the government's seriousness. Effective enforcement of comprehensive smoke-free legislation saves lives by reducing heart attacks, increasing quitting in the population, and reducing smoking among employees (Glasgow et al. 1997).

Raise taxes on tobacco

Raising taxes is the most effective way to reduce tobacco consumption quickly. Repeated and sufficiently high increases in tax drove the decline in consumption especially in high-income countries a few decades ago. On the other hand, with economic development and increasing incomes in LMICs such as China, the reduction in real tobacco prices has substantially contributed to increasing consumption. High prices are particularly effective in preventing the uptake of smoking in the young and reducing consumption among low-income people, with more quitting in both groups. Strong evidence has come from both high- and LMICs, such as the United Kingdom, South Africa, Morocco, and Israel (Eriksen et al. 2012). A more recent example is from France, where tripling the price of cigarettes has halved consumption and doubled government revenue in 2003–2004 (Gallus et al. 2006).

The seminal World Bank report in 1999 states that all evidence from high- and LMICs shows that price increases are highly effective in reducing demand. The statement that 'On average, a price rise of 10% on a pack of

cigarettes would be expected to reduce demand for cigarettes by about 4% in high-income countries and by about 8% in low- and middle-income countries' (World Bank 1999) has been widely cited. The *Tobacco Atlas*, 4th edition (Eriksen et al. 2012) shows different degrees of reduction, 2–6% in high- and 2–8% in LMICs. The model in the World Bank report shows that raising prices by 10% worldwide would result in 40 million smokers quitting in 1995 and preventing at least 10 million deaths. This estimate is conservative because if one in two smokers will be killed by tobacco, 40 million current smokers quitting would prevent about 20 million deaths. As price increases will also reduce uptake of smoking in young people, there will be further reduction of deaths in the more distant future.

Big variations in the excise tax as a percentage of cigarette prices are shown in the *Tobacco Atlas*. The WHO recommends that excise tax should reach at least 70% of the retail price but only five nations have achieved this standard (Eriksen et al. 2012). The World Bank proposes that taxes should account for two-thirds to four-fifths of the retail price (Mackay et al. 2006). Tobacco tax increase can also generate additional income for governments. As of 2010, at least 166 WHO Member States have imposed a tobacco excise tax, and at least 27 of them used a portion of the tobacco tax revenue for health purposes. Numerous economic analyses have shown that the economic costs of tobacco, including lost productivity and health and other expenditures from tobacco-induced disease burden, are greater than tobacco tax income. The 2012 Asian Development Bank report estimated that in China, India, Philippines, Thailand, and Vietnam, a 50% price increase would reduce tobacco deaths by over 27 million, and generate over $27 billion additional revenue annually (Asian Development Bank 2012).

Given these data, it is not clear why most governments have not implemented the WHO recommendation of at least 70%, even after they have ratified the FCTC. Collusion between the tobacco industry and government officials, the loss of tobacco tax revenue if consumption falls sharply, or inadequate funding allocation for tobacco control in LMICs are possible reasons. More research is needed to find the root causes for this, and effective ways to convince governments to do so.

Any tax increase is not welcomed in general by the public and may lead to dissatisfaction towards governments, which could result in protests and unrest. The economic argument that reduction of tobacco use can save healthcare expenditures has little direct immediate impact because such

savings are only realized in the future. A very strong argument from opponents is that high taxes will result in increased smuggling, making cheaper illicit cigarettes more available to many low-income smokers, especially the young. However, a recent report showed that tax increases in the United Kingdom have not led to increased smuggling.

Tobacco industry

In celebrating the fifth anniversary of the FCTC, WHO Director General Dr Margaret Chan said, 'the tobacco industry is ruthless, devious, rich and powerful. As we all know, neither WHO nor public health is rich, but with the Framework Convention now in place, we are indeed powerful' (WHO 2010). It is the only industry that has been openly and repeatedly discredited, condemned, and shamed by WHO.

The tobacco industry is dominated by several multinational tobacco companies. The China National Tobacco Corporation is the largest state-owned enterprise producing the greatest number of cigarettes in the world. Despite the progress in tobacco control in some countries, and the FCTC, the tobacco companies remain some of the most profitable in the world (Eriksen et al. 2012).

Tobacco company documents

Research and numerous reports have exposed the tobacco industry's various antipublic health measures. Most of the findings are based on the analysis of millions of pages of internal tobacco company documents exposed since 1994 and during litigation proceedings against the tobacco companies in the 1994 seminal judgement in the United States, now deposited in Minnesota, United States and Guildford, United Kingdom (Mackay et al. 2006; Shafey et al. 2009). These documents are still under-researched but are now easily accessible for public health professionals and researchers, particularly those interested in what the tobacco industry had said about their countries or regions and strategies including the targeting of children or women. They provide insights into the varied strategies employed by the tobacco industry to promote the continued use of tobacco among different communities and population segments (Mackay et al. 2006; Shafey et al. 2009; Eriksen et al. 2012; WHO 2013b).

Tobacco corporate social responsibility

The tobacco companies spend huge sums of money in funding smokers' groups, tobacco associations and institutes, and other alliances to oppose tobacco control measures; funding researchers to challenge the evidence of tobacco harms particularly from SHS; funding research but suppressing or distorting unfavourable results; and funding government and non-government organizations and various events or programmes on education, arts, culture and sports, environmental protection, and medical, health, or rehabilitation programmes to promote cigarette brands and corporate image and to buy in supporters or silence potential opponents (WHO 2013b).

Youth Smoking Prevention (YSP) programmes, funded by the tobacco industry, are particularly deceptive and troubling. These are ineffective as they focus on young people only and portray smoking as an adult habit thus making it more appealing for adolescents. YSP programmes have attracted NGOs interested in adolescent health, community leaders, and schools who do not understand their motivation. This has created much confusion and frustration for tobacco control advocates, who need to be extremely cautious about how to expose the tobacco connections and ineffectiveness of YSP programmes, yet not to alienate those who have been deceived. The WHO booklet from Western Pacific Regional Office on YSP is an invaluable resource (WHO 2003). How should youth programmes be organized that can be distinguished from YSP? In Hong Kong, the strategy is to promote the WHO booklet (Ho et al. 2010) and to launch youth quitting programmes instead of smoking prevention programmes. It is useful to bear in mind and emphasize that the great majority of young people do not smoke. Overemphasis on youth smoking may result in overestimation of peer smoking in adolescents, which can increase adolescent smoking (Ho et al. 2010).

The tobacco industry has not changed, as evidenced by their current efforts to use litigation and legal threats against governments that are planning or have introduced new control measures. The *Tobacco Atlas*, 4th edition, lists legal challenges against tobacco control measures by the tobacco industry in 18 countries (Eriksen et al. 2012). The tobacco companies will launch more of these in more countries. Some tobacco control advocates in the West have called for government to buy the tobacco companies to control them. However, the example of China's national tobacco monopoly indicates that the result could be even worse. Some

tobacco control advocates in China have called for the separation of the administration arm, which can then monitor and control the enterprise arm more independently.

Should governments sue the tobacco industry? A major landmark was the success of the US government's 1999 lawsuit which resulted in the major tobacco companies paying settlements of US$206 billion over 25 years to 46 states to compensate for government spending on smoking-related healthcare (Gruber 2001). The number of antitobacco legal cases has been increasing but only slowly. The ultimate legal defeat of the tobacco industry would be to make tobacco illegal.

WHO FCTC

The FCTC is an evidence-based treaty and a paradigm shift in developing a regulatory strategy on demand reduction and supply issues (WHO 2003). The success of the FCTC has prompted and inspired public health advocates to call for similar treaties, such as a framework convention on alcohol control (FCAC) (Casswell and Thamarangsi 2009; Lam and Chim 2010). The FCTC is a readable, action-oriented document that can be used by governments, public health professionals, and the public. It has led to a global movement and is a strong lobbying document to pressurize governments to comply with the international treaty that they have ratified. The FCTC only stipulates the minimum that governments must do, and Australia's plain packaging in 2012 clearly shows that more can be done.

Countries that have not ratified the FCTC are under great pressure to ratify. Many governments have not yet fulfilled their obligations to comply fully with the FCTC, and these are reported regularly in WHO MPOWER reports.

The FCTC is governed by the Conference of the Parties (COP), which comprises all Parties (countries or jurisdictions) to the Convention. It reviews and makes decisions to promote its effective implementation, and adopts protocols, annexes, and amendments to the Convention. Starting from COP3, the regular sessions of COP are held biennially.

The Protocol to Eliminate Illicit Trade in Tobacco Products, in pursuance of FCTC Article 15, is the first protocol adopted by the COP as effective, appropriate, and comprehensive domestic and international responses to

eliminate all forms of illicit trade (WHO Framework Convention on Tobacco Research 2012).

Framework Convention Alliance

The FCTC is not just for health ministries or governments. NGOs have played key roles from the beginning of its negotiation, and their influence is expanding. The Framework Convention Alliance (FCA) created in 1999 has over 350 organizations from more than 100 countries. It is a civic society alliance whose mission is to help develop and implement the FCTC as the basis for effective global tobacco control (FCA n.d.). The FCTC has become the benchmark for the evaluation of the performance and effectiveness of tobacco control measures of parties, countries, or regions. For example, those who have been performing badly are being shamed by The Dirty Ashtray Award by civil society; China received one such award for making excuses not to print warning pictures on cigarette packing at COP3 in 2008.

FCTC and UN Political Declaration on NCDs

The FCTC has laid the foundation for the 2011 UN Political Declaration for the control of NCDs, and now the reverse is happening. As a follow-up to the UN Political Declaration, WHO is consulting on the development of the NCD Global Monitoring Framework (WHO 2012b) and the Global Action Plan on NCDs (2013–2020) (WHO 2012c). After lobbying by the FCA, the draft Global Action Plan on NCDs (10 October 2012) now explicitly promotes the FCTC and urges all WHO Member States to accelerate its implementation. While the NCD Global Monitoring Framework includes a tobacco smoking target (voluntary, to be determined), FCA further advocates to monitor specific process and impact indicators on the implementation of FCTC policy measures. There will be rapid and major developments on all these fronts.

Research and evaluation

The FCTC is based on solid research conducted mostly in high-income countries. Evidence from LMICs is inadequate. Progress in policies and implementation in some countries has been rapid and great, and previous

experiences and evidence can become outdated while the impact of new measures needs to be rapidly evaluated to guide further action. In countries with slow progress, the lack of funding and research is very serious. Their needs for local data and evidence are more urgent and should be most relevant for local policies and implementation. Further and relevant research is needed for all countries to support and evaluate the implementation of the FCTC. The Global Network of the Society for Research on Nicotine and Tobacco (SRNT) has published a series of papers in a themed issue of *Nicotine & Tobacco Research* on the research requirements and needs for all the FCTC articles to support specific policies and practices (Leischow et al. 2012). This is a most thorough analysis of the state of science to provide new directions and priorities for research. A commentary by Mackay emphasizes that 'advocates and activities MUST keep their feet firmly based in science, and never stray from that science' but 'The need to bridge the existing gaps between research, policy, and practice appears to be a global phenomenon' (Mackay 2013).

Offer help to quit tobacco use

Quitting smoking saves lives and the earlier the better. In cancer patients, increasing evidence shows that quitting smoking can improve the effectiveness of treatment and survival and more successful trials are needed to motivate HCPs to help such patients to quit (McBride and Ostroff 2003; Parsons et al. 2010).

Most successful former smokers quit without pharmaceutical therapy or professional services ('cold turkey'). They do have different experiences including past failures that deserve further study. On the other hand, effective treatments are available which have helped many to quit. The pursuit for more effective pharmaceutical treatments, including nicotine vaccination will go on, as the existing treatments are expensive and failures common.

The 1990 USSG report on smoking cessation was the first comprehensive review about the benefits of quitting (US Department of Health and Human Services 1990). The excess risk of ischaemic heart disease is reduced by half after stopping for 1 year, but it takes 10 years of quitting for lung cancer risk to reduce to 30–50% of continuing smokers. The 2007 IARC report on risk reversal, the most recent comprehensive review, concludes that the evidence

is adequate for: (1) lower risk in former smokers; and (2) lower risk with prolonged abstinence for lung, laryngeal, oral, oesophageal (squamous cell), pancreatic, bladder, and cervical cancer (seven items), and CHD incidence and death in subjects with or without the disease, cerebrovascular incidence, and death in those without established disease (three items), and cough and phlegm, decline in forced expiratory volume in 1 second in healthy subjects, and those with mild to severe disease and COPD mortality (five items). For overall mortality, those 'stopping at 60, 50, 40 or 30 years of age gain, respectively, about 3, 6, 9 or almost the full 10 years of life expectancy, in comparison with those who continue to smoke' (IARC 2007). Those who stopped smoking before middle age, at about 20–30, avoid nearly all of the future mortality risks from tobacco (Doll et al. 2004; Pirie et al. 2013).

Quitting or preventing uptake?

Uptake prevention and quitting have different target subjects and need different strategies. Most people intuitively support very strongly the prevention of smoking in children and young people and believe that this is the *most* important measure. They want more health education against youth smoking and consider health education in schools the most important action. Such a belief is exploited by the tobacco industry's YSP programme.

The 1999 World Bank report states that if quitting results in reducing adult cigarette consumption by half by the 2020s, about one-third of tobacco-related deaths in the 2020s would be prevented and almost half would be prevented thereafter, preventing 20 or 30 million tobacco deaths in the first quarter and 100 million in the second quarter of this century. If young smokers are reduced by half by the 2020s, hundreds of millions of tobacco deaths would be prevented after 2050. This would prevent none of the 150 million tobacco deaths in the 2020s, about 10–20 million out of 300 million in the second quarter of the century. Hence, quitting will prevent more deaths more quickly in the first half of this century than that from preventing young people from starting, although the latter is also important for preventing deaths in the second half of the century.

Nicotine dependence or habit

Smoking is often wrongly described as a habit or a personal choice. Nicotine is strongly addictive and most smokers are both nicotine and psychosocially dependent. The Fagerstrom test is the most commonly used test to measure nicotine dependence (Heatherton et al. 1991). But the term 'nicotine addict' is seldom used to describe heavily nicotine-dependent smokers and the term 'treatment of nicotine dependence' is much less frequently used than 'smoking cessation therapy'. HCPs need to understand why smokers frequently fail in their attempts to quit, or relapse after a short time.

Smoking cessation interventions include smoking cessation clinics (which vary from simple counselling to specialized in-hospital treatment) or telephone quitlines, smoking cessation advice, and counselling during routine consultation, and pharmacological aids and therapies. Most of these have been confirmed by numerous trials to be effective and more cost-effective than other medical treatments. The Cochrane Library should be consulted for updated reviews and conclusions (Cochrane Review Groups n.d.). Effectiveness means greater quit rates after interventions than no interventions, but failures occur more often than successes.

The seminal randomized controlled trial by Russell (1979) that brief advice by general practitioners in the United Kingdom increased the quit rate from 0.3% to 3.3% has led to a strong argument that if all physicians can spare a little time advising patients to quit, even though the absolute quit rate is low, many smokers will benefit, resulting in major community impact. Thirty years later, the review by Aveyard and Foulds (2009) showed that a brief intervention of at least 1 minute is effective (versus no intervention). However, most clinicians are too busy to spare even 1 minute and many feel incompetent. They also do not have any incentive, support, or pressure to do so. Such barriers are still common in both high- and LMICs. To address these issues, a simple 30-second pilot intervention emphasizing a 'one in two risk' was recently conducted in China with promising results (Lin et al. 2013).

Do most smokers want to quit?

The 2008 MPOWER report states 'Among smokers who are aware of the dangers of tobacco, three out of four want to quit' (WHO 2008) without specifying the country. But the reference (Jones 2006) indicates that this statement is based on a survey of US adults in 2006 and it should be noted

that the denominator is *not* all smokers. While this may be true in countries at the late stage of the tobacco epidemic, the Global Adult Tobacco Use Surveys in China and other LMICs show that most smokers do not intend to quit (Cooper et al. 2010; Chinese Center for Diseases Control and Prevention 2012). A deeper understanding of the smoker's intention and the strength of their motivation or determination to quit or reduce smoking can guide public health policies and planning on cessation services. Social support from family, friends, co-workers, and employers is needed.

Clinical or public health approaches?

During the early years of tobacco control, the emphasis was mostly on public health measures such as legislation and taxation. These measures were deemed more effective than clinical services that target individual smokers, especially since few physicians or HCPs were prepared to act. The high costs of clinical services also rendered them less cost-effective. The controversy over these two approaches has become more complex as effective pharmaceutical treatments have become available (Chapman and MacKenzie, 2010; West et al. 2010). While the Bloomberg Initiative to Reduce Tobacco Use does not support smoking cessation services for individuals, these services are rapidly developing elsewhere, such as in the United Kingdom. More quitlines and international quitting campaigns such as Quit and Win have also been developed. The WHO has provided detailed guidelines for setting up and running national quitlines, especially in LMICs (WHO 2011).

Quit rates for all the existing nicotine replacement therapies and drugs are not high as most users fail to quit after receiving treatment. The costs are high and adherence is low. The high failure rate is demoralizing. The 5As in the United States (ask, advise, assess, assist, arrange) has been one of the most referenced guidelines (Cornuz and Willi 2008) but these are too demanding for busy HCPs. Simpler guidelines or methods are recommended such as ABC in New Zealand (McRobbie et al. 2008). Development and randomized controlled trials of shorter advice of less than 1 minute are needed (Lam 2012; Lam et al. 2012).

Public health professionals need to understand that the clinician's job is primarily treatment. If clinicians are frustrated by failures of smokers to quit despite their efforts, they should be made more aware and become more

motivated to support or join in public health advocacy campaigns. Clinicians and their professional organizations are strong allies for public health in general and tobacco control in particular. Public health professionals should collaborate with clinicians to develop more effective measures to increase cessation in individual smokers and in the population.

Pilot cessation clinics

In LMICs, many physicians are smokers, and they seldom advise their patients to quit smoking. Some smoke quite openly, if smoking is allowed in the healthcare settings, such as hospitals. Even non-smoking HCPs are mostly inactive (Lam et al. 2011). In recent years in China, smoking cessation clinics have been established in many hospitals as a requirement for designation as smoke-free hospitals. This was also done to comply with the FCTC. But most clinics have attracted few smokers, from the hospitals and the community. Opening a clinic without strong support from top management, including adequate funding, capacity building, and incentives for HCPs, will not work. Lacking strong tobacco control measures in the greater environment, and funding to promote the cessation clinics, the wait for smokers to come will be in vain.

As a first step, introducing a pilot smoking cessation clinic with provision of training and support can motivate a hospital and its management and some HCPs to become interested, firstly in treatment, and then in tobacco control in general. The pilot can act as a springboard, bringing tobacco control advocates into a hospital to train interested HCPs in both smoking cessation intervention and tobacco control advocacy. With a core of trained HCPs, the clinic can become a focal point for further actions, such as implementation of smoke-free hospital policy, and extending beyond the clinic and the hospital into the community, such as supporting smoke-free workplaces and tobacco tax increases or public education campaigns in the neighbourhood. The clinic can also motivate the smoking HCPs to quit smoking, or to discourage smoking within the hospital, and become a training site for other staff and medical and other students.

On the other hand, public health professionals should work closely with clinicians to set up strategies for proactive approaches to help smokers outside the clinic, such as in the wards and outpatient departments and to promote quitting and tobacco control within and beyond the hospital to

develop the cessation clinics into tobacco control advocacy centres. Systematic evaluation of the impacts and sharing of experiences are essential for further improvements and development.

Smoking cessation can also act as the ‘carrot’ for the ‘stick’ of government proposed policies to expand smoke-free places and increase tobacco tax. Tobacco control opponents often argue that the policies are unfair to smokers and unkind to the poor, leaving the smokers nowhere to smoke and depriving the poor of their only affordable pleasure. Many government officers have difficulty responding to such allegations. If government-subsidized free smoking cessation services are offered, the simple answer is that smokers are encouraged to quit using the pilot clinics. If they quit, they will not need to find permissible places to smoke and will save a lot of money for more healthy and pleasurable commodities for the whole family.

Some government officers also feel that because there are so many smokers, they will not have the resources or capacity to open an adequate number of cessation clinics to cope with the demand. Some even feel that smokers should pay for the services, using the money saved from buying cigarettes. In reality, only a small percentage of smokers will visit cessation clinics, and many more will quit by themselves, often with social support from the family and others. A few cessation clinics or a quitline should therefore be sufficient and the sudden increase in visits and calls serves as an indicator of the effectiveness of the new control measures. Furthermore, if all or even a percentage of the excess revenue arising from the increase in tobacco tax is used to support smokers to quit and to promote quitting, governments will have a strong justification that part of the money obtained from smokers will be used to benefit the smokers.

Quitting or smoking reduction?

Many smokers who claim that they have reduced smoking may not be reporting the truth, and total abstinence is the only proven way for the benefits to be realized. Smoking reduction may be a distraction from total abstinence. Evidence for the benefits of smoking reduction and organized or regular services or campaigns focusing only on smoking reduction are scarce. But there are many smokers who do not want to quit completely but are willing to reduce smoking. New evidence has shown that helping such

smokers can increase quit rate and reduction (Chan et al. 2011). Smoking cessation campaigns and services will not attract such smokers. New approaches are needed to assess the needs of smokers who are not willing to quit and to recruit and help them to reduce, and to follow-up and evaluate further whether such approaches are effective in eventually helping the smokers to quit.

Controversies of harm reduction

Evidence, mainly from Sweden, that smokeless tobacco users have a lower risk of lung cancer and other diseases than cigarette smokers, has triggered debates about switching from cigarettes to smokeless tobacco as a harm reduction measure (WHO 2003). Opponents to such switching argue that it does not reduce the harm substantially, and promotion of switching can be seen as promotion of smokeless tobacco use resulting in reduced motivation to quit. It may also increase uptake of smokeless tobacco use in young people. More broadly, such strategies effectively entail the replacement of nicotine from tobacco use with nicotine-containing products (Foulds and Branstetter 2012). The debate is continuing, but the tobacco companies are moving fast to promote smokeless tobacco and develop other nicotine products. The UK National Institute for Health and Care Excellence (NICE) has released draft guidance for consultation, which includes nicotine replacement therapy (NRT) and e-cigarettes but excludes smokeless tobacco (NICE 2013).

Endgame or endless war?

The rapid reduction of smoking prevalence in some countries, the increasing impact of the FCTC, and strong political will of some governments have led to optimism and aspirations that a smoke-free country has become reachable within 20 years. The Bhutanese 2004 law aims to end tobacco sale, the 2010 Finland Tobacco Act aims to end tobacco use, and the US government has the ‘vision of a society free from tobacco-related death and disease’ (US Department of Health and Human Services 2012). In March 2011, the New Zealand government committed to become an essentially smoke-free nation by 2025 and the website has much information on policies and actions (Smokefree New Zealand 2025 n.d.).

On the other hand, the war against tobacco and the tobacco industry has just begun in many LMICs, where political will is lacking to fight wholeheartedly. For the pessimists, new tobacco control advocates, and younger public health professionals, this appears to be an endless war, sometimes with more battles lost than won. However, a careful review of past battles, globally and in many countries with more advanced tobacco control measures, indicates many more victories, every one of which had been fought initially by only a few dedicated and courageous people (Lam 2013). Fighting a battle today anywhere is much easier than it was a few decades ago. We now have the FCTC and another new international treaty under the FCTC (COP5) and more will be forthcoming. We also have the UN Declaration against NCDs (and tobacco). When we are facing the aggressive challenges from the tobacco industry including suing governments, we know Big Tobacco is desperate and that eventually, the public health goals will prevail, despite occasional loss, compromises, and setbacks. For public health professionals, our experiences in tobacco control will guide us to tackle the other three risk factors. If tobacco cannot be controlled successfully, the chances for success in controlling the other risk factors will be slim. Fighting against the risk factors and NCDs will be an endless war, as promoting health and well-being of all people will be our never-ending mission.

ACKNOWLEDGEMENTS

We thank Dr L. Xu for her help in literature search, referencing, and preparing the figures. Our sincere gratitude goes to Professors J. Mackay and R. Peto, who have been inspirational and supportive to our research and public health advocacy on tobacco control.

9.2

Substance use and misuse

Considerations on global public health

Giang Le Minh and Steve Shoptaw

Psychoactive drug use and public health: introduction

Use and misuse of psychoactive drugs present major public health problems in most countries. Nicotine (in the form of tobacco products) and alcohol are the most commonly used and misused psychoactive drugs, and account for the greatest mortality and morbidity related to psychoactive drug use. Since nicotine and alcohol are discussed in Chapters 9.1 and 9.3, this chapter provides an overview of the epidemiology of psychoactive drugs, in particular cannabis, opiates, amphetamine-type stimulants (ATS), and cocaine.

The United Nations Office on Drugs and Crime (UNODC) compiles annual prevalence estimates of the use of various illicit psychoactive drugs and assesses trends over time. In the most recent *World Drug Report* published in 2019 the UNODC estimated that 271 million people, or 5.5% of the adult population (persons aged 15–64), used an illicit drug in 2017 (UNODC 2019). Of these, about 13% of persons using drugs were considered to use at levels that cause problems or drug use disorders (UNODC 2019). Prevalence of drug use disorders globally was relatively stable from 2009 to 2016; however, a small increase was observed in 2017 in large part due to findings of increased drug use in Nigeria and India (UNODC 2019). With respect to the use of specific illicit drugs, the UNODC estimated that cannabis was by far the most commonly used drug in 2017 with 3.8% of adults having used it in the previous year, followed by opioids (1.1%), ATS (0.6%), and cocaine (0.4%). Yet production continues to increase worldwide. In 2017, opium production reached 10,500 tonnes,

breaking the record since the beginning of twenty-first century (according to UNODC estimates). Cocaine manufacture also reached its highest level ever—1,410 tonnes in 2016. The quantities of other drugs such as amphetamines or new psychoactive drugs intercepted worldwide in the same year increased several times as well.

Involvement in substance use introduces serious consequences to health of individuals and societies among all nations. The Global Burden of Disease (GBD) study (https://www.theLANCET.com/gbd) estimates the numbers of deaths and disability-adjusted life years (DALYs), which is the sum of years of life lost due to premature death and years lived with disability by specific countries and by specific diseases. In 2017, there were approximately 585,000 deaths and 42 million years of 'healthy' life lost as a result of the use of drugs worldwide. Years of life lost due to premature death were attributed to approximately half of DALYs. Globally, the number of DALYs and deaths attributed to drug use has increased by 134 and 81%, respectively, over the past three decades (UNODC 2019). Despite the modest numbers of adults who use illicit drugs compared to alcohol and tobacco, they generate many costs to society, including lost productivity, increased disability and deaths, disruption of family and other social relationships, and costs of increased law enforcement and incarceration.

Research over the last two decades has increased understanding of the mechanisms of development and sustained expression of substance use disorder over the lifespan. This includes: (1) there is great individual variation in reactions to drugs; (2) repeated drug use leads to changes in brain cells (neurons) and the ways they communicate, particularly in systems related to reward, reinforcement and decision-making; (3) outcomes to treatment of substance use disorders (SUDs) involve ceasing (or cutting down) substance use *and* returning to abstinence following lapse or relapse; (4) SUDs are chronic and relapsing—there is no 'cure'—though effective treatments exist; (5) globally and across cultures there are strong similarities in how SUDs present; and (6) drug use is contemporary, with always changing complexities of the specific drugs used, their combinations, and the interventions that ameliorate harmful effects of drugs on the brain and behaviour. While knowledge of mechanisms underlying SUDs is likely to continue to increase rapidly, it is unrealistic to expect that there will be any 'magic bullet' breakthroughs for either the treatment or prevention of SUDs in the near future. As such, the public health challenge

is to support policymakers in understanding and responding to SUDs using models for managing other chronic diseases that in parallel fashion require ongoing treatment over the lifespan.

Global epidemiology and social determinants of substance use and substance use disorders

Geography is not necessarily destiny with respect to what drugs a person might use, but there are strong geographical patterns in the use of different drugs. The information on geographic differences in use of specific drugs that follows is summarized from the *World Drug Report* (UNODC 2019). The *World Drug Report* is based on reports from various participating countries producing variation in data quality; consequently, these data should be interpreted as estimates. Law enforcement information, particularly on seizures of drugs, is also used in assessing trends in international drug use. Despite some limitations, the *World Drug Report* is the best available single source on global use of illicit drugs.

Cannabis

Cannabis is the most prevalent of illicit substances used globally with 188 million individuals estimated to use cannabis worldwide in 2017. Cannabis products are most often smoked, but can be taken orally. In addition to the use of cannabis for its psychoactive properties, many around the world use cannabis and related products (e.g. cannabidiol) for relief of a range of medical complaints and conditions. Cannabis cultivation has increased in recent years, although many of the increases are small-scale growing operations. While the cannabis herb is prevalent in most countries, cannabis resin, or ‘hashish’, is more common in locations including Afghanistan, the Middle East, and small pockets of Western Europe and northern Africa. Among adults, the highest level of cannabis use is reported in North America (13.8%), followed by Oceania (10.9%), and West and Central Africa (10.0%). The prevalence of cannabis use among adults in Asia is low (1.8%); however, given the very large population of the region, it remains the largest population of individuals using cannabis worldwide. The relationship between cannabis exposure and health and psychosocial

deficits is documented, though a causal relationship is uncertain (Hasin 2018). For these reasons, and in the face of the failure of prohibition, decriminalization and legalization of cannabis use are increasingly advocated for in Europe and North America in the face of the failure of prohibition (van Ours 2012).

A novel health threat to cannabis and tobacco use involves lung health problems linked to using ‘vapes’, equipment that vaporizes oils and waxes for inhalation instead of burning combustible materials to produce smoke. Marketers of these devices promote fewer health risks to vaping cannabis and tobacco as smoke is not inhaled into the lungs. Even when considering the negative consequences to smoking combustible cannabis and tobacco, observations of severe lung disease, lung infections, and deaths that correspond with use of vaping devices elevate health concerns. These vaping instruments and cannabis and tobacco products are all unregulated complicating attribution of cause for severe illnesses and deaths linked with their use. In light of these factors, current medical opinion is to avoid vaping to administer cannabis and tobacco products (Christiani 2020).

Opioids

Among the 53 million people who used opioids worldwide in 2017, risk for overdose and death is high with two-thirds of deaths from drugs occurring in people who use opioids. Opioids are prescribed to relieve pain (predominantly oral medications), but opioids also can be injected or smoked for their euphoric properties (predominantly heroin). The highest levels of opioid use among adults were in North America (4.0%), Oceania (2.5%), South-West Asia and the Near and Middle East (2.3%), and South Asia (1.8%), all of which were higher than average global prevalence. It is important to note that those using prescription opioids outnumber those using heroin in North America and Australia, while in South-West Asia and the Near and Middle East and South Asia heroin is the main opioid of use. Deaths from the opioid epidemic in the US are alarmingly high and are now accounted mostly by increased use of synthetic opioids (such as fentanyl), often in combination with cocaine and methamphetamine (Hedegaard et al. 2018). In Europe, heroin use was the opioid used for most of the individuals who sought drug treatment.

Amphetamine-type stimulants (ATS)

Illicit use of ATS, which includes amphetamine, methamphetamine, and methylenedioxymethamphetamine (MDMA, ecstasy) is difficult to measure globally, complicated by small-scale local producers of these drugs, but was estimated to involve almost 50 million adults globally in 2017. The quantity of ATS seized from 1998 to 2017 increased more than tenfold, substantially more than cannabis, opioids, and cocaine, though, opioid seizures dominated drugs seizures from 2013 to 2017 (UNODC 2019).

ATS (excluding ecstasy) is most prevalent in Oceania—especially Australia (Farrell et al. 2019)—and North America, while there is evidence of increasing use in Asia, especially given increased seizure of methamphetamine in the region (UNODC 2019). ATS can be taken orally, smoked (e.g. 'ice'/crystal methamphetamine) or injected (excepting ecstasy, which is taken orally), and with strong positive attributes (especially for cocaine and methamphetamine) that include inducing euphoria, brightening mood, dampening appetite, increasing energy, sharpening body experiences (especially during sex), and focusing attention. Methamphetamine is considered to be the most worrisome ATS due to its neurotoxicity, addictiveness and the high burden of care associated with methamphetamine use disorder (Courtney and Ray 2014; Farrell et al. 2019). Despite lack of data in East and South-East Asia, there is a growing concern about methamphetamine use and methamphetamine-related issues in this region. East and Southeast Asia are the largest manufacture regions of methamphetamine worldwide. Trade routes often used for cocaine trafficking are increasingly also being used for ATS trafficking, with evidence of spillover into West Africa. At a prevalence of 0.4%, ecstasy use globally is comparable to cocaine use in the adult population, but higher rates are observed in specific regions including Oceania (1.7%), North America (0.9%), and Western and Central Europe (0.9%). Ecstasy, in particular, tends to be prevalent in young people and has recently seen a resurgence in use among the younger demographic after a period of stability or even decline from 2007 to 2012.

Cocaine

Cocaine consumption among adults has remained relatively stable with approximately 18 million users worldwide in 2017 (UNODC 2019). Cocaine is taken intranasally (powder) or smoked (crack), but also can be injected. Cocaine use is most prevalent among adult populations in North America (2.1%), Western and Central Europe (1.3%), and Oceania (1.7%). While cocaine use decreased or stabilized in the Americas and Europe by 2010, there have been increases in these regions as of 2017. Cocaine use increases correspond with increases in cocaine bush cultivation in South America a region where cocaine use accounts for a third of patients in treatment for SUDs. While limited data exist in Africa and parts of Asia, there are indications that there is increasing and emerging use of cocaine in those regions; this may reflect the increased trafficking of cocaine through these areas. Although increased cocaine use globally may be occurring, treatment for cocaine use makes up a small proportion of all drug admissions in all locales except Central and South America.

New psychoactive substances

New psychoactive substances (NPS), relative potency plant-based, or synthetic chemical compounds that mimic the effects of most types of drugs such as cannabis, opioids, hallucinogens, or stimulants, first emerged since the early 2000s in Western countries and late 2000s in Asia (Zawilska and Andrzejczak 2015; UNODC 2019). Examples of NPS include cathinones, phenethylamines, aminoindanes, and bath salts. NPS are worrisome for their neurotoxicity and lethality (Hohmann et al. 2014). Currently, East and Southeast Asia are perceived as the production factory of global NPS (UNODC 2019). Although the share of NPS in the drug market might be still limited (they account for only 3% of drug seizure cases), global NPS have been increasing in number, type and availability (Zawilska and Andrzejczak 2015). Although most countries have tried to regulate NPS, a significant number of these drugs remain uncontrolled (Lee et al. 2018). NPS are developed and appear on the market frequently with changes to molecular structure that present challenges to legal actions due to the sheer number and types of new compounds.

Poly drug use

Poly drug use is a frequent condition worldwide, often with mixtures of drugs used specifically for the subjective effects of the drugs together. Speedballs or goofballs are combination opioids (usually heroin) taken with cocaine, amphetamine, or methamphetamine, which brings energy to the mellow opioid 'high' experience. Marijuana often is used with stimulants to dampen the harshness of coming down from these drugs. Concurrent use of alcohol and cocaine metabolizes in the body to produce, cocaethylene, a compound that produces a high that is subjectively distinct from either cocaine or alcohol alone. As permutations vary by drug availability and preference, prevalence of poly drug use is difficult to measure in distinct combinations. Instead, estimates count those who report poly drug use and tally the constituents of the reported poly drug mixtures, which may bias prevalence estimates for each of the constituent drugs in the mixture.

Historical interpretation and implications for public health

There are identifiable patterns in drug use in different regions of the world. Some patterns reflect cultural differences, when drug is used in cultures and national societies for specific purposes, with acceptance and approval of those drugs (Jay 2010). Production, distribution networks and markets also affect ways drugs function culturally and reflect the way in which the reinforcing nature of the drug is woven into spiritual, religious, or hedonistic purposes. As drug use is integrated into culture, production and distribution of the drug can also be protected by local culture, including corruption of local authorities.

Supply-side responses at the level of the society to interrupt and prosecute global drug distribution networks have little impact on overall use (Csete et al. 2016). Where there are societal, cultural, and/or individual factors that produce a demand for drug, a distribution system and market will arise to meet the demand. On the other hand, demand-side efforts at prevention, harm reduction, and treatment are sorely needed to reduce the demand for drugs drives production and distribution.

Social determinants of substance use disorders

SUDs are complex with multiple etiological and risk factors that can be classified into three levels: individual, interpersonal, and contextual.

Individual risk factors include biological predispositions, mental health disorders (major depression, anxiety), family characteristics, and socioeconomic status that correspond with SUDs (Stone et al. 2012). People with drug use disorders are almost four times more likely to have major depressive disorder (OR 3.80, 95% CI 3.02–4.78) and three times more likely to have an anxiety disorder (OR 2.91, 95% CI 2.58–3.28) (Lai et al. 2015). Interpersonal risk factors for SUD include family dysfunction ranging from parenting styles to childhood trauma including child physical and sexual abuse. Important contextual factors that facilitate the development of SUDs include level of disorganization for the neighbourhood and social environment (Stone et al. 2012; Ford et al. 2017).

These factors heavily shape social norms for young adults and adolescents during development. Social networks that develop around youth who grow up in proximity to peer substance users can normalize perceptions of substance use, increasing likelihood youths will use substances (Arbour-Nicitopoulos et al. 2010).

Policies in law and taxation that shape availability of specific drugs strongly affect the prevalence of drug use and drug use disorders, especially in youth and others susceptible to socioeconomic forces. Laws that restrict legal drinking age and when alcohol can be sold can reduce alcohol consumption (Stone et al. 2012). Increasing prices of drugs leads to long-term reductions in SUDs, even among abusers (Pacula and Chaloupka 2001).

Public health consequences of substance use and misuse

Differentiation between substance use and substance use disorders

There are different adverse consequences of substance use and misuse, for individuals, their families, and for society as a whole. Though most people do not use substances or use at levels that do not cause problems, for those who occasionally use substance heavily or in hazardous situations can experience negative consequences that are aversive enough to modify behaviour—most cut down or stop using substance. The range of negative consequences with heavy use of substances include individual (e.g. physical

and psychological discomfort following binge use—a 'hangover'), interpersonal (e.g. a family member complains substance use is causing problems), employment (e.g. a supervisor fires the employee who repeatedly misses Mondays) and legal consequences (e.g. citation for driving under the influence). For the minority of people who continue to engage in chronic, heavy levels of substance use, adverse consequences usually increase in frequency and severity. Still more people will cut down or stop using the substance in response. Only a minority continues to use substance at levels that define addiction, especially in light of negative consequences.

Defining the substance use disorder diagnosis

There are no biological markers that confirm substance use disorder diagnoses. Tests that screen for substances or their metabolites in urine, saliva, breath, blood, or nails reliably document recent substance use, which confirms the key symptom underlying substance use disorder: active substance use. Instead, SUDs are defined by behavioural criteria. Major diagnostic manuals are the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) of the American Psychiatric Association and the *International Classification of Diseases* (ICD) system of the World Health Organization (WHO). The criteria for defining SUDs have undergone considerable evolution in both of these classification systems since their first presentation. The current DSM-5 (American Psychiatric Association 2013) and the ICD-11 (WHO 2018) are the latest versions that detail the diagnostic criteria of SUDs and substance dependence, respectively.

A major diagnostic change occurred in 2013 when the DSM-5 integrated two diagnostic categories, abuse and dependence, into one diagnosis that represents a spectrum disorder that ranges in severity determined by number of diagnostic criteria present. The DSM-5 now defines substance use disorder as having at least two of the following characteristics over a 12-month period that cause *clinically significant impairment or distress*: (1) hazardous use, (2) continued use despite social or interpersonal problems, (3) neglect of major roles in order to use, (4) withdrawal, (5) tolerance, (6) using in larger amounts or for longer periods than intended, (7) repeated efforts to stop or control use, (8) time spent getting, using and recovering

from drug, (9) continued use despite knowledge of negative consequences, (10) important activities given up in order to use, and (11) craving. Those with 2–3 criteria are classified as mild SUD, 4–5 as moderate SUD, and 6 or more as severe SUD.

The ICD-11 was released in 2018 and will take effect in 2021. The ICD-11 substance dependence diagnosis is based on three central features that are shared with DSM-5 and is used when there is evidence of at least two of these central features over a 12-month period—or continuous use over a one-month period: (1) impaired control over substance use; (2) increasing central role of substance use over other activities and responsibilities; and (3) physiological features as manifested by (i) tolerance, (ii) withdrawal symptoms following cessation or reduction in substance use, or (iii) repeated substance use (or pharmacologically similar substance) to prevent or alleviate withdrawal symptoms.

Public health and clinical impact of using these diagnostic systems have strengths in informing research and clinical efforts that contribute to scientific knowledge and treatment delivery. Globally, severity of diagnoses for SUD corresponds with likelihood to succeed with treatments for SUD, with those with mild disorder being more likely to meet substance goals in treatment than those with severe SUD. Use of diagnoses confirms a medical understanding of addiction, which confers far less stigma than non-medical model concepts. By doing so, rigour and precision in measuring fidelity of treatment delivery and rigour in measuring outcomes from treatment increase.

Infectious diseases

Substance-related infectious disease transmission occurs when persons who use substances engage in behaviours to get (e.g. exchange sex) or use those drugs (e.g. share injection drug equipment). Injection drug behaviours, including sharing of injection equipment and paraphernalia used to prepare drug for injection have high efficiency in transmitting infections during drug administration, particularly for Hepatitis C virus. Substance use can facilitate infectious disease transmission when psychoactive properties inhibit inhibitions or otherwise enhance condomless sexual experiences such as ‘chemsex’ (sex under influence of substance), extreme sexual

behaviours (multiple partner), or exchange sex). While lower transmission efficiency compared to injection drug use, far more people globally use their drugs but do not inject, which increases risks for sexually transmitted infections (Shoptaw et al. 2013).

HIV/AIDS

Given the efficiency of infectious disease transmission when sharing injection drug use equipment and paraphernalia, it is not surprising that in the beginning of the US HIV epidemic, people who inject drugs (PWID) represented a group with high incidence and prevalence. Early studies in New York City showed approximately half of PWID in the city had HIV infection (Des Jarlais et al. 1996). Sharp reductions in HIV incidence and prevalence began in the 1990s among PWID that corresponded with several developments. Public health officials recognized effective medications for opioid use disorder (MOUD), particularly agonist (methadone) and partial agonist (buprenorphine, buprenorphine/naloxone) medications reduced heroin injection and thereby reduced transmission events for this group. There are solid reasons for this action: methadone promotes ART adherence among PWID (Uhlmann et al. 2010), even among PWID living with HIV/AIDS who are homeless (Palepu et al. 2011). Since 2005, methadone and buprenorphine are included on the WHO essential medications list for their effectiveness as treatments for opioid use disorder and their ability to prevent infectious disease transmission (WHO 2019).

Also occurring during the 1990s, there were thrilling developments in treating HIV/AIDS, with development of multiple classes of medications that, when used in combination, dramatically slowed mortality, dampened transmission, and improved health for those living with HIV/AIDS. Policymakers recognizing this ensured access to HIV medications to all, including PWID living with HIV/AIDS. Concurrently, civil societies (grassroots groups of PWID and their allies) mounted effective campaigns at local, national, and global levels to ensure access to harm reduction (NSP—needle and syringe programmes) for individuals who use injection drugs. Modelling studies show that simultaneous access to these three elements (opioid agonist treatment, ART, and NSPs) will slow or stop new HIV transmissions among PWID (Degenhardt et al. 2010). Recognition of these elements and six other elements were compiled into a global consensus

document that promotes a framework for countries to use to prevent HIV transmission by ensuring access and by measuring outcomes of HIV prevention among PWID (World Health Organization, UNODC, United Nations AIDS 2012). Interventions also included HIV testing and counselling, prevention, and treatment of sexually transmitted infections, condom distribution programmes for PWID and their sexual partners, targeted information, education and communication, prevention, vaccination, diagnosis, and treatment of viral hepatitis infection and prevention diagnosis and treatment of tuberculosis. With these effective prevention interventions, there is no good reason for an additional incident case of HIV among PWID. Indeed, additional new cases identify a lack of political will to ensure PWID have access to the combination prevention services framework.

Sexual transmission of HIV among persons who use drugs

Around the world, far more people use non-injection methods to use drugs. Risks for HIV transmission linked with non-injection use of substances are indirect in that their use facilitates condomless sex with HIV-positive or status unknown sex partners. Non-injection substances can increase HIV transmission along four domains. Drugs (methamphetamine, cocaine) can directly interact with characteristics of cells to alter immune function and enhance HIV transmission dynamics. Substances can alter HIV transmission behaviours as well. Binge alcohol drinking (beer goggles) diminishes inhibitions; stimulants (cocaine, methamphetamine, ecstasy) enables sex at the extremes (longer, rougher sex sessions) and enable ‘chemsex’ or ‘high fun’, a unique sexual experience that occurs only when under the influence of these drugs among men who have sex with men (MSM). Substances can interact with individuals to support behaviours that enhance risks for HIV transmission (exchange sex) and that promote sex in high-risk environments (venues where sexually transmitted infections are common).

Groups of users around the world have preferences that can enhance risks for HIV transmission. Binge alcohol drinking is the predominant substance linked with HIV transmission behaviours among MSM in South America among others. Use of stimulants by MSM (especially methamphetamine) significantly corresponds with HIV incidence (Plankey et al. 2007). Non-

injection substance use interferes with consistent ART adherence, which can interfere with sustained viral suppression among those who are living with HIV/AIDS.

Over the past decade, HIV transmission was slowed or halted using pre-exposure prophylaxis (PrEP) medications (emtricitabine/tenofovir) for HIV-negative persons among high-risk groups (serodiscordant couples, MSM). Landmark research showed that people living with HIV with sustained undetectable viral load levels were unable to transmit HIV to their partners (Cohen et al. 2011). Undetectable equals untransmittable. Efforts to test biomedical HIV prevention among PWID have shown that providing opioid substitution therapy for PWID living with HIV not only reduces mortality and morbidity for the individual, but prevents HIV transmission to sexual partners (Miller et al. 2018). Research findings also show that providing PrEP to PWID who are HIV-negative prevents HIV infection in parallel fashion to groups who do not use drugs (Choopanya et al. 2013). Research has yet to show findings in parallel fashion to PWID for persons who use non-injection substances. Conceivably, non-injection use of these substances interferes with consistent adherence to ARVs among those who are living with HIV (treatment) or who are high-risk HIV-negative individuals who use substances (prevention).

Hepatitis C virus (HCV) among persons who inject drugs

While HIV and HCV are transmitted through sharing of drug injection equipment, HCV is dramatically more infectious than HIV. Less efficient transmission of HCV can occur when coming into direct contact with blood (sharing a toothbrush used by someone with bleeding gums) and when having condomless sex with multiple sexual partners. A minority of individuals exposed to HCV spontaneously clear the infection. About 75 to 85% of persons with HCV progress to chronic phase with about 20% developing end-stage liver disease. Given this, it is not surprising that more PWID are living with HCV infection than are living with HIV—and co-infection with HCV and HIV can accelerate HIV disease progression.

Untreated HCV infection represents the leading risk for morbidity and mortality for PWID. In meta-analysis, the time to significant liver damage is 26–38 years after time of infection, with cirrhosis 34–46 years afterwards (Smith et al. 2015). In the decade prior, treatment for HCV involved use of

ribavirin and pegylated interferon. This combination produced sustained viral suppression (cure) for some individuals, with better outcomes for persons with select genotypes of HCV and less or no efficacy for others. Another drawback to the ribavirin/interferon combination involved significant side effects including moderate to severe depression and exhaustion that led many to abandon the treatment. In 2013 direct acting antiretrovirals (DAAs) were developed. These medications act by disrupting viral replication and infection processes. The result is these medications shortened treatment periods, reduced side effects of the treatment and produced cure rates for most persons, independent of HCV genotype. Concerns over reinfection among PWID following successful treatment for HCV are not borne out by data (Martinello et al. 2017). The key drawback to using DAAs is their high cost—so high as to likely interfere with their use by PWID. Use of DAAs early in HCV infection for PWID, while expensive, prevents liver damage and corresponding higher-cost treatments later in life. As well, HCV cure for PWID earlier in life prevents potential for HCV transmission via drug or sexual transmission behaviours, which further reduces costs for healthcare. Despite the high efficacy for DAAs as treatment for HCV, the high costs will likely continue to dampen policymakers' willingness to scale them up even in the US and across the world for use among PWID until costs come down. One hopeful sign is that for most states in the US, DAAs are covered by Medicaid formularies, which portends access to these drugs for PWID.

Drug-induced (overdose) deaths

In 2015, 450,000 persons were determined to have died from drug use. Deaths from overdoses are a unique and extreme major adverse consequence to drug use. In North America, especially the US, drug overdose is the leading cause of accidental death. Over 72,000 fatalities were tallied in 2017 in the US (Ahmad et al. 2018) of which 47,600 were attributed to opioid overdose (Statistics 2018). This opioid epidemic has become North America's most widespread behavioural public health problem, with a higher number of deaths due to drug overdose in 2016 compared to deaths due to HIV at the peak of the AIDS epidemic in the US (CDC 2017). Cause of death due to overdose is attributed by medical

examiners based on results from drug screening tests and recorded on certificates of death. Reports on overdose deaths that rely on death records have some inherent unreliability as autopsies are not conducted on all deaths. When poly substance use is present at death, it may be difficult to determine which substance is the cause of death. Stimulant drugs such as cocaine and methamphetamine can also induce deaths, especially when these drugs are combined with opioids, benzodiazepines, alcohol, and other drugs.

Methodological toolbox for studying illicit substance use

As illicit drug use is, by definition, illegal there are many difficulties in collecting rigorous data on the topic. The difficulties include: (1) social desirability responding (Pauls and Stemmler 2003) in which persons who use drugs may deny (or minimize) their drug use in order to present a desirable image to the researchers and/or to themselves; (2) locating survey participants, as many persons who use drugs at high levels may be homeless or unstably housed; and (3) the effects of drugs on memory (though greatest memory problems may be associated with alcohol use). Various techniques have been developed to reduce these problems including: (1) audio-computer assisted self-interviewing (ACASI) (Des Jarlais et al. 1996), in which questionnaires are programmed into computers so that the research participant listens to the questions over headphones and responds to the questions using either the keyboard or a touch screen. ACASI does not require participants to be literate and the questions can be presented identically to all individuals; (2) respondent-driven sampling (Heckathorn 1997), in which participants are reimbursed for recruiting others. Restrictions are placed on the numbers of participants that any individual can recruit, and additional data is collected in order to increase generalizability to the underlying population; and (3) timeline follow back (Sobell and Sobell 1992), a method in which major events in an individual's life are used to anchor to the recall of events over long time periods.

Surveys and sampling strategies

There are several major methods for studying the epidemiology of illicit drug use. These include household surveys of the general population,

school surveys of drug abuse among young adults, and special studies aimed at examining drug use among particular groups, such as those who use drugs at high frequencies.

Household surveys of the general population

Surveys of random samples of household members provide what is usually considered to be the best estimates of the use of different drugs in a country. Such surveys are quite expensive but provide data that cannot be obtained through any other method. The US National Survey of Drug Use and Health is conducted annually with a sample of over 67,500 respondents age 12 years or older. In that year, 10.6% of adults reported illicit drug use in the previous month (the measure of current drug use). The most commonly used illicit drug reported was marijuana followed by opioids. Specifically, there were an estimated 11.5 million people who reported non-medical use of pain relievers in 2016; a fivefold increase from 2012.

School surveys

Surveys can also be conducted in schools. School-age youth are of particular interest because illicit drug use typically begins during adolescence, and trends in the use of different drugs are often much more pronounced in this age group. Thus, school surveys may be particularly useful for generating predictions about future drug use. ‘Monitoring the Future’ is the largest and longest running school survey in the US (Johnston et al. 2006). In the 2018 survey of the 44,400 students who were interviewed, 38.8% reported using illicit drugs in the previous year, with marijuana being the most commonly used illicit drug, (35.9%), and narcotics (other than heroin) being the second most commonly used illicit drug (6.0%).

Administrative data

Persons who use illicit drugs frequently come into contact with both law enforcement and health agencies. They may be arrested for possession of drugs and/or they may seek treatment for both their substance abuse disorder and for related health problems, such as overdose and infections. Administrative data can be useful to detect temporal trends in criminal

justice and treatment services. For example, According to the Treatment Episode Data Set (TEDS) (TEDS 2017), there were slightly more than 2 million admissions to publicly funded drug and alcohol treatment programmes in the US in 2017. Among those aged 12 and older who sought treatment, five substances accounted for 93% of admissions: opiates (34%, primarily heroin), alcohol (29%), marijuana/hashish (13%), stimulants (12%, primarily methamphetamine), and cocaine (5%). Over the past decade, administrative data using TEDS highlighted the way opiates exceeded alcohol as the primary driver of treatment admissions in the US with stimulants/methamphetamine taking the spot from cocain06 in the rankings of publicly funded treatment admissions for these five illicit substances.

Special studies

While carefully framed surveys can provide data about the breadth of drug use in the general and school populations, and administrative data can provide useful information about problems associated with illicit drug use, these types of studies do not provide the depth of information needed to understand the problems associated with specific forms of illicit drug use. Special studies usually recruit persons who use drugs at high frequencies. PWID with or at risk for HIV infection are an example. Special studies may also recruit subjects from clinical (drug treatment programme) settings from the community. They may be cross-sectional (one-time data collection) or cohort studies (with the same subjects followed over time).

This review of survey and method tools provides guidance and initial recommendations on how to use methods to collect data at the population level and within special populations that to advise prevalence, incidence, and potential interventions with important groups of persons who use substances.

Interventions: approaches to treatment and prevention of substance use disorders

While there are effective methods for reducing transmission of infectious pathogens and for reducing overdoses among persons who use drugs, the

ideal method for addressing these problems would be to eliminate drug use among persons with SUDs. Current treatments can be used to produce periods of abstinence from weeks to months, but there are currently no treatments that can produce permanent abstinence. This reality best frames SUDs not only as spectrum disorders, but as disorders that are chronic and relapsing over the lifespan. Multiple treatments often are required before abstinence is achieved.

For prevention, there exists an accepted framework for PWID drafted by the WHO, UNODC, and the Joint United Nations Program on HIV/AIDS (UNAIDS). This technical guide outlines a comprehensive package for prevention and treatment for PWID (World Health Organization, UNODC, United Nations AIDS 2012) that includes methods for setting country targets and for measuring progress in providing these services. Services include needle and syringe programmes, opiate substitution treatment, HIV testing and counselling, antiretroviral treatment, prevention and treatment of sexually transmitted infections, condom programmes for PWID and their sexual partners, targeted information, education, and communication for PWID and their sexual partners, prevention, vaccination and treatment of viral hepatitis, and prevention, diagnosis, and treatment of tuberculosis.

Opiate substitution treatment/medication for opioid use disorder

Effective pharmacological treatment is available only for opioid dependence. Solid evidence supports agonist maintenance treatments including methadone and buprenorphine (mono formula or in combination with naloxone) (Connery 2015). Still, as SUDs interrelated to various psychological and social factors, evidence suggests medication should be combined with other treatment components including cognitive behavioural therapies, motivational interviewing, contingency management, harm reduction, social support services, and integrated care to achieve optimal outcomes.

Methadone. Scale-up of methadone maintenance treatment (MMT) has been a major turning point in global public health for PWID. Methadone is a full opioid agonist (as is heroin) that activates opioid mu receptors on nerve cells located in areas of the brain that are the basis for analgesic and pleasure effects from opioids. This binding of methadone at mu receptors

prevents opioid withdrawal symptoms, largely without producing euphoria. Methadone stops (or reduces) use of supplemental opioids, allowing the treated patient to avoid behaviours of drug use and to engage prosocial behaviours. Notable country outcomes following rapid scale-up of MMT in China and Vietnam demonstrate dramatic improvements in drug-related public health and social issues, especially reductions in HIV transmission. For most countries a drawback to providing MMT include requirements to deliver the care in highly regulated, specialty care settings to prevent diversion of the drug. There are successful models where methadone is prescribed at outpatient pharmacies with few medical or social harms, though policymakers are slow to engage this option. MMT is a primary HIV prevention strategy for PWID: 40% of reduction in the risk of incident HIV from sharing of injection drug and equipment (MacArthur et al. 2012; Karki et al. 2016). Given the strong advantages to MMT, retention in care is the primary treatment goal (Karki et al. 2016)

Buprenorphine. Buprenorphine is an optional treatment to methadone approved in the US since 2002. Buprenorphine is an opioid partial mu agonist that is manufactured as a mono-product and a co-formulated product containing a naloxone tag that reduces concerns over injection use. The mono and combo products are available in oral (daily) form. Injection (weekly, monthly) and implant (6 months) formulations of buprenorphine are available in high-income countries. Buprenorphine tightly binds at the mu opioid receptor (preventing withdrawal symptoms), but binds so tightly that buprenorphine effectively blocks effects of supplemental opioid use. A key advantage to buprenorphine is the 'partial' agonist blockade function that is so effective that it protects against most risks for overdose (especially respiratory distress) when treated patients use supplemental opioids. This safety profile allows the medication to be prescribed in outpatient clinic settings. Systematic reviews that compare MMT with buprenorphine and placebo therapy show that both MMT and buprenorphine maintenance therapy (BMT) are more effective and cost-effective than no treatment and MMT is slightly more effective in retaining patients and suppressing illicit opioid use than buprenorphine (Mattick et al. 2014).

Naltrexone. Naltrexone is a long acting opioid antagonist that tightly binds at the mu receptor sites. It is available in oral (daily), injection (monthly) and implant (6 months) formulations. The antagonist action of naloxone is complete and blocks any opioids from producing euphoria,

which stops opioid use completely. The binding of naltrexone at the mu receptor is so strong that it will displace any opioid from the mu receptor site that may be remaining in the body (precipitating opioid withdrawal). This effect also is so strong that a liquid formulation (naloxone—injection, nasal spray) is used widely to reverse opioid overdoses in emergency settings. Naloxone also is distributed widely (often by syringe and needle programmes) among friends/family members of opioid users to use in cases of overdose. While naltrexone is on board, the medication blocks any opioid use, preventing relapse to opioids. When the medication has worn off, however, risks for overdose exist as individuals become overwhelmed by prior doses of opioids as tolerance is lost with sustained treatment by antagonists (Miotto et al. 1997). Outcomes show use of oral naltrexone yields no difference from treatment with placebo (Minozzi et al. 2011). The main failure of oral naltrexone is a high dropout rate (Minozzi et al. 2011). In 2010, the extended released injectable naltrexone was approved in the US, attempting to solve the issue of the oral formula. This monthly injection provides patients with opioid dependence with more freedom in managing their condition. It has been proved to be equally effective as buprenorphine/naloxone treatment for patients who have been detoxified (Jarvis et al. 2018; Lee et al. 2018).

There are no medications approved for use to treat stimulants. Recent developments in medication development have yielded promising results for use of mirtazapine for methamphetamine use disorders (Colfax et al. 2011; Coffin et al. 2019). These trials replicated a statistically significant and meaningful reduction of methamphetamine use by 15–18% compared to placebo over a period of 12 weeks. These effects were observed in the context of regular counselling sessions, underscoring the likelihood that any medication for stimulant use disorder will require both medication and psychosocial interventions. Improvements in trial design and conduct in evaluating putative medication candidates for stimulant use disorder signal a strong possibility of development of one or more medications for cocaine and methamphetamine use disorders in the next decade.

Cognitive behavioural therapy

Cognitive behavioural therapy (CBT), a multisession psychoeducation therapy, teaches persons with substance use disorder steps to initiate

substance abstinence (dispose of drug and paraphernalia, set a quit date), to respond to cravings and urges using psychological and imagery skills and to return to abstinence in the setting of lapse or relapse. Most models of CBT stem from the original work of Marlatt and Gordon's model of relapse prevention (Marlatt and Donovan 2005).

The signal size of CBT for drug use disorder is in the moderate range (d=0.45). CBT has larger effect sizes when evaluated for treatment of cannabis use disorder with small effect size for poly substance use disorder (McHugh et al. 2010), findings verified in a second meta-analysis (Magill and Ray 2009). Moreover, CBT effects are measurable in trials at up to one-year follow-up evaluations (Rawson et al. 2004). CBT is a mature behavioural treatment for substance use disorder—so much so that elements of CBT are widely integrated into many ecumenical and 12-step approaches to counselling for SUDs.

Contingency management

Contingency management (CM) is a treatment for SUDs that involves providing voucher incentives in increasing value for successive biological samples documenting drug abstinence. As such, the treatment is based in operant conditioning (Skinner 1938). Its application began in delivery of methadone maintenance therapy by providing take-home medications to individuals who provided evidence of no illicit opioids while in treatment (Stitzer et al. 1977). The treatment was first used to treat cocaine use disorder in the early 1990s (Higgins et al. 1993). The treatment is used with a range of SUDs successfully. Several meta-analyses reliably show effect sizes for CM range between d = 0.4 to d = 0.6 (Prendergast et al. 2006; Dutra et al. 2008; Benishek et al. 2014; Davis et al. 2016).

CM can be delivered using two distinct methods. One provides vouchers of increasing value for successive samples documenting drug abstinence while the other provides opportunities to draw from a fishbowl for chances to win a small, medium, or large size prize. With successive samples marking drug abstinence, additional draws from the fishbowl are earned. The differing procedures have roughly equal efficacy.

There are no treatments for stimulant use disorder with greater effect sizes than CM, yet adoption of the treatment remains lacklustre. In the US, the Veterans Administration Healthcare System has recently adopted

providing the treatment for veterans diagnosed with cocaine use disorder. Early outcomes from this work indicate that the treatment is feasible and shows similar effects as in efficacy trials (DePhilippis et al. 2018). Evidence for increasing scale-up of CM more broadly is provided in a recent meta-analysis showing significantly greater effects in producing outcomes in treatment for stimulant use disorder than CBT or other modalities (De Crescenzo et al. 2018).

Motivational interviewing

Motivational interviewing (MI) is an approach based in client-centred therapy that has the basic assumption that people change thinking and behaviour about their substance use along a series of stages (Miller and Rollnick 2013). A hallmark of this assumption is that individuals can enter into treatment at any of these stages. The therapy style for MI emphasizes the psychological basis of addiction being ambivalence—the simultaneous thoughts that substance use both is and is not a problem. Individuals frequently shift between beliefs that substance use is not a problem (followed by substance use) and beliefs that substance use is a problem (followed by an attempt to quit or cut down). Therapists trained in MI techniques elicit a process of 'natural' change (i.e. change that is identified, initiated, and maintained by the individual) using non-directive interventions. Outcomes show that MI engages individuals in longer term treatment and promotes specific behaviour changes. From this approach, 'denial' is not confronted by therapists. Instead, MI techniques focus on articulating ambivalent beliefs in individuals about their substance use and work to develop discrepancies in their beliefs with the goal of developing 'change talk'. Statements from individuals that emphasize disadvantages of the status quo, that emphasize need to change, that express optimism for change and that disclose intention to change are defined as change talk and correspond with positive outcomes in treatment (Magill et al. 2019).

Meta-analysis of MI outcomes for substance use disorder treatment show weak to moderate effect sizes (Sayegh et al. 2017). As with CBT, stronger effect sizes for MI are observed for cannabis use disorder and weaker effect sizes for alcohol, tobacco, and poly substance use.

Detoxification

For most who become addicted to opioids, detoxification becomes a goal at some point. Many fail during multiple attempts at detoxification before a minority of individuals successfully maintain opioid abstinence. As noted, this raises risks for overdose following return to opioid use following the detoxification attempt. Some seeking detoxification services may not wish to become abstinent, but instead reduce their tolerance level to a more affordable level. Treatment for detoxification for opioid use disorder involves starting individuals on methadone then tapering methadone dose over a period of 2–3 weeks. During some point of the taper, withdrawal symptoms will cause many to discontinue early and return to opioid use, though often at a level somewhat lower than at the start of the taper). Despite the many individuals worldwide who start detoxification, the literature describing outcomes using this approach is uneven and poorly articulated, presumably because the high early discontinuation interferes with drawing conclusions in randomized controlled trials. One meta-analysis on opioid detoxification concludes that variable and poor quality studies prevent comparisons and instead recommends patients be counselled toward opioid maintenance treatment (Amato et al. 2004). Detoxification outcomes can be improved some, however, by integrating psychosocial counselling approaches while conducting the taper during detoxification programmes (Amato et al. 2008).

Residential treatment

Residential treatment for SUDs involves providing direct service with multiple components within a licensed facility that can evaluate, diagnose, and treat the symptoms and disabilities linked with substance use disorder. Individuals in residential treatment receive services 24 hours as needed. Services range in intensity, from mild through intensive levels, with focus on instilling abstinence, preventing relapse, coping with triggers, mood management, 12-step involvement, physical exercise, congregant living skills, and activities of daily life (Reif et al. 2014b). Individuals who begin residential treatment generally receive more intensive services and as abstinence is established, mood improves and impulsive behaviour inhibited, intensity of services decrease allowing the individual to engage

independent behaviours. Lengths of stay at residential treatment facilities range from 28 days through several months. Toward discharge from residential treatments, individuals have opportunities to establish drug-free routines outside the facility. Many engage work, family, and other social activities, then return to the residential treatment facility to end the day.

Efficacy of the residential treatment approach shows that the approach has value, though the quality of the evidence prevents arriving at statistics that describe the extent of that value. Still this essential treatment approach for those with severe SUDs merits consideration as policymakers determine the mix of service intensities and modalities that are available to persons seeking treatment. Recovery housing provides a stepped down level of care that still provides direct service with multiple components that includes supervised, short-term housing to individuals with SUDs or co-occurring mental and SUDs after residential treatment. Recovery housing for persons with SUDs have positive effects on long-term substance use outcomes and improvements in functioning, including employment and criminal activity (Reif et al. 2014a).

12-step and related social programmes

The 12 Steps of Alcoholics Anonymous is a fellowship of people who share the problems that have become unmanageable due inability to control use of alcohol (AA), narcotics (Narcotics Anonymous—NA), cocaine (Cocaine Anonymous—CA), Crystal Meth Anonymous—(CMA) and other substances. Twelve Step programmes rely on the original or derivative programme of recovery set forth by the *Alcoholics Anonymous: The Big Book* (Anonymous 2002a) and the *Twelve Steps and Twelve Traditions* (Anonymous 2002b). A key distinction to these 12-step programmes is that they are not considered treatment for substance use disorder formally. Instead 12-step groups are a social fellowship in which persons with addiction meet, work the programme set forth in the Big Book, and provide and receive social support. As these programmes fiercely protect their anonymous nature, there are no randomized controlled trials that would describe their efficacy in producing or sustaining abstinence from substance. Despite efficacy indicators, the ubiquity of these groups around the world undoubtedly have the greatest effectiveness of any therapy or programme designed to instil and maintain substance abstinence worldwide.

The programme of the 12-Steps of Alcoholics Anonymous is built around a concept of a ‘God’ that can be defined in many ways that is central to admitting powerlessness over control of substance use. Discomfort with the God-concept among many has contributed to development of secular versions of the 12-Steps. These include: Rational Recovery, SMART Recovery, Women for Sobriety, Secular Organizations for Sobriety, and Moderation Management. These groups use differing conceptualizations about addiction and its treatment from the 12-Steps and from each other. Many of these emphasize CBT and related psychological constructs to support recovery. Some work toward a secular adaptation of 12-Step groups.

Harm reduction

Harm reduction among people who use drugs grew out of shared recognition among these individuals and their allies that due to stigma and lack of political support, health promoting and harm reducing strategies and interventions would not happen unless they banded together to demand them. The initial work of this grassroots movement was helping to institute and scale-up syringe and needle programmes worldwide. With the advent of the HIV/AIDS epidemic and the efficiency of transmission of virus via injection methods, efforts to broaden access to syringe and needle programmes gained acceptance in communities (Des Jarlais et al. 1996). This grassroots movement professionalized and developed organizations, leaders, and impact, especially on the global public health stage. Today, this involves a well-supported and effective ‘civil society’ movement. This movement has been able to organize civil disobedience and to build alliances with academic and community partners to achieve major accomplishments in ensuring harm reduction and health promoting interventions are available, worldwide, for persons who use drugs. In addition to syringe and needle programmes, harm reduction approaches have developed to include supervised injection facilities, primarily in response to the growing worldwide spread of fentanyl among PWID. Fentanyl is 50–100 times more potent than heroin, so the risks for overdose are now higher than perhaps any time in history. The supervised injection facility ensures that rescue medications and medical personnel are onsite for reversing unintended overdose. These harm reduction spaces also are

designed to be spaces that provide sterile injection supplies, that provide access and/or linkages to medical care (especially wound/abscess care, treatment for sexually transmitted infections) and linkages to formal treatment for SUDs.

Systematic review of trials on efficacy of syringe and needle programmes show these programmes provide social and physical environments that mitigate drug-related harms and increased access to social and material resources (McNeil and Small 2014). The specific elements of this support include refuge from street-based drug use settings, promotion of safer injecting in providing equipment and guidance for this objective, provide linkages to healthcare services and resources and protect from law enforcement. Given the stigmatized and victimized experiences common to PWID, provision of these safe spaces continue to be at the same level of priority as providing MOUD and access to naloxone reversal kits for persons living with opioid use disorder.

Alcohol

Robin Room

Alcohol and its effects

Alcoholic beverages have been consumed in most, if not all, human societies since the beginning of recorded history. Beverages containing ethanol (C_2H_5OH) can be fermented from a large number of organic materials that comprise carbohydrates, and in one part of the world or another, these products are prepared from fruits, berries, various grains, plants, honey, or milk. Under most circumstances, such fermented beverages can contain up to 14% ethanol. The most widely commercialized fermented beverages are beer prepared from barley or other grains (usually 3–7% ethanol), apple and other fruit ciders (usually 3–7% ethanol), and grape wine (usually 8–14% ethanol). Other fermented beverages are also common in particular cultures, often from home production or in commercial form: for example, sorghum or millet beers in Eastern and Southern Africa, palm wine toddy in West Africa and the Indian subcontinent, pulque (prepared from the maguey cactus) in Mexico, and rice wine (sake) in Eastern Asia.

Distilled beverages, in which ethanol is concentrated by evaporation and condensation from a fermented liquid, came to Europe from Arabia in the Middle Ages. In Europe, at first, their use was primarily medicinal, but by the 1600s, popular use as a social beverage spread rapidly. Distilled beverages can be made up of almost-pure ethanol, but those sold for drinking usually contain between 25% and 50% ethanol. Distilled alcohol is also added to wine, producing ‘fortified wines’ with about 20% ethanol. Because distilled beverages and fortified wines do not readily spoil, they could be shipped over long distances, even before refrigeration and airtight packaging became available, and played a particularly important part in

commerce and exploitation in the age of the European empires. Different cultures consume varying strengths of alcoholic beverages, often with water or a ‘mixer’ being added to distilled beverages and, in some cultures, also to wine and other fermented beverages.

Use-values of alcohol

Ethanol has many uses in human life. These include non-beverage uses as a fuel and as a solvent. Important beverage-related use-values include use as a medicine, as a religious sacrament, as a foodstuff, and as a thirst-quencher (Mäkelä 1983). But alcoholic beverages have received special attention as a public health hazard not only as a risk factor for chronic disease but also because of their psychoactive properties. These properties carry with them another set of use-values: in terms of psychopharmacology, ethanol is classified as a depressant, although its effect can also be stimulating (Hendler et al. 2011), and alcoholic beverages have long been used to affect mood and feelings, whether in a calming or in a stimulating direction. With enough consumption, alcohol becomes an anodyne and, indeed, an anaesthetic; distilled spirits were used as an anaesthetic in surgical practice before the mid-nineteenth century. Many drinkers seek and appreciate the levels of intoxication which lie between mild mood alteration at one end of the spectrum and being comatose at the other.

The decisions to drink and how much to drink are, however, often not made by the individual in isolation. Drinking is usually a social act, and the pace and level of drinking are frequently subject to collective influence, with drinking together being seen as an expression of solidarity and community. Although drunkenness may be sought to relieve misery or loneliness, it is more commonly associated with sociable celebration.

Adverse effects

Alcohol consumption can have a variety of adverse effects, some of which are acute effects associated with the particular drinking event. Drinking progressively impairs physical coordination, cognition, and attention, resulting in an increased risk of accidents and injury. Above a threshold level, drinking can also affect intention and judgement, so intoxication potentially plays a causal role in violent behaviour and crime (Graham et al.

1998). This relation appears to be culturally mediated, because there is a substantial variation between cultures in the association of intoxication with violence and crime (Room 2001). A sufficient amount of alcohol may result in a potentially fatal overdose, by interrupting various autonomic bodily functions.

Other adverse effects of alcohol consumption are chronic effects related to a repeated pattern of drinking. Alcohol consumption can adversely affect nearly every organ of the body, although some effects are not common. Chronic conditions in which alcohol is implicated as an important cause include liver cirrhosis; cancers of the upper digestive tract, liver, bowel, and breast; cardiomyopathy; and gastritis and pancreatitis (Rehm et al. 2017). Through a variety of mechanisms, alcohol is also implicated in the incidence and course of infectious diseases (Parry et al. 2009).

Repeated heavy drinking can also adversely affect mental health; specific neurological disorders are associated with sustained heavy drinking. More common concomitants include depression and affective disorders. Alcoholism—the experience of loss of control over drinking, along with other psychological and physical sequelae—has also been considered a mental disorder in modern times. In current nosologies, alcoholism has been replaced by the terms *alcohol use disorder* (in *Diagnostic and Statistical Manual of Mental Disorders* [DSM-5] terminology) and *alcohol dependence* (in the *International Classification of Diseases* [ICD-11]) (Saunders 2017).

The impairment of coordination and judgement produced by drinking potentially impacts on bystanders and the drinkers' acquaintances, friends, and family, as well as on the drinker. The effects can be through impairment of coordination or judgement during the drinking event, resulting in injury or distress, or through impairment of performance in family, friendship, work, and other social roles as a result of recurring drinking episodes (Laslett et al. 2011). The actual and potential adverse effects on others have historically been the primary justification for alcohol controls and other societal responses to problematic drinking (Room 1996); the effects on the adult drinker's own health have been of much less importance in determining public policy on alcohol.

Positive effects

For the drinker, and sometimes for those around, alcohol consumption can have positive effects. We have already mentioned the different use-values of alcohol—which mean that drinkers are usually willing to pay more than just the cost of production and distribution of the beverage. Apart from its valued effects on mental state, alcohol use has some positive outcomes on health. By far the most important of these, in terms of public health, is its potential for preventing particular forms of cardiovascular disease (CVD). Drinking is also often bad for the heart (Chadwick and Goode 1998; Poikolainen 1999). Data from countries in the former Soviet Union, where a pattern of intermittent intoxication is common, support the strong adverse effect of binge drinking on heart disease mortality (Zaridze et al. 2009; Rehm and Room 2009). A fairly consistent finding is that, in terms of net effect on CVD, drinking small amounts regularly protect against CVD—although relatively little is known about how any protective effect interacts with or overlaps other protective factors, such as regular exercise, diet, or taking aspirin (acetyl salicylic acid [ASA]) or other pharmaceuticals (Iestra et al. 2005). The net protective effect of light drinking on CVD is indeed still in question (Zhao et al. 2017), including from a Mendelian randomization meta-analysis of data from 56 epidemiological studies which found no net beneficial cardiovascular effects even for light drinkers (Holmes et al. 2014). Some protective effect of light drinking has also been found for Type-2 diabetes (Rehm et al. 2017).

Research on cumulative effects of alcohol

Effects on the drinker's health

The relationship between amount of drinking and overall mortality was long thought of as a J-shaped curve, with abstainers, and often, very light drinkers showing a higher mortality than those drinking a little more. It was clear that any net protective effect was at older ages: studies limited to younger cohorts typically found a monotonic relationship between amount of drinking and mortality (Andréasson et al. 1991; Rehm and Sempos 1995). In the 2010s, however, there has been increasing argument against a net protective effect at any level of drinking: that apparent J-curve results reflected a number of confounding factors, including the selective nature and often limited follow-up period of many cohort studies. After finding

repeated attenuation of apparent protective effects as other factors were controlled, Knott et al. (2015) concluded that 'beneficial associations between low intensity alcohol consumption and all-cause mortality may in part be attributable to inappropriate selection of a referent group and weak adjustment for confounders'.

There is no disagreement that beyond relatively low cumulative volumes of drinking there are net adverse effects of drinking on physical health. A study in 7 European countries with diverse drinking patterns found that the risk of dying with drinking as a cause rose above 1 in 1,000 at levels of drinking ranging between 7 gm and 20 gm of ethanol per day—that is, at or below two drinks per day (Shield et al. 2017). The pattern of drinking is also a potentially important factor in mortality due to alcohol. Although this has long been obvious in injury deaths, there is growing recognition of its significance in other causes of death. Variations among cultures in drinking habits may partly explain the variations in the relation of volume of drinking to mortality in different countries (Shield et al. 2017).

In recent years, advice on 'low-risk drinking' or 'safe drinking' guidelines has been formulated and publicised in a number of countries (e.g. Chief Medical Officers 2016). Whereas earlier guidelines were inclined to be stated only in terms of the volume of drinking, in line with the measurement methods of medical epidemiology literature, more recent guidelines have also emphasized limits on the amount consumed on a given occasion or day (Stockwell and Room 2012).

Current literature on the cumulative effects of drinking on health relies substantially on summations of prospective epidemiological literature, following the tradition set up by English et al. (1995). Using meta-analysis on studies of the relationship between volume of drinking and specific causes of death in which alcohol was either a risk or protective factor, studies following this tradition derive attributable fractions for different levels of the volume of drinking and apply these fractions to segments of the population at each level in order to arrive at estimates on total lives and life-years lost and gained, subtracting the projected protective effects of alcohol from the negative burden. In addition to life-years lost, the study's most comprehensive indicator, disability-adjusted life years (DALYs), includes a projection of the burden of disability attributable to alcohol.

According to estimates for 2010, 5.0% of the total burden of disease globally (as measured in DALYs) is attributable to alcohol (Lim et al.

2012). This compares with 6.3% for tobacco and 1.0% for illegal drugs. The burden is considerably higher for males than for females; in the 2016 estimates, alcohol ranked fourth for men as a risk factor for overall health, but nineteenth for women (Risk Factors Collaborators 2017). As earlier estimates showed (Ezzati et al. 2002), the alcohol share of the burden is highest in high-income societies, including Eastern Europe and Northern Asia, as well as in Latin America. The relative position of alcohol among risk factors is actually highest in middle-income countries, where it ranks first; although the alcohol share of all DALYs is lower in other developing regions, this fraction is calculated on the basis of a higher total burden of disease and disability in these countries.

Alcohol as an issue in public health

Shifting societal responses to problematic drinking

Efforts to control problematic drinking date back to the beginning of recorded history. These efforts have been many-sided, including informal responses in the family and community, as well as governmental controls. Religious teachings and movements have often been directed against drinking or intoxication: Muslims are forbidden by their faith to drink at all, and drinking is also discouraged or forbidden in at least some branches of all the major world religions.

In the last few centuries, European and Europe-derived societies have been hosts to conflicting trends in terms of alcohol issues. The production of alcoholic beverages became an important part of European economies and of imperial domination and trade in the age of European colonization. Alcohol production and exports took on political importance not only in the wine cultures of Southern Europe, but also in such countries as the Netherlands and Britain. In the British colonies as well as in America, in the late-eighteenth century, distilled spirits were the only profitable way to get grain to market (Rorabaugh 1979). In recent decades, alcohol beverage industries have become increasingly internationalized and concentrated (Jernigan 2010), and multinational companies, mostly based in Europe or North America, have pressed with considerable success to open up global markets for alcohol.

Starting in the early 1800s, there were substantial waves of popular, and eventually, governmental response to the problems that were resulting from the very heavy consumption of alcoholic beverages in English-speaking and Northern European societies (Blocker 1989; Levine 1991). As a culmination of decades of popular temperance movements, in the early twentieth century, alcohol prohibition was adopted in 13 countries (Schrad 2010) and imposed on indigenous people in colonial territories, and stringent controls were placed on the availability of alcohol in some other countries. Although alcohol's impact on public order and morals and on family life were more central to the temperance movement thinking than the public health issues, mainstream thought in medicine and public health acknowledged the substantial adverse impacts of alcohol on health (Emerson 1932), and prohibition or an alternative, stringent controls on the availability of alcohol (Catlin 1931), were often identified with the public health interest.

In the United States, and some other societies which had prohibited or greatly restricted alcohol availability, there was a strong reaction against it by the early 1930s, with middle-class youth in the lead (Room 1984a, 1984b). In this cultural–political context, as the new generation moved into professional and research positions, adverse effects of alcohol were downplayed or denied (Herd 1992; Katcher 1993), and alcohol issues almost disappeared from public health textbooks and discourse. Any problems with drinking were seen as attributable to a relatively small cadre of alcoholics, unable to control their drinking because of a mysterious predisposing factor. As late as 1968, the main emphasis of the American Public Health Association was on building treatment capacity for alcoholism (Cross 1968).

The 'new public health' approach

The last three decades of the twentieth century saw the rise of what has been termed in the alcohol literature the 'new public health' approach (Beauchamp 1976; Tigerstedt 1999) to alcohol issues (although its approach is much less individualistic than what has been called the 'new public health approach' in other fields). This approach brought together several strands of research and philosophy. In contrast to a concept in terms of a unitary disease, 'alcoholism', the approach was premised on a

disaggregated approach: there was a diversity of alcohol-related problems, fairly widely distributed among the drinking population (Knupfer 1967; World Health Organization, Expert Committee on Problems Related to Alcohol Consumption 1980). It was noted that for many problems, the heaviest drinkers accounted for only a minority, because there were so many more drinking at somewhat lower levels (Moore and Gerstein 1981); picking up Rose's (Rose 1981) phrase, Kreitman (Kreitman 1986) termed this the 'preventive paradox'. Attention was, therefore, paid not only to the heaviest drinkers, but also to the whole range of drinking levels, and indeed, to the distribution of consumption in the population (Ledermann 1956; De Lint and Schmidt 1968). What happens with moderate drinkers, it was argued, influences the social climate for heavy drinking, because drinking is largely a social activity, marked by mutual influences and norms of reciprocity (Bruun et al. 1975a; Skog 1985). In a given population, it was found that rates of alcohol-related problems tend to rise and fall with changes in the level of consumption (Seeley 1960). Controls on the availability of alcohol, including taxes, affect the level of consumption, and thus, also the rates of alcohol-related problems (Seeley 1960; Terris 1967; Popham et al. 1976). The level of alcohol consumption in a population, and controls on alcohol availability, is thus seen as a public health concern, and part of a society's overall 'alcohol policy' (Bruun et al. 1975a).

In enumerating the elements of the approach, we have given references for early statements of each element. It will be seen that the strands of this approach were woven together gradually over a period of some years. A 1975 report by an international group of researchers (Bruun et al. 1975a) became a pivotal document for the approach. A few years later, the approach was given an authoritative endorsement in the United States by a committee of the National Academy of Sciences (Moore and Gerstein 1981). The most recent restatement of the approach by an international group of scholars appeared in 2010 (Babor et al. 2010), with a somewhat parallel analysis oriented to the developing world (Room et al. 2002).

The approach has had considerable influence on World Health Organization (WHO) programmes in the field of alcohol (Room 2005; WHO 2007). For instance, action on the availability and marketing of alcohol and on pricing policies are key elements of WHO's Global Strategy to Reduce the Harmful Effects of Alcohol, adopted in 2010 (WHO 2010). At national levels, there has been a considerable variation in its influence on

policy. In Sweden, where it is known as the Total Consumption Model, it attained dominance as the basis for official policy (Sutton 1997). However, policies based on this approach have been eroded as a consequence of Sweden's accession to the European Union (Holder et al. 1998). The approach also has had considerable backing in other Nordic countries.

In English-speaking countries, it has encountered substantial resistance in the cultural–political realm. Those allied with the alcoholic beverage industry have strongly attacked the approach, both in analyses and polemics (e.g. Mott 1991; Grant and Litvak 1998) and through direct political action to remove official proponents (Room 1984c). An approach that contemplates government regulation and influencing of private consumer choices is also unwelcome to those committed to consumer sovereignty and the primacy of individual choice (e.g. Peele 1987). Often, proponents of approaches seeking to 'domesticate' drinking—to reduce problems from drinking by integrating it into everyday life—have portrayed the new public health approach as antithetical to this (Olsson 1990), although some researchers have noted that there is no necessary antithesis (Whitehead 1979).

In terms of its influence on policy, the approach has undoubtedly had some effect in strengthening the defence of existing control structures and regulations. But efforts to get the approach adopted as the practical base for policy have met with resistance and failure in a number of countries (Hawks 1993; Room 2004). One response to this resistance has been some calls for an alternative approach (Stockwell et al. 1997), arguing that policy measures directed at heavy and problematic drinkers are more politically acceptable than measures directed at all drinkers. But the main public health response, as in the WHO's Global Strategy on alcohol (WHO 2010) and its 'best buys' on alcohol policy for tackling noncommunicable diseases (WHO 2017), has been to emphasize whole-of-population policies such as on availability and taxes.

The policy approach offered as an alternative is a focus on harm reduction, primarily by reducing instances of intoxication or insulating the drinkers from harm (Plant et al. 1997; Stimson et al. 2007). However, there is in fact usually no conflict between approaches aimed at total consumption and approaches aiming to reduce harm from heavy drinking. As Stockwell et al. (1997) noted, 'aggregate consumption levels are in fact likely to fall if effective (harm reduction) strategies are introduced'.

Conversely, many measures that affect the whole drinking population—taxation being a good example—are especially hard on heavier drinkers. Nor are targeted harm-reduction measures necessarily more politically acceptable than measures that affect all drinkers. Old systems of rationing and individual buyer surveillance (Järvinen 1991), which were directed specifically at restraining heavy drinking, are now politically unacceptable in any high-income society, although rationing, at least, was highly effective as a targeted prevention measure (Norström 1987).

Beyond its specific features, the controversy over the new public health approach replicates familiar patterns of controversy over public health approaches in general, particularly when those approaches impinge on familiar and valued patterns of behaviour, with substantial economic interests at stake. At the level of the knowledge base, the approach has had considerable success: the empirical evidence underlying the approach has considerably strengthened since the approach was first put forward. Thus the approach has remained dominant in public health thinking and advice, as in the WHO's Global Strategy on alcohol (WHO 2010) and its 'best buys' on alcohol policy for tackling noncommunicable diseases (WHO 2017). At a political level, however, the approach has had only limited success, and primarily in areas peripheral to its main focus—that is, in drinking–driving and minimum-age limits for drinkers.

Strategies of prevention and control and their effectiveness

Simplifying them, there are seven main strategies to minimize alcohol problems. One strategy is to educate or persuade people not to use alcohol or about ways to use it so as to limit harm. A second strategy, a kind of negative persuasion, is to deter drinking-related behaviour with the threat of penalties. A third strategy, in the positive direction, is to provide alternatives to drinking or to drink-related activities. A fourth strategy is in one way or another to insulate the user from harm. A fifth strategy is to regulate availability of alcohol or the conditions of its use; prohibition of supply may be regarded as a special case of such regulation. A sixth strategy is to work with social or religious movements oriented to reducing alcohol problems. And, a seventh strategy is to treat or otherwise help

people who have in trouble with their drinking habits. We will consider, in turn, these strategies and the evidence on their effectiveness.

Education and persuasion

In principle, education can be offered to any segment of the population in a variety of venues, but it is usually education of youth in schools that first comes to mind in the prevention of alcohol problems. Community-based prevention programmes, which are often also directed at adults, also may include an educational component.

Education offers new information or ways of thinking and leaves it to the listener to draw conclusions concerning beliefs and behaviour. However, most alcohol education programmes go beyond this. A common theme in North American evaluative literature on alcohol education is that 'knowledge-only' approaches do not result in changes in behaviour (Botvin 1995). School-based alcohol education has, thus, usually had a persuasional element, aiming to influence students in a particular direction.

Persuasion is directly concerned with changing beliefs or behaviours, and may or may not also offer information. Mass-media campaigns aimed at persuasion have been a very common component of prevention programmes for alcohol-related problems, but this can also be pursued through other media and modalities.

In most societies, public-health-oriented persuasion about alcohol must compete with a variety of other persuasive messages, including those intended to sell alcoholic beverages. The evidence that alcohol advertising influences teenagers and young adults towards increased drinking and problematic drinking is becoming stronger (Casswell et al. 2002). Even where alcohol advertising is not allowed in the mass media, these messages are often conveyed to consumers and potential consumers in a variety of other ways.

Evidence on effectiveness

The literature on effectiveness of educational approaches is dominated by studies on school-based education from the United States. This means that alcohol education has usually been in the context of drug and tobacco education and that the emphasis has been on abstention (Beck 1998) or at

least on delaying the start of drinking, in cultural circumstances where the median age of actually starting to drink is about 13 years although the minimum legal drinking age is 21 years. In general, despite the best efforts of a generation of researchers, this literature has had difficulty showing substantial and lasting effects (Foxcroft et al. 2003; Gorman et al. 2007). There is a good argument from general principles for alcohol education in the context of the consumer's health, but there is little evidence from the formal evaluation literature at this point of its effectiveness beyond the short term (Babor et al. 2010).

Persuasive media campaigns have also been a favourite modality in many places in recent decades. In general, evaluations of such campaigns have been able to demonstrate impacts on knowledge and awareness about substance use problems, but show little success in affecting attitudes and behaviours (Babor et al. 2010). As with school education approaches, there are hints in the literature that more success may come from influencing the community around the drinker—in terms of attitudes of significant others or popular support for alcohol policy measures—than from directly persuading the drinker himself or herself. Thus, media messages can be effective as agenda-setting mechanisms in the community, increasing or sustaining public support for other preventive strategies (Casswell et al. 1989).

Deterrence

In its broadest sense, deterrence means simply the threat of negative sanctions or disincentives for behaviour—a form of negative persuasion. Criminal laws deter in two ways: by general deterrence, which is the effect of the law in preventing a prohibited behaviour in the population as a whole; and specific deterrence, which is the effect of the law in discouraging those who have been caught from doing it again (Ross 1982). A law will have a greater preventive effect and be cheaper to administer to the extent it has a strong general deterrence effect.

Prohibitions on driving after drinking more than a specified amount are now in effect in most nations (WHO 2014, pp. 67–70). In many societies, there have also been laws against drinking in public places, against public drunkenness (being in a public place while intoxicated) and against obnoxious behaviour while intoxicated. Other common prohibitions are concerned with producing or selling alcoholic beverages outside state-

regulated channels and with aspects of drinking under a specified minimum age.

Evidence on effectiveness

Drinking–driving legislation, such as ‘per-se’ laws outlawing driving while at or above a defined blood-alcohol level, has been shown to be effective in changing behaviour and reducing rates of alcohol-related problems (Ross 1982; Hingson 1996; Babor et al. 2010). The effect is through both general and specific deterrence. The quickness and certainty of punishment as well as its severity are important in the deterrent value (too much severity tends to undercut the quickness and certainty). Drinking–driving is an ideal area for applying general deterrence, as the gains from breaking the law are limited and automobile drivers typically have something to lose by being caught.

Many English-speaking and Scandinavian countries have had a tradition of criminalizing drinking in public places or public drunkenness as such. The trend in the 1970s and following was to decriminalize public drunkenness, although in many places it remains illegal. In the 1990s and following, there has been some trend to criminalize drinking in specific public places (Pennay and Room 2012). Criminalization of such behaviours has some effect in moving behaviour around, but is not very effective in changing the behaviour of marginalized heavy drinkers who have little to lose.

Providing and encouraging alternative activities

Another strategy, in principle involving positive incentives, is to provide and seek to encourage activities that are an alternative to drinking or to activities closely associated with drinking. This includes initiatives such as making soft drinks available as an alternative to alcoholic beverages, providing locations for sociability as an alternative to taverns, and providing and encouraging recreational activities as an alternative to leisure activities involving drinking. Job creation and skill development programmes are other examples.

Evidence on effectiveness

‘Boredom’ and ‘because there’s nothing else to do’ are certainly among the reasons given by some for drinking. And, there are often good reasons of general social policy for providing and encouraging alternative activities. But as has been noted, the problem with alternatives to drinking is that drinking combines so well with many of them. Soft drinks are indeed an alternative to alcoholic beverages for quenching thirst, but they may also serve as a mixer in an alcoholic drink. Involvement in sports may go along with drinking as well as replace it. The few evaluation studies of providing alternative activities, again from a restricted number of societies, have generally not shown lasting effects on drinking behaviour (Moskowitz et al. 1983; Norman et al. 1997), although they undoubtedly often serve a general social purpose in broadening opportunities for the disadvantaged (Carmona and Stewart 1996).

Insulating use from harm

A major social strategy for reducing alcohol-related problems in many societies has been measures to separate the drinker, and particularly heavy drinkers, from potential harm. This separation can be physical (in terms of distance or walls), it can be temporal, or it can be cultural (e.g. defining the drinking occasion as ‘time out’ from normal responsibilities). These ‘harm-reduction’ strategies, as they are called in the context of illicit drugs, are often built into cultural arrangements around drinking, but can also be the object of purposive programmes and policies (Moore and Gerstein 1981), such as promotion of ‘designated drivers’, where one person in a social group is chosen to abstain and drive in the particular social situation (DeJong and Hingson 1998).

A variety of modifications to the driving environment positively affect casualties associated with drinking and driving, along with other casualties. These include mandatory use of seat belts, airbags, and improvements in the safety of vehicles and roads. Many other practical measures to separate intoxication episodes from casualties and other adverse consequences have been put into practice, although usually without formal evaluation.

Evidence on effectiveness

Drinking–driving countermeasures are a prime example of an approach in terms of insulating drinking behaviour from harm, as they seek to reduce alcohol-related traffic casualties without necessarily stopping or reducing alcohol use (Evans 1991). There is substantial evidence on the success of a range of such countermeasures, including environmental change approaches as well as deterrence (DeJong and Hingson 1998; Babor et al. 2010). Some environmental measures that reduce traffic casualties in general—such as requiring the wearing of seat belts in cars or providing sidewalks separated from the road—may prevent casualties associated with intoxication even more than other casualties.

Regulating the availability and conditions of use

In terms of the substantial harm to health and public order they can cause, alcoholic beverages are not ordinary commodities. Governments have, thus, often actively intervened in the markets for such beverages, far beyond usual levels of state intervention in markets for commodities.

Total prohibition can be viewed as an extreme form of regulation of the market. In this circumstance, where no one is licensed to sell alcohol, the state has no formal control over the conditions of the sales that occur nevertheless, and there are no legal sales interests, controlled through licensing, to cooperate with the state in market regulation.

With a general prohibition, typically, the consumption of alcohol does fall in the population, and there are also declines in the rates of the direct consequences of drinking such as cirrhosis or alcohol-related mental disorders (Moore and Gerstein 1981; Teasley 1992). But prohibition also brings with it characteristic negative consequences, including the emergence and growth of an illicit market and the crime associated with this. Partly for this reason, alcohol prohibition at a national level is now a live option only in Islamic societies, where the law reflects religious belief, which helps to sustain compliance. Local-area alcohol prohibitions are more widespread.

The features of alcohol control regimes that regulate the legal market in alcohol vary greatly. Special taxes on alcohol are very common, imposed often as much for revenue as for public health considerations. Most societies have minimum-age limits forbidding sales to underage customers and many have regulations forbidding sales to the already intoxicated.

Often, the regulations include limiting the number of sales outlets, restricting hours and days of sale, and limiting sales to special stores or drinking places. Rationing of alcohol purchases—limiting the amount individuals can buy in a given time period—has also been used as a means of regulating availability. Regulations restricting or forbidding advertising of alcoholic beverages attempt to limit or channel efforts by private interests to increase demand for particular alcoholic beverages. Such regulations potentially complement education and persuasion efforts. State monopolization on sales of some or all alcoholic beverages at the retail and/or wholesale level has also been commonly been used as a mechanism to minimize alcohol-related harm (Room 1993).

Effectiveness of specific types of regulation on availability

The decades since the 1970s have seen the development of a burgeoning literature on the effects of alcohol control measures. Reference guides for communities, summarizing the research evidence and attuned to particular national or regional conditions, are becoming available (e.g. Neves et al. 1998; Grover 1999). Specific types of regulation of the alcohol market, and the evidence on their effectiveness, are discussed as follows:

Minimum-age limits: A minimum-age limit is a partial prohibition, applied to one segment of the population. There is a strong evaluation literature showing the effectiveness of establishing and enforcing minimum-age limits in reducing alcohol-related problems (Babor et al. 2010). However, this literature is mostly based on North America, focusing mostly on youthful driving casualties and evaluating reduction from and increases to age 21 years as the limit, a minimum-age limit higher than in most societies. There is limited evidence on the applicability of the literature's findings in other societies and where youth cultures may be less automobile-focused (but see Møller 2002; Kypri et al. 2006).

Taxes and other price increases: Generally, consumers show some response on the price of alcoholic beverages, as on all other commodities. If the price goes up, the drinker will drink less; data from high-income societies suggests this is at least as true of the heavy drinker as of the occasional drinker (Babor et al. 2010). Studies have found that alcohol tax increases reduce the rates of traffic casualties, of cirrhosis mortality, and of incidents of violence (Cook 2007).

An alternative policy for price increases is the imposition of a minimum unit price or floor price—a requirement that alcoholic beverages not be sold at less than a specified price per unit of ethanol. Such a policy tends to differentially affect off-premise drinking—in homes or public places—since on-premise drinking includes servers' wages, etc. Heavier drinkers are more likely than moderate drinkers to be buying the cheapest alcohol (Callinan et al. 2015), so instituting a floor price is more targeted at problematic drinking than a tax increase. There is good evidence that setting a floor price reduces levels of alcohol-related hospitalizations and other problems (Stockwell et al. 2013).

Limiting sales outlets, and hours and conditions of sale: A substantial body of literature shows that levels and patterns of alcohol consumption, and rates of alcohol-related casualties and other problems, are influenced by such sales restrictions (Livingston 2013; Wilkinson et al. 2016; Sanchez-Ramirez and Voaklander 2018), which typically make the purchase of alcoholic beverages slightly inconvenient, influence the setting of and after drinking, or shorten late-night drinking sessions. If they are substantially enforced, rules influencing 'house policies' in drinking places on not serving intoxicated customers, for example, have also been shown to have some effect (Saltz 1997).

Monopolizing production or sale: Studies of the effects of privatizing retail alcohol monopolies have often shown some increase in levels of alcohol consumption and problems (Hahn et al. 2012), in part because the number of outlets and hours of sale typically increase with privatization (Her et al. 1999) and partly also because the new private interests typically exert political influence for further increases in availability. From a public health perspective, it is the retail level that is important, although monopolization of the production or wholesale level may facilitate revenue collection and effective control of the market.

Rationing sales: Rationing the amount of alcohol sold to an individual potentially directly impacts on heavy drinkers and has been shown to reduce levels both of intoxication-related problems such as violence and of drinking-history-related problems such as cirrhosis mortality (Schechter 1986; Norström 1987). But, although a form of rationing—the medical prescription system—is well accepted in most societies for psychoactive medications, general rationing of alcohol has been politically unacceptable nowadays for alcoholic beverages in high-income societies. Individual

control measures are coming back in play, but mostly in the form of individual bans on purchasing or drinking imposed by the justice system (Room 2012). Such bans, enforced by ankle bracelets measuring any alcohol consumption, have been shown to be effective in preventing drink-driving and alcohol-related intimate violence (Kilmer et al. 2013).

Advertising and promotion restrictions: Many societies have regulations on advertising and other promotion of sales of alcoholic beverages (WHO 2014, pp. 75–80). Although it is well accepted that advertising can strongly affect consumer choices on products in the market, it has proved difficult to measure the effects of advertising on demand for alcoholic beverages as a whole, partly because the effects are likely to be cumulative and long-term, making them difficult to measure. Bans of advertising in specific media do not seem to have much effect on overall consumption levels (Nelson 2010), perhaps because the resources which were spent on marketing through that channel will just be diverted to promotion on other media. Even the relatively restrictive French Évin Law on alcohol advertising does not appear to have shielded teenagers from the industry's marketing efforts (Gallopel-Morvan et al. 2017). However, there is some evidence of a relation between trends in teenage drinking and changes in the exposure of teenagers to alcohol advertising (White et al. 2017), and a systematic review of 20 studies found a 'relatively consistent association between alcohol promotion (predominantly advertising) and drinking outcomes in adolescence' (Scott et al. 2016).

Social and religious movements and community action

Substantial reductions in alcohol-related problems have often been the result of spontaneous social and religious movements, which put a major emphasis on quitting intoxication or drinking. Less common have been reductions in drinking without large-scale social movements, although such a reduction has happened among teenagers in many high-income countries in the early 2000s, with some variation in timing (de Looze et al. 2015: Kraus et al. 2018; Pennay et al. 2018). In recent decades, efforts have also been made to form partnerships between state organizations and non-governmental groups to work on alcohol problems, often at the level of the local community. There has been an active tradition of evaluated community action projects on alcohol problems, often using a range of

prevention strategies (Giesbrecht et al. 1990; Greenfield and Zimmerman 1993; Holmila 1997; Holder 1998; Room 2017). School-based prevention efforts have also moved increasingly to try to involve the community, in line with general perceptions that such multifaceted strategies will be more effective (Paglia and Room 1999).

Although some of the biggest historical reductions in alcohol problem rates have resulted from spontaneous and autonomous social or religious movements, support or collaboration from a government can easily be perceived as official co-optation or manipulation (Room 1997). Thus, there is considerable question about the extent to which such movements can or should become an instrument of government prevention policies. But adopting public health-oriented alcohol policies may become more feasible, and such policies can build on and support such changes.

Evidence on effectiveness

In the short term, movements of religious or cultural revival can be highly effective in reducing levels of drinking and of alcohol-related problems. Alcohol consumption in the United States fell by about half in the first flush of temperance enthusiasm in 1830–45 (Moore and Gerstein 1981). Rates of serious crime are reported to have fallen for a while to a fraction of their previous level in Ireland in the wake of Father Mathew's temperance crusade (Room 1983). The enthusiasm that sustains such movements tends to decay over time, although they often leave behind new customs and institutions of much longer duration. For instance, although the days when the historic temperance movement in English-speaking societies was strong are long gone, the movement had the long-lasting effect of largely removing drinking from the workplace in these societies. The community action projects in recent decades can show some success (Midford and Shakeshaft 2017), but their approaches have often been limited by a lack of power at the community level to implement policy change (Room 2017).

Particularly in the developing world, religious or cultural renewal movements oriented to reducing or prohibiting drinking are often a strong avenue of preventive action (Room et al. 2002). For instance, a reform movement among poor indigenous people in a region of Ecuador touched off in 1987 by religious renewal movements and an earthquake appears to have had lasting effects on popular sobriety (Butler 2006).

Treatment and other help

Providing effective treatment or other help for drinkers who find they cannot control their drinking can be regarded as an obligation of a just and humane society. The help can take several forms: a specific treatment system for alcohol problems, professional help in general health or welfare systems, or non-professional assistance in mutual-help movements such as Alcoholics Anonymous. To the extent such help is effective, it is also a means of preventing or reducing future alcohol-related problems in the person helped, although its effectiveness at a population level is less clear.

Treatments for alcohol problems need not be complex or expensive. The evaluation literature suggests that brief outpatient interventions aimed at changing cognitions and behaviour around drinking are as effective in most circumstances as longer and more intensive treatment (Long et al. 1998). Positive results from such interventions in primary healthcare settings have been clearly established (Kaner et al. 2018), including in a diverse range of countries in a WHO study (Babor et al. 1994).

Evidence on effectiveness

In terms of the effects of treatment on those who come for it, there is good evidence on the effectiveness of treatment for alcohol problems. Typically, the improvement rate from a single episode of treatment is about 20% higher than the no-treatment condition: further treatment episodes are often needed. Brief treatment interventions or mutual-help approaches usually result in net savings in social and health costs associated with the heavy drinker (at least where healthcare is not self-paid), as well as improving the quality of life (Holder et al. 1992; Holder and Cunningham 1992).

The effectiveness of providing treatment as a strategy for reducing rates of alcohol problems in a society is more equivocal. In a North American context, it has been argued that the steep increase in alcohol problems treatment provision and mutual-help group membership in recent decades contributed to reducing alcohol problems rates (Smart and Mann 1990). But the strength of the evidence for this contention is disputed (Holder 1997; Smart and Mann 1997). A treatment system for alcohol problems is an important part of an integrated national alcohol policy, but as an instrument of prevention—of reducing societal rates of alcohol problems—it is unlikely to be very cost-effective (Anderson et al. 2009).

Building integrated alcohol policies

Alcohol policy at a community or societal level

Often, the different strategies for preventing alcohol problems appear to be synergic in their effects (DeJong and Hingson 1998). For instance, controls on availability are more likely to be adopted, continued, and respected when the public has been successfully persuaded of their effects and effectiveness. But strategies can also work at cross-purposes: a prohibition policy, for instance, makes it difficult to pursue measures that insulate drinking from harm.

In a society where alcohol is a regular item of consumption, in view of the resulting rates of alcohol-related social and health problems, there is a strong justification for adopting a comprehensive policy concerning alcohol, taking into account production, marketing, and consumption, and the prevention and treatment of alcohol-related problems. In recent years, the idea that there should be an integrated alcohol policy at community or national levels, reaching across the many sectors of government and civil society that deal with alcohol issues, has become a common public health aim, although accomplishing this has often proved difficult (Smart and Mann 1997; Crombie et al. 2007; WHO 2010).

In terms of strategies we have reviewed for managing and reducing the rates of alcohol problems in the society, there is a clear evidence for effectiveness and cost-effectiveness of measures regulating the availability and conditions of use, and measures which insulate use from harm. With respect to some aspects of alcohol problems, notably drinking–driving, deterrence measures also fall in the same category. Along with availability (taxes and hours and days of sale), the WHO also identifies control of advertising and other marketing as a ‘best buy’ for public health policy on alcohol (WHO 2017). Despite their perennial popularity, evidence of the cost-effectiveness of education or persuasion and treatment strategies in reducing societal rates of problems is limited at best. Education and treatment are good things for a society and a government to be doing about alcohol problems, but they do not constitute in themselves a public health policy on alcohol (Babor et al. 2010). These strategies will nevertheless be pursued in most societies, and they can best be pursued with attention to

using cost-effective methods, and to integrating targets and messages with other aspects of alcohol policy.

Alcohol policy in a global perspective

Apart from agreements made a century ago among the European colonial powers about control of the spirits trade in Africa (Bruun et al. 1975b), there is little tradition of collaboration on alcohol policy at the international level. It has been largely up to each nation to cope on its own with the serious social and health problems associated with drinking. Although alcohol smuggling has a long history, the nation-state could usually rely on distances and traditional trade barriers to keep alcohol issues largely a matter within its borders, in terms of the supply as well as of the problems.

Since the 1980s, an accelerated rate of economic globalization has increasingly rendered obsolete the assumption that alcohol issues are local issues. This globalization affects alcohol issues in three main ways. The first of these is the influence of a global ideology of free markets. In its sweep, this ideology has caught up and dismantled a variety of market arrangements that served to hold down and to structure alcohol consumption. State and provincial alcohol monopolies in North America were weakened or dismantled (Her et al. 1999). In Eastern Europe and the countries in transition, alcohol monopolies were swept away along with most other governmental intrusions in the market (Moskalewicz 1993). Many of the municipally run beer halls in Southern African countries were privatized (Jernigan 1997). In line with the general ideology, privatization of alcohol production and distribution has been often suggested, abetted, or imposed on developing countries by international development agencies (White and Batia 1998). Where the market is organized in a state licensing system for private interests, free-market ideology has often overriden any concerns about public health risks or community need (Room 2004).

Second, trade agreements, trade dispute mechanisms, and the growth of new sales media have effectively reduced the ability of national and subnational governments to control their local alcohol markets. The influence of trade agreements and trade dispute decisions in breaking down alcohol controls, including control of price through taxation, has been most fully documented for North America (Room et al. 2006) and Europe (Tigerstedt 1990; Holder et al. 1998), but these mechanisms also operate in

the developing world. For instance, average taxes on alcoholic beverages in South Korea were lowered in 2000 as a result of complaints to the World Trade Organization by the European Union and the United States (Kim 2000). In 2010–2012, the EU and US joined by Australia, Canada, and five other countries, argued that Thailand's proposed warning labels on alcohol bottles would violate trade agreements (O'Brien 2013), and Thailand has been dissuaded from taking this step by the implied threat of a trade dispute. Global alcohol producers, acting through compliant countries, are successfully pushing for limits in trade agreements on the placement of warnings on the main label of bottles or cans (O'Brien et al. 2017).

Third, alcohol production, distribution, and marketing became increasingly globalized (Room et al. 2002; Jernigan 2010). Transnational alcohol companies expanded rapidly into low- and middle-income countries in search of new markets, benefiting from weak policy environments and the sweeping tide of market liberalization. Although most alcoholic beverages are still produced in the country in which they are sold, industrially produced beverages were increasingly produced in plants owned, co-owned, or licensed by multinational firms. To promote increased sales, these firms have been able to transform and step up the marketing techniques used in the national market, bringing to bear all the marketing resources and expertise they have developed in other markets.

In light of these converging trends, there is a growing need for mechanisms to express public health interests in alcohol issues at the international level, both in trade agreements and settlements of trade disputes, and in creating mutual obligations for one nation to back up rather than subvert the alcohol regulations and policies of another. There are growing calls for a framework convention on alcohol control to be negotiated under the WHO auspices or otherwise, on the model of the tobacco convention (A framework convention on alcohol control 2007; Room et al. 2008), although there has been some debate in public health about the advisability of this path (Taylor and Dhillon 2013; Room 2013).

Conclusion

The comparative risk analysis in the estimations of the global burden of disease has underlined the substantial role of alcohol in death and disability,

particularly in middle- and high-income countries. Over the last 30 years, a substantial literature has emerged which allows a differentiation of prevention strategies and policies in terms of their effectiveness. Some strategies—for example, school education, public information campaigns, and provision of alternatives—are often politically popular but have limited or no effect. A few strategies that have proved effective—notably, drinking–driving countermeasures—have been applied in a number of countries. Other effective strategies—especially controls on price and availability—have been widely resisted in the political process, and undercut by trade agreements. In a globalized world, control of the alcohol market in the interest of public health is needed not only at the local and national level, but also internationally. This need has led to calls for a framework convention on alcohol control, which would also provide an impetus and template for actions at national and subnational levels.

9.4

Injury prevention and control

The public health approach

Corinne Peek-Asa and Adnan A. Hyder

Introduction

Injuries contribute significantly to premature life lost and years lived with disability for all countries, all regions of the world, and all age groups, and disproportionately impact the young. According to analyses of the 2016 Global Burden of Disease data, injuries cause over 4.6 million deaths per year, accounting for nearly 8.4% of all deaths and 10.7% of disability-adjusted life years (Global Burden of Disease Study 2016). For children between 5 and 14 years of age, road traffic crashes, drowning, conflict, and terrorism, falls, and interpersonal violence are all in the leading 15 causes of death. Deaths represent just a small proportion of the many injuries that cause potentially lifelong disability, and injuries also cause significant psychological trauma and financial loss. The burden of traumatic injuries necessitates that injury prevention be considered an international public health priority.

Because the majority of people will suffer multiple minor injuries throughout their lives, most of which cause only minor discomfort or inconvenience, populations and decision-makers may be lulled into believing that injuries are just part of life. However, a serious injury or the traumatic death of a loved one can completely change the course of the lives of those affected. The toll of these injuries is also extremely deleterious to families, communities, and societies.

Injuries can be prevented, and global investment in trauma and injury prevention will have significant long-term health and financial benefits. For high-income countries, progress has been made in reducing the toll of

injuries. In the United States, for example, road traffic crashes per million vehicle miles travelled decreased by 37% between 1994 and 2014 (National Highway Traffic Safety Administration 2017). Mortality rates have decreased for deaths from drowning, residential fires, homicide, poisoning, among others. However, these rates remain unacceptably high knowing that many effective prevention strategies have not yet been widely implemented. The World Health Organization (WHO) anticipates that, if current trends continue, road traffic injuries, self-harm and falls will all be among the leading 20 causes of death by the year 2030 (WHO 2018).

The burden of injury worldwide is disproportionately concentrated in lower-income countries. The WHO anticipates that, if current trends continue, road traffic injuries, violence and self-inflicted injuries will all be among the leading 20 causes of disability-adjusted life years lost by the year 2030 (WHO 2002, 2018). Road traffic crashes, which in 1990 ranked as the tenth leading cause of disability-adjusted life years lost, is ranked sixth in 2016 (GBD 2016). Operations of war will rise from the rank of 16 in 1990 to 8 by 2020, and interpersonal violence will rise from rank 19 to 12. Despite some successes in many areas of injury prevention, new risks, changing environments, and increasing population size constantly challenge injury control efforts.

Effective injury prevention strategies will require organization of the public health response and increased integration of professionals from many backgrounds. Modern injury control research combines ideas and skills from public health, biomechanics, engineering, behavioural sciences, law, law enforcement, medicine, and urban planning, among others. Research that identifies how effective interventions in high-income countries can be translated in low- and middle-income settings is a priority, but injury prevention strategies will need to be appropriate for local environments. Injury prevention activities that integrate multiple approaches within an organized public health response have a stronger chance of success.

This chapter will present the current state of knowledge regarding the burden of injuries and will introduce the basic concepts of building injury prevention infrastructure and capacity.

Causal model of injuries

Injuries are generally divided into the two broad categories of intentional and unintentional. Intentional injuries are those in which there was an intent to commit harm, either to oneself or someone else. Unintentional injuries occur without a direct intent to commit harm, even if gross negligence was involved. For example, a motor vehicle occupant death caused by a drunk driver would be considered an unintentional injury even though in many countries the driver could be prosecuted for a crime.

Injuries are further classified by their cause, such as motor vehicle occupant injuries, drowning, suicide/attempted suicide, homicide/assault, or residential fire injuries. Until the late 1990s, cause and intent were coded together, so that, for example, a poisoning death would not be distinguished as intentional or unintentional. In the 1990s, collaboration between the US Centers for Disease Control and Prevention and the American Public Health Association recommended that cause and intent be considered as separate components of describing an injury, and most data are now coded accordingly (Centers for Disease Control and Prevention 1997). Through this collaboration, a matrix to code injuries by intent and cause using the International Classification of Diseases, 9th revision, was developed. This matrix served as a template to create codes for injury cause and intent that are now included in the 10th revision of this coding system.

Injury causes are very broad and represent a diverse range of physical harm, and thus can be difficult to tie together conceptually. The traditional epidemiologic model for infectious diseases provides a framework for the epidemiologic study of traumatic injury (Fig. 9.4.1). At the centre of the causal pathway for injuries is the agent-host interaction. The agent, which in the case of injuries is energy, is absorbed by the host to cause injury. Energy can take many forms, such as mechanical, electrical, chemical, radiation, and thermal. An example of an agent-host relationship is a motor vehicle crash, in which the energy exerted on the individual is mechanical. The reservoir is the place in the environment where the agent is found. The potential for energy transfer exists everywhere, but its potential to cause injury is limited to specific conditions. For instance, the potential energy in a motor vehicle exists only when the car is being driven, and causes injury only when the vehicle crashes.

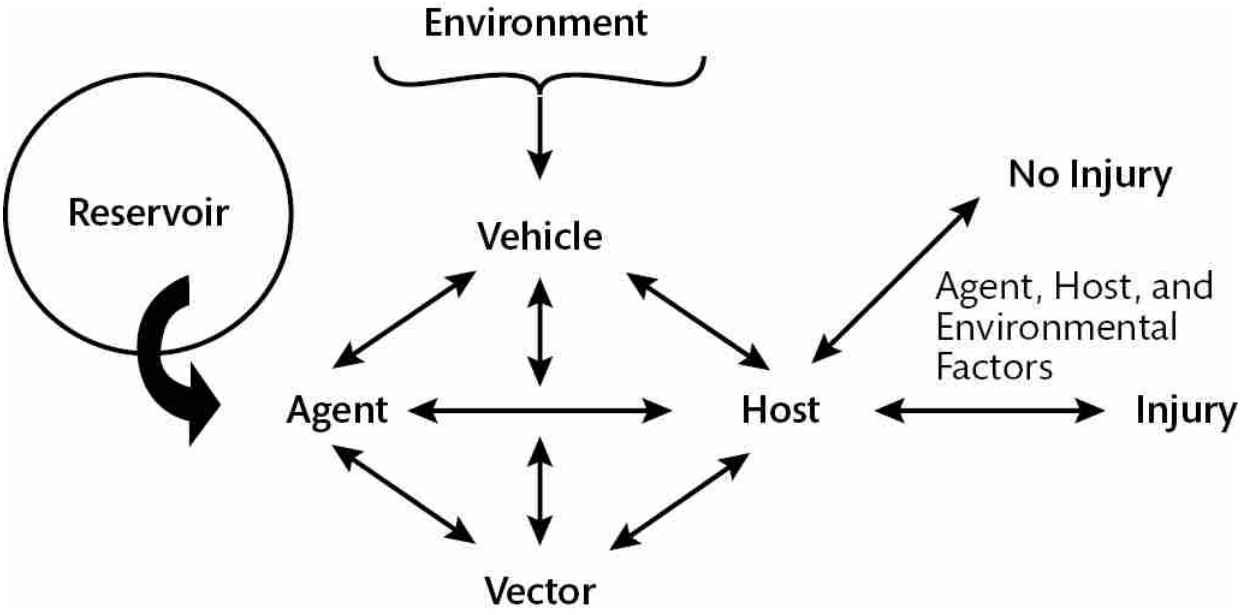

Fig. 9.4.1 Framework for the epidemiologic study of traumatic injury.

Vehicles and vectors are mechanisms which transport energy from the reservoir to the host. A vehicle can be an inanimate object, such as a motor vehicle; or animate, such as a dog biting a child. For many injury causes, vehicles and vectors are both involved in energy transfer, such as when one individual (vector) stabs another with a knife (vehicle). The injury outcome is the trauma or injury sustained by the individual, and is influenced by host responses to the energy. Only energy transmitted beyond a host's tolerance causes an injury, and therefore not all exposures to energy result in noticeable injury. A human has some resistance to energy which can be increased through exercise or protective devices, or reduced through changes in intrinsic factors such as existing medical conditions or age and through extrinsic factors such as fatigue and alcohol.

This causal model is important when considering injury prevention strategies. Injury prevention aims to prevent energy transfer or to reduce the amount of energy that is transferred. Prevention activities can focus on the host, on the environment, on vehicles or vectors, or combine all of these components. A theoretical approach to injury prevention based on this model is presented later in this chapter.

Injury Data Sources

Globally, improved data infrastructures and increased access to data has aided in the rising awareness of the burden of injury and violence as a health problem. Data that provide information related to injuries can be found from a wide variety of sources, both within and outside of the health sector (Institute of Medicine 1999; Hyder and Morrow 2006). Mortality data, most frequently collected through vital statistics reporting, is the most commonly used source for measuring the burden of injury. Most countries have some structure for death reporting that includes the cause of death, although the quality of these data varies markedly around the world.

Efforts to combine global mortality data to compare incidence, years of potential life lost, and disability-adjusted life years have improved our knowledge of the burden of injury. The Global Burden of Disease Study attempted to collect consistent and internationally comparable health data (GBD 2016) and is one of the most comprehensive sources of injury mortality data. The study is going to be updated each year and so estimates will change annually—including prior estimates which will be updated at the same time. The data, however, have limitations in terms of available data at country level, quality of reporting, and coding injury types, and thus are may be an underestimate of overall injuries. The recent 2016 Global Burden of Diseases, Injuries, and Risk Factors study is the most recent effort to compare incidence and risk factors for injuries and diseases (GBD 2016, 2017. This effort made several key advances in global data comparisons which included expanded and clarified definitions of causes of death; the integration of risk factors and risk behaviours; and, improved estimates to reduce uncertainty.

The WHO also reports injury data in both global and disease specific outlets. For example, WHO's Global Health Estimates are the main death and disability data generated by WHO and updated periodically (see: http://www.who.int/healthinfo/global_burden_disease/en/). In addition, road safety data is reported periodically through their Global Status Reports on Road Safety including data provided by countries and those modelled by WHO (see: http://www.who.int/violence_injury_prevention/road_safety_status/2015/en/).

Although these global estimates are extremely valuable for comparisons, they often provide little detail about contextual risk factors and circumstances for injuries. Detailed surveillance systems that focus on

specific types of injuries have been very helpful to identify and prioritize prevention approaches. For example, the Fatal Accident Reporting System of the United States Department of Transportation provides details of road traffic deaths and has helped improve car and road design and has assisted in development and implementation of safety policies. The Census of Fatal Occupational Injuries maintained by the United States Bureau of Labor Statistics has also helped compare workplace fatalities by occupation and industry and prioritized workplace hazards.

In comparison with mortality data, population-based data of non-fatal injuries and their outcomes are more challenging to collect and far less available, especially in the developing world. In high-income countries, population-based data describing non-fatal injuries can be found within hospital reporting data, often used to monitor national health indicators. Sources that include injuries as one of many health outcomes often lack detail to inform injury prevention approaches. Other sources are specific to certain types of injuries, such as trauma registries. Efforts to pool trauma data, such as the United States' National Trauma Data Bank or Canada's National Trauma Registry, are helpful in describing larger patient samples, but trauma registries can rarely be tied to a population base. Many data sources outside the health sector also cover a wide spectrum of injury-related events, such as data from law enforcement, the transportation sector, criminal and justice sectors, and insurance companies. This diversity of data sources makes the field of injuries and violence unique in terms of the intersectoral nature of the information (Norton et al. 2006).

In many instances, data sources can be linked together to provide a more complete description of the injury. Motor vehicle crash injuries, for example, often require data from traffic enforcement to describe the cause and nature of the crash, and data from the health sector to describe the injuries and their severity. Linking these data sources can be impeded by issues of privacy and access to identifying information for linkage, as well as data quality issues. In low- and middle-income countries these data systems, when they exist are often not computerized and have seldom been evaluated for quality, making such linkages even more challenging. However, information from multiple sources is often necessary to examine causal hypotheses about injuries.

A growing emphasis on improving health behaviour has led to global efforts to collect data on risk factors. Many countries conduct surveys of health behaviours, such as the United States' Youth Risk Behavior Survey

(Eaton et al. 2012). More recently, multicountry surveys have been launched to compare risk behaviours across countries. One example is the Health Behaviour in School-aged Children study, which surveys adolescents in more than 40 countries (Roberts et al. 2009). Evaluations of large scale prevention efforts can also provide important risk factor data, such as a collection of city-wide observational road safety risk factor studies conducted undertaken as part of the Bloomberg Initiative for Global Road Safety (Gupta et al. 2017). These surveys help establish ties between the prevalence of risk behaviours and experiences with injury and violence.

Despite improvements in data infrastructures that have been possible with technological advances, access to high-quality and detailed data on injury and violence remains an important limitation in most countries. Data limitations are particularly problematic in low-income countries. In many low-income countries, death reporting is the only major source of information about the burden of injuries, and these data can have gaps in reporting and coding. The public health infrastructure and routine collection of health information in the developing world has been fragile, especially in regions such as sub-Saharan Africa and South Asia. It is thus not surprising that there has been little tradition of developing specific information sources for injuries. Population-based studies from low- and middle-income countries, though, consistently conclude that the injury burden is higher than reported in national official statistics and that injuries are significantly underreported in these regions.

Global burden of injury

According to the 2016 Global Burden of Disease Study, over 4.6 million deaths occur as a result of injuries around the world (Table 9.4.1) (GBD 2016). More than 25% of these deaths are caused by road traffic injuries (RTIs), with self-inflicted injuries (self-harm) and falls comprising a further 17.7 and 14.7% respectively. Likewise, injury death rates are highest for RTIs, followed by self-inflicted injuries and falls; similar patterns are observed for non-fatal health outcomes using disability-adjusted life year (DALY) rates per 100,000 population (Fig. 9.4.2). Unintentional injuries, including RTIs, falls, drowning, fire burns, and poisoning, together result in more than 2.5 million deaths in 2016.

Table 9.4.1 Deaths from injuries worldwide, 2016

	Total	Females	Males
All injuries	**4,610,991**	**1,395,618**	**3,215,373**
Road injuries	1,342,284 (29.1)	318,141 (22.8)	1,024,143 (31.9)
Self-harm	817,148 (17.7)	257,624 (18.5)	559,523 (17.4)
Falls	678,458 (14.7)	294,501 (21.1)	383,957 (11.9)
Interpersonal violence	390,794 (8.5)	73,112 (5.2)	317,682 (9.9)
Drowning	302,932 (6.6)	87,836 (6.3)	215,096 (6.7)
Forces of nature, conflict, and terrorism	161,895 (3.5)	48,019 (3.4)	113,876 (3.5)
Exposure to mechanical forces	154,844 (3.4)	38,431 (2.8)	116,412 (3.6)
Fire, heat, and hot substances	132,084 (2.9)	64,708 (4.6)	67,376 (2.1)
Adverse effects of medical treatment	126,733 (2.7)	60,822 (4.4)	65,911 (2.0)
Foreign body	106,266 (2.3)	41,457 (3.0)	64,809 (2.0)
Other unintentional injuries	98,288 (2.1)	17,157 (1.2)	81,131 (2.5)
Other transport injuries	95,006 (2.1)	18,585 (1.3)	76,421 (2.4)
Animal contact	91,588 (2.0)	38,824 (2.8)	52,764 (1.6)
Poisonings	57,077 (1.2)	21,023 (1.5)	36,053 (1.1)
Environmental heat and cold exposure	55,596 (1.2)	15,375 (1.1)	40,221 (1.3)

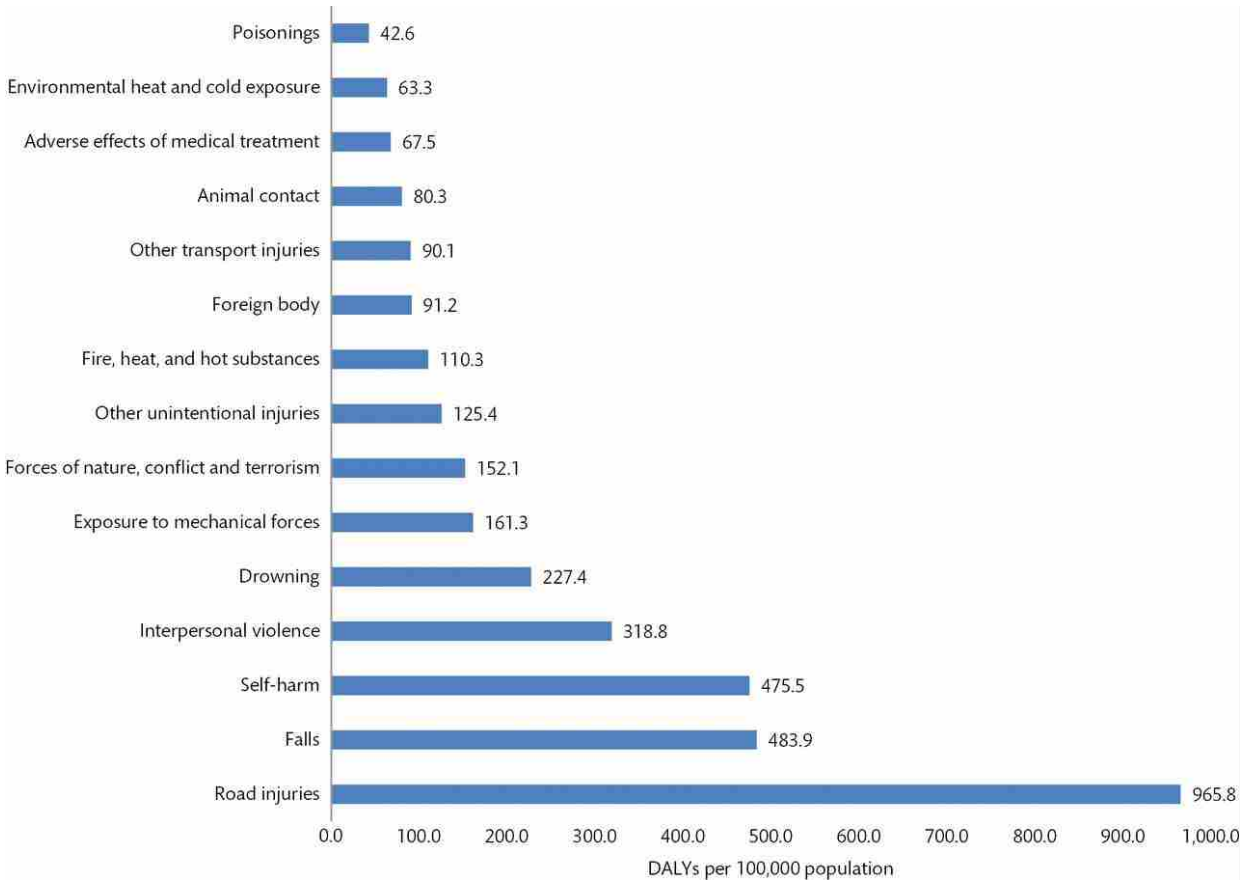

Fig. 9.4.2 DALY rates per 100,000 population.

RTIs alone kill over 1 million people every year. In 2016, RTIs became the ninth leading cause of death worldwide, down from eighth in 1990—a per cent change of 20.2%. Males account for more than three-fourth of these deaths. According to the WHO's *Global status report on road safety*, the majority of those killed are from low- or middle-income countries (LMICs) (WHO 2015). The absolute number of fatalities and the mortality rate resulting from RTIs vary considerably across countries, and although all age groups are affected young adults, particularly males, are most at risk of loss of life. Since this age group corresponds to the most economically productive segment of the population, RTIs have serious implications for national economies and also account for more than 71 million DALYs—some 965.8 DALYs per 100,000 population.

Falls are the second leading cause of unintentional injury deaths and there were over 678,000 fall-related deaths in 2016. This constitutes a mortality rate of 9.2 per 100,000 population. More males die from falls than females

(approximately 56.6% and 43.3% respectively). In addition, falls account for over 35 million DALYs or 483.9 DALYs per 100,000 population.

Drowning and fire burns are also significant causes of fatal injury—contributing 6.6% and 2.9% to the global burden of unintentional injury deaths respectively. Drowning amounts for over 300,000 deaths in 2016—more than 50,000 of these drowning deaths were among children under 5 years of age. Males comprise the majority (60%) of drowning deaths across all age groups till 70 years of age. The mortality rate from drowning is approximately 4.1 per 100,000. Non-fatal drowning events result in more than 16 million DALYs lost per year.

Well over 132,000 deaths in 2016 were caused by fire burns, which result in more than 8 million DALYs—110.3 DALYs per 100,000. Slightly more males than females die from fire burns (compare 51% and 49% respectively). In 2016, there were more than 57,000 fatal poisonings were estimated, which correlates to a mortality rate of nearly 0.77 per 100,000 population. Other unintentional injuries including unintentional exposure to firearms, and non-venomous animal contact, i.e. bites or attack, among others contributed 13.7% of the global burden of injuries and result in nearly 630,000 deaths worldwide.

In 1990 self-harm ranked fourteenth in the top 25 causes of worldwide deaths; and in 2016, they ranked seventeenth and are the second leading cause of injury death after RTIs, and the leading cause of intentional injury deaths. Self-inflicted injuries, including suicides, attempted suicide, self-destructive behaviours, and self-mutilation, cause the deaths of over 800,000 people globally, resulting in more than 35 million DALYs lost. Self-harm or self-inflicted injury deaths peak in the 20–24 years age group and more than 65% of self-inflicted injury deaths in 2016 were among males (68.4%). Although self-harm ranks twenty-first on the top 25 causes of death among females, overall, it ranks sixth in the Eastern Europe, tenth in Central Asia and South Asia, twelfth in Oceania, thirteenth in Southern Sub-Saharan Africa, and fifteenth in East Asian regions. On the other hand, self-harm mortality rates among females are highest in South Asia and Eastern Europe (12.7 and 1.4 per 100,000 population respectively).

Interpersonal violence, including assault by firearm, sharp objects or other means cause more than 390,000 deaths worldwide; and females account for less than 20% of these deaths. The mortality rate due to interpersonal violence is approximately 8.5 and 2.0 per 100,000 population for males and

females, respectively. However, the extent to which intimate partner violence (IPV) is accurately reported as interpersonal violence is unknown given varying cultural norms and reporting tendencies around the world. For example, a case of apparent self-immolation may in fact be domestic violence involving fire. Women in countries who have conducted programmes to screen and respond to IPV, including victim assistance programmes and social marketing campaigns against IPV, may be less inhibited to divulge their experiences with violence. Thus, the use of country or regionally specific demographic surveys as a supplement to global aggregate data is essential to determine the actual burden.

Conflict and terrorism were estimated to cause more than 150,000 deaths worldwide in 2016, more than 70% are males. Conflict and terrorism results in some 10,000,000 DALYs lost.

Economic and societal burden

The average annual cost of road traffic crashes was historically estimated at about 1% of the gross national product in developing countries, 1.5% in countries in economic transition, and 2% in highly motorized countries. The annual economic cost of RTIs globally was estimated at about US$518 billion (Jacobs et al. 2000). At that time, the annual cost of road traffic crashes in low- and middle-income countries was about US$65 billion, exceeding the total annual amount received then by these countries in development assistance. More recent estimates have been regional or national—and in general indicate that the cost of RTIs ranges from 1% to 3% of annual gross domestic product (or gross national product). Policies that reduce deaths and injuries from RTIs can save millions of dollars regardless of the income or development level of the country.

Studies exploring the economic and social costs of RTIs in low-income countries show that males who provided the majority of the household income in India and Bangladesh were the most common victims of road traffic fatalities and the consequences included reduced household income and reduced food consumption for the victim’s family (Aeron-Thomas et al. 2004). In addition, the poor were found to spend a much greater proportion of their income on funeral and/or medical costs than the non-poor. A recent qualitative study of the intangible costs of RTI in Mexico acknowledges similar findings but also emphasizes the loss of a family member to RTI can

impact not only a family's household economy, but the very stability of the familial unit—in whichever form—as well as the individual family member's sense of her or his life's purpose (Pérez-Núñez et al. 2012). A multicountry study from South Asia found that household with a road traffic injury patient tend to incur significantly high out-of-pocket costs on health-related expenditures, hospital care, and medicines, thus high lighting the need for mechanisms to provide financial risk protection for such households (Alam and Mahal 2016).

Estimates of the cost of violence in the United States reach over 3% of the gross domestic product. In England and Wales, the total costs from violence amount to an estimated US$40 billion annually. The economic effects of interpersonal violence are expected to be more severe in poorer countries, and yet, there is a scarcity of studies on the costs of violence in low- and middle-income countries (WHO 2004). However, estimates from low- and middle-income countries indicate that the overall costs of violence are substantial, ranging up to 25% of annual gross domestic product. Comparisons with high-income countries are complicated by the fact that economic losses related to productivity tend to be undervalued in lower-income countries. For example, child abuse results in US$94 billion in annual costs to the US economy (1% of GDP) and IPV costs the US economy nearly US$13 billion (0.1% of GDP); this can be compared to 1.6% of GDP in Nicaragua and 2% of GDP in Chile. The cost of gun violence also has been calculated at US$155 billion annually in the United States.

Theoretical basis for injury prevention

The causal model for injuries allows the injury process to be categorized into distinct phases which are important for prevention (Haddon 1970, 1972). The *pre-injury* phase is the period prior to the energy transfer, the *injury* phase is the often millisecond period in which the energy is transferred to the host, and the *post-injury* phase is the period of recovery and rehabilitation. Prevention approaches affect the injury process in one or more of these three injury phases.

Primary injury prevention includes strategies that aim to prevent the transfer of injury to the host, and thus act in the pre-injury phase. Examples of successful primary prevention strategies include roadway designs that

reduce motor vehicle collisions, child-resistant caps on medication bottles to prevent ingestion and poisoning, and pool fences to prevent submersion and drowning (Graham 1993; Thompson and Rivara 2000).

Secondary injury prevention includes strategies that reduce the amount of energy that is transferred to the host. While these strategies are often put in place long before the injury event, their function acts to reduce energy transferred during the injury phase. Examples of secondary prevention strategies include seat belts and air bags (Evans 1995), motorcycle and bicycle helmets (US General Accounting Office 1991; Thomas et al. 1994). Seat belts and helmets do not prevent the crash itself, but they reduce the amount of energy transmitted to the host during the crash. Secondary prevention strategies might not prevent injury completely. For example, lower extremity injuries are not prevented by either seat belts or helmets. However, studies have consistently shown that when these devices are present, the risk for mortal injury is much less and injury severity is reduced.

Tertiary prevention strategies act in the post-injury phase to help with recovery and rehabilitation once an injury has occurred. One example is the development of trauma systems, which help with triage and transport of an injured individual to reduce the time between injury and definitive medical care (Mann et al. 1999; Nathens et al. 2000). Optimizing resources to enable recovery and rehabilitation does not prevent the injury or reduce the amount of energy transfer, but tertiary prevention strategies can have enormous impact on improving survival, function, and quality of life following an injury.

The Haddon Matrix is a framework that combines these injury phases with the major components of the injury causal model to help identify prevention approaches (Table 9.4.2). This matrix, developed by Dr William Haddon in the United States, was the foundation for the study of motor vehicle crashes and countermeasures for highway safety and continues to be an applicable theoretical framework for injury prevention (Haddon 1972). Using the three injury phases, Haddon categorized prevention approaches into those that affect the host, vehicles, and vectors, the physical environment, and the sociocultural environment. An example of the Haddon Matrix with examples from motor vehicle occupant protection is included in Table 9.4.2.

Table 9.4.2 The Haddon Matrix for motor vehicle safety (illustrative)

Phases	Factors			
	Human	**Vehicle**	**Physical environment**	**Sociocultural environment**
Pre-injury	Reduce alcohol intoxication, programmes to increase defensive driving and decrease road rage	Increase vehicle stability, increased visibility	Improvements in road structure and traffic controls, traffic calming measures	Support safety programmes and increase consumer awareness of safety issues
Injury	Use of seat belts and car seats, proper placement of car seats, booster seats	Increase energy absorbed by the vehicle frame, safety features such as air bags, head rests, shatterproof windshields, and collapsible steering columns	Install energy-absorbing guard rails	Programmes to provide car seats, educational programmes about car seat installation and placement
Post-injury	Stabilize serious injuries, reduce bleeding and other complications	Design for easier extrication	Enhanced emergency medical systems and field care	Support infrastructure of trauma care, including 911 system, emergency and trauma care, and rehabilitation services

The Haddon Matrix provides a framework for identifying individual approaches to injury prevention. However, one single intervention strategy is unlikely to be highly effective. Multiple collaborative approaches need to be combined to maximize success. For example, the success of seat belt use in reducing motor vehicle occupant fatalities in the United States required a combination of engineering, education, policy, and enforcement that led to the current use rate of 80% (National Highway Traffic Safety Administration 2007). Although seat belts were developed and available from the early 1900s, they were not required to be a standard feature on passenger cars in the United States until 1968. The steps to getting seat belts installed as a regular feature in passenger cars required considerable advocacy and policy initiatives. However, once the seat belts were installed, use rates without any occupant incentive or education were about 11%. Efforts in the areas of

legislation, enforcement, and public education were necessary to achieve the high use rates currently observed. Stricter legislation, for example, is associated with higher use, as evidenced by the higher use rates consistently observed among states with primary (not wearing a seat belt is by itself a citable offence) compared with secondary (not wearing a seat belt can be cited only along with another citation) laws in the United States (National Highway Traffic Safety Administration 2007).

Risk factors for injuries

The Social-Ecological Model is helpful in conceptualizing the relationship of injury risk factors and also the level at which different types of prevention strategies work. The most common Social-Ecological Model used in injury prevention includes four levels: individual, relationship, community, and societal (Fig. 9.4.3) (Centers for Disease Control and Prevention 2009; Dahlberg and Krug 2002). This model posits that individual behaviour is largely determined by the influence of interpersonal relationships, community norms, and societal factors such as culture and political influence.

Fig. 9.4.3 Social-ecological model.

Individual-level variables that influence injury risk include age, gender, socioeconomic status, health status, and personality characteristics such as risk tolerance and the practice of safety behaviours. Many examples of the influence of individual-level characteristics on injury risk have been documented. For example, men have higher rates of injury than women for almost all causes of injury, and this difference is found consistently across the world. However, women appear to be at greater risk of fire-related burn injuries compared with men, and burn-related injuries account for a much higher proportion of injuries in young children when compared with other age groups (Jie and Ren 1992; Liu et al. 1998). Individual characteristics have been widely documented to influence the risk for motor vehicle-related deaths. Driver speeding, drinking, distraction, or drowsiness have been identified almost universally around the world as risk factors (Liu et al. 2003; WHO 2004). Declining resiliency and poor health status is an important individual risk factor for injuries among the elderly, particularly falls (Carpenter et al. 2009). Low bone density; poor nutritional status; low body mass index; low calcium intake; comorbid conditions (hypertension,

diabetes); poor performance in activities of daily living; poor cognitive function; poor vision; environmental factors affecting balance; family history of hip fracture; and alcohol consumption have all been identified as individual characteristics associated with increased fall risk (Cummings et al. 1995; Dargent-Molina et al. 1996; Clark et al. 1998; Boonyaratavej et al. 2001). Individual-level interventions often focus on increasing knowledge and encouraging behaviour change.

Relationship-level factors that predict injury include family and interpersonal relationship influences, including the environment in which these relationships occur. Interpersonal relationship factors can increase or decrease risk for injury. For children, parents are a key factors in safety; and limited adult supervision has been associated with pedestrian, drowning and poisoning injury risk in young children (Azizi et al. 1993; Soori 2001; Brenner 2003; Chadbunchachai et al. 2012). Parent communication style has been tied to risky driving attitudes of teens, and parent driving may influence the driving behaviour of their children (Mirman and Kay 2012; Yang et al. 2013). As we mature, peers and long-term partners become strong influences. The home environment can also influence injury risk. Low socioeconomic status, poor home conditions, and failure to remove home hazards are all factors associated with high and differential rates of home injury (Edelman 2007; Nyberg et al. 2012). Relationship-level interventions often focus on influential communication or changes in the home environment.

Community factors include schools, workplaces, neighbourhoods, all of which are influenced by community social norms and environments. Globally, community factors and characteristics vary more than individual characteristics. For example, the majority of drowning incidents in high-income countries are associated with recreational or occupational activities, while in most low- and middle-income countries they are associated with everyday activities near natural bodies of water (Kobusingye et al. 2001; Brenner 2003; Hyder et al. 2008). Rural and urban environments also have distinct and different patterns of injury, with injury rates from such causes as road traffic, drowning, poisoning, and occupational-related causes higher in rural communities (Peek-Asa et al. 2004). Prevention strategies usually are designed to impact the climate, processes, and policies in a given local community.

Societal factors encompass the cultural norms and socio-political characteristics that influence safety specifically, such as the safety culture. Broad social factors such as population health, socioeconomic status, and political stability also influence injury risk (CDC 2009). For example, injury death rates are far higher in low-income countries when compared to high-income countries. For road traffic deaths, motorization rates rise with income to a certain level (Kopits and Cropper 2003). In high-income countries, high motorization rates are not strongly correlated with road traffic deaths (Graham 1993). However, a growing number of LMIC that are experiencing very rapid increases in motorization have had a disproportionate increase in road traffic fatality rates (Ghaffar et al. 1999). Much of this increase is due to the lack of an organized safety culture, lack of road traffic safety laws and their enforcement, and governing agencies not prioritizing road safety. Prevention strategies at the societal level often focus on policy implementation and enforcement as well as efforts to change social norms.

Successful injury prevention strategies

Reducing the burden of injury requires multifaceted and comprehensive efforts. As demonstrated through the Haddon Matrix and the Socio-ecological Model, injuries occur as a complex interplay between individuals and their physical and sociocultural environments. Injury rates have very clear patterns and determinants that are affected by individual, family, community, geographic, and sociocultural factors. These factors and their interplay must be understood for effective intervention and prevention. Although individual, one-time programmes can have impact by increasing knowledge, encouraging behaviour change, or modifying an environment, long-term and sustainable reductions in injury usually require changes at the sociocultural level.

As the evidence base of successful injury prevention and intervention strategies increases, so do opportunities to translate these programmes to new populations. Translational research, both at the clinic and community level, is a promising priority for injury prevention. Considerations for translation of programmes to new populations include the priority of the injury problem in the new population; human and economic resources to implement and sustain the programme; and cultural relevance of the

programme (Woolf 2008). Injury prevention research, which tends to have a relatively short period between action and measurable impact, will likely gain in priority as nations realign research investments to focus on high-impact projects (Zerhouni 2005).

Resources to identify successful injury prevention programmes

A growing evidence base helps guide decisions on the most effective injury prevention strategies. In addition to information to measure the scope, burden, and cost of injuries, several good resources are available to identify evidence-based injury prevention approaches.

The Cochrane Collaboration provides scientific evidence-based reviews of healthcare interventions through the Cochrane Library. The library has more than 100 reviews on the prevention, treatment, and rehabilitation of traumatic injuries, including topics such as fall-related injuries to older persons, pool fencing to prevent drowning in children, and interventions for promoting smoke alarm ownership and function. Abstracts are available free of charge (http://www.cochrane.org/reviews/index.htm) and full reviews are available by subscription, with most major libraries holding subscriptions. Cochrane reviews are highly weighted towards evidence from randomized controlled trials, which excludes many of the observational evaluations conducted for injury interventions. The search strategy protocol requires inclusion of international findings as well as unpublished data, and when sufficient data are present meta-analyses are conducted. Thus, these reviews are meant to be applicable to an international audience. Recent additions on injury prevention include home safety education, alcohol interventions, and a synthesis of evaluations of the WHO Safe Communities programme (Spinks et al. 2009; Kendrick et al. 2012; Muckle et al. 2012).

The Campbell Collaboration, begun in 1999, includes systematic reviews of social intervention, divided into the categories of education, crime and justice, international development, and social welfare. The goal of the collaboration is to provide evidence for policy decisions regarding social issues. While the majority of injury prevention-related reviews are found within the crime and justice reviews, many reviews in the other categories are strongly related to injury and violence prevention. The Campbell Collaboration includes evidence from all types of study designs, and has methods groups to ensure systematic interpretation of findings. Recent

injury-related reviews address safety interventions to reduce workplace injury, community policing, and school-based bullying prevention programmes (Mazerolle et al. 2012; Farrington et al. 2008). Reviews are available at: http://www.campbellcollaboration.org/.

The Guide to Community Preventive Services: Systematic Reviews and Evidence-Based Recommendations (the *Guide*) was developed by the Task Force on Community Preventive Services, established by the United States Centers for Disease Control and Prevention. The *Guide's* recommendations are primarily based on evidence of effectiveness, including the suitability of the study design, but they also assess the applicability of the intervention to other populations or settings, the economic impact, barriers observed in implementing the interventions, and if the intervention had other beneficial or harmful effects. The *Guide* then provides a recommendation as to whether the approach is 'strongly recommended', 'recommended', has 'insufficient evidence' or is 'discouraged'. The Guide has injury-related reviews in the categories of alcohol, motor vehicle, physical activity, substance abuse, worksite, mental health, social environment, and violence. Reviews are available at http://www.thecommunityguide.org/default.htm.

The *Disease Control Priorities Network*, funded by the Bill and Melinda Gates Foundation, integrates economic evaluation to identify health priorities globally. The *Network* provides evidence on intervention impact, including cost-effectiveness, for the most prevalent global health conditions. This effort expands prior strategies by integrating economic elements and by placing a higher emphasis on evidence-based policies. The *Network* publishes the *Disease Priorities Handbook*, now in its third edition, that provides a synthesis of programme effectiveness and priorities by world region (Disease Control Priorities Network 2018).

Many global sources of information provide guidance on a variety of injury issues. The National Center for Injury Prevention and Control in the United States (http://www.cdc.gov/injury/) provides information about many injury prevention programmes and includes WISQARS, an injury and violence data query tool (http://www.cdc.gov/injury/wisqars/index.html). The Department of Violence and Injuries Prevention of the WHO (https://www.who.int) offers a diversity of guidelines and manuals that provide assistance in implementing programmes or conducting research. Examples include guidelines for establishing injury surveillance systems, conducting community-based surveys and evaluating prehospital care.

International non-governmental organizations also offer a variety of assistance and expert members on specific issues. Examples include the Society for the Advancement of Violence and Injury Research (http://www.savirweb.org/), the Safe States Alliance (http://safestates.org/), and the United Nations Road Safety Collaboration (http://www.who.int/roadsafety/en/).

Successful injury prevention strategies: road traffic injuries

With increased knowledge about the burden of RTIs globally there is growing attention to making roadways safer. Over the last several decades, many high-income countries have experienced decreases in motor vehicle occupant death rates, even while the total miles driven, and thus exposure to the roadway, have increased. In contrast, middle- and low-income countries have experienced large increases in road traffic fatality rates. Nearly 90% of road traffic deaths now occur in LMICs, although these countries have only 54% of the world's registered vehicles (WHO 2015). Worldwide, almost half of road traffic deaths are among pedestrians, cyclists, and riders of 2-wheeled vehicles. As the fleet of vehicles on these roadways gets more complicated, especially with a growing number of passenger and industrial vehicles, there is potential for continued increases in fatality rates. Efforts to reduce RTIs throughout the world are a good case study of how an integrated approach can lead to successful prevention.

The main reason for success in high-income countries has been a comprehensive approach to intervention that has included integration of environmental, engineering, legislative, and educational approaches. These changes have evolved over decades, leading to the development of a safety culture around road traffic. A "culture of safety" exists when safety is embraced as a fundamental goal at multiple levels: government, community, and individual. The paradigm shift to a traffic safety culture was first formalized in 1997 by the Swedish government with their Vision Zero initiative (http://www.visionzeroinitiative.com/). Since then, many other countries have adopted similar initiatives which include a traffic safety culture as the foundation.

Historically, as the number of passenger vehicles increased with industrialization, many high-income countries focused efforts on protecting vehicle occupants, and these efforts have shown many successes. In the

United States, The National Highway Traffic Safety Administration and the Federal Highway Safety Administration estimate that 243 000 lives were saved between 1966 and 1990 as a result of highway, traffic, and motor vehicle safety programmes (Institute of Medicine 1999). Road modifications mandated by the Federal Highway Traffic Safety Act of 1966 led to safer roadway infrastructures which allowed more cars to travel at higher speeds while reducing crash risk (Graham 1993). At the same time, changes to the motor vehicle itself (technological advancements to crashworthiness) increased the likelihood of survival in a crash. In addition to the implementation of seat belts and then air bags, legislation required modifications that improved vehicle crash worthiness. Some examples of these modifications include shatter-resistant windshields, collapsible steering columns, crash-friendly dashboard surfaces, frames that are resistant to passenger space intrusion, increased strength of the vehicle frame, seat, and doors, lap and shoulder belts, and airbags (Haddon and Baker 1981). Studies have found that these safety improvements to the motor vehicle led to a 24–40% decrease in fatal crashes and saved over 9,000 lives each year (Robertson 1981; Institute of Medicine 1999).

Most of these changes were due in part to legislative efforts, and these efforts were themselves multifaceted in nature. For example, the implementation of many of these laws required a successful engineering development as a foundation—improved crash worthiness of cars was based on concentrated research to identify the most successful design features, which were then required legislatively. Other legislative approaches are more behavioural in nature, such as laws that require seat belt use, driver training, speed limits, and laws that aim to reduce drunk driving. Implementation of these laws requires successful advocacy and education of legislators. However, their effectiveness varies dramatically. For example, most countries have laws against drinking and driving, yet countries have wide variation in the rate of alcohol-involved crashes as well as the number of drinking drivers, drivers cited for drinking and driving, and punished for drinking and driving. While this variation has much to do with factors associated with patterns of alcohol consumption, access to transportation, and the driving culture, this variation is also due to factors associated with the laws themselves. The effectiveness of legislative approaches depends on the level of enforcement that accompanies them and on the perception that the legislated consequences will actually occur (Mann et al. 2003). For

example, the effectiveness of drinking and driving laws is influenced by the level of enforcement, the ability of courts to impose penalties, and that the nature of the penalties serves as a deterrent.

The focus on motor vehicle occupants without concomitant integration of urban planning, sustainable transportation, and pedestrian and bicycle safety may be problematic in the long run. More recently, countries throughout Europe as well as Australia and the United States have introduced an approach called ‘traffic calming’ that aims to control motor vehicle traffic and speed in neighbourhoods, and thus increase safety and walkability in communities (Ewing 1999). The concept of traffic calming dates back to the Dutch city of Delft in the 1960s, when residents angry with fast-moving cars cutting through their local streets blocked them with gardens, social areas, and playgrounds (Ewing 1999). Modern traffic calming involves a variety of approaches to reduce traffic volume and speed in residential areas using visually appealing strategies.

Success in reducing road traffic deaths has depended on the development of an infrastructure that can identify and respond to road hazards, and a wide variety of approaches to address these hazards. In some developed and many developing countries, the car culture is growing without concomitant safety cultures (Bishai et al. 2003; WHO 2015). Highway design standards are often outdated or translated too directly from an industrialized country, and insufficient resources for roadway maintenance complicate the issue (Transport and Road Research Laboratory 1991). Poorly designed and maintained roadways are even further stressed by an ever-increasing number and variety of vehicles. In addition to a growing number of passenger cars and a high proportion of commercial vehicles and buses, developing countries’ roadways include animal-powered vehicles, small engine vehicles (such as scooters and motorcycles) that carry multiple people, bicycles, human-powered transport vehicles (such as a rickshaw), and pedestrians. This complex mix of vehicles contributes to increased deaths on the road.

In order to avert the growing toll of road traffic deaths, the WHO has called for a ‘systems approach’ in which the interaction between vehicles, roads, road users, and their physical, social, and economic environments form the basis for a multisectoral response (WHO 2004). The implementation of comprehensive traffic safety laws has been identified as one of the most important actions to reduce global RTIs, and these laws must include enforcement with appropriate penalties and concomitant public

awareness campaigns. The WHO has also called on governments to identify lead agencies in traffic safety, and to give these agencies a clear mission and authority for creating safer roads. Governments must also encourage multisectoral collaboration and support ongoing collection of data. These steps all fit within defined models of creating a global traffic safety culture.

Successful injury prevention strategies: drowning

Drowning prevention efforts often focus on three types of strategies: (1) remove, reduce, or change the water hazard; (2) change behaviour in risk taking, supervision or skills around water; and (3) prevent contact between people and the water environment (Wilson and Rogmans 2006). While these strategies remain relevant in all settings, drowning is experienced differently in HIC and LMIC settings. In HICs drowning events are often associated with recreational swimming, in swimming pools, or along the coast; while drowning in LMICs often occurs as a result of everyday activities near open bodies of water, ditches, or uncovered wells (Hyder et al. 2008). Therefore, successful drowning prevention strategies are often not transferable from HIC to LMICs.

Since the 1970s, HICs have implemented well-established preventive measures to prevent drowning events including: mandating fencing and self-closing or self-latching gates around domestic and public swimming pools; requiring supervision by certified lifeguards at public pools and swimming beaches; and recommending the use of personal flotation devices for boaters and novice swimmers (Thompson and Rivara 2000; Pearn et al. 2008; Centers for Disease Control and Prevention 2012). For adults, basic swimming instruction is an important skill, and deters the likelihood of drowning particularly in domestic or public swimming pools. Educational campaigns, such as one conducted in Australia to improve beachgoer recognition of rip currents to prevent surfing related drowning, are also effective preventive measures (Hatfield et al. 2011). The knowledge of basic life support or resuscitative measures, i.e. cardiopulmonary resuscitation, among non-medical personnel is also crucial to treat drowning victims. Alcohol is an emerging and important risk factor for drowning that ought to be banned whether at swimming pools, at swimming beaches, or on watercrafts including recreational boats through appropriate laws.

Many of these drowning prevention strategies are applicable to children though swim instruction thus far has been understudied and has yielded limited effectiveness (Asher et al. 1995). Attentive supervision of children in and around domestic swimming pools, swimming beaches, and around the home is crucial. And yet, a recent Cochrane review of home interventions found there was a lack of evidence that home safety interventions were effective in preventing children being left alone in the bath, which is a common cause of drowning among children (Kendrick et al. 2012).

In LMICs, the epidemiology of drowning is quite different as children comprise the largest burden. In Bangladesh, for example, drowning is one of the most common causes of death in children aged 1–4 years (Borse et al. 2011). More importantly, the critical risk factor–water–abounds; a single district alone might have 50,000 or more ditches and ponds[2]. Obviously, fencing off these bodies of water is not feasible in this context; however, other barrier-based interventions for drowning prevention in children less than 5 years have been piloted in rural Bangladesh (Callaghan et al. 2010). Door barriers (which prevent young children from leaving the home) and playpens (which limit movement of young children) appear to work in pilot settings, especially for children aged 1–3 years at high risk of drowning when their mothers are busy performing their daily household tasks. In addition, *crèches* (day care centres) have also shown promise by removing children from high risk contexts during the highest risk time of day in similar settings (Rahman et al. 2010). These interventions might be effective ways to reduce the number of drowning events and to ease the burden of supervision on mothers. Producing such barriers in the community or making them available at little or no cost to low-income families in LMICs, particularly in regions where drowning is most endemic, is an important agenda for global public health. However, large scale studies are needed to determine the true effectiveness of these interventions before they can be widely recommended.

Successful injury prevention strategies: Burns

There are sufficient data available from HICs to support the claim that burns can be successfully prevented using education, engineering changes, enforcement of legislative protection and environmental modifications

(Gielen et al. 2018). A range of successful burn prevention strategies such as smoke detectors, fire sprinklers, regulating hot water heater temperatures, mandating flame-resistant children's sleepwear, and enforcing safe and proper electrical wiring of residences and businesses have been implemented across HICs (Gielen et al. 2018). Installing smoke detectors in the United States, for example, has been associated with a 61% reduction in the risk of death from residential house fires (Marshall et al. 1998). This reduction has been made possible by programmes such as the Smoke Alarm Installation and Fire Safety Education of the National Center for Injury Prevention and Control (Centers for Disease Control and Prevention) which targets low-income households since 1998 and has installed approximately 553,000 smoke alarms with 3,755 lives potentially saved (Kress et al. 2012). Further, should someone in a HIC suffer a burn, she or he is likely to be transported to a dedicated burn centre in a timely fashion to receive specialized care necessary to reduce damage and restore functioning.

Many of these strategies are impractical for LMICs given certain institutional and environmental challenges and a different epidemiology of burns. Common risk factors are poor living conditions, overcrowding, lack of education, lack of infrastructure to minimize burn risk and damage and limited access to burn care and rehabilitation (Clark et al. 2018). For example, childhood burns risk factors include: use of kerosene, cooking in open spaces, overcrowding, and lack of parental supervision (Mashreky et al. 2010; Van Niekerk et al. 2010). Interventions that have been proposed include separating the cooking area from the living area, increasing height of cooking surfaces, making separate cooking stations outside the house, reducing the amount of flammable substances available in the household, use of safer oil lamps, and enhancing child supervision (WHO 2008).

Two vulnerable groups can be identified in LMICs—young infants and children and adolescent/adult females. For younger children, a partitioned area imposed during cooking hours, shelves at appropriate heights, supervision to avoid young children carrying hot objects are being suggested. In addition, timely outpatient assessment and treatment is vital to mitigating the impact of such burns, and creation of social awareness has been used for mothers and caretakers (Mukerji et al. 2001). Interventions for the second risk group (young women) include safe, inexpensive, and efficient kerosene lamps and stoves (see next) placed above the floor level (McLoughlin 1995). Other efforts at encouraging women (through

grassroots education and multimedia) to wear appropriate clothing to reduce clothes catching fire and using flame-resistant materials in the manufacturing of local dresses are being explored.

Some of these interventions have been reiterated by the WHO's world report on child injury prevention which also promotes the use of safe kerosene lamps, separating cooking areas from living areas, raising cooking facilities off the ground, and banning of fireworks and flame-retardant clothing materials (WHO 2008). In LMIC households, cookstoves are commonly used for cooking and heating and unfortunately, poor manufacturing standards, low quality control, and a lack of safety features have made this a key risk factor for burns (Peck et al. 2008). In response, the Global Alliance for Clean Cookstoves, led by the UN Foundation, seeks to encourage 100 million homes in LMICs to adopt clean and safe cook stoves by 2020 as well as support a clean and innovative cook stove industry. Such cook stoves will dramatically reduce fuel consumption, exposure to harmful emissions and smoke, and the risk of fire burns (http://www.cleancookstoves.org).

Successful injury prevention strategies: acute care

Many injuries lead to death because of inadequate emergency and trauma care, and prehospital deaths are disproportionately large in low- and middle-income countries. In low-income countries, prehospital mortality is extremely high. For example, one study found that 81% of trauma deaths occurred in the prehospital setting in Ghana, a low-income country, compared with 72% for Mexico, a middle-income country and 59% in the United States (Mock et al. 1998).

Improvements in emergency medical response and trauma care have had a major impact in preventing deaths from injuries. Reducing the time between injury and definitive treatment leads to improved outcomes (IOM 1999). The most effective way to reduce time to treatment is through the implementation of a trauma system, which changes in the social environment to include better coordination between agencies, triage, and transport protocols, assignment of treatment levels to trauma centres, and improved training and certification at all levels of emergency care delivery.

Early evaluations of trauma systems conducted in high-income countries focused on the number of deaths that could be prevented, and estimates were

in the range of 20% to 40% (Mackenzie et al. 1992; Mullins et al. 1994; Shackford et al. 1986). One meta-analysis of the effectiveness of prehospital trauma systems in low- and middle-income countries concluded that injury mortality could be reduced by approximately a quarter (Henry and Reingold 2012). Effects were strongest for middle-income countries, largely because they had stronger health infrastructures on which to build trauma systems. One study estimated that if injury case fatality rates in low- and middle-income countries could be reduced to the same level as those in high-income countries, more than 1.7 million deaths, over a third of all injury deaths, could be reduced globally (Mock et al. 2012).

Developing systems for coordinated care, especially when out-of-hospital coordination is involved, is a challenge. In many countries, no organized system to identify and transport patients to the hospital exist (Nielsen et al. 2012). In low-income countries and in rural areas, patients are more likely to arrive at the hospital in commercial (e.g. minibus, taxi) and private vehicles other than in an ambulance (Young et al. 2003; Nielsen et al. 2012). The private citizens who provide emergency transport are also the most likely to provide first aid in the absence of trained emergency response personnel. Because building emergency transportation infrastructures would be expensive, experts have proposed formalizing relationships with commercial vehicles and local citizens to create an organized approach (Mock et al. 2012).

Lack of trained specialists in emergency care, both in the field and in hospitals, is another barrier to reducing trauma death. Many countries lack trained medical personnel, equipment, and infrastructure (Kobusingye et al. 2005). An evaluation of trauma care capabilities in Mexico, Vietnam, India, and Ghana indicated that even when a sufficient number of healthcare professionals were trained, ‘brain drain’ from rural to urban and from low- to higher-income communities led to widespread provider shortages (Mock et al. 2006). In order to develop a stronger trauma response system, improvements must be made in the areas of increased human resources, physical resources, security for healthcare personnel, transportation systems to get patients to definitive treatment, and administrative infrastructure with effective leadership and governance (Kobusingye et al. 2005; Mock et al. 2006).

Although many of these improvements require new resources, system-wide changes are possible through effective planning even in the absence of

significantly increased resources. For example, several low-cost trauma training programmes have been developed and used effectively in low-income countries, and these have contributed to decreased injury mortality (Kobusingye et al. 2005). Administrative changes, such as making necessary diagnostic equipment available for critical trauma cases, are also low-cost. However, identifying and implementing low-cost strategies cycles back to the need for data. Finding the low-cost strategies that will work in a healthcare facility will be enhanced by data systems that can track trends in patient treatment and be used for quality assurance. These systems are lacking in many healthcare organizations throughout the world.

Improving emergency medical systems and trauma treatment capacity could greatly reduce injury mortality worldwide, and also reduce the physical, emotional, and financial consequences of severe injuries. These efforts need to be in collaboration with general worldwide efforts to improve access to public health and medical services. Over the past few years, WHO has released guidelines for prehospital and trauma care with a special focus on low- and middle-income countries (https://www.who.int), and approaches to improved acute care are increasingly evaluated in different countries.

Building capacity for injury prevention

In order to identify and implement successful injury prevention strategies, countries, states, and local communities need to develop necessary infrastructure and capacity to conduct the essential activities of an injury prevention programme. Infrastructure includes the designation or creation of agencies and leadership to oversee and integrate essential injury control activities within an intersectoral strategic framework. Capacity includes the availability of human, financial, relational, and structural resources. Both components are vital to the sustainability of any injury prevention and control programme. Since there is a lack of trained injury prevention professionals in many LMICs, capacity development efforts are critical in the developing world to address their high burden of injuries and unique challenges.

The WHO Department of Violence and Injury Prevention and Disability responded to this need by outlining three key domains for such efforts in *Capacity Building for Preventing Injuries and Violence: Strategic Plan 2009–2013*. These domains include:

Human resources: people and the knowledge and skills they require;
Institutional and infrastructural capacity: the systems and structures necessary to allow for effective human resources; and
Networks and partnerships: a means by which capacities can be strengthened within and across settings (http://www.who.int/violence_injury_prevention/capacitybuilding/strategic_plan/Strategic_plan.pdf).

In order to facilitate such efforts, the WHO has developed two training programmes, Teach Violence and Injury Prevention (TEACH-VIP) and Mentor Violence and Injury Prevention (MENTOR-VIP). TEACH-VIP, is a comprehensive injury prevention and control curriculum which is delivered via PowerPoint presentations and supplementary information structured around a set of lessons—some 'core' and others 'advanced' (http://www.who.int/violence_injury_prevention/capacitybuilding/teachvip/en/print.html). Whereas the TEACH-VIP training curriculum focuses on the transfer of knowledge, MENTOR-VIP offers an opportunity for junior investigators and injury prevention professionals to further develop key skills. MENTOR-VIP is a 12-month mentorship programme which matches mentees with leading injury prevention experts to accomplish specific goals (http://www.who.int/violence_injury_prevention/capacitybuilding/mentor_vip/en/).

The development of a critical mass of trained injury professionals within a country or region to understand the local environment, develop, implement, and evaluate appropriate prevention programmes is a crucial step. The Fogarty International Center of the National Institutes of Health in the United States has provided opportunities for twinning between US-based and developing country institutions for capacity development which targets all three WHO domains (http://www.fic.nih.gov/Programs/Pages/trauma-injury.aspx). These programmes cover collaborations in countries like China, Colombia, and Pakistan; topics from traumatic brain injuries, violence, to emergency care; and promote sustainable research and dissemination of results to influence policy and investments in each country.

Individual institutions and projects have also been successful in promoting capacity development initiatives including: online training programmes from universities (e.g. https://publichealth.gwu.edu/programs/graduate-summer-institute); funded foundation programs (e.g. Bloomberg Philanthropies);

advocacy training by the Global Alliance of NGOs for Road Safety (http://roadsafetyngos.org/); and others.

Conclusion

Despite the high burden of injuries throughout the world, investment in safety and injury prevention infrastructure has been low. In many countries, the amount invested in prevention is far surpassed by the amount spent on the treatment of traumatic injuries, and thus studies that focus on cost-benefits are badly needed. International assistance has also not prioritized safety or injury prevention. External assistance to the health sectors of low-income countries was US$2–3 per DALY lost to infectious diseases, but only US$0.06 per DALY lost to injuries (Mock et al. 2004).

Since 90% of the world's population lives in low- and middle-income countries, and the burden of injuries is predicted to increase in these countries, it is imperative that future research and development activities focus especially on their needs. Basic research to describe the existing burden, causes, and distribution of injuries is still needed in LMIC. Trials of injury interventions have largely not been conducted in LMIC, and there is a great need to modify, adapt, and test existing, as well as new interventions in these specific settings. Work is also required to assess barriers to implementation of such interventions globally.

The role of international organizations (such as WHO and the World Bank) and national agencies (such as ministries of health or medical research councils) needs to be emphasized in moving ahead the injury prevention agenda. The international movements currently underway for violence prevention and RTIs prevention as promulgated through the two World Reports are examples of how joint global-national partnerships are needed for making change.

Progress will also be supported if a growing number of professionals become advocates for safety. Professionals from public health, medicine, engineering, social services, urban planning, law, and law enforcement, among others, can all have a strong voice in raising awareness for safety programmes and to encourage individuals to make safe choices.

Key points

Injuries and violence are a leading cause of mortality and morbidity worldwide.

Injuries disproportionately affect young and vulnerable populations, and injury rates are disproportionately high among low- and middle-income countries.

Prevention of injuries is very feasible and works best with a multidisciplinary and integrated approach.

A growing body of research and resources can help identify potentially effective approaches to prevent and reduce the consequences of injury.

Building capacity for injury prevention should be a priority for all countries, but is an urgent need for low- and middle-income countries.

Interpersonal violence

Rachel Jewkes

Introduction to interpersonal violence

Violence is a violation of human rights that has a profound impact on the physical and mental health and social functioning of its victims and survivors. It impacts households, families, communities, businesses, and economies. It is recognized globally as an obstacle to development, and the ambition to reduce or eliminate violence is expressed in two of the Sustainable Development Goals (SDGs). SDG 5.2 is to eliminate all forms of violence against all women and girls in the public and private spheres, including trafficking and sexual and other types of exploitation and SDG 16 is to promote peaceful and inclusive societies for sustainable development, provide access to justice for all and build effective, accountable, and inclusive institutions at all levels, with SDG 16.1 seeking to significantly reduce all forms of violence and related death rates everywhere. The use of interpersonal violence is, however, a social construct that is inherently preventable.

The *World Health Report on Violence and Health* described interpersonal violence as encompassing child maltreatment, youth violence, intimate partner violence, sexual violence, and elder abuse (Krug et al. 2002). Other forms of violence are increasingly being recognized including peer violence and the abuse of disabled persons. This is categorization spans the life cycle. For many forms of violence the victims are mostly likely to be girls or women, notable exceptions being peer and youth violence. In settings where there is a pronounced culture of violence, adults of all ages may use violence to resolve conflict or assert dominance in a range of other settings including conflict between neighbours, in contexts of crime, in prisons, in the workplace, and between health professionals and patients.

Interpersonal violence is experienced and perpetrated by millions of people worldwide each year and the health and social impact is huge. In 2013, interpersonal violence was in the top 20 leading causes of death and the 22nd leading causes of years of life lost worldwide, and 404,000 deaths were attributed to it. In the age group of 20–44 years, however, interpersonal violence is the second most important cause of mortality for men and women. In 2013, interpersonal violence was among the top 10 causes of years of life lost in many countries and global regions, and is the second highest cause in the Latin America and Caribbean Region, and the fifth in sub-Saharan Africa. Although not high across Europe, it was in the top 10 in Albania and Russia. Evidence of the preventability of death from interpersonal violence is provided by the fact that the age standardized mortality rate, which was 5.6 per 100,000, had declined by 16% since 1990.

Commensurate with this scale of violence is a massive economic impact. A report published in 2004 estimated the cost of violence in the United States to be 3.3% of the gross domestic product, and in England and Wales, the total costs from violence were estimated to amount to $40.2 billion annually (Waters et al. 2004). A costing study of intimate partner violence estimated that in 2009 it was more than £15 billion in England and Wales alone (Walby 2010). Similarly a study of the economic costs of intimate partner violence in Viet Nam that included both direct costs due to lost earnings and out-of-pocket expenditure of affected women found that nearly 1.4% of the GDP was lost annually and amounted to 2.5 billion VDN in 2010. Women experiencing violence were estimated to earn 35% less than those who did not (Duvvury et al. 2012).

Magnitude of interpersonal violence

One of the most common forms of interpersonal violence, and in all global settings the most common form of violence against women, is intimate partner violence. This encompasses physical, sexual, emotional, and economic abuse, and a range of acts from threats of violence, social isolation, intimidation, insults, through to rape, beatings, and at the most extreme end of the spectrum, forms of torture. A recent systematic review concluded that globally 30% of women aged 15 and over have ever experienced physical or sexual intimate partner violence (Devries et al. 2013). There is considerable variation in prevalence between global regions

and settings. In the Eastern Mediterranean, Africa, and South East Asia the lifetime prevalence was 37%, compared to 23–25% in high-income countries, the Western Pacific, and European regions (World Health Organization (WHO) 2013). Greater diversity, however, is seen in the proportion of women who report having been exposed to intimate partner violence in the past year. In the United States, 2.9% of women experience physical intimate partner violence in the past year (Smith et al. 2018), compared to 6.1% in Cambodia, 29% in Ethiopia and 21.3% Bougainville, Papua New Guinea (Garcia-Moreno et al. 2005; Jewkes et al. 2017). Similarly the proportion who have experienced intimate partner sexual violence in the past year has been shown to range from, for example, 1.3% in Japan, to 22.2% in Bangladesh and 44.4% in Ethiopia (Garcia-Moreno et al. 2005).

Global estimates of intimate partner violence often do not include economic and emotional violence. The types of acts commonly included as emotional abuse include, but are not limited to, personal insults, being belittled, socially isolated, acts of coercive control, yelling, intimidation, and threats of physical violence. The economic and structural violence acts include having earnings taken and being prevented from earning. In higher income countries, as the prevalence of physical and sexual violence has declined over time acts of emotional and economic abuse has remained more common. There is also greater gender parity in experience and perpetration of these acts in these settings. Thus in the United States 36.4% of women and 34.2% of men had ever experienced psychological aggression, compared to 18.3% of women and 8.2% of men who had experienced contact sexual violence from an intimate partner (Smith et al. 2018).

In some countries, like South Africa, intimate partner violence is the most common cause of female homicide, accounting for 52% of cases (Abrahams et al. 2013), but globally intimate partner violence is estimated to account for 36% of female homicides (WHO 2013). In some global settings, intimate partner violence occurs as part of a broader experience of abuse of married women within the home by in laws, wider domestic violence. This is a particularly important problem for women in parts of central and south Asia, in highly patriarchal settings where women's movement is controlled. A key perpetrator is the mother-in-law. Exposure to such broader domestic violence has been shown to be associated with even more severe mental ill-health than exposure to partner violence alone (Jewkes et al. 2019).

The global estimate for the proportion of women who have experienced non-partner sexual violence is 7.2% (95% confidence interval = 5.3% to 9.1%), with the prevalence ranging from 5% in South East Asia to 12% in Africa (Devries et al. 2013). Research with men on perpetration has shown that in some settings, including South Africa and Papua New Guinea, 20–40% of men have ever raped a female non-partner (Abrahams et al. 2011; Jewkes et al. 2013). In some global settings the prevalence of rape is particularly high, including some conflict-affected regions and areas of high population crowding, mobility, and poverty, notably informal settlements, or slums. For example among displaced women in the United Nations' Protection of Civilians (POC) sites of Juba, South Sudan, 25% has ever been raped by a non-partner. Some of the men in Juba had also experienced rape, but it was much less prevalent than among women (1%) (Global Women's Institute and International Rescue Committee. 2017). Sexual workers across the global are at particularly high risk of rape from clients, intimate partners, acquaintances, and men in authority, notably the police. In a RDS sample of sex workers from Soweto, South Africa, 53.8% had experienced physical and/or sexual intimate partner violence (IPV) in the past year, 46.8% violence from clients, and 18.5% by police. In all 70.8% had been exposed to sexual and/or physical violence by any perpetrator in the last year and 62.4% had ever been raped (Coetzee et al. 2017)

Child abuse can be physical, sexual, or emotional, and may also encompass physical and emotional neglect. Research has often used very different definitions and these often reflect cultural differences in normative child-rearing practices. Comparability across settings can thus be hard, but the recent global initiative of Violence Against Children Surveys (VACS) has enabled the generation of comparable data from many low- and middle-income countries (LMICs). An one estimate from high-income countries is that each year 4–16% of children are physically abused and one in ten is neglected or psychologically abused (Gilbert et al. 2009). This contrasts with the VACS, where their initial surveys in several African countries showed between 53%–75% of children had experience physical violence, with this being more common for boys, and between 1 in 4 and 1 in 3 emotionally abused (National Population Commission of Nigeria et al. 2016). Further during the whole of childhood, between 5% and 10% of girls and up to 5% of boys are exposed to penetrative sexual abuse, and 15–40% are exposed to any type of sexual abuse (Reza et al. 2007; Gilbert et al. 2009).

An estimated 200,000 deaths occur each year among young people aged 10–29 and that for each death 20–40 require hospitalization (Krug et al. 2002; WHO 2015). Youth violence mortality predominantly occurs in LMICs, notwithstanding the recent rise in death from stabbing in the United Kingdom, and is highly gendered. The overwhelming majority of perpetrators and 83% of victims are male. Recent research for South Africa, for example, has shown that the rate of homicide (21.7/100,000) for teenage boys (15–17 years) was nearly five times the teenage girls' rate (4.6/100,000) (Mathews et al. 2013).

Peer violence is a part of the problem of youth violence, and commonly occurs at school, in communities and in families. Both girls and boys con be victims and perpetrators, but the prevalence tends to be higher among boys. Peer violence overlaps with the phenomenon of bullying, and generally is considered to include physical violence and threats emotional abuse and name calling, damage to property, spreading rumour and social exclusion. Its definition highlights that it is a repeated act and intended to cause harm. It has been said to affect 10–65% of children in schools globally, but prevalences as high as 90% have been reported in parts of the United States and in Pakistan (Karmaliani et al. 2017).

Elder abuse is a much less researched form of interpersonal violence. Its subcategories generally include physical, psychological, sexual, financial, and discriminatory abuse and neglect. It is generally measured as exposure to people aged over 65 or over 60 (Cooper et al. 2008). The category is often measured in a way that fails to distinguish between other forms of violence experienced by older people (e.g. IPV) from violence that is a result of the constrained power of older people (i.e. because a person is elderly). This is an area that is growing in recognition, especially for elderly people with cognitive impairment. The main perpetrators are family members and caregivers. In some parts of sub-Saharan Africa a particularly horrific dimension of elderly abuse is seen in witchcraft-related violence and murders (Meel 2009). Understanding and preventing abuse of the elderly is an area that requires considerable further research.

Violence against adults and children with disabilities has fairly recently been given much greater recognition as part of the overall global problem of interpersonal violence. A review on the prevalence of violence experienced by children with disabilities found that they were four times more likely than children without disabilities to experience violence. This also included

sexual violence, and overall they were 2.9 times more likely to experience sexual violence, but among those with mental or intellectual impairments the increased risk was 4.6 fold (Jones et al. 2012). Adults with disabilities are also at increased risk of interpersonal violence, including women with disabilities at elevated risk of IPV. A recent meta-analysis has found the risk of physical or sexual partner violence to be 2 times higher among women with disabilities (Dunkle et al. 2018). Disability also increases women's risk of non-partner sexual violence and the risk of this and IPV rise with increasing severity of the impairment.

Health consequences

The health impact of interpersonal violence follows two pathways: immediate and longer term. Immediate health impact is normally injury, which may be fatal, and may lead to complications in a pregnant victim. Medium and longer term impacts can be particularly profound. These may be physical, in the case of disabling injuries, but a very important area of impact is on mental health, resulting in depression and anxiety, post-traumatic stress disorder (PTSD), self-harm, and substance abuse. The mental health impact is particularly severe with emotional and economic abuse, sexual abuse, or rape and with exposure to life threatening violence. For example, South African research shows that adolescent women who have experienced emotional neglect in their lives are at greater risk of depression, suicidality and alcohol abuse, and adolescent men were at greater risk of depression and drug abuse (Jewkes et al. 2010a). The same study found sexual abuse associated with alcohol abuse and depression in the men and alcohol abuse in the women. Peer violence, including bullying, has been likewise shown to have an important negative impact on children's mental health elevating the risk of depression (Asad et al. 2017).

Mental health is also impacted by experience of IPV and non-partner rape. Women so exposed are at more than twice the risk of depression, and the latter group also have more than twice the risk of alcohol abuse (WHO 2013). Rape is also particularly likely to result in PTSD, and in fact is more likely to cause PTSD than any other violence exposure (Tolin and Foa 2006). Emerging research has highlighted the importance of emotional and economic partner violence in mental health impact, showing that greatest levels of depression and suicidal ideation are found in women experiencing

both emotional or economic violence combined with physical and/or sexual partner violence (Gibbs et al. 2018).

Exposure to interpersonal violence can also have complex impacts on health. One of the more complex mechanisms of impact is illustrated by the pathways through which IPV impacts HIV acquisition in women, and undermines the use of and adherence to antiretroviral therapy (Jewkes 2010; Jewkes et al. 2010b, Hatcher et al. 2015). Research from South Africa and Uganda shows that nearly one in four new HIV infections could be prevented if women were not subjected to IPV and relationship power inequalities and exposure to sexual abuse in childhood in one South African study resulted in a two-thirds greater risk of incident HIV infections (Jewkes et al. 2010b; Kouyoumdjian et al. 2013). The complex web of impact is illustrated by Figure 9.5.1. This shows that this is a very direct pathway, in that women may become directly infected with HIV through rape, but a much more important mechanism of risk is indirect, through partner violence and child sexual abuse exposed women having less control of their sexual encounters, as a result of violence and controlling behaviours of their partner, with the result that they have sex more frequently, use condoms less, more sexual transmitted infections and engaging more often in a range of risky sexual practices, including having more, and often concurrent partners, transactional sex, substance abuse-related sex, and even sex work. These increase the risk of HIV acquisition as well as rendering women vulnerable to further male violence. The mechanisms of increased risk are partly though the mental health consequences of violence, including insecure adult attachment which is associated with difficulties in emotional relationships and having more partners. It is also the case that men who are violent towards women often have more risky sexual practices and sexual transmitted infections and HIV (Decker et al. 2009; Jewkes et al. 2011b). Women who have more complex and chaotic as a result of exposure to men's violence are less able to adhere to antiretroviral therapy. Research has shown that in the absence of treatment, women with HIV who have been exposed to emotional abuse experience a more rapid decline in cellular immunity (Jewkes et al. 2015).

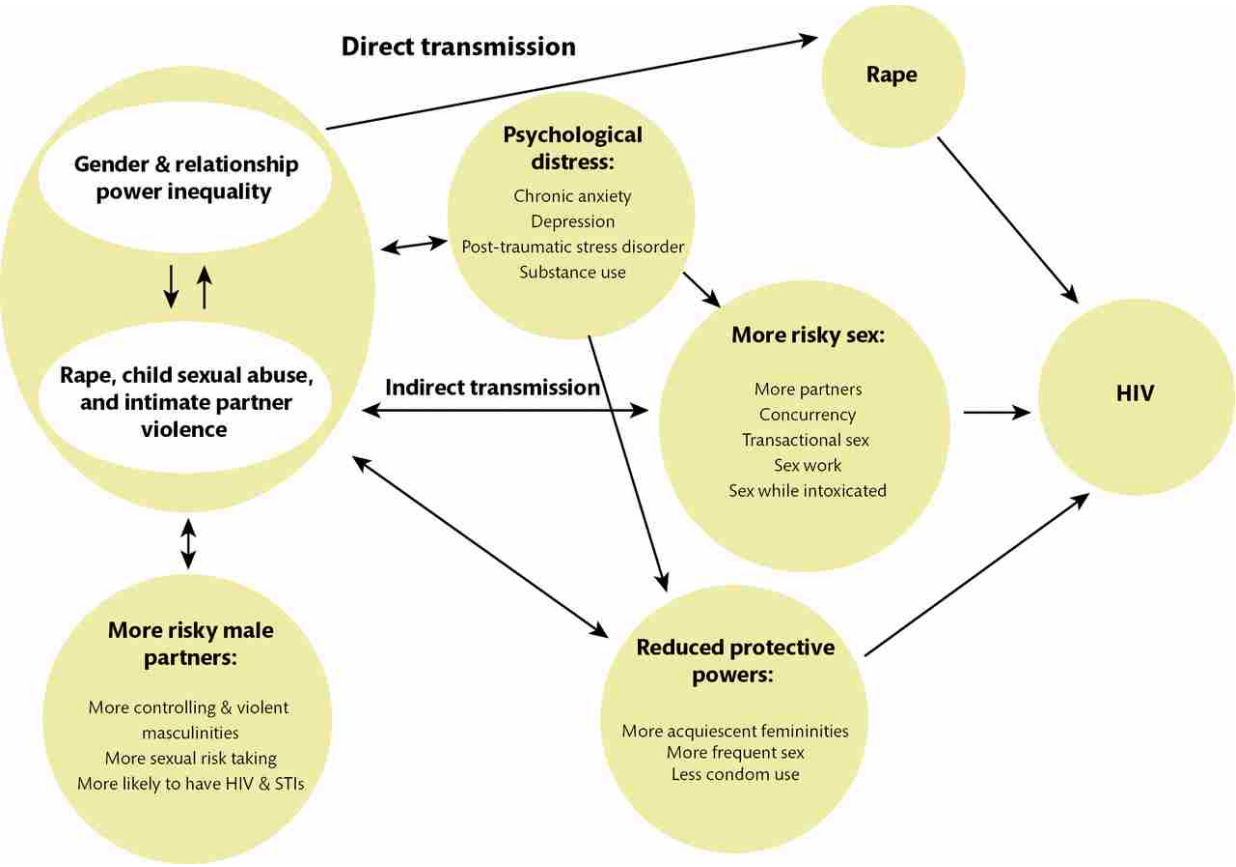

Fig. 9.5.1 Transmission.

Interpersonal violence has a major impact on women's reproductive health. IPV exposure is associated with a 30% increased risk of unintended pregnancy, also of infertility and subfertility, induced abortion, young teenage pregnancy as well as low birth weight and preterm birth (Hill et al. 2016; Stellar et al. 2016; Maxwell et al. 2018). Childhood sexual abuse and child marriage increase the risk of early pregnancy and childbearing with higher maternal and infant mortality.

Interpersonal violence also has a range of social and economic consequences apart from out-of-pocket costs for healthcare. These include, for women, a greater risk of school dropout due to pregnancy, which impacts on future employment and lifetime earnings. Violence results in more time off due to injury and its mental and other health effects, and even women not working experience social incapacity, impacting on childcare and homemaking. Women who experience violence who attend work have periods of lower productivity due to violence, presenteeism, and reduced productive engagement. A consequence of all of this is that it enhances

women’s dependency and lowers their power within the household, which in turn enhances their risk of experiencing IPV.

Understanding its roots

Interpersonal violence has different forms, is used in different settings and contexts, with diverse perpetrators and victims, that may be seen as only united by the common use of physical force to cause hurt or injury. But there is much more overlap in the roots and drivers of violence than first meets the eye. On closer examination its apparent that in many cases the same people perpetrate different forms of interpersonal violence at different times. For example, the aggressive young school bully may engage in violent fights with other youths, be sexually and physically violent to women, beat his children, and engage in be very violent in his job as a policeman. While people may be violent in one context and not in others, violence is strongly patterned and a propensity to the use of violence in one situation increases the likelihood of its use in others. This applies to both men and women.

Many perpetrators of violence have themselves been victims, particularly of emotional or physical maltreatment in childhood, of sexual abuse or bullying, and have witnessed their mother exposed to IPV. The complexity interrelationship was illustrated by a study of adolescents in the United States in which it was found that the connection (pathway) between experience of physical abuse in childhood and perpetration of sexual IPV was completely mediated by involvement in delinquent behaviour, which commonly includes use of other violence (Casey et al. 2009).

Victims of interpersonal violence do not bring the violence on themselves, except in gang fights, yet victimization is by no means random. Very commonly one exposure to violence, especially abuse in childhood, increases the risk of re-victimization. For example, women who have experienced sexual abuse as children are more likely to be raped as adults, and to experience IPV.

To explain the interconnectedness, it is important to understand that different forms of violence have overlapping root causes and risk factors. The use of violence to communicate dominance, punishment, or defend honour, is a learned, and it may be deployed when this is intended in multiple contexts. Social learning spans how violence is used, in what forms, who are appropriate victims, acceptable or required triggers for its use,

meanings that will be attached to its use, and patterns of reward or punishment that can be expected to follow. For example, Wood et al. (2007) researching in South Africa's Eastern Cape Province found use of violence by a man against how female partner to be widely regarded as a normal part of gender relations and considered unexceptional by the community, family, and providing the victim was not injured by the violence. Moreover it often viewed as deserved, good for teaching right from wrong, and when submission as the result of the violence it was socially rewarded. A further cultural dimension of interpersonal violence relates to the thresholds that trigger its use. Some societies, such as parts of Papua New Guinea, having very low thresholds for the use of many forms of interpersonal violence. In other cultural settings, thresholds are very much higher, and generally the use of violence in interpersonal relations is viewed as inappropriate. Social rewards for the use of interpersonal violence vary greatly, but in some settings 'men of violence' are revered, their physical power viewed with awe, and political power and economic rewards may flow from this. The use of violence is often coded into ideas of appropriate male behaviour, especially where demonstrating toughness, competition and honour are prominent features of masculinity and this further explains the cultural licence for violence use.

An obvious explanation for re-victimization is that victims of violence are often selected because they are vulnerable. This explains part of the higher risk of people with disability, poorer women, and children, and those working illegally as sex workers. Victimization increases such vulnerability, through its mental health impact and perceived disempowerment, furthermore negative coping strategies after some types of victimization may including problem drinking, create further vulnerability. In this way interpersonal violence creates cycles of vulnerability across different types of violence.

Risk factors for interpersonal violence

Risk factors for violence perpetration have been described as operating at a range of different ecological levels. This has been presented in an ecological model that highlights how some of these pertain and exert effects at an individual level, others at a family, peer, or relationship level, others at a community level and still others at a societal level.

Individual level

Genotype

There is evidence that genes are important in the development of aggression. Research points towards a general heritable tendency to antisocial behaviour, of which sexual coercion is one form. There may be important gene × environment interactions, particularly with the expression of aggression in genetically susceptible individuals after exposure to a harsh environment, or else a person with antisocial tendencies might be more likely to be drawn to situations and settings where antisocial behaviour is more common or more possible (Johansson et al. 2008). The evidence is predominantly focused on non-sexual aggression. However both sexual aggression and general aggression are heritable in mice (Canastar and Maxson 2003) and one study of twins concluded that over a quarter of sexual coercion was explained by genetic factors, but the genetic element in psychopathy was higher (Johansson et al. 2008).

The monoamine oxidase A gene (*MAOA*) has been described as impacting on a heritable tendency for antisocial behaviour. This encodes the MAOA enzyme, which metabolizes neurotransmitters such as norepinephrine (NE), serotonin (5-HT) and dopamine (DA) and thus inactivates them (Shih et al. 1999). It is very rare for the gene encoding MAOA to have been deleted, although this is found associated with heritable aggression in humans and mice (Rowe 2001). More common are functional polymorphisms that result in lower activity of the MAOA enzyme (Caspi et al. 2002). A prospective study conducted in New Zealand has shown that child maltreatment has a much stronger association with subsequent antisocial behaviour in males with low MAOA enzyme activity, than those with higher activity (Caspi et al. 2002). In this study 11% of violent convictions were attributable to the gene. Findings of research on exposure to physical punishment in early childhood, having the *MAOA* gene and likelihood of subsequent delinquency are inconsistent (Reif et al. 2007; Prichard et al. 2008; Edwards et al. 2010). The role of genetics in interpersonal violence, including sexual aggression, is clearly an important area for further work.

Other biological influences: androgens and neurological deficits and sexual offending

The role of androgens in interpersonal violence is questionable. A positive relationship between testosterone and self-reported aggressiveness has been reported for men and women (Christiansen and Knussmann 1987), but this has not been confirmed by all authors (Campbell et al. 1997). Several researchers have investigated links between blood testosterone levels and sexual or other aggression in prison populations, but found no evidence that testosterone levels influence the likelihood of sex offending, any more than general violent offending (Giotakis et al. 2003).

The role of brain damage in sexual offending has been the subject of research but the overall conclusion of a recent review of the literature is that the evidence is extremely weak (Fabian 2012). One of the few controlled studies with paedophiles found no differences on neuropsychological measures or positron emission tomography scans (Cohen et al. 2002). While brain trauma may be important in some individuals, there is currently no evidence that brain damage makes an important contribution at a population level.

Early years' exposures

Irrespective of genotype, there is evidence that an individual's risk of perpetrating interpersonal violence can be shaped in the first days, months, and years of life. Perpetrators of interpersonal violence, including sexual violence, are more likely to have failed to form secure attachment bonds in childhood. This is linked to exposure to emotional, physical, and sexual abuse as well as to domestic violence, removal from the family, family disruption, and parental loss due to death or divorce may be risk factors for perpetration (Maniglio 2010).

Attachment

One of the critical pathways through which the childhood home environment, particularly in early childhood, impacts upon psychological development is through attachment to primary caregivers, usually mothers (Bowlby 1969, 1973, 1980). If attachment bonds between the child and their primary caregiver are secure, children acquire the necessary skills to establish close relationships and grow to desire the intimacy of others. If these bonds are insecure, children do not acquire the necessary skills to establish close relationships, and may grow to fear intimacy with other

individuals, exhibit hostility or aggression within their relationships, or to seek intimacy in maladaptive ways (Bowlby 1969, 1973). The failure to form secure attachment bonds is due to poor socialization experiences, such as violent parenting, and disordered attachment has in particular been described as consequent of parenting that combines harsh punishment and expressions of affection (Marshall and Barbaree 1990; Fonagy and Target 2003). A failure to form secure attachment bonds in childhood results in a failure to learn interpersonal and other skills necessary to achieve intimacy as adults. Insecure attachments are marked by an expectation that what is needed will not be given, and as a result coercion, whether through physical violence, emotional manipulation, or sexual violence, is often used to get it (Bowlby 1969, 1973, 1980). In the arena of relationships, insecurity may result in more dismissive and hostile attitudes towards others and a tendency to perceive others negatively and distrustfully. This has been shown in sex offenders, but is also likely to increase propensity to IPV, youth violence and interpersonal violence in the community (Marshall 1989; Stirpe et al. 2006; Whitaker et al. 2008). Individuals with disorganized attachment are much more aggressive, distrustful, and less empathetic when older and have a propensity to general interpersonal violence (Fonagy and Target 2003).

Dysfunctional parenting and disturbed family histories, with unstable caregiving often due to maternal post-natal depression, or parental IPV, have been shown to be associated with interpersonal violence and various categories of offending among children, including sexual offending (Lightfoot and Evans 2000; Seto and Lalumiere 2010).

Child abuse victimization

Physical and emotional abuse and neglect in childhood are exposures that result in a failure to form secure attachments. Emotional abuse and neglect has been given less emphasis in research than physical abuse, but a six-country study on men's violence in Asia and the Pacific has shown that men who rape non-partners and those who have been violent to intimate partners are more likely to have been exposed to all of these in childhood, and these findings support the research from South Africa (Jewkes et al. 2011a; Fulu et al. 2013).

The evidence of childhood sexual abuse as a risk factor for subsequent perpetration is very extensive and probably has been the most comprehensively investigated of all risk factors for perpetration. In a meta-

analysis, a history of child sexual abuse was five times more common among adolescent sexual offenders than among adolescent non-sexual offenders (Seto and Lalumiere 2010). Further, sexual offenders against children are much more likely to have sexual abuse victimization histories than non-offenders or non-sexual offenders (Whitaker et al. 2008). Several large national studies of US adolescents and men in college have found that those who had sexually assaulted a partner were significantly more likely to have experienced sexual abuse themselves (Borowsky et al. 1997; Casey et al. 2009; Malamuth et al. 1991, 1995).

Witnessing IPV in the home is both extremely traumatic for children and may be part of social learning about intimate relations. Both of these may explain the consistent finding that men who have been so exposed in childhood are more likely to be physically or sexually violent towards their intimate partners (and girls so exposed to experience violence themselves) (Malamuth et al. 1991, 1995; Borowsky et al. 1997; Fulu et al. 2013). South African research has also shown that men who have been exposed in childhood are more likely to get involved in fights at work and in the community, and have been arrested for having an illegal firearm (Abrahams and Jewkes 2005). In Pakistan girls and boys who have witnessed violence against their mothers at home were more likely to perpetrate peer violence (Karmaliani et al. 2017).

Personality

These early years of exposure have a profound impact on personality when older. Psychopathy has been the most extensively discussed in relation to perpetration of interpersonal violence. Psychopathy is a constellation of personality traits and socially deviant behaviours, spanning affective, interpersonal, and behavioural traits. Hare has proposed that the characteristics of psychopathy include egocentricity, lack of remorse and empathy, pathological lying, manipulativeness, and the persistent violation of social norms (Hare 1996). These traits enable psychopaths to treat others as objects and feel no guilt or remorse. They are thus much more likely to perpetrate interpersonal violence, particularly severe physical violence, emotional violence, and rape.

In the US general population the prevalence of psychopathy is usually estimated at 1%, but the prevalence of psychopathic traits without a full

clinical diagnosis is higher (Lilienfield 2005). Individuals with heightened levels of some of the characteristics of psychopathy have been described as subclinical and non-clinical psychopaths (LeBreton et al. 2006). The prevalence of psychopathy as a diagnosis is dependent on assessment measure scores. Research on Canadian incarcerated sex offenders shows that a relatively small difference in cut point (25 versus 30) on the PCL-R (Hare Psychopathy Checklist—Revised) (Hare 2003) resulted in twice as many offenders being diagnosed as psychopathic (29% vs. 13%) (Olver and Wong 2006). This suggests that the presence of psychopathic traits may be important in understanding interpersonal violence at subclinical levels and indeed this has been suggested by research in South Africa where two traits were measured, Machiavellian egocentricity and blame externalization, and were significantly higher among men who had raped in both the past year and their lifetime (Jewkes et al. 2011a). There are similar findings from US college students, among whom subclinical scores on psychopathic traits have been associated with rape perpetration (Ouimette 1997; DeGue and DiLillo 2004; Abbey et al. 2011). Psychopaths have been described as having an inability to connect sexual behaviour with emotional feelings, such as warmth and tenderness, and a hedonistically orientated lack of impulse control and are thus more likely to be sexually as well as physically violent (Cleckley 1988).

Personality disorders of offenders

Research on personality disorders in populations of offenders shows that sex offenders against children and adults show significantly more Cluster A, Cluster B, and antisocial personality disorders than non-offenders (Whitaker et al. 2008). Psychopathy is common among more violent child sex offenders (Rosenberg et al. 2005). Schizoid personality features include social detachment and restricted emotionality, and avoidant features include social inhibition and inadequacy. Both of these interfere with the development of normal peer relationships, including intimate relationships with women, and are more prevalent among sex offenders, particularly against children (Fazel et al. 2002; Whitaker et al. 2008). Men who sexually molest children are socially and emotionally immature, have poor social skills, low levels of self-esteem, poor impulse control, and more signs of psychotic thinking (Finkelhor and Araji 1986). Relating to children provides

a sense of power and control and opportunity for dominance not available to them in adult relationships (Finkelhor and Araji 1986).

Substance abuse

Alcohol abuse is strongly associated with use of interpersonal violence (Machisa et al. 2019). There are physiological effects, but also complex cultural beliefs about and meanings given to the relationship between alcohol and violent, including sexually violent, behaviour. Alcohol has a physiological effect of reducing inhibitions, reasoning, and, in men who were more irritable, prone to anger, and have low levels of anger control, can result in ready use of violence (Finkelhor and Araji 1986). Research on IPV and rape in particular commonly finds that men who are violent are more likely to have heavy alcohol use (Koss and Dinero 1988; Jewkes et al. 2006, 2011a; Tsai et al. 2011; Fulu et al. 2013). Many cultures (or subcultures) link alcohol consumption to disinhibition, sexual desire, and performance, and perceive it to give courage to make advances that men may be reticent to make when sober, and as mitigating antisocial or aggressive behaviour (Lightfoot and Evans 2000; Seto and Lalumiere 2010). Alcohol abuse also has an economic impact on families, leading to greater financial strain, and may be a trigger for conflict over finances.

A further question is whether violence associated with alcohol more often results in serious injury or mortality. There is some evidence that shows that when a perpetrator is drunk and the victim sober there was a greater likelihood of rape completion and victim injury than when they had both been drinking (Brecklin and Ullman 2002). In the case of youth homicide, alcohol is estimated to be responsible for 26% and 16% of years of life lost by men and women, respectively, with the proportion lower in high-income countries and as high as 40% in low-income countries (WHO 2004).

Drug use

Drug use is also intimately connected with youth violence and homicide, most directly because the trade in drugs in many settings is associated with violence and turf wars between dealing gangs (Blumstein et al. 2000). Research on rape has shown that men who have raped are more likely to use drugs, indeed a prospective study from South Africa concluded that 24% of all rapes would have been prevented if drug use had not occurred (Jewkes et

al. 2012). The great majority of the drug use reported was marijuana use, but the authors argued that drug use was most likely an indicator of engagement in a subcultural peer context where both drug use and rape was seen as 'normal' (Jewkes et al. 2012). This conclusion is supported by findings of a multicountry study that drug use was associated with having ever engaged in multiple perpetrator rape (sometimes referred to as gang rape), but not single perpetrator rape (Jewkes et al. 2013).

Post-traumatic stress disorder (PTSD) and depression

PTSD symptoms have been associated with perpetration of several forms of interpersonal violence. PTSD symptoms of dysphoric arousal in particular have been were positively associated with violent behaviours. A recent systematic review of mental ill-health and recent IPV perpetration found that there was a positive association between this and having PTSD symptoms, but not with current depression (Machisa et al. 2019). This is not withstanding the observations that men who have used violence against intimate partners are often found to be more likely to be depressed (Nduna et al. 2010; Fulu et al. 2013). It is not clear whether depression causes men to become violent, or is an emotional response to having used violence and the negative impact that this has on a relationship.

Propensity to use violence

The use of interpersonal violence in one context is closely related to its use in others. This has particularly been highlighted with violence against women and children, for example rape of non-partners is more commonly perpetrated by men who are physically violent towards partners and men who beat women are more likely to beat their children (Malamuth et al. 1991, 1995; Jewkes et al. 2006, 2011a, 2013). It seems likely that a system of patriarchy and gender hierarchy that legitimates the use of physical violence by men to assert dominance in a relationship and 'correct' behaviour of wives and girlfriends would also find expression in sexual violence, as well as other forms of violence, such as verbal violence. There is also some evidence that verbal violence against women is more common among sexually coercive men in US colleges and among South African working men (Malamuth et al. 1991, 1995; Abrahams et al. 2004).

Relationship, peer, or microsocial level

Conflict

The dynamics of particular relationships are important influences of the propensity for use of violence. IPV is more common in relationships that are more conflictual, and experimental evidence suggests that interventions that build communications skills and reduce relationship conflict are impactful in reducing IPV (Jewkes et al. 2008). Poor communication skills of either partner may result in conflicts escalating readily to violence. Conflict escalating to violence is also more common in relationships where one partner is more irritable and prone to outbursts of anger. Perceived challenges to men's 'right' to what they perceive as traditional gender privileges and their non-fulfilment of expected provider roles are often causes of conflict.

Social learning around violence acceptability

In teenage peer relationships, it has been observed that friends are similar in respect to propensity for aggression (McPherson et al. 2001). There has been considerable debate about whether aggressive young people choose each other as friends or whether as friends they become more alike (Snyder et al. 1997; Steglich et al. 2010). Longitudinal research from Chile suggests that children do not select friends based on their levels of aggression, rather that similarity among friends is a product of the friendship, although it is also possible that aggressive male youth may be forced together if non-aggressive peers reject them (Steglich et al. 2010). This partly explains the strong connection between gang membership and violence perpetration that has been described in many settings (Bourgois 1996; Jewkes et al. 2006, 2011a). The importance of perceived social acceptability of violence was also highlighted by a study that found the parents of violence perpetrators, when compared with parents of non-perpetrators, were much more likely to have encouraged gang membership (Morris et al. 2002).

Social learning about sexual violence as normative, is demonstrated in research with incarcerated American adolescents that has shown that sexual assault perpetrators were nearly four times as likely as non-perpetrators to know a perpetrator of sexual assault (Morris et al. 2002). Among a community-based sample of men, perceived peer approval of coercing sex was much higher among men who rape (Abbey et al. 2007). A further aspect

of social learning is reflected in the perpetration of sexual abuse by those who have themselves been sexually abused in childhood. Research from New Zealand provides an additional perspective when sexually abusive adolescents and children were found to have been more likely to have had contact with adults who were known paedophiles, or suspected to have engaged in sexual abuse of other children, even when they did not have confirmed sexual abuse victimization themselves (Lightfoot and Evans 2000). These children may have experienced abnormal sexual socialization through exposure to inappropriate sexual experiences (e.g. pornography exposure or verbal experiences) (Lightfoot and Evans 2000).

There is also a social learning element in the use of violence in child-rearing practices, particularly physical punishment. Physical violence is generally used to punish or gain control over a child and is used more readily by parents raising children in contexts where beating is more common and where there is less role modelling of non-violent parenting and discipline practices.

Delinquent behaviour

The use of interpersonal violence, including rape, among adolescents is strongly associated with other antisocial behaviour (Ageton 1983; Malamuth et al. 1991; Calhoun et al. 1997; Knight and Sims-Knight 2003). Delinquency is an area where multiple risk factors and violent behaviour intersect. There may be genetic roots in some young men, as research has shown that men with genetically determined low MAOA enzyme activity and exposure to harsh punishment in early childhood are more likely to become delinquent (Edwards et al. 2010). Further it is strongly related to personality traits of psychopathy, which themselves may be genetically determined (Abbey et al. 2011). Delinquency is also socially modelled and much more common among youth who have themselves experienced physical aggression in childhood, and are more susceptible to peer pressure (Malamuth et al. 1995; Casey et al. 2009).

Multicountry research on both IPV perpetration and rape perpetration has shown that these are associated with having currently or previously been in a gang (Borowsky et al. 1997; Jewkes et al. 2011a; Fulu et al. 2013). They are also associated with having been involved in other interpersonal crime or theft, having a weapon, and having had an illegal gun (Jewkes et al. 2011a; Fulu et al. 2013). School bullying is one manifestation of delinquent

behaviour, and often a precursor of antisocial behaviour in adulthood (Bender and Lösel 2011). South African research has shown perpetration of school sexual bullying to be strongly associated with subsequent rape perpetration (Jewkes et al. 2011a).

One of the important avenues in the prevention of delinquency is health and education sector interventions for children with conduct disorders. Children with conduct disorders may go on to develop personality disorders as adults, particularly antisocial personality disorders. Conduct disorders are treatable in children, but they require parents to be trained in managing problem behaviour, or out-of-home placements with staff or foster parents appropriately trained. Treatment is most effective when provided to younger children (pre-adolescent); this has been part of the theoretical basis for the Incredible Years programme of Webster-Stratton and colleagues.

Masculinities and delinquent peers

Gang, or otherwise delinquent, peer contexts are also ones in which the masculinities of involved boys are shaped. Negative early childhood influences that generate feelings of insecurity greatly increase the likelihood that as boys grow into men they will adopt masculinities that emphasize strength, toughness, and demonstrate control over others. Such masculinities are familiar within a gang, or otherwise pugilistic peer context, where there is a readiness to show toughness among gang members, between them and potential rivals, dominance over women and to display power over others (e.g. in the context of crime).

Within any social setting there are multiple ways of, and aspirations for, being a man or boy. Some subcultural masculinities are particularly violent, and emphasize dominance over women, with a heightened sense of male sexual entitlement, which readily translates into rape (Bourgois 1996). This is particularly commonly found associated with gangs and among men positioned on the antisocial fringes.

Community level

Many of the structural drivers of interpersonal violence operate at a community level. These include poverty, patriarchy, and structural influences on these such as race or ethnicity. In a profound way these impact on the culture of the local context.

Poverty

Poverty, low educational attainment, and social disadvantage are structural drivers of interpersonal violence. Gangs, which are archetypically associated with many forms of violence, are very largely confined to life in low-income areas. In conditions of poverty, gangs provide young men access to experiences of power when other routes of attainment of power and status are unattainable, such as through working or fulfilling provider roles (Bourgois 1996; Wood and Jewkes 2001; Wood et al. 2007). Poverty increases the risk of IPV and child maltreatment both because it increases economic strains on families and relationships, and also because it generates feelings of inadequacy and powerlessness that may be expressed through the use of violence. Poverty further traps women within violent relationships and can reduce their options for taking action to protect themselves, or to get the violence to stop. Economic empowerment interventions for women have been shown to be a very fruitful avenue for enabling women to protect themselves from IPV (Pronyk et al. 2006).

The relationship between rape and poverty is complex. Multiple perpetrator (gang) rape is most clearly linked to poverty because this is important in the context of gangs (Jewkes et al. 2013). The role of social disadvantage in single perpetrator rape is less clear because perceptions of sexual entitlement are a very powerful part of the context of rape and these may stem from social advantage rather than disadvantage. South African research has shown that among the less well off, it is the slightly less poor or less disadvantaged who are more likely to have raped (Jewkes et al. 2006, 2011a). Authors have argued that a sense of entitlement stemming from relative advantage, within a context of general disadvantage, is played out in a perverse way in a context in which few or none would be able to attain objectively high levels of material ‘success’ (Jewkes et al. 2011a).

Social norms: the cultural scaffolding for interpersonal violence

For all forms of interpersonal violence, social learning around the acceptability of the use of violence, and for gender-based violence, the acceptability of directing it to women, within subcultural contexts is important in perpetration. The importance of social norms on the use of violence in partner violence perpetration was first made visible by anthropological work looking at factors associated with violence across a

wide range of cultural settings (Levinson 1989). More recently research on IPV has increasingly explored the importance of community level norms on the use of violence, for example indicated by community murder rates, as a risk factor for IPV and found it to be highly associated (Koenig et al. 2006).

Social norms on gender relations and violence are also very important. The phrase 'cultural scaffolding' was coined by Gavey to describe the protective social context that enables the reproduction of sexual violence through allowing men to reconfigure sexually coercive behaviour, especially with dates, girlfriends, or wives as 'not rape' (Gavey 2005). The scaffolding includes an array of rape myths that place the blame for rape at the feet of women and enable a cognitive justification for coercive behaviour, ideas of sexual entitlement within marriage (conjugal rights), and the positioning of women as worthy objects of male sexual conquest. This scaffolding is argued to stem from a framework of patriarchy whereby men are positioned as hierarchically superior to women and accorded greater social value. This ideological scaffolding provides the cultural space for men to perpetrate rape without embracing an identity as 'a rapist' or 'a perpetrator'. Similarly youth violence and bullying are often seen as being normal for the age group and is seen as 'not violence' but more the rough and tumble of growing up (Wood and Jewkes 2001).

In some settings the use of interpersonal violence is integrally related to culturally constructed notions of legitimate entertainment. This is very clearly seen in research on rape where men have been asked about their motivations. For example, in a six-country study on men's use of violence in Asia and the Pacific 59% of men who had raped a non-partner indicated that one of the reasons they did it was for entertainment (Jewkes et al. 2013). In South Africa, seeking 'fun' motivated nearly half of South African men who had raped (Jewkes et al. 2011a). Quite similar findings pertain in youth violence, where research in the United Kingdom has shown that fights in bars are very often started for fun (Graham and Wells 2003).

The cultural scaffolding around child abuse is such that physical violence used by caregivers against children is often described as being 'necessary' in order to teach children how to behave and instil discipline, and is thus seen as 'not violence'. In many cultures the use of violence in child-rearing is so ubiquitous that many parents and teachers cannot imagine that there is any other way to properly raise children. Further settings such as in sub-Saharan Africa, societies are characterized by a very pronounced age hierarchy (as

well as gender hierarchy) and children are raised to be obedient to adults in all ways, including to relative strangers. This can lead to children being placed in positions of vulnerability, especially to sexual abuse (Jewkes et al. 2005).

Masculinities

The most pervasive ways in which culture influences interpersonal violence is in the arena of gender. Gender attitudes held at an individual level are usually rooted in cultural models of gender relations, but within these there is considerable individual variation. Sexually aggressive men from diverse settings have greater hostility towards women, stronger sexual dominance desires, and more traditional attitudes towards gender roles and sexual relationships (Koss and Dinero 1988; Malamuth et al. 1991, 1995; Abbey et al. 2011; Jewkes et al. 2011a). IPV is much more common among men who hold more gender inequitable views as well as those who engage in more controlling behaviours (Fulu et al. 2013). However, individually held attitudes and social norms theory do not on their own explain the social structure of gender. R.W. Connell (1987), a highly influential gender theorist, describes the existence of multiple, mutable masculine positions and identities, that are produced against a backdrop of history, cultural, and material circumstances, arranged hierarchically with respect to each other (some are viewed as legitimate while others are censored), and superior to women. Recognizing the global dominance of patriarchy, Connell argues that all masculine positions are constructed within a gender value system that values men over women and within which men are more powerful. Connell emphasizes that gender identities are socially constructed and integrally linked to hierarchies of power. Her analysis is critical to understanding both gender relations (i.e. between men and women) as well as the interrelationships among men. Connell argues for the existence in a particular setting of a hegemonic masculinity, which is a cultural ideal of manhood that gains its legitimacy from acceptance that is shared between those who embody and benefit from the ideal and those subordinated through it (after Gramsci (1971)). Hegemony connotes the existence of agreed values and practices, not necessarily associated with repression and violence. However, in many contexts, being dominant and in control of women are important aspects of hegemonic masculinity, and violent

behaviours are justified in pursuit and demonstration of this (e.g. Wood and Jewkes 2001).

The different masculine positions that are adopted by men in a given setting vary, but there are global commonalities that have been observed. The first is that in any given setting there are normally masculinities that are notably violent and combine practices of violence between men with violent domination over others, particularly women. Men who adopt these masculine positions often are involved in illegal and antisocial behaviour. Further their dominance over women encompasses both the use of violence against women and demonstrations of power through (hetero)sexual success with or dominance over women, for example, in paying for sex, having many sexual partners, and so forth. These masculinities are sometimes referred to as hyper- or emphasized masculinities and are very closely associated with violence between men as well as sexual and physical violence against women.

The hegemonic masculinity within a given setting is much more moderate than this. It may not be numerically the most common position, but has the greatest cultural power, in that it is a masculinity that generally embodies a recognized cultural ideal of how men 'should' be, even if some men are unable to occupy the position due to economic circumstances. Hegemonic masculinities vary considerably globally, particularly in their relationship with men's violence. In some settings, such as South Africa, showing toughness and strength is absolutely integral to a hegemonic position. Men may be expected to be head of a household, a provider, and for women to be obedient. The cultural legitimacy accorded to a hegemonic masculine position results in men being able to exercise power over women without the use of violence, rather through women's acquiescence to men's dominance, but violence may be used. In some countries, such as Sweden, hegemonic masculinities are much more gender equitable and not expected to entail violence (Hearn et al. 2012). The relationship between hegemonic masculinity and the use of violence is extremely important in understanding the prevalence of interpersonal violence within a given cultural setting.

There are of course other masculinities and some are much more gender equitable and less violent, even in contexts of very patriarchal hegemonic masculinities. Some are constructed as resistance masculinities and may strive to be different, as is the case with gay masculine identities. Hegemonic masculinities often emphasize heterosexuality and are constructed very

consciously in opposition to the feminine or homosexual, and indeed men may be identified as victims of male violence because they are perceived as being ‘unmanly’.

The importance of masculinities in interpersonal violence should not mask the role of women. Women are responsible for perpetration of much violence against children, but for other forms of interpersonal violence the majority of perpetrators are men. Women do use violence against intimate partners, but much of it is retaliatory violence and where they initiate it their violence differs in meaning with the violence of men because it is not perpetrated within an overall context of gender power inequity. They also may engage in youth violence with other women. In a given setting women also adopt multiple feminine positions, some of which are highly acquiescent to dominant positions of men. These positions may render women vulnerable to violence but they may also provide some protection. Femininities which are constructed as resistance femininities may be viewed by men as threats and make women deliberate targets of violence, for example, in attacks on lesbians. There is an increasing literature from high-income countries and some settings with rapid social change, such as South Africa, on ‘modern’ femininities. These are characterized by women adopting many of the practices of men, without necessarily challenging the dominance of men in the gender order. They may be associated with particularly risky behaviour such as fighting among women, binge drinking, and having many sexual partners (Jewkes and Morrell 2010).

The importance of understanding gender identities in relation to interpersonal violence is that they provide a unifying framework for understanding both male dominance over women and the use of violence between men and between women. Other connected practices such as alcohol bingeing very often stem from links between alcohol excess and control and toughness, or alcohol and resistance (e.g. in conservative settings), which is highly gendered. It also connects interpersonal violence with some of its associated sexual practices and associated health risks. First, by linking gun or weapon ownership, or carrying, with manhood. Secondly, sexual assault and rape perpetrators from a range of countries, including the United States, South Africa, Botswana, and Swaziland, have more dating and consensual partners and more casual sex than other men, although they may not have more frequent sex as they have less emotionally engaged relationships with partners (Koss and Dinero 1988; Malamuth et al. 1991,

1995; Abbey et al. 2006; Jewkes et al. 2006, 2011a, 2011b; Kalichman et al. 2007; DeGue et al. 2010; Tsai et al. 2011). Changing the values upon which gender identities are constructed is an important avenue for intervention in interpersonal violence reduction.

Stigma

Gender values of a society are also expressed in perceptions of blame in cases of gender-based violence and in social responses to victims. Rape stigma is particularly powerful as it may be expressed in perceptions that women and girls who have been raped are sullied, and to blame for what happened, and this can lead to their ostracism. In some settings the rape is seen as a mark against the family's honour and not just a woman's own, and they may even be killed. Children born of rape may be rejected by families and communities too. Rape stigma is a very substantial barrier to access to services and legal redress after rape, and thus creates impunity for those who perpetrate.

Societal level

At a societal level it is important to understand that the dominant social values, especially gender values, are expressed in laws, policies, and through social institutions such as the police and courts. Thus in very patriarchal societies, except in settings with a strong commitment to building human rights (such as South Africa), laws very often restrict women's autonomy and may increase their vulnerability to violence and reduce their ability to bargain with, or leave, violent partners. Examples of such laws are those that make divorce hard to access, allow parents to marry very young girls, fail to criminalize rape in marriage, restrict married women's access to property and inheritance, or render women as legal minors.

Dominant values are also reflected in systems implementing laws and policies, even where laws are more progressive. The police may refuse to open cases if they believe an act not to be a crime, this has particularly been reported in cases of rape and domestic violence. Courts may have a low threshold for declining to prosecute and where women are viewed with suspicion their evidence in court may be insufficient for a conviction (Jewkes and Abrahams 2002). If women cannot get legal redress for acts of

IPV or rape or child abuse, perpetrators are sent a powerful message that they may anticipate impunity and that their acts are not viewed as serious.

At a societal level, laws and policies may influence access to risk and protective factors, including alcohol, and support networks. In some countries, alcohol is cheap, easily accessible at all hours, and poorly regulated. These factors result in considerably higher alcohol consumption patterns, especially by young people, and so to a stronger link between interpersonal violence and heavy drinking. Similarly firearms are very effectively controlled by laws in some settings. South Africa is an example of a country where tighter gun control translated into a substantial reduction in gun-related homicides, these accounted for 17% of female homicides in 2009, a reduction of nearly 50% from one decade earlier (Abrahams et al. 2013). In comparison in the United States, with its very liberal gun laws, 67.5% of homicide is perpetrated with a firearm. Some countries have considerable investment in service provision for victim/survivors of interpersonal violence, enabling them to get support, counselling, and assisting access to justice through legal channels. Where such support is provided through women's organizations, these often also play important roles as raising awareness and advocating for women's rights at a local level and can make a powerful impact on social norms on violence. In Nicaragua a substantial reduction in violence against women was found in surveys over a period of 20 years and has been largely attributed to the activities of the organized and empowered women's sector.

Summarizing the prevention challenge

A comprehensive review of risk factors for interpersonal violence, as provided earlier, includes many which are amenable to intervention in the short or medium term and others which require change across generations. We can draw from them seven key tasks for prevention of interpersonal violence: empowering women, changing gender relations and building gender equality; preventing the use of all forms of violence and changing violence-supportive social norms; reducing structural inequalities such as poverty and low levels of education; building relationships skills, especially communication skills; strengthening mental health and reducing substance abuse; elevating the status of children to strengthen child protection and rights and end corporal punishment; and to provide legal and social

frameworks of protection for women and girls and other vulnerable groups, and to enhance justice for victims of interpersonal violence.

Research shows the amenability of forms of interpersonal violence to prevention through interventions (Ellsberg et al. 2015; Lester et al. 2017). Knowledge of the field of prevention of violence against women and girls has been considerably advanced over the last decade by the DFID-funded *What Works to Prevent Violence Against Women and Girls? Programme* (https://www.whatworks.co.za). This has conducted research in 15 countries to understand drivers of violence, social and economic costs, and what works in prevention. Evidence from the Programme suggests that well-designed evidence-based multicomponent interventions, that address multiple drivers of violence, have considerable success in reducing violence. A critical feature of their design is the need for them to be built on a strong theory of change—rooted in an analysis of the local drivers of violence—with the preventive interventions using robust behaviour change and skills building methodologies. In the field of prevention of violence against women and girls, gender inequity is centrally important and so more effective interventions have a unifying characteristic of being based on theories of gender and power. In some settings small decreases in violence have been measured with single component interventions in the form of cash transfers, but these have also been shown to increase women's exposure to violence in other settings, as shown by research on the impact of short term cash transfers for conflict-affected women in Syria. Where violence prevention interventions engage individuals in journeys of behaviour change, successful interventions use participatory methods with single-sex groups, build relationship skills and seek to engage the individuals targeted at an emotional level through critical reflection and responding empathetically towards survivors. These need to be delivered by well-trained, experienced, and supported individuals who espouse the values of the programme.

Awareness arising is a key element of work on interpersonal violence in settings where awareness is low, but it does not change behaviour on its own. Effective interventions that have been implemented across communities that use awareness raising have this as a pillar of more complex interventions which also include providing support for survivors, constructively engaging, and often strengthening, local services (such as health sector and police responses) and engaging couples where the wife

experiences violence directly with counselling. Even in very conservative and fragile settings, gender attitudes and practices of gender relations including the use of violence, are amenable to change and interventions have been able to demonstrate this, but such interventions take time to deliver and to demonstrate impact.

Interventions that have been shown to be effective in reducing violence against women include those that seek to elevate the status of women through gender empowerment programming and some form of economic empowerment intervention. This modality was first demonstrated in the IMAGE study in South Africa with a brief gender empowerment intervention, microfinance, and mobilization of women into community action against violence (Pronyk et al. 2006). These interventions have subsequently been shown to be successful with multiple modalities of economic empowerment including cash transfers, microfinance, and assistance in establishing small enterprises. In highly conservative, patriarchal settings, such as Tajikistan and Nepal, family-based interventions have been shown to be valuable for protecting younger women. Elsewhere the evidence seems to suggest these interventions empower older women more consistently to protect themselves from violence, than younger women. Research with very poor and disempowered young men, suggests that their perpetration of violence may be reduced by an intervention combining livelihood strengthening programming and gender transformative elements. This is important as there are a key group at very high risk of perpetration of violence.

Community action driven interventions have been shown to effectively reduce violence where they have been delivered over multiple years in sufficient intensity to impact communities. The prototype was the SASA! Intervention in Uganda (Abramsky et al. 2014). A key feature of these are the training of members of the community, often nominees from communities, in gender equity and non-violence, and often counselling, and supporting them in outreach activities. The overall impact is shifting gender attitudes and challenging norms around the use of violence across communities, as well as individual couple and survivor impact through work engaging couples and supporting survivors directly. These interventions usually engage traditional and religious leadership in communities as well, and in some versions have worked in interpretation of scriptures to promote gender equity and non-violence.

Interventions that are designed as workshop series which seek to empower men to critically reflect on their masculinities, relations with women, and use of violence have also been shown to be effective in preventing violence. Early rigorous evaluations tested the South African adaptation of Stepping Stones, and showed impact in reducing men's perpetration of violence, a finding which has been confirmed in a second randomized controlled trial (Welbourn 1995; Jewkes et al. 2008). Other similar interventions have been effective in building more gender equitable attitudes among men such as Program H in Brazil (Ricardo et al. 2012). More recently couples' interventions have also been tested and shown to be effective in complex settings, notably Rwanda.

A particularly challenging dimension of partner violence is that where male perpetration of violence is substantially influenced by alcohol and drug use and poor mental health. A psychotherapeutic intervention has been developed and tested in Zambia using the Common Elements Transdiagnostic Approach (CETA) with an additional substance abuse module, and this has been shown to enable a substantial reduction in both substance abuse and violence, sustained for 2 years in couples.

Interventions with children has been designed to prevent different forms of violence. There is considerable evidence that peer violence can be prevented by socioemotional programmes, cognitive behaviour and life skills interventions delivered in schools, and recently a play-based life skills intervention was shown to be impactful in the challenging setting of Pakistan (Lester et al. 2017). There is very little evidence of effective intervention to reduce corporal punishment in LMICs where it is often illegal but widely practised. An exception is the Good Schools Programme in Uganda, which was shown to be effective in reducing this as well as violence among children in school (Devries et al. 2015). Dating violence has been an area in which interventions have been developed and tested in schools. Success has been mixed, and in LMICs there are still no examples of successful programmes. In Canada, the participatory 4th R intervention is a notable example of one that has been shown to be effective in reducing boys' perpetration of violence (Wolfe et al. 2009).

There have also been a series of key systematic reviews showing that interventions can be effective in reducing child maltreatment and strengthening positive parenting (McCloskey 2011; Knerr et al. 2013). More recent work has sought to focus on interventions with older children and

their parents, including harnessing the power of parents to protect teenage children from violence. Notable examples here are the Skhokho Programme and the Parenting for Lifelong Health (Sinovuyo) intervention in South Africa, which provide some evidence that these programmes can improve a range of parenting and adolescent outcomes.

A key element in interpersonal violence prevention is also the framework of laws and policies and their implementation, including support for survivors of violence. This includes interventions to strengthen child protection systems, supporting and assisting victim/survivors of violence to gain justice as well as in managing the health sequelae. It involves improving the functioning of police and courts in cases of interpersonal violence, rehabilitation of offenders and adopting and enforcing a range of other legislation and policies to reduce risk including those focused on gun control, illicit drug laws and prevention of trafficking, anticorruption measures, and the prevention of problem drinking. Support for women experiencing violence, who often do not have access to assistance from the State, or are unable to use legal avenues, through an active women's sector is incredibly important.

Over the last few years the INSPIRE (https://www.who.int/inspire) and RESPECT (https://www.who.int/topics/respect) frameworks have provided a practical basis for understanding the prevention challenge with respect to ending violence against children and violence against women. There is considerable overlap between the two frameworks.

Addressing violence globally is a daunting task, but available data on trends show that violence can be prevented. National data from several countries show declines over the last few decades due to a constellation of social change. However there are also settings where interpersonal violence has escalated, sometimes with declines reversed, notably in relation to drug-related activities. The best confirmatory evidence of preventability comes from the United States, where the prevalence of all forms of interpersonal violence has very substantially declined over the last 30 years. For example child maltreatment and victimization is believed to have declined by 40–70% (Finkelhor and Jones 2006), IPV has declined by 49%, and figures from the Federal Bureau of Investigation show that the homicide rate declined from 9.8 to 4.7 per 100,000 from 1990 to 2010, making the current homicide rate comparable to that of 1960. It is much less clear which interventions worked, if indeed it was a product of interventions, and why the impact has

been greater in some states than in others. Criminologists and public health researchers have extensively debated the causes of the decline, because of the importance of understanding this for its replication in other settings, but unfortunately they only agree that they do not know how to attribute it. The period of the decline was one in which there was much more public health intervention to raise awareness of, and the prevention of, child maltreatment. There was a 24% reduction in families living in poverty and there were increasing policing interventions and crime reduction activities, as well as a range of other social changes including changes to build gender equity (Finkelhor and Jones 2006). The clustering of reduction in all forms of interpersonal violence (except child neglect, but this may be an artefact of case identification) strongly supports an argument that they are all closely interconnected and the need for a multipronged approach to prevention.

Conclusions

Interpersonal violence is a problem of huge global magnitude, responsible for a very substantial global burden of disease and with considerable economic impact. It is largely preventable and this chapter has sought to argue that although forms of interpersonal violence differ, prevention can substantially be unified as there are a common set of risk factors. Further when interpersonal violence does decline, as in the United States, a decline across all forms is seen to occur. Social norms around gender and the use of violence are extremely important in all forms of interpersonal violence and need to be a key focus for intervention. The prevention agenda in interpersonal violence, especially gender-based violence and child maltreatment, has historically been dominated by secondary prevention, with responses from child protection and the criminal justice system and the provision of services to victims. This is very important, but it is only a small part of what is needed to effectively prevent violence. First prize for the future will go to developing robust multisectoral primary prevention interventions that have an impact on multiple risk factors and change the social context within which interpersonal violence occurs.

9.6

Collective violence

War

Barry S. Levy

Introduction

There are three categories of violence: self-directed violence, interpersonal violence, and collective violence. Collective violence is ‘the instrumental use of violence by people who identify themselves as members of a group —whether this group is transitory or has a more permanent identity— against another group or set of individuals in order to achieve political, economic, ideological, or social objectives’ (Krug et al. 2002, p. 215). Collective violence includes armed conflict (such as war), state-sponsored violence (such as genocide, repression, disappearances, and torture), and organized violent crime (such as gang warfare and banditry). This chapter focuses on war. (Chapter 8.7 focuses on self-directed violence. Chapter 9.5 focuses on interpersonal violence, including gang warfare. Chapter 8.19 covers *bioterrorism*.)

During 2019, there were 32 armed conflicts: 15 in sub-Saharan Africa, 7 in the Middle East and North Africa, 7 in Asia and Oceania, 2 in North American and South America, and 1 in Europe. Most of these were intrastate conflicts (mainly ‘civil wars’), occurring within a low- or middle-income country between government forces and one or more armed non-state groups. There were three wars with 10,000 or more battle-related deaths in 2019—in Afghanistan (approximately 41,900), Yemen (25,900), and Syria (15,300) (Stockholm International Peace Research Institute 2020).

There are multiple underlying and precipitating causes of war. Many wars are caused by disputes over government power, territory, or

environmental resources. Risk factors for war include: (a) demographic factors, such as high infant mortality and high population density; (b) social and community factors, such as inequality among groups, availability of small arms and light weapons, and racial, ethnic, or religious tensions; (c) political factors, such as inadequate public role in decision-making, rapid regime change, and unequal access to power; (d) economic factors, such unequal access to or distribution of resources; and (e) other factors, such as deterioration in public services and cycles of violent revenge (Krug et al. 2002, pp. 213–39; Carnegie Commission on Preventing Deadly Conflict 1998). Conflicts over access to freshwater, which are increasing (Gleick 2018), can lead to war (Levy and Sidel 2011). Climate change, by causing increased temperature and extremes of precipitation with associated consequences, may increase the risk of armed conflict (Levy and Patz 2015). Ethnic tensions, militarism, and the arms trade contribute to the risk of war.

The health and environmental consequences of war

The consequences of war include morbidity and mortality due to weapons; damage to the health-supporting infrastructure of society; contamination of air, water, and land; forced displacement; violation of human rights; diversion of financial and human resources; and promotion of additional violence (Levy and Sidel 2008, 2013). Each of these consequences is described in more detail next.

Morbidity and mortality due to weapons

Many people, including an increasing percentage of civilians, have been killed or injured by weapons during war. An estimated 191 million people died directly or indirectly as a result of conflict during the twentieth century (Ferguson 2006). More than half of those who died were civilians and tens of millions of people died as a result of mass murder and genocide (Rummel 1994; Power 2002). In addition to physical injuries and illnesses, wars cause—both among military personnel and civilians—mental health consequences, including anxiety, depression, posttraumatic stress disorder,

alcohol and drug abuse, violence inflicted on family and friends, and suicide (Blore et al. 2015; Bonde et al. 2016).

From the early twentieth century to the start of the Second World War, the vast majority of deaths during war were among uniformed combatants, usually members of national armed forces. Although non-combatant civilians suffered from the social, economic, and environmental consequences of war, they were usually not targeted. However, since 1937, when Nazi forces bombed Guernica, a city in Spain, military operations, in addition to causing 'collateral damage' to non-combatant civilians as a result of attacks on military targets, have increasingly targeted—and injured and killed—non-combatant civilians (Tirman 2011).

Damage to the health-supporting infrastructure of society

Much morbidity and mortality during war, especially among non-combatant civilians, results from damage to the health-supporting infrastructure of society. In some wars, such as the civil war in the Democratic Republic of the Congo (in which more than five million people died during the war and its aftermath), the vast majority of deaths among non-combatant civilians have been caused by infectious diseases, malnutrition, and pregnancy- and neonatal-related conditions—largely due to damage to the societal infrastructure (Coghlan et al. 2008). This damage includes adverse effects on medical care and public health services. Physicians, nurses, and other health workers are injured or killed or they flee; clinics and hospitals are physically damaged; public health services are reduced or eliminated; and there is inadequate or no access to essential medicines and vaccines. Damage to the societal infrastructure also includes adverse impacts on food and water supply systems, sewage disposal systems, power plants and electrical grids, and transportation and communication systems.

Contamination of air, water, and soil

The physical environment may be contaminated during war—or the preparation for war—by military exercises on land, in air, and in water and by the production, testing, use, and disposal of weapons. Hazardous wastes

from military operations can contaminate air, water, and soil. For example, groundwater contamination occurred due to disposal of petroleum products and other hazardous materials at the Otis Air Force Base in Massachusetts. Pesticides, solvents, other chemicals, and radioactive materials were dumped for over 30 years at the Rocky Mountain Arsenal in Colorado. Benzene, arsenic, chromium, and mercury have been detected at the McChord Air Force Base in Washington State (Westing 2008). In addition, release of hazardous and toxic substances from damaged industrial facilities can contaminate the environment. For example, during the Iraq War, environmental contamination occurred due to hazardous materials from a metal-plating facility, pesticides, and petrochemicals warehouses, a sulphur mining complex, and a military scrapyard site (United Nations Environmental Programme 2005).

Conventional weapons have accounted for the overwhelming majority of adverse environmental consequences in war. During the Second World War, for example, extensive carpet bombing of cities in Europe and Japan caused many deaths and injuries, as well as widespread devastation of urban environments. During the Gulf War, more than 600 oil fires in Kuwait caused widespread environmental devastation and respiratory disorders among people who were exposed to the smoke from these fires. Bombing during the Vietnam War destroyed mangrove forests; resultant bomb craters remained long afterward, often filling with stagnant water that enabled breeding of mosquitoes that transmit malaria and other diseases.

Forced displacement

War uproots people. Many of the approximately 26 million refugees globally were forced by war to leave their native countries; the five leading countries of origin of refugees in late 2019 were Syria, Venezuela, Afghanistan, South Sudan, and Myanmar, all of which had experienced war or internal conflict. Refugees often flee to neighbouring low- and middle-income countries, which are often already facing significant challenges in addressing the public health needs of their own populations. Seven of the eight countries sheltering the most refugees in late 2019—Turkey, Colombia, Pakistan, Uganda, Germany, Sudan, Iran, and Lebanon—are low- and middle-income countries already challenged in meeting the needs

of their own citizens. Many of the approximately 46 million internally displaced persons and approximately 8 million stateless people were also forced to leave their homes as a result of war. In 2019, there were approximately 11 million people newly displaced, mainly by conflict and violence; the leading countries in which they were internally displaced were Syria, Colombia, the Democratic Republic of the Congo, Yemen, Afghanistan, Somalia, and Nigeria—all of which had experienced significant conflict and violence. The vast majority of all these uprooted people are women, children, and elderly people, many of whom are at increased risk of injury and illness, threats to their safety and security, and death. Internally displaced persons are generally worse off than refugees because they frequently do not have security or access to safe food and water, healthcare and public health services, shelter, and other basic human needs.

Violation of human rights

Human rights have often been violated during war. These violations have included assaults on civilians, including sexual assaults on women and abduction of children into military forces; mass killing; torture of prisoners and other violations of the Geneva Conventions; and violations of medical neutrality. There are more than 250,000 children forcibly engaged in armed conflict. They have been abducted to join fighting forces or to serve as ‘sex slaves’. These children suffer physical injuries and illnesses, including mental health problems (Song and de Jong 2015).

The Geneva Convention IV mandates the protection of civilian populations during war. This convention states that civilian populations and individual civilians shall not be the objects of attacks. It prohibits acts or threats of violence whose primary purpose is to spread terror among civilian populations. It prohibits indiscriminate attacks on civilians, such as those that are not directed at a specific military objective or those that may be expected to cause incidental civilian deaths or injuries and/or damage to ‘civilian objects’. In addition, it bans reprisal attacks against civilian populations or civilians.

Diversion of resources

Former United States President Dwight D. Eisenhower said: ‘Every gun that is made, every warship launched, every rocket signifies, in the final sense a theft from those who hunger and are not fed, those who are cold and not clothed’ (Eisenhower 1953). Military expenditures, which often constitute a high percentage of national budgets, often divert financial—and human—resources away from health and human services and other beneficial activities. In many countries, the total amount of military expenditures approximates the amount spent on healthcare and public health. In 2019, the United States spent $732 billion on military expenditures, representing 38% of global military expenditures—more than the next 10 countries (China, India, Russia, Saudi Arabia, France, Germany, the United Kingdom, Japan, South Korea, and Brazil) combined (Stockholm International Peace Research Institute 2020, p. 226). As a reflection of diversion of resources, the United States ranks first among the nations of the world in arms exports, military expenditures, and military technology, but ranks 30th in life expectancy and 43rd in infant mortality rate.

As another example of the impact of the diversion of resources, the first $204 billion spent by the United States on the Iraq War could have achieved all of the following goals for three years: a 50% decrease in world hunger, a comprehensive global programme to address HIV/AIDS, complete immunization of all children in ‘less-developed countries’, and meeting all needs globally for clean water and sewage treatment (Bennis et al. 2005).

Promotion of additional violence

Violence often promotes further violence. In the aftermath of war, a number of factors can lead to additional violence, such as persistent hatred and unresolved disputes among warring countries or groups, militarism, and the international arms trade. There are many examples in which, in the aftermath of war, persistent hatred and unresolved disputes have led to further armed conflict, such as in the Middle East. Additional violence can result from militarism, which is defined as a philosophy or a system of beliefs and attitudes that a country should develop and maintain strong

military power and aggressively deploy it consistent with its values and national interests. The international trade in conventional weapons also heightens the risk of violence especially in low- and middle-income countries. The volume of international transfers of major arms increased 5.5% between the 2010–2014 and 2015–2019 periods. During the 2015–2019 period, the five largest suppliers of major weapons were the United States (36%), Russia (21%), France (7.9%), Germany (5.8%), and China (5.5%), and the Middle East region received 35% of imports of major weapons (Stockholm International Peace Research Institute 2020, p. 278 and p. 295).

The United Nations General Assembly, in 2013, took a major step towards regulating the international trade in conventional weapons by overwhelmingly approving the Arms Trade Treaty, which links purchases of arms to the human rights records of the purchasing countries. The treaty is designed to prevent exported weapons from contributing to human rights violations, terrorism, or organized crime, and to prohibit arms shipments that are deemed to be harmful to women or children.

Types of weapons

Conventional weapons

Conventional weapons consist of small arms and light weapons, heavy conventional weapons (such as tanks, artillery, combat aircraft, warships, and missiles), explosives, and incendiaries. Small arms and light weapons, which include pistols, rifles, machine guns, and other hand-held or easily transportable weapons, are the weapons that are most often used in war. They have occasionally been described as ‘weapons of mass destruction’ because the number of deaths that they cause ‘dwarf that of all other weapons systems—and in most years greatly exceed the toll of the atomic bombs that devastated Hiroshima and Nagasaki’ (Annan 2000).

Armed drones are a category of conventional weapons. Since 2004, the United States has been conducting armed drone strikes in Afghanistan, Pakistan, Somalia, and Yemen, in attempts to kill suspected terrorists. The Bureau of Investigative Journalism has reported that, through 2020, most of the people who had been killed in 14,040 armed drone strikes in these countries had been militants, but at least 910 of them were civilians.

Nuclear and radioactive weapons

The detonation of nuclear bombs over Hiroshima and Nagasaki in August 1945 during the Second World War immediately killed about 200,000 people, primarily non-combatant civilians, and later caused many more deaths from malignancies and other diseases. These attacks injured and disabled many more people, and caused massive devastation—and radioactive contamination—of the environment in these two cities (Sutton and Gould 2008).

As of 2020, there were 13,400 nuclear warheads possessed by nine nations—in order of decreasing number of warheads, Russia, the United States, China, France, the United Kingdom, Pakistan, India, Israel, and North Korea (Stockholm International Peace Research Institute 2020, p. 326). The United States (with 5,800 nuclear warheads, 1,750 of which are deployed) and Russia (with 6,375 nuclear warheads, 1,570 of which are deployed) possess the vast majority of nuclear weapons. Both countries have hundreds of nuclear warheads on alert on land-based intercontinental ballistic missiles and submarine-launched ballistic missiles. All of the nuclear-armed countries are planning major programmes to upgrade and modernize their nuclear weapons and delivery systems. In addition to the possible intended or accidental use of nuclear weapons by these countries, it is increasingly recognized that non-state actors, such as terrorist groups, could acquire and detonate nuclear weapons.

Atmospheric testing of nuclear weapons by the United States, the former Soviet Union, and other countries caused environmental contamination, with increased rates of leukaemia and other cancers among downwind populations. In addition, production of nuclear weapons caused environmental contamination. For example, the Techa River in the Chelyabinsk Region of Russia was heavily contaminated with radioactive materials from the nuclear weapons production facility there (Burmistrov et al. 2006). Leakage from stored radioactive wastes at the nuclear weapons production facility at Hanford, Washington, has also caused environmental contamination (Westing 2008).

There are several international treaties concerning nuclear weapons. The Partial Test Ban Treaty (PTBT) of 1963, promoted in part by concerns about radioactive contamination of the environment, banned nuclear tests in the atmosphere, under water, and in outer space. The expansion of the

PTBT, the Comprehensive Nuclear-Test-Ban-Treaty (CTBT)—a key step towards nuclear disarmament and preventing proliferation of nuclear weapons—was opened for signature in 1996 but has not yet entered into force. The CTBT bans explosions of nuclear weapons, for either military or civilian purposes, but it does not ban computer simulations and subcritical tests, which some nations use to maintain the option of developing new nuclear weapons. The CTBT has been ratified by 168 nations and signed, but not ratified, by another 16 nations. Entry into force requires ratification by the 44 nuclear-capable nations; by 2018, only 36 had ratified the CTBT and the following eight nuclear-capable nations had not: China, Egypt, India, Iran, Israel, North Korea, Pakistan, and the United States.

The Treaty on the Non-Proliferation of Nuclear Weapons (the ‘Nuclear Non-Proliferation Treaty’, or NPT) attempts to prevent the spread of nuclear weapons by restricting transfer of certain technologies. It relies on a control system operated by the International Atomic Energy Agency, which also promotes nuclear energy. In exchange for the non-nuclear-armed countries’ commitment not to develop or otherwise acquire nuclear weapons, the NPT commits the nuclear-armed countries to good-faith negotiations on nuclear disarmament. The NPT was opened for signature in 1968 and entered into force in 1970. A total of 191 countries have ratified the treaty. All of the five nuclear-armed countries recognized under the NPT —China, France, Russia, the United Kingdom, and the United States—have ratified it. Every 5 years since 1970, the states-parties to the treaty have held a review conference to assess implementation of the treaty. In 1996, the International Court of Justice (the World Court), in an advisory opinion, urged that the nations possessing nuclear weapons move expeditiously towards nuclear disarmament, as is required by the NPT.

All of the nuclear-armed countries can help stop the spread of nuclear weapons by actively supporting and adhering to these treaties, and can renounce the first use of nuclear weapons and the development of new nuclear weapons. The United States and Russia can collaborate in dismantling their nuclear warheads and can secure nuclear materials better so that they will not be acquired by non-state actors.

Attention is increasingly being focused on the total elimination of nuclear weapons. In 2017, the United Nations adopted the Treaty of the Prohibition of Nuclear Weapons (TPNW), which comprehensively bans nuclear weapons, including their possession. The TPNW is akin to the chemical and

biological weapons conventions. Under the treaty, it is illegal for its parties to develop (or finance to develop), test, produce, acquire, possess, store, transfer, transport, plan or threaten to use, or use nuclear weapons. Nuclear-armed countries that join the treaty will need to destroy their nuclear weapons and terminate their nuclear weapons programmes. The treaty also mandates that parties to the treaty assist victims of nuclear weapons testing and use and it requires environmental remediation of areas contaminated by nuclear weapons. By the end of 2020, the treaty had been signed by 86 countries and ratified by 51.

Possible deployment of ‘dirty bombs’, which are conventional explosive devices mixed with radioactive materials, and possible attacks on nuclear power plants represent other risks. So does depleted uranium (DU), from which the uranium isotope usable for nuclear weapons or for fuel rods in nuclear power plants has been removed. DU is used militarily as a casing for armour-penetrating shells. An extremely dense material, uranium increases the ability of shells to penetrate the armour of tanks; uranium also bursts into flames on impact. DU-encased shells were used by the United States during the Gulf War, the Iraq War, and the war in Kosovo; similar shells were used by the United Kingdom in the Iraq War. DU, which is both radioactive and toxic, can contaminate soil and groundwater (Bešić et al. 2018). Use of DU is considered legal by the nations that have used it, but its use is considered by other nations to be illegal under the Geneva Conventions and other international treaties.

Chemical weapons

Chemical weapons, which were first used during the First World War, have been used on several occasions since then. The government of Syria under President Bashar al-Assad has used chemical weapons during the civil war in Syria many times against civilians, causing many deaths (Arms Control Association 2020). A Japanese cult, Aum Shinrikyo, used sarin in the subway system of two Japanese cities in the mid-1990s, killing 19 people and injuring thousands.

The Chemical Weapons Convention (CWC), which came into force in 1997, prohibits development, production, acquisition, stockpiling, transfer, and use of chemical weapons. It requires each participating country to destroy its chemical weapons and chemical weapons production facilities,

as well as any chemical weapons it may have abandoned on the territory of another participating country. The CWC has been signed by 193 nations; one nation has signed, but not yet ratified it; and three nations have neither signed nor ratified it. The verification provisions of the CWC affect not only the military sector but also the civilian chemical industry with restrictions and obligations regarding production, processing, and consumption of chemicals that are considered relevant to the convention. These provisions are verified by reporting requirements, routine onsite inspection of declared sites, and short-notice challenge inspections. The CWC established the Organization for the Prohibition of Chemical Weapons (OPCW) in The Hague to ensure implementation of its provisions (Lee et al. 2012). Stockpiles of chemical weapons, which remain in a number of countries, pose a continuing threat to health and the environment.

Biological agents

Biological agents, which consist of bacteria, viruses, other microorganisms, and their toxins, can produce illness in humans and can be used against other animals or plants, thereby adversely affecting agricultural resources, food supplies, and human health. Biological agents have been used as weapons since ancient times (Barras and Greub 2014). In the sixth century BC, Persia, Greece, and Rome tried to contaminate drinking water sources with diseased corpses. In AD 1346, Mongols besieging the Crimean seaport of Kaffa placed cadavers of plague victims on hurling machines and threw them into the city. During the French and Indian War in the United States in the mid-eighteenth century, a British commander sent blankets infected with smallpox to Native Americans. During the First World War, Germany dropped bombs containing plague bacteria over British positions and used cholera in Italy. During the 1930s, Japan contaminated food and water supplies of several cities and sprayed the cities with cultures of microorganisms. In 1942, a test use of anthrax spores by the United Kingdom and the United States contaminated Gruinard Island, off the coast of Scotland (Harris and Paxman 1962). During the 1950s and 1960s, secret large-scale open-air tests at the US Army Dugway Proving Ground in Utah used the microorganisms that cause Q fever and Venezuelan equine encephalitis (Cole 1988). In 1979, the accidental release of anthrax spores

near Sverdlovsk in the Soviet Union resulted in at least 77 cases of inhalation anthrax, at least 66 of which were fatal (Meselson et al. 1994).

Biological agents could be used as terrorist weapons. In 2001, anthrax spores were disseminated through the US Postal Service, causing 23 cases of inhalational and skin anthrax, five of which were fatal. The Centers for Disease Control and Prevention (CDC) has identified three categories of diseases caused by biological agents, according to level of concern that they may be used as terrorist weapons. Category A consists of the agents that can be easily disseminated or transmitted from person to person, result in high mortality rates and have the potential for major public health impact, might cause public panic and social disruption, and require special action for public health preparedness. Category A agents include those that cause anthrax, botulism, plague, smallpox, tularaemia, and viral haemorrhagic fevers, such as the Ebola, Marburg, and Lassa viruses. Category B consists of the agents that are moderately easy to disseminate, result in moderate morbidity rates and low mortality rates, and require specific enhancements of CDC's diagnostic capacity and enhanced disease surveillance. Category B agents include those that cause brucellosis, glanders, melioidosis, psittacosis, Q fever, typhus fever, viral encephalitis, water safety threats, and food safety threats (such as *Salmonella* and *Shigella* species, and *Escherichia coli* O157:H7), as well as epsilon toxin of *Clostridium perfringens*, ricin toxin from castor beans, and staphylococcal enterotoxin B. Category C agents include emerging pathogens that could be engineered for mass dissemination in the future because of availability, ease of production and dissemination, and potential for high morbidity and mortality rates and for major health impact (Centers for Disease Control and Prevention 2018).

The 1975 Biological and Toxin Weapons Convention (BWC), prohibits the development, production, transfer, or use of biological weapons. The BWC has been signed and ratified by 183 countries; signed, but not ratified, by four countries; and neither signed nor ratified by 10 countries. The verification measures included in the BWC are weak and attempts to strengthen them have been unsuccessful. The United States has blocked attempts to strengthen the verification measures of the BWC, stating that such measures might lead to exposure of US industrial or military secrets.

Antipersonnel landmines and unexploded ordnance

Antipersonnel landmines, which are designed to be exploded by the presence, proximity, or contact of a person, can incapacitate, injure, or kill one or more people. Together with unexploded ordnance (UXO), they represent significant hazards in many countries and continue to account for much morbidity and mortality (Frost et al. 2017). Millions of antipersonnel landmines are still deployed in many countries. Antipersonnel landmines injure or kill thousands of people annually; the vast majority of landmine victims are civilians, primarily poor people, including children, living in rural areas. It is estimated that half of all landmine victims die of their injuries before they reach appropriate medical care. Although a mine may cost only a few dollars to produce, it may cost more than US$1,000 to remove, and its economic impact on human health and well-being can be substantially higher.

Antipersonnel landmines, in addition to maiming and killing people, make large areas of land uninhabitable. Remaining in place for many years, they pose long-term threats to people, including refugees and internally displaced persons returning to their homes in the aftermath of war. Since the Mine Ban Treaty entered into force in 1997, production of landmines has been markedly reduced and millions of landmines that had been implanted in the ground have been removed (International Campaign to Ban Landmines n.d.). However, about 36 countries continue to retain antipersonnel landmines and millions of landmines are still deployed in 58 countries; additional resources will be required to unearth and destroy them, tasks that pose inherent risks to demining personnel (Sirkin et al. 2008). A total of 164 nations are parties to the Mine Ban Treaty. Thirty-two nations have neither signed nor ratified it, including the United States, Russia, and China.

Prevention

Public health workers and other health professionals can play important roles in minimizing the health and environmental consequences of war and preventing war itself (Levy and Sidel 2008; Wiist and White 2017). Categories of preventive measures include: (1) documentation; (2) education and awareness-raising; (3) advocacy and support for policies and

programmes to minimize the consequences of war and to prevent war; and (4) provision of preventive services.

Documentation

It is important to document the health and environmental consequences of war in order to inform policymakers and the public about these consequences, provide necessary services to affected populations, document violations of international law, protect human rights, and reduce the likelihood of future war or other forms of violent conflict. Documentation can be performed by surveillance, epidemiological surveys, and rapid assessment (Levy and Sidel 2016).

Public health surveillance includes the systematic collection, analysis, and dissemination of data. Before, during, and after war, surveillance can provide information on morbidity and mortality as well as hazardous exposures and other factors that place non-combatant civilians at increased risk of injury, illness, or death. Even before a war has begun, surveillance may be able to identify population-based risk factors that may lead to interventions that may prevent the war from occurring.

Epidemiologic studies may provide critically important information on the nature, severity, and magnitude of morbidity and mortality, as well as on related risk factors. These studies are usually cross-sectional, but prospective and retrospective studies generally provide more accurate morbidity and mortality data.

Rapid assessment is often performed intensely during a short period, but can still be used to obtain preliminary information on a disastrous event or situation during war or its aftermath. It is also used to estimate the nature and magnitude of future health and related problems so that appropriate services can be provided.

Challenges to documenting accurately the adverse effects of war include inadequate or absent data systems, social breakdown, forced displacement, biases in reporting of data, problems in distinguishing combatants and non-combatant civilians, inadequate concern for the health of ‘enemy’ civilians, and ‘the fog of war’.

Education and awareness-raising

Much can also be accomplished by health professionals educating and raising the awareness of other health professionals, policymakers, and the general public about the health and environmental consequences of war. A multifaceted approach can include presentations and publications by professional organizations and citizens' groups, reports by the news media, and use of social media and other forms of communication. Health professionals who have witnessed war and its consequences and non-combatant and military personnel who have suffered from the consequences of war can be very effective in raising awareness about the impact of war.

Advocacy and support for policies and programmes

Health workers can advocate for and support policies and programmes to minimize the consequences of war, such as protecting the health-supporting infrastructure of society during war and its aftermath, preventing the exploitation of women and children, protecting the rights of displaced persons and prisoners of war, and maintaining safe zones for hospitals and other healthcare facilities. Advocacy is often most effective when conducted by professional associations, such as the American Public Health Association, or advocacy organizations, such as the International Physicians for the Prevention of Nuclear War and its national affiliate organizations, including Physicians for Social Responsibility and Medact.

Provision of preventive services

Health professionals can directly provide preventive services during war and its aftermath. These may include providing healthcare, including mental health services, for displaced individuals and populations; providing immunizations and other preventive services for children, women, and other civilians; and assisting in the restoration of healthcare and public health services.

Roles of the United Nations

Since its founding in 1945, the United Nations has had as its primary mission the maintenance of international peace and security. The United Nations works to accomplish its mission by preventing conflict, helping

nations and other groups involved in conflict achieve peace, providing peacekeeping activities, and promoting conditions in which peace can be sustainably maintained and flourish.

The Security Council of the United Nations determines the presence of a threat to peace or an act of aggression. It asks parties to a dispute or conflict to settle it by nonviolent means and it often recommends terms of settlement. The Security Council can implement a number of measures, such as economic sanctions and international military action, to restore or maintain peace and security among nations.

The United Nations General Assembly provides a forum for member nations to express their perspectives on issues and to try to find consensus on challenging matters. It makes decisions concerning issues of peace and security.

By using special envoys, political missions, and other forms of diplomacy, the United Nations tries to resolve conflicts before they become violent. In addition, it engages in peacekeeping activities to assist member countries in transitioning from conflict to peace. With troops and police contributed by member states, it maintains peace and security and also promotes peaceful political processes, protects civilian populations, and promotes disarmament, demobilization, and reintegration of former combatants. It also supports constitutional processes, helps to organize elections, protects and promotes human rights, and helps restore the rule of law. The United Nations has deployed 71 peacekeeping missions since 1948 and currently has 13 peacekeeping missions. The United Nations also engages in peacebuilding activities for countries that have recently been engaged in conflict, supports sustainable peace and development, coordinates efforts to counter terrorism, and works to eliminate weapons of mass destruction and regulate conventional arms.

Roles of non-governmental organizations

Non-governmental organizations (NGOs) can be important partners for health professionals in preventing the health and environmental consequences of war. These civil society organizations can help by intervening to mitigate the consequences of war (such as by providing humanitarian assistance to victims of war), performing research on the health and environmental impacts of war, educating the general public and

policymakers, and advocating for policies and programmes to prevent war and promote peace.

Levels of prevention

The public health framework of primary, secondary, and tertiary prevention can be applied to the prevention of war and its health and environmental consequences. In this context, *primary prevention* refers to preventing war before it begins, *secondary prevention* refers to prevention and minimizing the consequences of war after it has begun, and *tertiary prevention* refers to treating or ameliorating the health and environmental consequence of war.

Health professionals can contribute to the primary prevention of war in a number of ways. As previously described, they can educate policymakers and the general public about the health and environmental consequences of war on civilian populations. They can help identify the presence of risk factors for war, including socioeconomic inequalities and other forms of social injustice (Levy 2019). They can promote disarmament and the reduction and elimination of weapons of mass destruction. They can promote international cooperation through partnerships with health professionals in other countries. And they can promote a culture of peace, in which conflicts and disputes are settled by non-violent means.

When war occurs, its consequences can also minimized by secondary prevention measures to limit injuries, illnesses, and deaths (especially among non-combatant civilians), by preventing damage to the environment, and by supporting a prompt end to hostilities. Secondary prevention measures include strengthening and ensuring compliance with the Geneva Conventions.

During war and its aftermath, health professionals can promote and support:

Protection of non-combatant civilians.
Prosecution of targeting of civilians as a war crime.
Protection of the health-supporting infrastructure of society.
Evaluation of non-combatant civilians who are at risk of illness, injury, or death.
Maintenance of medical neutrality.
Transformation of the public mindset about civilians during war, including demonstrating that non-combatant civilians are not enemy supporters or members of the enemy's military and addressing social and psychological forces that permit and encourage military forces to injure and kill civilians.

In the aftermath of war, many tertiary prevention measures are critically important. For example, it is necessary to rehabilitate and reintegrate people who have incurred disabilities due to the war; repair the damage to the physical, social, cultural, and economic environments; and take measures to prevent further violence. After conflict is over, health workers have important roles to play, such as advocating for prompt return and restoration of communities and livelihoods and opposing forced relocation or return to insecure environments. They can also help to restore essential health services, which may include recruiting and training health workers. They can help to address mental health problems that may be otherwise overlooked. They can help restore food and water supply systems that were disrupted during war. And they can also promote and support programmes for truth, justice, and reconciliation. These programmes may include processes for determining the truth about crimes committed during war, ensuring trials and punishment for these crimes, compensating victims for their losses, and establishing memorials to commemorate the victims of these crimes.

Host-agent-environment model

The traditional host-agent-environment framework for prevention in public health (Fig. 9.6.1) can be adapted as an approach to the prevention of war, with people representing the 'host', weapons and the military representing 'agent', and the conditions in which people live representing 'environment' (Fig. 9.6.2). This framework can enable development of war-prevention strategies, such as the following:

Strategies aimed at people, including promoting understanding and tolerance, economic and social interdependence among countries, nonviolent resolution of disputes and conflicts, and developing the popular and political will to prevent war and promote peace
Strategies aimed at weapons and the military, including controlling the international arms trade, eliminating weapons of mass destruction, reducing military expenditures, and intervening in disputes to prevent war
Strategies to improve the conditions in which people live, including protecting human rights and civil liberties, reducing poverty and economic disparities, improving education and employment opportunities, and ensuring personal security and legal protections.

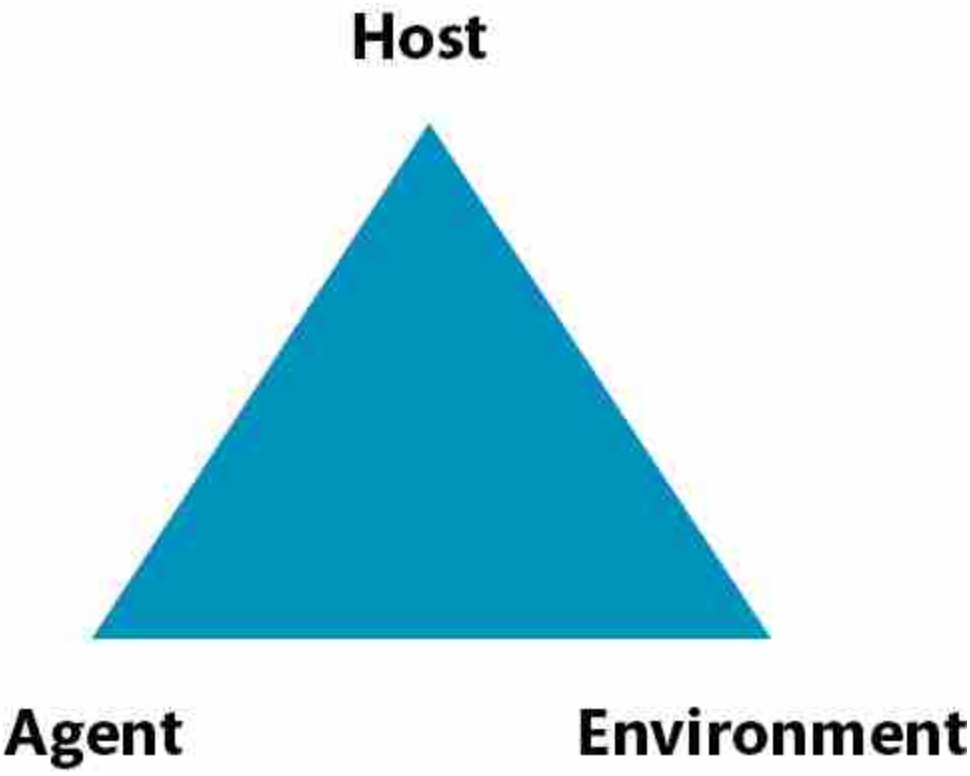

Fig. 9.6.1 Host-agent-environment model used to develop preventive measures in public health.

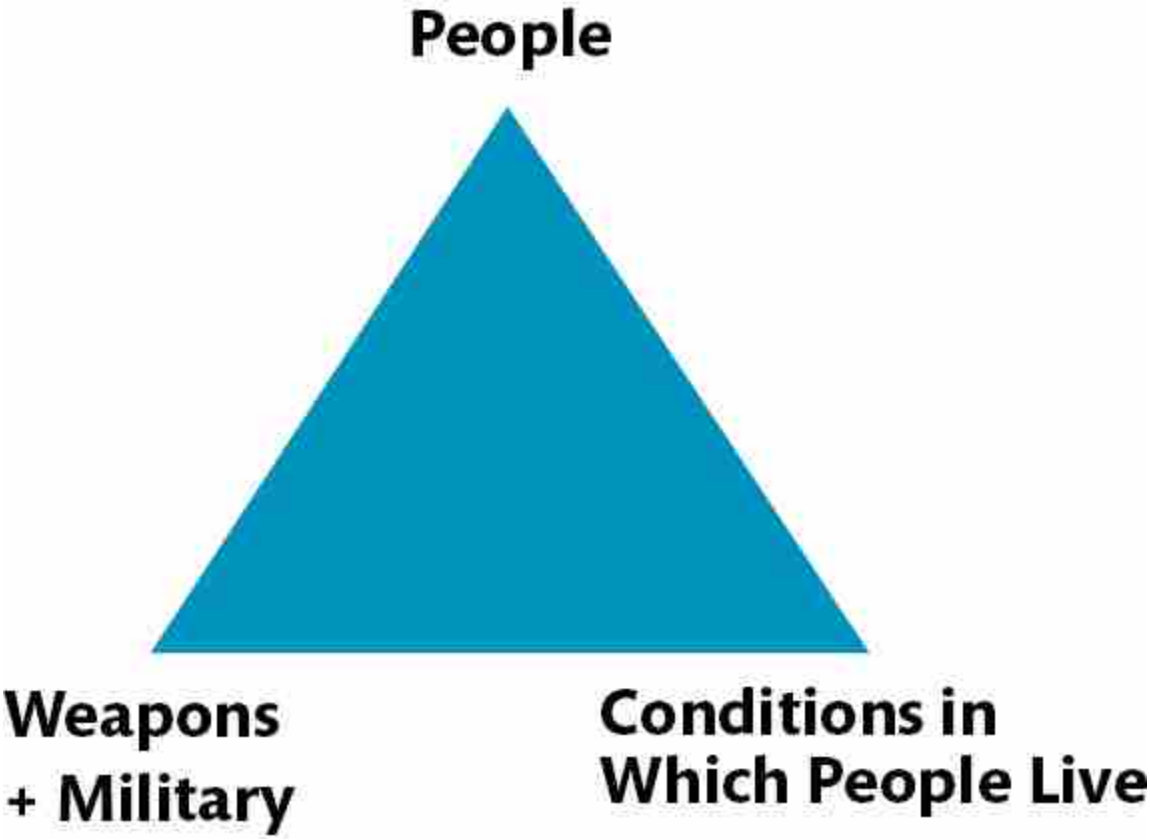

Fig. 9.6.2 Host-agent-environment model applied to the prevention of war.

The only way to prevent all of the health and environmental consequences of war, however, is to prevent war.

The changing family

Ann Evans and Gavin W. Jones

Family change across the world

Kinship, family structure, and effect of socioeconomic and ideational change

> For the past thousand years, the Western family systems have been very different from those in China, India, Japan, and the Arab countries. … We cannot, then, view non-Western family systems as basically similar to the Western system at some undefined earlier historical phase just before industrialization. In fact, their differences extend for centuries back in time. (Goode 1963, p. 22)

Goode went on to propose that there would in future be a convergence towards some form of nuclear, or conjugal, family system. In this, he was mistaken (Cherlin and Furstenberg 1988, p. 578; McDonald 1992). His key point that family systems in different regions have to be studied in their own right, however, holds. ‘No useful analysis of African family systems can be undertaken using European concepts of marriage, household, parenthood, kinship’ (Oppong 1992, p. 82). There is also no doubt that almost everywhere, family systems are changing in response to pervasive and far-reaching technological, socioeconomic, and ideational forces. One of the best-known family sociologists in the United States recently wrote: ‘it is no exaggeration to say that the American, and more broadly the Western, family changed more dramatically in the latter half of the twentieth century than in any comparable span of time in our history’ (Furstenberg 2011, p. 192). Is the same generalization true for the rest of the world? Though conditions differ so greatly that it is difficult to generalize, Furstenberg‘s comment is certainly equally applicable to the East and Southeast Asian family, including China, and to the family in Latin America, though arguably not to the South Asian family.

What are some of the socioeconomic changes that have been impinging on family life? Firstly, the rapid pace of urbanization and rapid economic development in many parts of the world that were once characterized as ‘less developed countries’ has dramatically changed the options and the imperatives for family members. Latin America and East Asia are now heavily urbanized regions, and although urbanization is not as advanced in the rest of Asia or in Africa, even there some countries that were once predominantly rural, such as Indonesia, have passed the 50% urban population threshold. With more of the population drawn into the cities, and rising levels of education, particularly for women, the forces of globalization and neo-liberal economic structures have both drawn more women into the workforce and lessened job security. Then there have been remarkable technological developments in such fields as high-speed transportation, thus cutting travel times, and in social media, enabling a wider net of contacts to be maintained and providing instantaneous access to knowledge of all kinds. Technological developments in the medical field have widened the options in extending life and in avoiding conception and birth, options which bring with them not only benefits but also a range of ethical issues.

Across many developed countries in Europe, the United States and beyond these technological and economic changes have led to increasing social stratification, and the impact of disadvantage on family behaviour has changed. Cohabitation, once typified by increasing education and economic power of women (Lesthaeghe 2010), is becoming more widespread as young people navigate their way through young adulthood and settle on a marriage partner (Guzzo 2014; Sassler et al. 2018). There is now increasing evidence that marriage is not as accessible for the less educate and those with no or low skills (McLanahan 2004; Perelli-Harris and Lyons-Amos 2016; Manning et al. 2019). Indeed fertility within cohabiting relationships now signals a pattern of disadvantage where the least educated are more likely to have births within cohabitation than marriage (Perelli-Harris et al. 2010; Heard 2011).

In Asia, the world’s most populous continent, trends in family change differ greatly between subregions and countries. Common elements in most cases are rising levels of female education and labour force participation, fertility decline and a trend towards later age at childbearing (partly resulting from postponement of marriage), and rising rates of divorce. Both rising levels of education and economic (and advertising) pressures to maintain or

increase consumption worked to propel women into the labour force. Ideological changes led to increased demands for equality in the workplace and in the home. Improved contraception has both loosened the tight connection between sexual gratification and marriage and enabled married women to postpone childbearing.

Family structures differ markedly between Asian countries, but it is possible to detect general patterns which differentiate Southeast Asia from the other main regions of Asia. Rigidly patrilineal kinship systems characterize northwest India, China, and Korea, with patrilocal residence. In such systems, 'daughters were effectively lost to their parents when they married' (Das Gupta 2010, p. 128); women had no role as sister and daughter, but only as wife and mother. In the Indian system, there was resistance to enabling husbands and wives to be too emotionally attached, as this could threaten the unity of the patriarchal family (Caldwell et al. 1982). In contrast, the Southeast Asian region is characterized by bilateral kinship, which provides flexibility in post-marital residence, and continuing close relations between a woman and her natal family. In this region, there is a desire for children of both sexes; it is noteworthy that the only part of Southeast Asian that suffers from distorted sex ratios at birth due to misuse of pre-natal diagnostic techniques for non-medical purposes is northern Vietnam, which is the one area of Southeast Asia where most of the population does not follow a bilateral kinship system (Jones 2009, p. 13; Guilmoto 2012a). Southeast Asian kinship systems also facilitate the option of divorce if a marriage turns out unsatisfactorily.

These family systems have major health implications, for example through the distribution of resources within and across generations. How resources are allocated depends on relationships of authority within families. Those in the family whose status is relatively low (typically based on sex, age, or birth order) tend to receive fewer resources. In societies where there is a strong preference for male children, infant mortality is higher among girls than boys (for India, see Das Gupta 1987; for Egypt, see Yount 2003; for China, see Coale and Banister 1994; Croll 2000), though in recent years the son preference has been manifested more in sex-selective abortion, as a result of the ability to detect the sex of the foetus at an early stage (Guilmoto 2012b).

Accepted gender roles within families determine how much time women spend in the paid labour force as compared with childrearing and housework.

There are complex implications for resource allocation and health. In Western countries, working women's greater earnings and increased status have given them more control over resources, but have probably contributed to increases in divorce rates and in rates of non-marital childbearing, both of which have resulted in increased poverty among women and children. Also, the dual responsibilities of market work and childrearing and housework responsibilities (see Hochschild and Machung 1989) can take a toll on women's physical and mental health, and potentially have adverse effects on other members of the family.

Smaller families

The size and composition of households is a dynamic process, changing over the life cycle as children are born, grow up, and leave the family. Migration affects household composition, as does the decreasing prevalence of extended family forms where these were once more prominent. Smaller nuclear, or conjugal, families do not necessarily mean fewer family relationships; as in many parts of the world, including Western countries, families tend to be 'residentially nuclear but functionally extended', in the words of a Filipino sociologist (Castillo 1979), and engage in 'intimacy at a distance'. The web of contacts, in other words, can be quite dense although members of the extended family may be living far apart, even in different countries. Revolutionary developments in communications have made such contacts easier to maintain.

Household composition, of course, is not the same as family composition. Solitary living has increased enormously in Western societies. Whereas in 1950, just 10% of households in Europe were one-person households, five decades later, they accounted for 30% of British and 40% of Swedish households (Coontz 2004, p. 975). But solitary residence does not necessarily mean lack of family contact; nor are absent members necessarily uninvolved in family matters. Indeed, maintenance of the role of absent members—including those who live overseas for lengthy periods—both in household functioning and decision-making is increasingly observed and accepted as part of the reality of a globalizing world with mobile populations (see, for example, Parrenas 2008; Douglass 2011).

Whether we focus on the residential household or the family, however, the declines in fertility that have taken place almost universally except in parts

of sub-Saharan Africa, clearly make for smaller family size. As measured by the total fertility rate (TFR)—the number of children a woman would bear by the end of her reproductive period if she followed the currently prevailing age specific fertility rates throughout her childbearing ages – fertility over the past three decades remained very low in Europe, declining from 1.8 to 1.6; it declined from 2.6 to 1.6 in East Asia, from 4.6 to 2.4 in Southeast Asia, from 4.6 to 2.4 in South Asia and from 3.5 to 1.6 in Latin America. Only in sub-Saharan Africa did fertility remain really high, slightly below five children per woman in 2015. Fewer children being born into families directly lowers the number of family members living together, though more complex factors also affect family size. In particular, different family types —whether nuclear or some kind of extended family, have different implications for family size. Nuclear families are the norm in Western countries and in a wider range of non-Western countries than was often recognized.

Average household size has been falling almost everywhere. For example, in Indonesia, average household size decreased from 4.87 in 1971 to 4.27 in 1995 and 3.84 in 2010. In Thailand, it declined from 4.4 in 1980 to 3.8 in 1990, and to 3.1 in 2018 (Peek et al. 2015). Extended family contacts will, of course, widen the network of interaction, but not to anything like the extent in the past, when an average individual in Thailand had five siblings, six children, 30 nieces and nephews, 10 uncles and aunts, 60 first cousins, 120 first cousins of his parents and 720 second cousins (Mason et al. 1993, p. 70).

When fertility falls to very low levels, there are fewer close relatives for an individual to interact with. An extreme example was the one-child family in China, resulting from a policy that required over one-third of the population to have only one child, and over another half to have ‘1.5 children’ (i.e. those whose first child is a girl can have a second child); in other words, more than 60% of all Chinese couples were required to have only one child (Baochang 2009, pp. 76–80). Where each family has only one child, that child has no siblings, and while he/she may have a number of uncles and aunts, because the parent generation was not yet subject to the one-child family rule, there will be very few cousins. Once the second generation of one-child families emerges, the web of close relatives shrinks further. If two only children, who are themselves the children of only children, marry, between them they will have eight grandparents (living or

deceased) and four parents, but no cousins, aunts, or uncles at all. Hence extended family relationships disappear in this context. Not only this, but the family responsibility to care for the elderly falls squarely on the young couple.

Many countries have even lower fertility rates than China. Where fertility has fallen to really low levels—TFR below 1.5—half of all women have at most one child (Le Bras 1979). This does not necessarily mean that most children are growing up as only children. For one thing, children are born to a cohort of women whose average number of children is currently higher than suggested by the cross-sectional snapshot provided by period fertility rates. But this aside, many women are not having children at all. The proportion of women not marrying before reaching the end of their reproductive period is now 19% in Japan, around 14% in Singapore and Myanmar, well above 10% in South Korea and Thailand, and considerably higher than this for the tertiary educated in these and some other Asian countries. Having children outside of marriage is rare in these countries. Moreover, some of those who marry are not having children. In European countries, though having children outside of marriage is now common, an increasing proportion of adults are remaining childless; in Western Europe, around 10–20% of the cohort of women born in 1965 remained childless at the end of their reproductive period. However, the situation appears rather different when viewed from the perspective of the child; no children, of course, grow up in no-children families. Among women who have children, many are having just one, but many are having two or more. Taking into account childless women, this can still average out at just above one per woman. As Preston (1976, p. 105) and Le Bras (1979) noted, women with large families contribute disproportionately to the average family size of children.

Comparing the families of five or six children typical of earlier generations and those averaging two children, there are significant differences in the way children are raised and the social dynamics within the family. Typically, in large families, the older children play a role from a young age in assisting with the raising of their younger siblings, and perhaps later in financing their education. With low fertility, parents' attention is focused on just one or two children. This has positive implications for human capital; the investment of money and time by the parents will no doubt assist their one or two children achieve better results in school and in

career-related activities. The trade-off between quantity and quality of children has been resoundingly resolved in favour of quality in the East Asian countries (Montgomery et al. 2000), in Western countries and more recently in countries as varied in background as Brazil and Iran, and this is a major reason for the very low fertility they are now experiencing. The smaller cohorts of children should also enable government investment in education to achieve more per child.

What are the downsides to small family size? In China, both parents and the government fear the so-called 4-2-1 syndrome. This can be interpreted in two alternative ways: a great deal of attention focused on the one child by two parents and four grandparents, or as a weighty responsibility placed on the one child for the care of two parents and four grandparents as they age. When two only children marry, they will be responsible for four parents and eight grandparents. The young couple can only live with one set of parents, which means that the other half of their parent and grandparent families will be 'empty nesters'. What proportion of families is in this situation? It has certainly risen substantially, though exactly how much needs to be carefully studied. The issue is not unique to China. There are many single child families throughout East Asia, despite the absence of a one-child policy, though in the other East Asian countries ultra-low fertility is due to a much larger extent than in China to non-marriage, and therefore to a larger proportion of potential couples with no children at all (Frejka et al. 2010).

The issue of 'self-centredness' of only children is also frequently raised—the 'little emperor' syndrome. It is frequently speculated in China that divorce rates will rise with the clash of wills and personalities when two 'little emperors' marry each other. Inherently plausible as these speculations may be, they require evidence and research to back them up.

Delayed marriage and the rise of cohabitation

In Western countries, the 'golden age' of marriage from the 1950s to the 1970s (Festy 1980) has given way to an age of delayed marriage and increased cohabitation. Even though the rise of cohabitation has meant that delays in marriage do not accurately reflect the delay in forming relatively stable unions, overall, union formation and childbearing has been delayed (Mathews and Hamilton 2009). There are large differences between Western countries in the extent of the rise in cohabitation. Three broad groupings are

evident. Cohabitation is very common in the Nordic countries, France, the United Kingdom, and the Netherlands (where among those aged 20–34 who are either married or cohabiting, 40 to over 50% are cohabiting); there is an intermediate group of Germanic and Eastern European countries, the United States, and Australia, where the proportion is around 20–30%; and the Southern European countries and Poland, where cohabitation is less common (around 5 to 15%) (OECD Family database).

The United States differs from the countries of Europe in significant ways in matters affecting cohabitation patterns; for example, Americans are more religious than other Westerners, though this religiosity is adapted to a culture of expressive individualism (Cherlin 2009, pp. 103–4; p. 113). Americans begin to have partners (whether married or cohabiting) at a relatively younger age than most Europeans, and to become parents at a younger age. Marriages and cohabiting relationships in the United States, and to some extent in Great Britain (Kiernan 2003, p. 32; Beaujouan and Bhrolcháin 2011) are far more fragile than in most of Europe. American women are much more likely to spend time as lone parents in their teens or twenties than are women in Western Europe (Cherlin 2009, pp. 16–18). Overall, in the United States, about 41% of births were non-marital in 2010—in other words being borne by single mothers or those in cohabiting relationships (Martin et al. 2012). The widening interval between sexual debut and marriage has exposed many more teenagers to the risk of pregnancy and childbirth outside marriage (Furstenberg 1990, p. 150), although the rate of teenage childbearing has declined considerably over the past two decades. In developing countries, very early marriage has long characterized most of sub-Saharan Africa and South Asia, as well as parts of Southeast Asia, the Caribbean, and Central America. In recent decades, average age at marriage has risen almost universally, but substantial proportions of women are still marrying very early. The latest figures show that globally, 21% of young women married before their 18th birthday, the highest incidence being 38% in sub-Saharan Africa and 30% in South Asia (UNICEF 2018).

Unlike Western countries or Latin America, cohabitation does not feature importantly in Asian patterns of partnering, though it is becoming more common in Japan, China, and the Philippines and probably elsewhere. Asia does, however, show remarkable diversity in marriage systems and marriage patterns. While in general, average age at marriage is rising for both males and females throughout Asia, this rise is from a base that varies greatly. It is

in East and Southeast Asia that truly remarkable changes in marriage patterns have taken place. In recent decades, the traditional universal marriage norms have been abandoned and the average age at marriage and proportions not marrying at all have risen sharply (Fig. 10.1.1; for more detail, see Jones 2007; Jones and Gubhaju 2012). However, there are wide differences between countries, and even between different ethnic groups within one country, such as Malays, Chinese, and Indians in Malaysia.

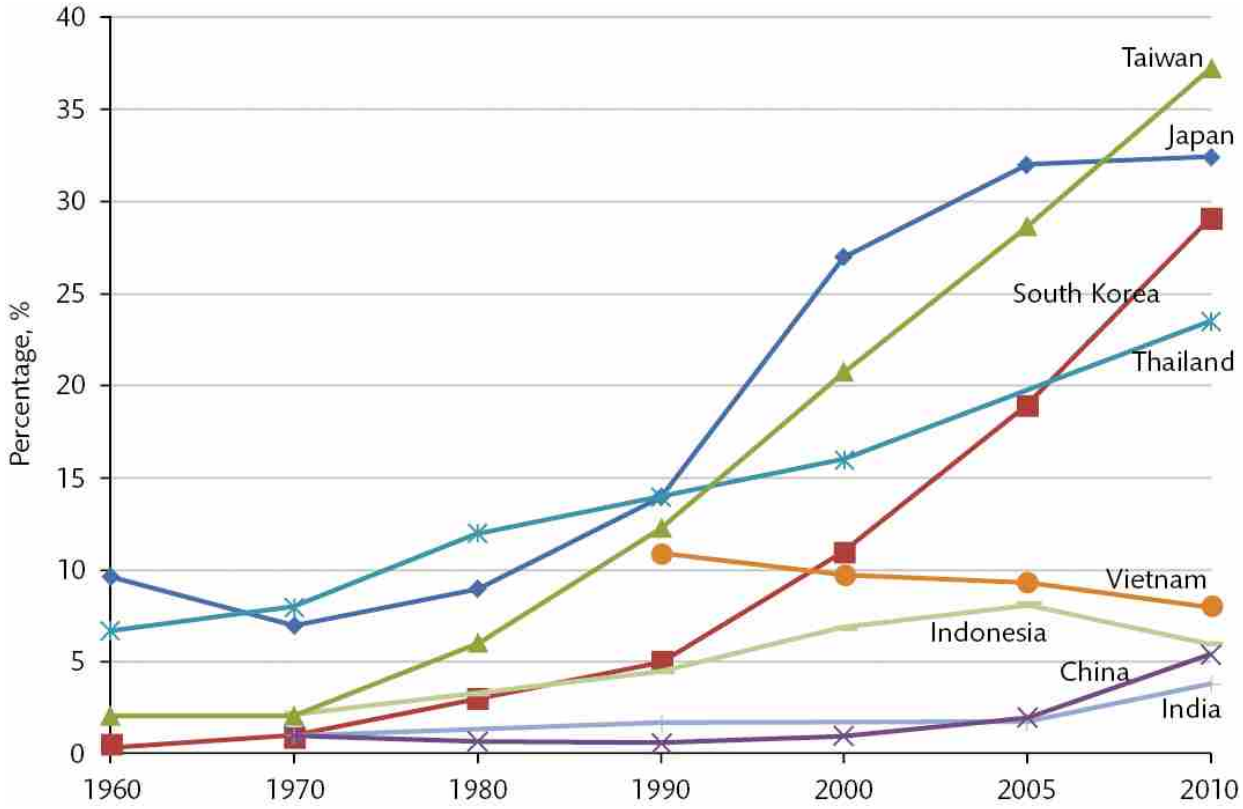

Fig. 10.1.1 Proportion of single among females aged 30–34, 1960–2010.
Source: data compiled by Gavin W. Jones from population census reports for various years for the countries included.

Broadly comparing East Asia, Southeast Asia, and South Asia, the changes in Southeast Asia as a whole are not as great as those in East Asia (excluding China), while most of South Asia remains firmly locked in an entirely different pattern of universal, arranged marriage. South Asian marriage systems have turned out to be remarkably enduring. While in East and Southeast Asia the location of most marriages on the continuum from

parent-arranged to self-arranged marriage has shifted decisively towards the self-arranged end, very little such change has occurred in South Asia.

Socioeconomic change is undoubtedly responsible for much of the change in marriage patterns, but it is hard to explain the very high singlehood in Myanmar and the lack of change in Vietnam in these terms. Within East Asia, Chinese marriage patterns differ widely from elsewhere; though average age at marriage for women is rising in China, marriage is 'concertinaed' at ages in the 20s, and by age 30, only a tiny proportion of Chinese women remain single. By contrast, in Japan, Korea, Thailand, Myanmar, Singapore, and among the Chinese population of Malaysia, delays in marriage have been such that substantial proportions of women remain single in their late 30s, an age beyond which not much childbearing takes place. Indonesia has seen gradually rising age at marriage but this has reversed according to the 2010 Population Census.

Turning attention to South Asia and South-West Asia, The Islamic Republic of Iran shows a strong shift towards a delayed marriage pattern, with the proportion of women single at ages 35–39 not much below that in the Republic of Korea. However, in the Indian subcontinent, the relatively tardy change in arranged marriage patterns in the face of very considerable socioeconomic change is striking. Evidence from a large survey in India (the India Human Development Survey 2005, IHDS) indicates that

> Marriage decisions remain within the purview of the family, and less than 5% of the IHDS respondents had a primary role in choosing their husbands. However, nearly 62% of the respondents felt that they were consulted in this decision. (Desai and Andrist 2010, p. 675)

'Consultation' clearly did not go to the extent of arranging for the spouses-to-be to meet; among the respondents who felt they had a choice in partner selection, around 55% met their husbands on or around the day of the wedding. The persistence of early and arranged marriage in India is seen by Desai and Andrist (2010, p. 681) as 'part of a script in which gender is performed by women through a symbolic display of segregation, modesty and chastity, and early marriage is part and parcel of culture in action'. However, rising education levels in South Asia have led to an increase in involvement of brides in the selection of their partners, with parents seeking appropriate matches with the involvement of and consent from the bride and groom (Yeung et al. 2018).

In Latin America, as in Europe, the key trend in union formation is the rise in cohabitation, which appears to have been just as marked as in Europe,

though from a more complex starting point. Latin America was marked by patterns of ‘old cohabitation’ (characterizing countries with mixed indio, mestizo, and European populations, and those with a history of slavery) and ‘new cohabitation’ (characterizing countries with more dominant European populations, notably Argentina, Chile, Brazil, Mexico, and Colombia). Cohabitation has increased sharply throughout Latin America in recent decades, though to varying degrees in different countries (Fussell and Palloni 2004; Esteve et al. 2012), and the long-standing educational gradient, whereby the better educated cohabited less and married more, has been attenuated. The factors lying behind these trends are complex, but ideational change in the direction of greater secularization and tolerance of non-conformist behaviour appears to be strongly implicated, except perhaps in Brazil (Esteve et al. 2012).

Late marriage, delayed transition to adulthood, and the role of singles

A trend affecting most of the world is the tendency for children to be dependents for a longer period of time, and to remain in the natal home until a later age. In agrarian and early industrial societies, children frequently began to work at quite a young age. Though age at marriage was young in many such societies, young marrieds frequently continued to live in the home of one or other set of parents until they had the resources to form their own household. The rise of universal schooling tended to delay both entry into the workforce and marriage, to a marked degree in countries where most children continue through secondary education and substantial proportions pursue tertiary education.

In the United States, 50 years ago, the vast majority of women and most men had completed schooling, left home, entered the workforce and begun families of their own by the time they reached their early 20s (Furstenberg 2010). These transitions have now been considerably delayed (Arnett 2004). Likewise, in much of Asia, extended education and delayed marriage are leading to later home leaving and in general a delay in reaching the milestones that signify adulthood and independence (Xenos et al. 2006). If adolescence is defined as the period between attaining sexual maturity and marriage, then it is a lengthening period in most young Asians’ lives, though

in South Asia, with the exception of Sri Lanka and to some extent Pakistan, early marriage remains the norm. In most of Asia, unlike in most Western countries (though the 'family-centric' Mediterranean countries share characteristics with Asian countries in this respect), there is a continued tradition of living at home until married, and in many countries, the need to do so is strongly reinforced by the high cost of owning or renting housing, and the convenience of living at home without paying board (on Japan, see Retherford and Ogawa 2006, p. 17–19; on Singapore, see Jones 2012). Therefore, young people are living longer at home, in an unmarried state.

Many issues have to be negotiated between parents and children in this evolving situation. In East and Southeast Asian countries, only in the last few decades has extended singlehood become really common, so those who are remaining single into their 30s are a pioneering group, whose roles in family and society are still being negotiated (Maeda 2008; Situmorang 2007, 2011; Tan 2010; Ibrahim and Hassan 2009). Japan, Thailand, Singapore, and Myanmar are somewhat different in that over a fairly long period, substantial proportions of men and women have been remaining single, and this has led to adjustments of societal expectations, such that most singles do not feel much pressure to marry from family and friends. Little is known about the role of such singles beyond their immediate family, for example, whether working singles are contributing financially to education of cousins, nephews, and nieces.

In societies where girls were formerly married off on reaching puberty, or shortly thereafter, the transition to adulthood was abrupt and, for many, traumatic. This remains the case in much of Africa and South Asia. But elsewhere in Asia, delayed marriage has led to an extended period of adolescence between puberty and marriage, raising issues about sexuality and relationships with the opposite sex that simply did not arise in times of early, parent-arranged marriage (Lloyd et al. 2005). In Indonesia, for example, extended education for girls, long past the age at which their grandmothers were already married and having children, and widened employment opportunities, has brought them out of the household and into daily contact, not only with a range of men, but also with the stimulus of sexually explicit material through movies, videos, magazines, books, and the internet. Premarital sexual activity is taken for granted in many of these information sources, but the material is designed to stimulate and titillate rather than to educate. Very little sex education is provided in schools or

other contexts (Utomo and McDonald 2009, p. 137). At the same time, influences deriving from religion and ethnicity are still strong, and in some ways growing stronger. ‘Faced with the conservative forces of idealized morality portrayed through religion, on the one hand, and Western influences promoting a more liberal approach on the other, it is little wonder that many teenagers are confused’ (Jones 2002, p. 232).

There are other aspects of delayed marriage to keep in mind. One has to do with the maturity of the marriage partners. Five decades ago, when half of Malay girls in Malaysia were married before they reached age 17, they were unlikely to be emotionally mature at the time they married. But at least co-residence with one or other set of parents—most commonly the bride’s parents—meant a period of ‘apprenticeship’ into many aspects of married life. Age at marriage has now increased dramatically, and the age at which Malay women are bearing their first child is four years older than for their mother’s generation and seven years older than their grandmother’s generation; some of them are having their first child in their mid to late 30s. There are a number of possible implications of later childbearing in both Asian and Western countries. Women are no doubt emotionally more mature when they are bearing their children, but they and their husbands may be more settled in ‘child-free’ ways, requiring a greater adjustment when the first child comes along than for couples who married at a younger age. The window of opportunity for having a second child is also very small when childbearing is postponed to these ages. Furthermore, there is a somewhat greater risk of birth abnormalities occurring when the mother and/or father are older. The greater availability of *in vitro* fertilization (IVF) and assisted reproductive technologies enables more older mothers to have babies, but the risks of multiple pregnancies and premature births could contribute to chronic health problems in the children.

Divorce

In the second half of the twentieth century, divorce rates were on the whole higher in Western countries, particularly the United States and Russia, than in most of Asia (Dommaraju and Jones 2012). In South Asian countries, divorce is a rare event; divorce is not a feasible way out of a disharmonious marriage, because the options of returning to the natal family, or of earning an independent income, are not generally open to a divorced woman.

However, the gap between Western and East Asian countries has narrowed because divorce rates stopped rising in many Western countries around the 1980s, while in East Asian countries, divorce rates have been rising steadily since 1980, particularly in the period since 1990 in the case of Japan, Republic of Korea, and Hong Kong. The rise in Republic of Korea was particularly sharp between 1995 and 2000—the period in which the Asian financial crisis occurred. In China, freeing up of divorce regulations in 2001 and 2003 may have contributed to the sharp rise in divorce rates in the 2000–2005 period. In Taiwan, as in other East Asian societies, increase in divorce has taken place in a context of decreased prevalence of marriage. The chance of re-marriage after divorce has declined (Yang and Tsai 2009), indicating a growing acceptance of and perhaps preference for singlehood.

Japanese divorce rates have risen to such an extent that Japan can no longer be considered as a society characterized by low levels of marital dissolution. About one-third of Japanese marriages are now likely to end in divorce (Raymo et al. 2004). Traditional marriage stability in Japan, while it did not necessarily have much to do with whether a marriage was happy, at least gave some assurance that children would be cared for, and that wives could expect economic security. With the awareness of increasing fragility of marriage, decisions about whether to marry and about whether to raise children when single motherhood is a possibility, come more into play (Bumpass et al. 2009, p. 223).

Trends in divorce in East Asia appear, then, to be going the way of the West, and partly for the same reasons (Dommaraju and Jones 2012). Substantial increases in divorce rates in East Asian countries signify a significant change in circumstances and attitudes to divorce, because in the past divorce carried a considerable stigma, and the pressure to remain in a disharmonious marriage for ‘the sake of the children’ and also for the sake of appearances and family honour, was very strong. It would appear that factors such as increasing economic independence of women, and the pressures (and widened range of personal contacts) in the big city environments in which an increasing proportion of East Asians live, are influencing divorce trends.

In Western countries, divorce rates no longer reflect very accurately trends in the breakdown of long-term relationships, because of the rise of cohabitation. It is impossible for couples who are not officially married to divorce. Understanding the relationship of cohabitation to breakdown of

unions requires analysis of the proportion of cohabiting relationships that are dissolved; the proportion that are converted to marriages; and the proportion of such marriages that are dissolved. In Europe, around one-third of cohabiting unions are dissolved within five years (Kiernan 2003), considerably higher than the proportion of marriages that are dissolved within the same length of time; of cohabiting relationships that are converted to marriages, divorce rates also tend to be higher than for marriages that did not commence with a cohabiting relationship, though 'when the pre-existing characteristics of those who cohabit are taken into account, the risk of marriage breakdown is no different from and may be lower among those cohabiting before marriage than among those who marry directly' (Beaujouan and Bhrolcháin 2011, p. 19). In any case, official figures on divorce trends clearly do not fully reflect the breakdown of long-term relationships, many of which, both marital and cohabiting relationships, involve children. It might be noted that in Japan, while divorce rates do not fully reflect relationship breakdown because cohabitation is increasing, the breakdown of cohabiting relationships rarely involves children, because very few children are born to cohabiting couples.

Non-marital childbearing, divorce, and effects on children

In Europe, 'sexual activity, childbearing and marriage have become disconnected so that increasingly it is socially acceptable to have one without either of the other two. But this has happened in different ways in different parts of Europe' (Pritchett and Viarengo 2012, p. 67). Notably, in northwest Europe, childbearing remains reasonably robust, much of it in non-marital relationships; in many countries of Eastern and southern Europe, though, marriage rates remain high and extramarital births are rare but fertility is very low.

Changing conventions about marriage and divorce in the West and in East Asian countries have multiple causes. 'Throughout Western Europe and North America family relations have become more discretionary; a greater premium is placed on emotional gratification and a lower value on obligation and authority' (Furstenberg 1990, p. 153). Such factors, stressed in 'second demographic transition' theory (van de Kaa 1987; Lesthaeghe 2010) have explanatory power for Western countries and perhaps for Japan; for East Asia more generally, however, more important than individualism

may be women's willingness to break from the shackles of patriarchal structures in a context of widened economic opportunities. Moreover, some weakening in these countries of community perceptions of divorce as a disgraceful event has undoubtedly lowered the bar to the decision to divorce.

In all these contexts, however, the effect of divorce on children needs to be considered. As Carlson and England (2011, p. 2) put it, 'The freedom to leave unhappy relationships might be counted as a victory for adults, but the same cannot be said for children'. Multiple studies suggest that 'children of divorce are at higher risk for experiencing a variety of developmental problems during late childhood and early adolescence, including school failure, delinquency, precocious sexual behaviour, and substance abuse' (Furstenberg 1990, p. 161–2). Nevertheless, the effect of divorce on children is a complex subject. Many studies suffer from methodological shortcomings, and assessments differ, particularly with regard to whether family conflict produces more adverse effects on children than divorce itself (Cherlin 2009, pp. 19–24; 192–7).

The effect of marital disruption (and more generally, in the era of cohabitation, relationship disruption) on children is a controversial and emotional issue. Many studies show that children raised by solo mothers or by a mother in unstable relationships are more likely to experience emotional and behavioural problems than children growing up in stable married families. For example, in Britain, 'children born into cohabiting families where the parents had separated and solo mothers who had not married the natural father … were around three times more likely than children in stable married families to be exhibiting behavioural problems' (Kiernan and Mensah 2009). However, careful control for factors lying behind the differences in the family situation in which children grow up is necessary before attributing the behaviour to the family situation itself. In the British study under discussion, 'Taking account of the mental well-being of mothers and family poverty attenuated the differences and the introduction of additional controls attenuated them still further. However, there are still indications that children born to cohabiting parents who separate and children of solo mothers who cohabit with the natural father or partner another man are more likely to be exhibiting behavioural problems.' (Kiernan and Mensah 2009). On the other hand, when the child's emotional well-being was the dependent variable, it appeared that the parental socioeconomic circumstance and mother's mental well-being may fully

account for differences between children living in different family trajectories.

Similarly, when considering the health and well-being of adults, family relationships have been found to play a role. Research has found that marriage offers health benefits to men and women through boosting economic resources (Waite and Gallagher 2002), social networks and support (Umberson et al. 2010; Umberson and Montez 2010). But some of this difference may in fact be due to different levels of access to partnerships and marriage due to health and socioeconomic circumstances evident through childhood (Perelli-Harris et al. 2018; Perelli-Harris et al. 2019).

In sub-Saharan Africa, patterns whereby many fathers do not continue to live with their children are common (Adepoju and Mbugua 1997; Therborn 2004, pp. 177–81). In parts of Africa characterized by polygyny, the mother–son bond tends to be strong. In South Africa, among the African population, in 2007 only 29% of children aged 17 years or younger were living with both parents, while 43% were living with mother only and 26% were living with neither parent (Republic of South Africa 2013). Almost half of children whose father was alive had no contact with him; unfortunately, in South Africa, '… family instability in childhood plays a major role in setting young people on pathways to adulthood that potentially compromise their life chances'.

Ageing and the family

The trend towards an older population is an inexorable one in most parts of the world. Japan has the oldest age structure of any country in the world (26% of the population aged 65+ in 2015), followed by Europe as a whole (17.6%). Some Asian countries—Republic of Korea, China, Singapore, and Thailand—are well along in the ageing process, with between 10% and 13% elderly. But many of the higher-fertility countries in Africa and South Asia have only around three or four% in the over-65 age groups. Everywhere, however, the percentage of elderly is rising, and by 2030 it is expected to reach 30% in Japan, 23% in Europe, 17% in China, and 19% in Thailand.

There is little doubt that issues related to population ageing will be central, not only to national policy reactions to ultra-low fertility, but also to family level adjustments needed to cope with radically altered population structures. At an aggregate level, the issues can be well illustrated by trends

in ageing support ratios—i.e. the ratio of the population ages 20–64 to the population aged 65+. Admittedly, the age limits used for this calculation do not accurately reflect the actual dependency situation, which depends on the ages at which people actually enter and withdraw from the labour force, and on the proportion of the elderly requiring various kinds of support (in the case of physical support, usually quite small). But as a general indicator, the ageing support ratio does give a sense of the trends which are so dramatic that modification of these ages will not alter the picture greatly.

The ageing support ratios were vastly different in different world regions in 1980 (see Fig. 10.1.2). Since then, they have fallen sharply in East Asia and South America, and this sharp decline is expected to continue until 2050. South Asia is 35 years behind East Asia in reaching an ageing support ratio as low as 8. In the 40 years between 2010 and 2050, the ageing support ratio will halve in Japan, and will fall to less than one-third its current level in countries such as China, Thailand, and Brazil. Leaving aside Africa, where the decline in the ageing support ratio will be very slow, and South Asia, where it will be relatively slow, there will be a marked convergence in ageing support ratios in the different regions at very low levels—around 2 to 3. Such declines will require major adjustments of policies with regard to income support programmes, orientation of health services to give much more weight to gerontology, and labour market policy, including retirement ages.

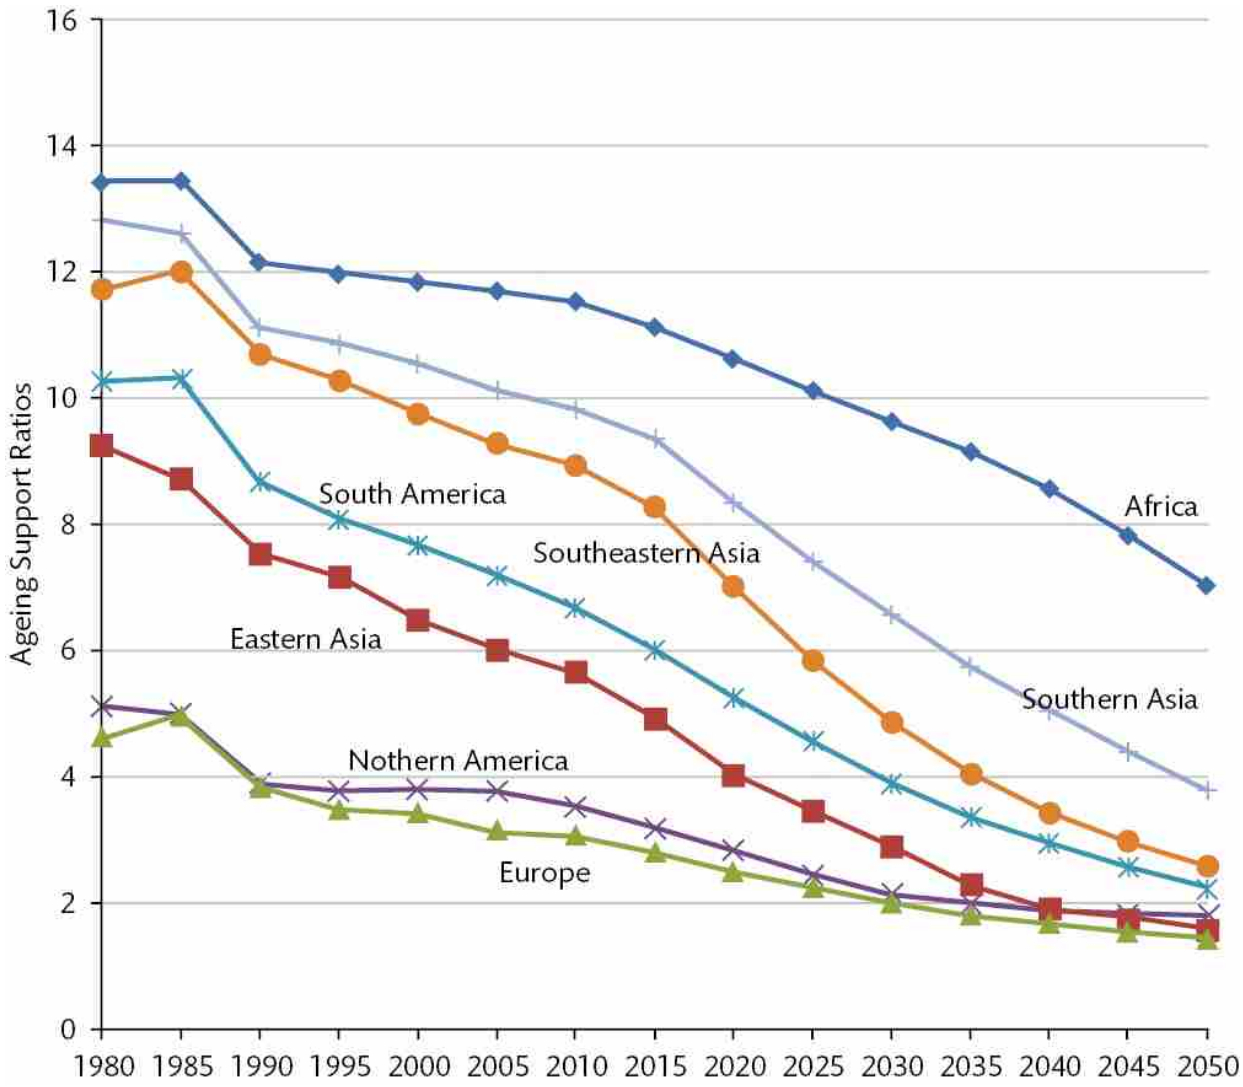

Fig. 10.1.2 Ageing support ratios (population aged 20–64/65+) by region.
Source: data from the detailed indicators in United Nations Population Division, World Population Prospects: The 2012 Revision, Copyright © 2014 United Nations, available from http://esa.un.org/unpd/wpp/unpp/panel_indicators.htm.

It should be noted that living arrangements of the elderly differ considerably in Asia from those in Western countries, with a much higher proportion living with a child or grandchild (United Nations 2005). And although the percent of elderly Japanese and Koreans living with a child or grandchild has been gradually declining, it does not appear likely to reach levels as low as in France or the United States. Demographic trends do, however, raise issues about whether the family can be relied on as in the past to provide care for those elderly who need it. There are a number of aspects to the problem. The first is the sharply declining ratio of potential carers to

numbers of elderly, as crudely indicated by trends in the support ratios. The number of living children of older persons has been declining through movement of smaller birth cohorts into the main 'caring ages'. And as documented by Schroder-Butterfill and Kreager (2005) in a study in East Java, *de facto* childlessness may differentially affect the poorest and most vulnerable groups. The second is that a high proportion of the potential carers (usually women) are now drawn into the paid workforce (consistent with government policy in these countries), and are therefore not available for full-time caring work. Moreover, many of these potential carers are in the so-called 'sandwich generation', required to support not only the grandparent generation but also their own children who are spending a longer time living with (and depending on) their parents. The third is that, despite the general improvement in health status of the elderly at any given age, the rising proportion of the elderly, and the rising proportion of the elderly who are 'old-old' (i.e. 75 years and above) will inevitably mean a rising load of frail and disabled elderly, who need full-time care. The ratio of elderly population who suffer from senile dementia to non-working women at various ages is projected to rise substantially over the coming two decades in Japan (Ogawa 2006). This suggests that Japan will not be able to rely on the traditional family support network to care for the infirm elderly; the rise in the burden placed on middle-aged Japanese women providing in-home nursing care will simply be too great.

There will be less possibility of the family providing intensive care for the increasing number of disabled or frail elderly in Asian countries, for three reasons: the lowered proportion of children per elderly person, the increased labour force participation of women (the traditional carers), and the movement of children of the elderly to other localities. These trends have major implications for policy on elder care. Despite the tradition in Asian families of caring for family members in various kinds of need, and official rhetoric about the key support role of the Asian family as a fundamental (and by implication, unchanging) characteristic of Asian societies, this traditional reliance on family will be subjected to intensive pressures. Governments will almost inevitably be forced to step in.

We need to bear in mind that co-residence is not the only indicator of close caring relationships. Assistance can notionally be divided into three categories: financial assistance, emotional support, and physical support. The first two of these do not require co-residence, particularly in the age of

the cell-phone. In Thailand, there has been an extraordinary rise in the proportion of the elderly living in houses with a telephone—from 15% in 1994 to 76% in 2007. Moreover, while the proportion of elderly living in the same house as a child is slowly declining in Thailand, the proportion is considerably higher if those living in close proximity are included (Knodel and Chayovan 2008, p. 41).

The care needs of the elderly should not be exaggerated. The great majority of the elderly do not need care; for example, in Thailand, more than 80% of those in their 70s and even 65% of those aged over 80, say that they can care for themselves (Knodel and Chayovan 2011). The positive contributions made by the elderly in society and family, for example through taking care of grandchildren and through serving as mentors and confidants of their grandchildren as they enter adolescence need to be recognized and supported (Tengku-Aizan and Nurizan 2008; Ananta and Ariffin 2009).

The challenge, of course, in harnessing the capacities of grandparents to develop a special relationship with their grandchildren, is to avoid burdening them with what are sometimes exploitative child-minding arrangements. In all societies, the role of grandparents in childcare appears to be greatly valued, as opposed to the alternatives of formal childcare arrangements or, in some countries, reliance on domestic servants. ‘Grandparent care is commonly viewed as the ‘next best thing’ to parental care, and is highly valued for its supposed intrinsic benefits: the fostering of closer intergenerational relationships, the quality of grandparent care in contrast with the formal market, and the satisfaction that grandparents apparently derive from the caregiving role’ (Jenkins 2010, p. 6; see also Wheelock and Jones 2002). However, grandparents are not always so positive about the role, which can be very stressful, especially when they feel that they lack the choice to determine the parameters of their caregiving.

The family, development, and health

Being born into the wrong family can almost guarantee a difficult life. ‘The family has long been a mechanism by which advantage—and disadvantage—is transferred across generations.’ (Carlson and England 2011, p. 9). In the American context, Lareau and Cox argue that class differences in parents’ cultural resources (e.g. knowledge necessary to help their children interact with institutions—such as gaining access to college-prep courses in high

school and navigating the college admission process) serve to exacerbate inequality in the life chances of youth from different classes, especially in getting a college education. (see Carlson and England 2011, p. 14). In Indonesia, only 2% of the children of the poorest 20% of the population continue to tertiary education, compared with 40% of children of the richest 20%.

From a public health perspective, issues abound in relation to conventional family structures as well as to rapid changes in these structures. Many examples could be given, but one will be chosen here: reproductive health issues arising from two contrasting situations—patterns of early marriage and childbearing in Africa and South Asia, and delays in marriage in other developing countries.

In many sub-Saharan African countries, as well as in Bangladesh and parts of India, data from the 1980s and 1990s showed that more than 10% of women in their early 20s had had a child by age 15, and between a quarter and a half had a child by age 18 (Singh 1998). In conditions of high mortality, 'socialization processes that support and encourage early marriage and childbearing are often deeply entrenched' (Singh 1998, p. 133), and these socialization processes do not change rapidly in the face of declining mortality. The dangers of early childbearing to the health of mother and child are well known. But other dangers emerge when marriage is delayed and young people are exposed to the risks of premarital intercourse for longer periods of time: a greater risk of unintended pregnancies, induced abortion and sexually transmitted infections (STIs). Increased levels of infection by STIs and HIV can affect young women's health and indeed survival, the outcome of their pregnancies, as well as their future fertility. Yet policies in many countries make it difficult for the unmarried to obtain access to contraception.

The family is seen in most countries as the key institution on which a stable society is built. Thus changes in family form and function are normally suspected of threatening the social order. One concern tends to be about ageing, and whether the family will continue to have the capacity to provide the necessary physical, social, and emotional support for the elderly as their share of the population increases. Delayed marriage also leads to disquiet, though not, in most countries, to specific policies to encourage marriage. But it raises important issues about the role of singles in society, as

well as practical issues such as their access to contraception, which proves to be divisive in many countries.

Family policy in many countries tends to be conservative in promoting the generally accepted family values. The model of universal heterosexual marriage in which children are raised in an intact family until they marry and leave home is the norm. In Asian countries, this of course remains overwhelmingly the main family form, and there is a great deal to be done to enhance the quality of life for mainstream families of this kind. One key need is to develop policies that will facilitate marriage and enable women and men to combine work with childrearing—to avoid the low fertility trap that East Asian countries have perhaps entered into, but also to enable women to realize the potential resulting from their higher levels of education, without succumbing to the exhaustion of the 'double shift'. At the same time, in countries such as India, Bangladesh, and Indonesia, stricter enforcement of legal minimum ages at marriage is needed, to lower the proportion of girls being married below this age.

But there are also other family forms in all societies, including childless couples, those cohabiting without entering formal marriage, blended families following re-marriage, the various kinds of lesbian/gay/bisexual/transgender (LGBT) pairings (Blasius 2001
), single parents post-divorce raising a child or children, and singles continuing to live with parents until into their 30s. The reality of considerable pluralism in family types and functions needs to be recognized. It is important that those who are not in mainstream family relationships are not made to feel ostracized and discriminated against by policy.

On elder care, increased strain will be placed on families whose characteristics and circumstances are changing in ways that will make it increasingly harder to deal with these strains. For example, in India, the percentage of elderly people is expected to double in 27 years after 2015, to 11.2%. In Thailand, this percentage is expected to increase by 2.5 times over the same period, to 26.7%. Although the percentage of elderly in India in 2042 will be less than half that in Thailand and less than a third that in Japan, even the smaller increase India faces poses significant challenges. The policy emphasis in all countries must be on active ageing, financial independence, and a positive attitude towards the contribution the elderly make within families. Nonetheless, an increasing role of government in elder care cannot be avoided. The retirement age in many countries also needs to

be increased, as it reflects the life expectancy situation decades ago, and will be increasingly untenable in terms of providing income maintenance for the rapidly increasing number of retirees. The extent to which government needs to replace the role of family in elder care, and its capability of doing so, will vary across regions.

10.2

Women, men, and health

Diane Cooper and Hanani Tabana

Introduction

This chapter focuses on sex (biological) and gender-related influences on women and men's health. We pose the questions: what determines women and men's health status? What are the effects of sex and gender? What else influences health status, policies, programmes, and service provision? These questions are of critical significance in improving women and men's health status and promoting policies, programmes, and services that improve their well-being. A gender focus in health systems should aim at informing the development of a more 'strategic, effective and equitable health systems interventions, programs and policies' (Morgan et al. 2016, p. 1).

We highlight key health issues that are influenced by a mix of interlinking sex and gender factors. The categories 'women' and 'men' are not a binary categories and biological sex differences and gender-related factors do not influence health conditions homogeneously (Spence and Pilote 2015), but interact with a host of other factors.

Cross-cutting social determinants of health

We focus specifically on sex and gender factors impacting on women and men's health, with their influence needing to be understood within the context of other cross-cutting determinants of health. The social determinants of health (SDH) (CSDH 2008)—gender, class, race, or ethnicity, family structures, migration status, geographical location, age, sexuality, sexual orientation, and ability/disability combine in varying ways within and across time, influencing people's health lifespan. The SDH are

individually determined and underpinned by social, economic, and political systems embedded in power structures. Education significantly impacts positively on girls' and women's health. These are at personal, proximal, and distal levels (Krieger 2008). A socioecological model encompasses individual, interpersonal (relationships with partners, families, community), systems (such as the healthcare system) and structures (social, political, economic, cultural) (Bronfenbrenner 1979). Adopting a life-course approach, the contexts, experiences, and health status during childhood and adolescence has an impact on the health of adults (Dick et al. 2015; Chandra-Mouli et al. 2017). Within and between societies, these shape equitable or inequitable opportunities for people's good health enjoyment (CSDH 2008). Institutionalized through legislation, and culture and traditions (Christodoulou and Zobnina 2009), the health system can facilitate or hinder the attainment of good health. Health and the health system were influenced by the Millennium Development Goals (MDG) and now monitored by the Sustainable Development Goals (SDG). SDG 3 health goal consists of 13 targets with a number of implementation targets, that cross-cut each other. These include nutrition, environmental risk, reproductive and maternal health. SDG 3.1 includes reducing maternal mortality. This broader health vision links to health systems issues such as Universal Health coverage and biological and socially determined risk factors. SDH are often considered outside of the ambit of health, but are critical if we are to address health's root causes and promote intersectoral collaboration. In our chapter, we document health system and integrated interventions to enhance health (World Health Organization 2016a).

What does this chapter cover?

We begin by clarifying what we mean by the terms sex and gender. These terms are frequently confused and written interchangeably in health literature. We discuss various gendered approaches to health. Next we provide an overview of differences in life expectancy and the Burden of Disease in women and men and their determinants. We then examine more closely the manner in which sex and gender shape five specific examples of health issues: HIV, gender-based violence (GBV), cardiovascular disease (CVD), mental health problems, and maternal mortality. Each one is chosen to emphasize the varying manner in which gender and sex influence health.

We discuss biomedical interventions to address these examples of health problems and discuss gender transformative health interventions. We conclude by emphasizing conceptualizing health as a complex interplay between many determinants, of which gender is one key social determinant. These have key implications for we how we address them, approach research, develop health policy, and design services.

Sex and gender differences in health

Sex refers to the biological differences between females and males. Some health phenomena and experiences are biologically exclusive to males and females. These include male or female specific reproductive health events such as pregnancy and childbirth and illnesses such as female or male reproductive cancers. Other sex-related differences include conditions that appear to be commoner in women or men. For example, autoimmune conditions such as thyroid disease, rheumatoid arthritis, lupus, and multiple sclerosis is commoner in women (Whitacre 2001). Whereas, strongly related to lifestyle issues such as alcohol and tobacco use, liver and respiratory health conditions are commoner in men (Murray and Lopez 1997) (Box 10.2.1).

Box 10.2.1 What is sex/biology?

Sex-related health differences between women and men include anatomical, genetic, biochemical, physiological, and physical factors (Wizemann and Pardue 2001). These characteristics are universal and tend to be constant, differentiating humans as males and females. However there are variations and fluidity in the sex or biological characteristics of individuals, with some individuals possessing both, combined in different ways (Christodoulou and Zobnina 2009).

Cellular and molecular research is needed for a fuller understanding of biological explanations for women and men's health conditions. Many of the original biological explanations for an excess of certain health conditions in men or women are open to debate. Biological vulnerability does not act in isolation in placing women and men at more risk or advantage. It is frequently difficult to disentangle the mixed influences of biological and non-biological factors in women and men's health. Whether these biological

health risks lead to health problems depends on a host of non-biological factors.

Box 10.2.2 What is gender?

Gender is a social construction that embodies social attitudes, values, and norms and varying expectations of women and men's roles and responsibilities between and within societies, across time and space. It includes how individuals perceive themselves and others as female and male, and how they behave and engage with each other. It includes learned social attributes that comprise roles, activities, and responsibilities attributed to being female or male. It is therefore acquired through socialization and is changeable, varying across time and cultural contexts. It includes societies' perceptions of how women or men should act, what is valued in being a woman or a man and what behaviour is seen as permissible, respectively. In general these differences equate to inequalities between females and males in their responsibilities, activities, resource access and control and opportunities for decision-making (Christodoulou and Zobnina 2009; Sprague 2018).

Some frequently used key terms in gender analyses include gender identity, expression, and sexual orientation (Box 10.2.2 and 10.2.3).

Box 10.2.3 What is gender identity and sexual orientation?

Gender identity refers to an individual's personal and social identity regardless of their biological sex. Cisgender is a term used for an individual who identifies with their sex assigned at birth. Transgender includes identities of individuals who do not identify or do not wholly identify with their sex assigned at birth. Sexual orientation refers to sexual attraction and intimacy. For lesbian women, homosexual men, gay, queer, or bisexual individuals, attraction and intimacy is directed primarily or additionally to a person of the same sex (Christodoulou and Zobnina 2009).

While gender constructions are fluid (Sprague 2018), dominant socially stereotypical representations of masculinities are portrayed as idealized, heterosexual forms of masculinities. These are associated with characteristics such as self-reliance; competitiveness; containment of emotions; aggression; physical strength; primary economic providers; and prowess in sexual achievement (Jewkes et al. 2015). There are similarly stereotypically and idealized forms of emphasized femininities, associated with gentleness, empathy, sensitivity, care, and accommodating the interests and desires of men. Hegemonic forms of masculinities develop patterns of practices of masculinities that dominate and allow a global, ideologically

legitimate basis for subordination. This suggests that women and men position themselves in terms of power, in relation to these hegemonic or dominant patterns (Connell and Messerschmidt 2005, p. 832). These reflect systems of gender inequity. Inequity can be seen as not adequately addressing the different health needs of women and men (Fig. 10.2.1).

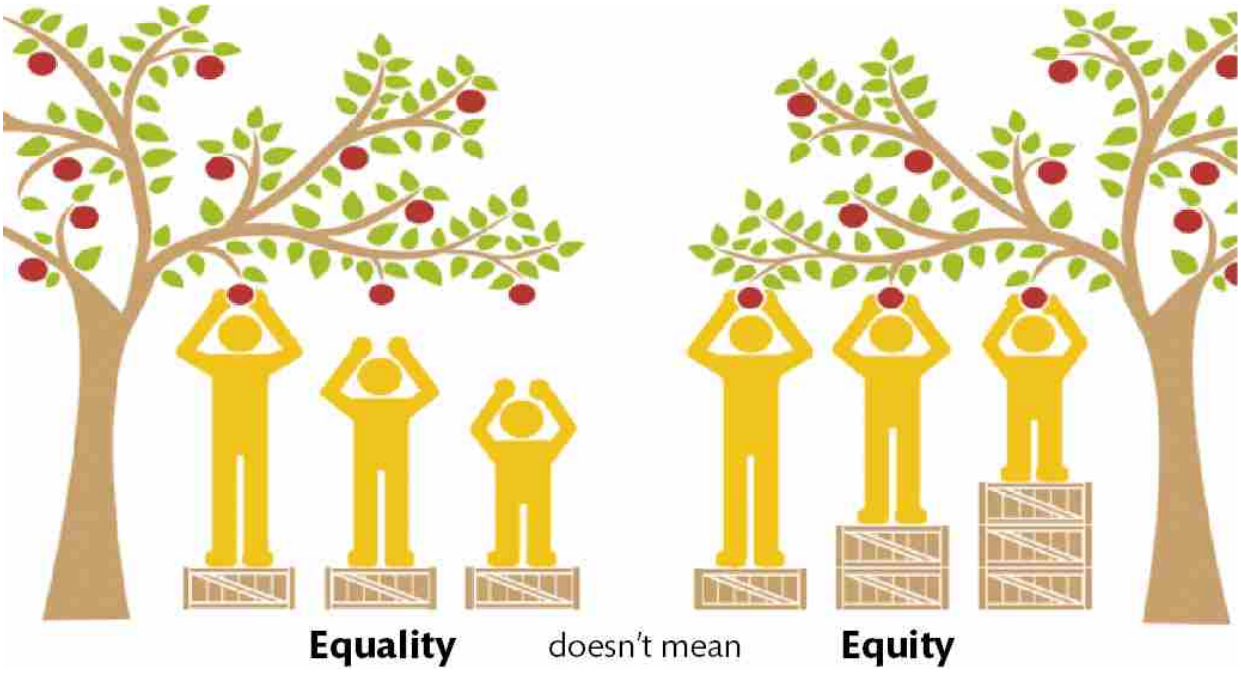

Fig. 10.2.1 The difference between equity and equality.

Power hierarchies include symbolic and actual power relations, acted upon at an individual, interpersonal, institutional, and societal level. Butler's (1999) concept of 'performative' gender recognizes gender as a set of social, economic, and political practices, *performed* by men and women. This concept of 'hegemonic' masculinities provides a framework for examining institutionalized hierarchies in gender relations within and between societies.

Despite the dominance of certain forms of masculinity and femininity, multiple forms of masculinities and femininities exist (Connell 2012; Jewkes and Morrell 2012; Morrell et al. 2016; Shefer 2016). Within the contextual nature of masculine and feminine norms gender socialization reflects a diverse range of female and male characteristics, social expectations, and identities (Hammarström 2018). 'For men, hegemonic masculinities emerge

in a contested process, among vying identities' (Connell and Messerschmidt (2005) in Sprague 2018, p. 53). Women and of men who adopt non-hegemonic patterns of practice are vulnerable to censure and marginalization. This makes for a complex analysis of how gender affects female and male power in achieving health status, health practices, and healthcare provision.

Gender hierarchies have changed historically, new forms replacing older ones (Connell and Messerschmidt 2005, p. 836). How individuals or groups of people 'perform' gender differs across time and social contexts. While there are multiple masculinities and femininities, there are socially central forms that predominate, associated with greater power for men (Box 10.2.4).

Box 10.2.4 Key messages

- There are important conceptual differences between sex and gender.
- Considering both is critical to understanding women and men's health status policies, programmes, and services and specific health problems.
- Gender is socially constructed, influencing roles, behaviours, activities, and attributes assigned to females and males and perceptions of their appropriate behaviour.
- Multiple masculinities and feminities exist.
- Hegemonic masculinities and feminities 'affects how people live, work and relate to each other at all levels, including in relation to the health system' (Morgan, et al. 2016, p1).

Intersectionality

The origins of intersectionality theories and approaches, emphasizing cross-cutting factors influencing health, are a blend of legal, critical feminist, race, anticolonial, and queer theories (Hankivsky 2014). They focus on analysing diversity in inequity, exclusion, and social injustice. Power, privilege, and marginality emerge from a multiplicity of interacting contextual social stratifiers, including class, race, or ethnicity, gender, geography, family structures, ability/disability, migration status, religion, and sexual orientation. These interlocking systems of power (Larson et al. 2016, p. 1) are reflected in laws, policies, and institutions (Larson et al. 2016, p. 2). As different and interdependent types of privilege, vulnerability, marginalization, and exclusion exist; they argue we should not a priori assign one component as a most significant health inequity factor. They

argue centralizing one factor encourages an add-on of other power influences as discrete factors, rather than in conjunction with each other (Hankivsky 2014, p. 252). Their analysis focuses on relative social privilege or disadvantage depending on people's life contexts (Hankivsky 2014). This influences understanding of poorer health and health service availability and access in vulnerable or disadvantaged groups (Larson et al. 2016, p. 3)

Gender mainstreaming

An approach that was popularized internationally from the mid-1990s is *gender mainstreaming*. The United Nations Economic and Social Council in 1997, the World Health Organization (WHO) and development organizations adopted it. It was in response to promoting gender as including women and men and addressing limitations in development-oriented activities. These included failing to integrate gender considerations into the work of all departments (Mannell 2010). It involved incorporating a gender perspective into policies, strategies, programmes, project activities, and administrative functions and into the organizational cultures—ways of thinking and doing.

While the contribution of gender mainstreaming is acknowledged in promoting the need to address gender inequality and power relations in the policy sphere, its health and development impact has been limited. One reason is its different interpretation in various implementation contexts. This led to vagueness and dilution of awareness and action on gender issues. Its orientation was primarily on equal female and male representation. A key and most serious critique is that it depoliticised gender power relations in its emphasis on integration and a largely technocratic approach (Tolhurst et al. 2012, p. 1,826). Issues of gender should not be mere add-ons or ticked boxes but should be integrated and analysed to illuminate how systems and institutions generate gender inequalities or perpetuate them and how to change these (Morgan et al. 2016).

Gender inequity remains important

Witter et al. (2017) argue that *not* focusing specifically on gender inequity leaves an unintended a gap in health and health system analysis. While an explicit focus on poor women, unemployed men, and female-headed households is needed to achieve health system equity (Witter et al. 2017), gender needs to be recognized as a critical division. It commonly impacts on

people's access to health systems resources and services. The predominance of reproductive health needs in low- or middle-income countries (LMIC) countries, disadvantages women as a group. They focus on the disadvantaging gendered effects of the out-of-pocket health expenditure on women, using an Indian case study. Their findings showed that while teenage pregnant women suffered most out-of-pocket cost-related decreased access to maternal health services, all women experienced reduced access. They found that untreated illness was higher in women than men, even among educated women with higher socioeconomic status and caste (Witter et al. 2017, p. v8). This is one specific case study, but draws attention to the continued value of considering gender inequity in designing healthcare policies and programmes. Hegemonic forms of masculinities are a useful concept to understand dominant patterns of gendered practices. Jewkes and Morrell (2012) and Shefer (2016), build on Connell's (2012) approach, in examining gender influences on women and men's health issues. It acknowledges that gender roles, relations, and identities are unstable, continuously undergoing active change (Tolhurst et al. 2012); that there are dynamic links between multiple gender identities and hierarchies of power that play out in complex ways. At the same time it highlights intersecting sex, age, social, and economic determinants, that impact differentially on different groups of women and men's health (Jewkes and Morrell 2012; Stern et al. 2014a) (Box 10.2.5).

Box 10.2.5 Key messages

- Theories and frameworks, such as intersectionality; approaches highlighting gender to avoid unintended negative health consequences; acknowledging the dynamic links between gender identities and hierarchies and their intersection with broader SDH, are helpful in analysing the roots of women and men's health problems.
- Gender inequity and power that favours dominant heterosexual forms of masculinities is key in understanding women and men's health differences.

Gender, sex, and key health issues

Our discussion of HIV highlights sex and gender determinants while GBV primarily reflects the effects of gender dynamics. The development of

cardiovascular disease (CVD) and mental health problems in women and men underscores biological and gendered influences. Their diagnosis and outcomes show the gendered effects of the health system, health professionals' decision-making, and treatment and healthcare. The effect of gender on health remains strongly mediated by other social factors. Maternal health foregrounds women's maternal mortality and morbidity differences. Similar divides between men exist.

Gender analysis recognizes that gender power relations are reflected in the division of labour, resources, and rewards (Gupta 2000). These are important in health-related interventions to improve men and women's health status, decision-making, behaviour, health service access, and management and treatment of health problems. We should aspire to change gender relations in health and health systems, but at the very least not further worsen them.

Life expectancy and Global Burden of Disease

A crude health measure is life expectancy. Estimates of life expectancy at birth show that women generally live longer than men. Average global life expectancy for children born in 2015 was approximately 4.7 years longer for females than males (73.8 years for females and 69.1 years for males) (WHO 2016b). This is due to biological, behavioural, and environmental factors, including sex-specific patterns in exposure to health risks and access to treatment.

In most countries, there is higher mortality risk for boys <5 years than for girls, contributing to lower male life expectancy. There is inconclusive evidence of whether there are biological differences. Sex-related theories for shorter male life expectancy have also been based on the possibility that the oestrogen may offer women premenopausal protection against cardiovascular disease (CVD), a key cause of earlier male mortality. However, most recent research does not appear to support this (Phillips 2006).

Gender differences affecting men's lower life expectancy are clearer. There are differences between women and men in accidental and non-accidental deaths. The gender division of labour has typically placed men in more hazardous jobs in construction, transport, and emergency services, with more dangerous work environmental conditions and accidents (Doyal 1995). Gender-related behavioural patterns, with young men more likely to engage

in greater risk-taking behaviours than women, combined with socioeconomic factors influence premature male mortality. Non-accidental deaths in young men (14–44 years) are due to road traffic accidents, homicides, and health-related conditions from higher male rates of smoking, alcohol, and substance abuse (Prince et al. 2007).

There are huge differences in overall in life expectancy between countries. In Japan, a country with the highest world life expectancy, females born in 2015 can expect an average lifespan of 86.8 years and males 80.5 years (Table 10.2.1). This contrasts with Sierra Leone, with the lowest life expectancy—females and males born in 2015 can expect a lifespan of 50.8 and 49.3 years, respectively (WHO 2017).

Table 10.2.1 Life expectancy at birth 2015 (top five and bottom five countries in years)

Country	Female	Male
Japan	86.8	80.5
Switzerland	85.3	81.5
Singapore	86.1	80.0
Australia	84.8	80.9
Spain	85.5	80.1
Cote d’ iVoire	54.4	52.3
Chad	54.5	51.7
Central African Republic	54.1	50.9
Angola	54	50.9
Sierra Leone	50.8	49.3

Source: data from World Health Organization 2017.

Lower overall life expectancies for women and men within and between countries, indicates inequity in health, between the wealthier and the poorer and marginalized. Life expectancy is much higher for women and men in high-income countries (HIC) than LMIC. Poverty-related factors: poor

nutrition, sanitation, low household income, and weak health systems underpin differences. Improvements in social, economic, and environmental conditions and access to good, quality healthcare have increased life expectancies in HIC. Even in HIC there are sharp differences in life expectancies, with poorer, more marginalized populations experiencing substantially shorter life expectancies.

Situations of war and conflict in certain regions and countries have led to lower life expectancies for populations overall, but particularly for men. High maternal mortality lowers female women's life expectancies in regions with poor maternal healthcare. Before antiretroviral therapy became universally available, AIDS-related mortality caused dramatic decreases in life expectancy in sub-Saharan African countries. In Eastern Europe and Russia, lower male life expectancy peaked in the period leading up to and after the dissolution of the USSR. These were attributed to gender-related male lifestyle practices such as excessive alcohol consumption, in response to the tremendous socioeconomic and political upheavals (Pietilä and Rytkönen 2008, p. 1,070).

The Burden of Disease (BOD) is a good indicator of the health quality of life people enjoy or lose. Amatya Sen captures this: 'we are not able to do much if we are disabled or ceaselessly bothered by illness' (Sen 2004, p. 28 in Sprague 2018, p. 126). The WHO adopted the concept of the Global Burden of Disease (GBD) to take account of illnesses and disabilities. It uses disability-adjusted-life years (DALY), quality-adjusted life years (QALY), and disability-adjusted life expectancy (DALE) as measures to quantify quality of health (Sprague 2018, p.128). This occurs throughout the life cycle with childhood and adolescence setting much of the scene for later adult health status. Perceptions of health vary between individuals and societies. Actions taken to decrease the BOD and promote enjoyment of health recognizes the special nature of health as a 'social good' (Sprague 2018).

LMIC countries especially in sub-Saharan Africa continue to struggle to contain major infectious or communicable health conditions such HIV/AIDS, tuberculosis, and Malaria. Interventions to address these are human resource and skills intensive. Many LMICs have limited infrastructure, human resources, and technical expertise to contain epidemics and devote resources to other health and social, economic, education, and development needs (Box 10.2.6).

Box 10.2.6 Key messages

- Overall, women enjoy a longer life expectancy than men.
- This varies within and between countries, reflecting the influence of a complex mix of sex, gender, age, behavioural, and social determinants of health.
- Lower female than male life expectancy signifies higher levels of societal gender discrimination.
- The WHO uses a number of measures for compromised health quality of life—the burden of disease.
- Child and adolescent health influence the health trajectory in adulthood.
- LMIC countries struggle with a dual epidemic of communicable and non-communicable diseases.

The impact of sex and gender on specific health problems

HIV/AIDS

HIV is one of the most significant threats to women and men's health in many parts of the world. The primary modes of HIV transmission are through unprotected vaginal or anal sex, use of contaminated needles during injecting drug use, and vertical transmission. We will on focus on the impact and variation in HIV's impact on women and men's health in LMIC in Southern Africa that bear the greatest burden of HIV infection (Abdool Karim et al. 2010; Ramjee and Daniels 2013).

Sprague's (2018) model in Figure 10.2.2 is valuable in showing graphically, the biological and structural factors impacting on HIV acquisition.

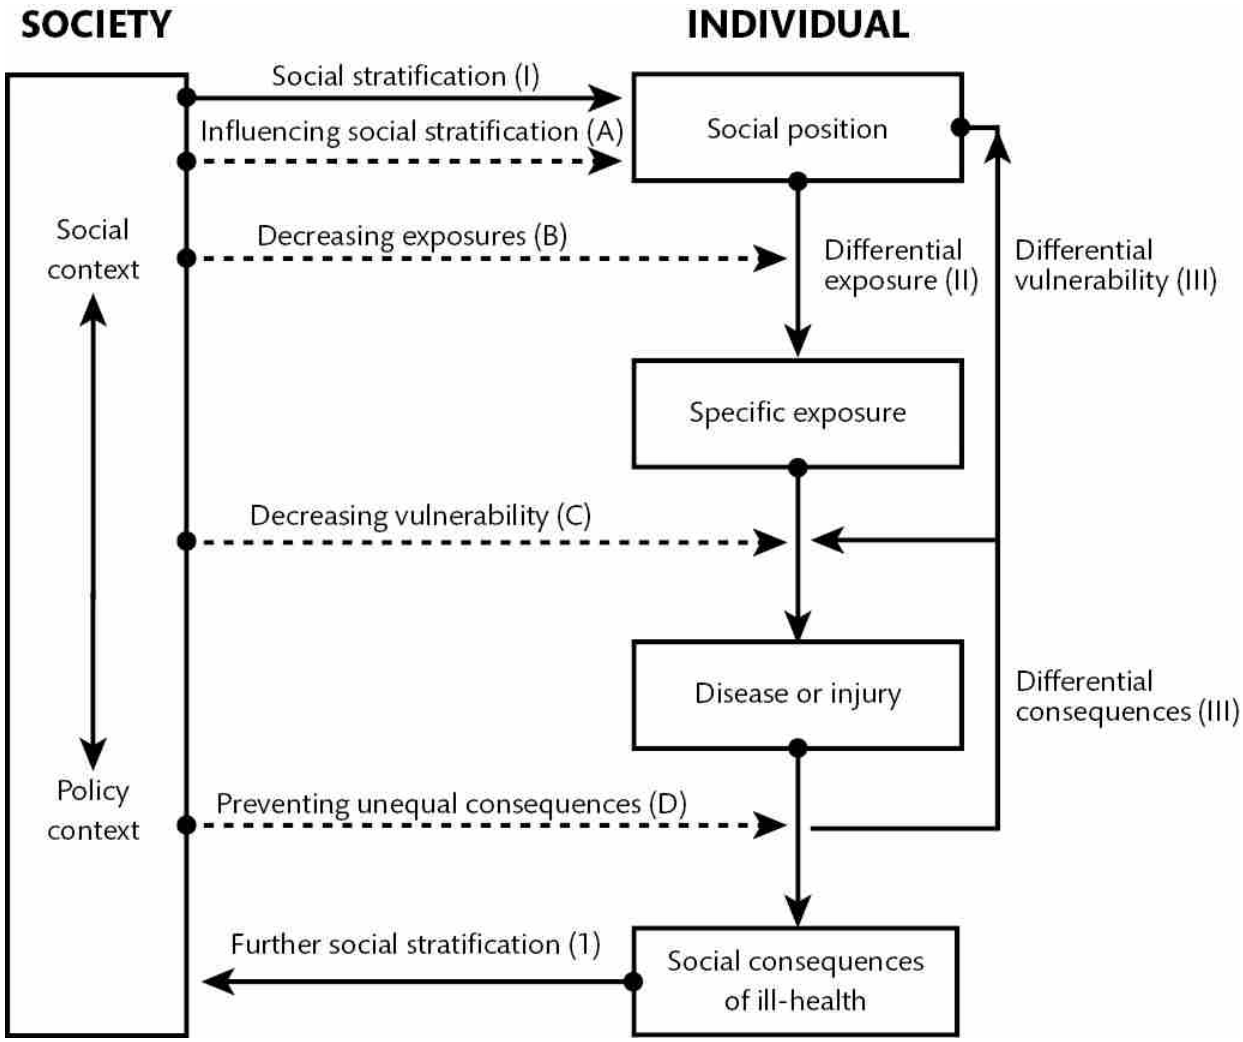

Fig. 10.2.2 Pathways in vulnerability and consequences of HIV acquisition.
Adapted with permission from Prof Finn Diderichsen from his and his colleagues framework that appears as figure 2.2. in Sprague (2008, p 47).

Biological HIV vulnerability

Women are biologically significantly more vulnerable than men to HIV infection. This is on a physical, genetic, and immunological level. The female vaginal tract (and the anus) has a larger mucosal surface exposed to the virus during condomless sex. It is also exposed to HIV for a longer period (Abdool Karim et al. 2010; Ramjee and Daniels 2013). The greater susceptibility of the vaginal, cervical (and anal) mucosal surface to microabrasions during sex facilitates HIV entry. This may be due to inflammations, ulcerations, lesions, and pre-existing sexually transmitted infections (STI). Undiagnosed STI are commoner in women, due to low

knowledge, greater difficulties in symptom diagnosis problems and access to STI healthcare is more stigmatized for women (Abdool Karim et al. 2010). The herpes simplex type 2 virus is linked to increased transmission risk ((Ramjee and Daniels 2013) and bacterial vaginosis (BV) and syphilis are also implicated. This is particularly significant for sub-Saharan Africa that has high levels of HSV-2, BV, and HIV.

Young women, aged 15–24 years, are up to 8 times more likely to be HIV-infected than their male peers (Dellar et al. 2015, p. 64). Gendered social and economic factors are combined with heightened biological risk of HIV transmission, due to young women's cervical immaturity and higher levels of genital inflammation (Abdool Karim et al. 2010; Ramjee and Daniels 2013). Hormones and immunological responses may also play a role. Increased levels of oestrogen after ovulation may increase HIV infectivity (Ramjee and Daniels 2013). Women's hormonal and physiological changes during pregnancy and lactation may be linked to higher rates of HIV acquisition (Ramjee and Daniels 2013). There are increased risks of maternal mortality as a result of untreated HIV-related infections (Kendall et al. 2014). There is potentially enhanced HIV risk for women using the injectable progesterone contraceptive Depo-Provera (Abdool Karim et al. 2010). This is currently under intensive study (Harper 2015; Tasker et al. 2018).

Gender and other social factors impact on HIV vulnerability

Biological factors interact with social, economic, and behavioural factors, to increase HIV infection vulnerability. Gender inequity is a key factor underscoring HIV infection vulnerability (Abdool Karim et al. 2010; Jewkes and Morrell 2012).

Hegemonic patriarchal cultures of masculinity underpin men frequently dominating in in heterosexual intimate relationship decision-making. Women have lesser say in whether to engage in condomless sex than men. Hegemonic forms of masculinities promote men having multiple concurrent sexual relationships and older men engaging in sex with younger women. This heightens young women's HIV vulnerability (Dellar et al. 2015, p. 67). Women may experience violence if they refuse sex or insist on condom use (Jewkes and Morrell 2010; Ramjee and Daniels 2013). Sexual violence can be a cause and a consequence of HIV (Jewkes 2014).

Young women's disadvantaged socioeconomic status is associated with earlier and coerced sexual debut, less condom use, multiple partners, and having transactional sex with more likely to be infected older men (Abdool Karim et al. 2010; Ramjee and Daniels 2013).

Social constructions of masculinity may lead to increased male risks of HIV infection. Social expectations that 'real' (heterosexual) men show their masculinity through condomless sex and multiple partners places pressure men to engage in riskier sexual behaviour. Traditional social norms combine with a health system with poor integration of sexual and reproductive health (SRH) and HIV. Men's involvement in SRH, apart from for STI, is not encouraged. As Gutmann (2007, p. 11) states men are 'the missing (f)actors in reproductive health'. Social context and barriers within health services hinder Lesbian, Gay, Bisexual, Transgender, Intersex, Questioning, and other gender identities (LGBTQI+) individuals and groups from seeking SRH care.

There are marked differences in women and men's use of HIV care. Gender norms make it more acceptable for women to seek healthcare. Women seek care for reproductive health and child health needs. In parts of the world where the HIV epidemic is most severe, prevention of infant HIV transmission programmes has added to women's greater health-seeking behaviour. This has created its own set of problems for women. Because they are frequently the first partner in an intimate relationship to test for HIV, if infected, they could face stigma and blame. However, women's access to testing and diagnosis for HIV and access to ART has led to greatly improved healthcare access and outcomes for women living with HIV. Gender norms, that perceive seeking healthcare as a display of 'weakness', may discourage men from seeking healthcare until very ill (Stern et al. 2014b; Jewkes et al. 2015). Men are less likely to test for and be diagnosed with HIV infection, initiate ART, be retained in care and more likely to die of AIDS-related illnesses (Cornell et al. 2017). Men are less likely to participate in social support structures for people living with HIV (Madiba and Canti-Sigaqa 2012) (Box 10.2.7).

Box 10.2.7 Key messages

- Biological and gender-related factors make women, particularly younger women, more vulnerable to HIV infection.
- They are more likely to be tested, diagnosed with HIV, and access and remain on ART due to greater health service access. However, this can lead to stigma and blame.
- Hegemonic masculinities promote riskier sexual behaviour. This and less health service contact deter men from health-seeking and testing, being diagnosed with HIV, and accessing and remaining on ART.

Cardiovascular disease

Non-communicable diseases (NCD) represent a significant BOD in the twenty-first century (Mendis and Chestnov 2014). Of the estimated 36 million deaths globally approximately 63% in 2008 were caused by NCD. Cardiovascular diseases (CVD) has the largest individual proportion of NCD deaths (48%) (Mendis and Chestnov 2014). Coronary Heart Disease and Stroke are the leading causes of CVD death and disability. Key risk factors include high blood pressure, overweight or obesity, and higher cholesterol levels. These appear to have similar effects on CVD outcomes for women and men.

The Gendered nature of CVD

Despite CVD perceived for decades as a ‘male’ disease, it is commoner in women (Appelman et al. 2015), likely due to stroke being commoner and due to women’s longevity. Women present with CVD on average 7–10 years later than men. This has led to speculation that oestrogen plays a protective role against CVD for women. However, recent research fails to support this (Riska 2010) and has shown no benefit in prevention of CVD through hormonal replacement therapy (Spence and Pilote 2015, p. 209).

Younger women have specific sex-related risk factors for CVD associated with pregnancy-related health problems such as gestational hypertension, diabetes and preeclampsia and endocrine disorders (Appelman et al. 2015). Risk factors such as migraine, commoner in women than men, appears to be associated with stroke in women. While smoking is commoner in men than women, multiple studies show that prolonged heavy smoking in women increases their relative risk of CVD compared to men (Appelman et al. 2015, p. 213).

NCD in LMIC

NCD have become increasingly common in LMIC, influenced by lifestyle changes due to the health transition (Kengne et al. 2013). CVD shows a prevalence of pre-transitional diseases such as rheumatic fever and idiopathic cardiomyopathies, with high levels of hypertensive disease and stroke and health transition diseases. Common individual risk factors include tobacco use, physical inactivity, and unhealthy diets. Risk factors vary by sex, with tobacco use commoner in men and obesity in women (Mayosi et al. 2009). The African region has the highest age standardized death rate from NCD, 779 per 100,000 (Mendis and Chestnov 2014). The double burden of infectious diseases and NCD is referred to as 'colliding epidemics' (Mayosi et al. 2012, p. 5). NCD are the second leading cause of death in Sub-Saharan Africa comprising 30% of deaths in 2011 (Airhihenbuwa et al. 2016). Hypertension is a major underlying cause of CVD. The numbers of people with hypertension is expected to increase by 68% from 7.5 million in 2008 to 126 million in sub-Saharan Africa by the year 2025 (Airhihenbuwa et al. 2016). An analysis of country variation in strokes show that the poorest countries have the highest BOD (Mayosi et al. 2009, p. 936). The WHO estimates the burden of NCD in South Africa is two to three times higher than that in HIC and deaths due to CVD are likely to double by 2040. This is similar to that in other sub-Saharan Africa countries and central European countries, increasing in rural and poor urban communities. This is 'driving a rise in the demand for chronic disease care' (Mayosi et al. 2009, p. 935). Prevention and treatment of NCD in LMIC including CVD, is neglected due to the overwhelming burden of infectious illnesses (Mayosi et al. 2009, p. 934). HIV has exacerbated the burden of NCD. This demonstrates an important role for improved health services in reducing health inequities that underpin these conditions (Mayosi et al. 2009, p. 936).

CVD and healthcare

Health systems factors play an important role in the gender differences in women's perceptions of and presentation with possible symptoms of heart disease. Women present more frequently with symptoms of tiredness, weakness, light-headedness, palpitations, or loss of appetite rather than chest pain (Aggarwal et al. 2018, p. 3). When women report with symptoms of chest pain, this is more often attributed to unexplained chest pain (Crea et al.

2015, p. 159), because these do not conform to typical male symptoms (Crea et al. 2015; Aggarwal et al. 2018). Diagnostic tests for women and men with potential heart disease have differed. The Euro Heart Survey, in which 42% of patients were female, found physicians are more likely to conduct exercise ECG and coronary angiography on men with reported chest pain or discomfort than women. It found gender biases in the use of evidence-based medical treatment for women, leading to under or inappropriate treatment (Crea et al. 2015, p. 160).

The risk of heart disease has been underestimated in younger women in whom, in-hospital post-acute myocardial infarction mortality is higher than among their male peers (Crea et al. 2015, p. 157). Factors related to younger women and ethnicity in the United States (black, Latino and south Asian women) create subgroups of women who are more disadvantaged and marginalized in recognition of heart attack symptom recognition and treatment (Aggarwal et al. 2018, p. 5). Angina and heart attacks are perceived as 'male diseases', with poorer recognition of symptoms and quality of care in women. Previously a greater proportion of men reportedly died from sudden, pre-hospital cardiac attacks. This is no longer the trend (Crea et al. 2015, p. 161). This is viewed as due primarily to gender biases in perceptions of cardiac attack symptoms.

Less post-cardiac rehabilitation occurs in women. This may be due to health service and socioeconomic related factors, such as poorer promotion and referral by healthcare providers, cost and transport problems, inadequate social support systems, and the burden of family responsibilities (Aggarwal et al. 2018, p. 5). Socioeconomic factors are similarly likely to affect women's prevention activities and health-seeking behaviour with respect to CVD (Spence and Pilote 2015, p. 209).

Further research into potential biological risk factors for CVD in women and men can improve our understanding of the aetiology of CVD and assist in tailoring specific interventions for detection, treatment, and management (Appelman et al. 2015) (Box 10.2.8).

Box 10.2.8 Key messages

- Contrary to perceptions that CVD is a ‘male disease’ due to higher levels of hypertension and strokes, it is commoner in women.
- Younger women and those with HIV have specific CVD risks.
- Difference risk factors including socioeconomic influences lead to different CVD outcomes in women and men.
- Healthcare professionals’ gender bias in detection, diagnosis, testing and treatment has had negative outcomes for women.
- LMIC have ‘colliding epidemics’ of infectious diseases and NCD.

Gender-based violence

GBV covers a wide range of categories of violence (Box 10.2.9).

Box 10.2.9 Gender-based violence

The United Nations defines Gender-based violence against women (VAW) as: Any act of GBV that harms of may result in harm (physical, sexual, or emotional/mental) or suffering to women (Sprague 2018, p.63). This may include threats or acts which coerce or deprive women of freedom. Physical violence includes being slapped, punched, choked, having objects thrown at one, pushed or shoved, beaten, intentionally burnt, or threatened with a weapon. This can be in either the private or public sphere. Rape or sexual violence includes any form of forced sexual act, including those due fear of harm or intimidation (WHO 2013, p. 6) It can be perpetrated regardless of the relationship of the perpetrator to the survivor, in any place. It includes penetration with a body part or object (Sprague 2018, p. 63). GBV includes femicide, homicide, and intimate partner (domestic) violence. These are most commonly perpetrated by men against women.

Violence against women

There is pervasive violence against women internationally. Thirty-five percent of women report physical or sexual violence by a male intimate or non-intimate partner (WHO 2013). Women are most likely to be exposed to violence in the home or its surroundings. Most physical and sexual violence against women is by an intimate partner (WHO 2013). While physical and sexual violence is more visible, intimate partner emotional abuse or violence, especially from male intimate partners, including ‘verbal abuse, threats of violence, engendering fear, humiliation, destruction of property, enforcement of social isolation, taking or withholding earnings, and flaunting other sexual partners’ (Jewkes 2010, p. 851) is less recognized and addressed (Matheson et al. 2015). Emotional abuse’s reported prevalence is

between 9 and 70% (Jewkes 2010, p. 851). People experiencing abuse frequently face unsympathetic criminal justice services (Meyer 2016) and unprepared health services (Global Burden of Disease Study 2013 Collaborators et al. 2015).

Violence, including femicide against lesbian or gender non-conforming women, those living and not living with HIV, is a specific form of violent hate crime (Cooper et al. 2016). In some regions there is violent abduction of women for sex and/or marriage. For example in the Eastern Cape province of South Africa, a specific form of sexual violence, known as *ukuthwala* occurs—this includes abduction, forced marriage, and rape of young girls. It is a distortion of a past custom for consenting, eloping young adults (Monyane 2013).

Male-on-male violence

Almost all violence against men is perpetrated by other men. It is estimated that for every violence male death, there are 29 male-on-male assaults serious enough to warrant healthcare (Krug et al. 2002).

Gender-related factors promoting notions of toughness, competitiveness, and a desire for dominance over other men, as positive attributes of 'being a man' (Jewkes et al. 2015) are most prominent in underpinning male-on-male violence. These occur against a backdrop of other socioeconomic risk factors for male-on-male violence. Like male-on-female violence, these include socioeconomic deprivation, urban concentrations of poverty, and substance abuse (Global Burden of Disease Study 2013 Collaborators et al. 2015).

Interpersonal violence

The global prevalence of interpersonal violence (IPV) against women is estimated as 15 to 71% (Sprague 2018, p. 63). IPV was responsible for 8.5% of deaths in 2013 (Global Burden of Disease Study 2013 Collaborators et al. 2015). GBV-related DALY differs by sex, age, and region. Injuries are higher among men than women, except in the older age group and apart from road accident injuries are due to male-on-male assault and homicide. Homicide in adult males aged 15 years to 49 years, in DALY are 2,651 per 100,000 population in western Europe and 10 780 in Eastern Europe (Global Burden of Disease Study 2013 Collaborators et al. 2015, p. 6). Interpersonal violence is responsible for 317/100,000 DALY. This is commoner in LMIC,

with boys under the age of 15 years having a low rate of 468.4 per 100,000 DALY in Western Europe and a high rate of 6,471.4 in central Africa. Male-on-male interpersonal violence has reached epidemic proportions, among young men in a country such as South Africa, that is not at war (Norman et al. 2010).

No convincing biological factors underpin interpersonal violence. Testosterone in men doesn't explain why all men are not violent. Greater physical strength in men than in most women enables them to engage in more physical violence. GBV against women and in male-on-male violence is highly gendered.

While several other factors cross-cut gender in influencing male violence against women, a key driver is gender power inequity in interpersonal relationships and society (Jewkes 2002). This manifests in male controlling behaviour, notions of male entitlement and power to 'punish' women that is condoned by individuals, within communities, the criminal justice system, and among policy makers and service providers (Seedat et al. 2009). There is an interaction between women's experiences of violence and mental health problems. Violence against women has important negative mental health consequences such as depression and anxiety (Jewkes 2010). Physical health effects of violence include injury or death and limited sexual and reproductive control and health-seeking behaviour. This can lead to unintended pregnancies, with poorer maternal and perinatal health outcomes and risk of STI.

Same-sex IPV has been under researched. However, research among gay men link emotional, physical, and sexual abuse in intimate partnerships to dominant forms of masculinities in which one partner exercises controlling behaviour and power over another (Coles 2009; Creighton and Oliffe 2010). Given that men are the main perpetrators of IPV, gay men may suffer disproportionately among men (Oliffe et al. 2014). Like men generally, they frequently view physical and mental injuries as 'part of being a man' (Oliffe et al. 2014, p. 574). This has health system and services implications due to reluctance to seek medical or other assistance (Oliffe et al. 2014) (Box 10.2.10).

Box 10.2.10 Key messages

- Violence against women and male-on-male violence among young men is of epidemic proportions. Males are generally the perpetrators.
- Interpersonal violence is commonest for women and men, particularly from non-strangers.
- Several socioeconomic factors influence GBV, but gender power inequity in interpersonal relationships and society, with males more powerful, is the key GBV driver.
- GBV has severe negative physical and mental consequences.
- Unsympathetic criminal justice systems and unprepared health service present major problems in detecting and addressing GBV.

Mental health

The burden of mental health and gendered aspects—commonalities and differences

The burden of mental, neurological, and substance (MNS) use problems have increased by between 1990 and 2010. It currently accounts for one out of 10 healthy years of life lost globally. This causes excess mortality, impacting socially and economically on those affected, caregivers, and society. Historically, mental health research has focused on women's issues (Smith et al. 2016). This focus may have led to a neglect of men's mental health problems. Gender differences in mental health problems can be viewed through a gender conception and practices lens. During the industrial revolution, men left home for work, while women assumed child caring responsibilities in the home.

This gendered labour division influenced on how men and women were viewed and expected to behave in society. Productive work in the public sphere became associated with men and masculinity, while socioemotional and domestic work became associated with women and femininity. Women were normatively viewed as fragile and emotional beings, with children requiring their mothers' special care for moral and psychological development (Rosenfield and Smith 2010). While the current global shifts in ideological norms empower women striving for equality especially in the workplace, gender power divisions between men and women, in responsibilities, remain relevant for women and men's mental health. Given dominant feminine role expectations, women tend to put others' interests first more often, promoting internalizing problems (Doyal 1995). Childcare and household responsibilities often take a psychological toll on women, ultimately resulting in high stress levels. Where childcare is secure and home responsibilities are shared with spouses, women's depressive and anxiety

symptoms resemble the lower levels diagnosed among men. Gender norms encourage women to maintain social ties that are emotionally intimate. They enjoy higher levels of feeling that others care deeply about them (Taylar and Turner 2001). However, close ties that bring support can also be sources of negative interactions with conflicting demands (Taylar and Turner 2001). Negative interactions can offset the benefits of supportive interactions, leaving women with higher distress levels. Neurological differences in women and men's mental health are contested and social factors, including gender play a dominant role in mental health problems.

Large-scale epidemiological studies assessing mental health problems in the United States (Kessler et al. 2005) and elsewhere (Andrews et al.1999; Seedat et al. 2009), found no differences in men and women's overall rates of psychopathology. The differences lay in the diagnoses (Rosenfield and Smith 2010). Men exhibiting problems of substance abuse and antisocial behaviour, are likelier to be destructive and problematic to others as well as themselves. Alcohol and drug addiction can lead to serious psychological or physical consequences. Research shows that men are likelier to take their lives in violent ways, hence suicide death rates are higher for all ages of men than women (Zarit and Zarit 2011). Antisocial personality disorder is more commonly diagnosed in men, as are schizoid and paranoid personality disorders. In contrast, histrionic, dependent, and avoidant personality disorders (female stereotyped), are more commonly diagnosed in women (Torgersen et al. 2001). Eating disorders are diagnosed as 10 times commoner in women than men (Byrne and McLean 2001). These occur mostly in late adolescence and early adulthood. Rates of dementia, perhaps related to longevity, are higher for older women, leading to older women having a greater need for mental health services.

For women and men mental health problems are commonly comorbid with physical disorders such as CVD, cancers, metabolic disorders, and HIV (De Hert et al. 2009; Murthy 2004).

Notions of hegemonic masculinities encourage males to suppress emotions (feelings of helplessness, worry, and insecurity) defined these as feminine and weak. These expectations ultimately prescribe how men and women express their feelings. Men and women develop coping mechanisms, which for men may lead to hiding their feelings, often turning to substance abuse. Some describe substance abuse as a male version of depression (Rosenfield et al. 2005). Men may experience negative mental health

consequences through greater gendered difficulties in forging close long lasting social ties (Castillo et al. 2007).

The health system and gendered mental health practices

Health system-related, health services and health practitioners' behaviour, and clinician measurement bias has likely influenced much of the scholarship and current findings on gender and mental health. This has led to problematic assumptions about gendered mental health symptoms (Currin et al. 2011). Health professionals tend to perpetuate gender stereotypes about men and depression, by being less likely to correctly diagnose men presenting with symptoms of depression or anxiety (Borowsky et al. 2000). Men's mental problems tend to be underestimated. Clinicians are less likely to use standard psychological measurement tools to assess men's symptoms (Martin et al. 2013). Research comparing men's and women's mental health has tended to focus on different outcomes of stress instead of similarities and differences in men and women's mental health experiences (Elliott 2013) (Box 10.2.11).

Box 10.2.11 Key messages

- Four conventional explanations for gender differences in mental health are gender socialization, help seeking, coping, and symptom stratification (Currin et al., 2011).
- Understanding factors underlying mental health problems among women and men involves adopting a holistic consideration of the biological social, cultural, economic, and personal contexts of their lives (Judd et al. 2009).
- Researchers, policymakers, and clinicians should reassess the validity and reliability of current measurement tools for detecting symptoms for men and women, and focus on what factors might be particularly relevant for men's experiences (Smith and Hemler 2014). This can more effectively address mental health in women and men.

Maternal health

In 2015, the maternal mortality ratio (MMR) (the number of female deaths during pregnancy, childbirth and immediately after childbirth per 100,000 live births) was an estimated 216. The overall MMR declined by 44% and

2.3% annually from 1990 to 2015. It would need to decrease to a minimum of 7.3%, to reach the SDG target of 70 by 2030 (WHO 2016a).

Differences between women and women: region, class, and ethnicity

The overall decline in global MMR, belies huge differences in the position of pregnant women based on class, race, age, and within and between world regions. High levels of maternal morbidity and mortality are key indicators of global inequity reflecting structural inequity between women in different parts of the world. Women's higher maternal morbidity and mortality in LMIC are linked to poverty. The World Bank's 2018 Health Equity database found that people in 35 and 34 countries faced catastrophic and impoverishing health expenditure, respectively (Wagstaff et al. 2018). Poor maternal health and related problems remain important causes of women's death and disability in LMIC. In HIC the risk of maternal death is 1 in 3,700 compared to 1 in 38 in in sub-Saharan African countries (United Nations Development Programme 2015). LMIC accounted for roughly 99% of global maternal deaths in 2015, with sub-Saharan Africa accounting for approximately 66%, followed by Southern Asia (WHO et al. 2015, p. xi). Eighteen sub-Saharan African countries had a MMR ranging between 500 and 1,000 deaths per 100,000 live births (WHO et al. 2015). India, Nigeria, Pakistan, Afghanistan, Ethiopia, and the DRC together had more than half of the global number of maternal deaths (Hogan et al. 2010). MMR in LMIC regions such as in sub-Saharan Africa and south Asia are similar (351 and 336 per 100,000 live births, respectively).

The health system and healthcare

Gender-related factors hinder women's maternal healthcare in some regions, where women need permission from or be accompanied by a male partner, to attend health services. However, most differences in maternal health outcomes are due to preventable conditions related to health system and service issues, such as skilled birth attendance (WHO 2016a). While overall skilled birth attendance was estimated to be 73% by 2013, in Africa and Southeast Asia, more than 40% of births took place without skilled healthcare. Poor healthcare provider attitudes in maternal care, low healthcare provider knowledge and inadequate training underpin problems with access to skilled maternal healthcare (Sprague 2018, p. 98).

Younger, poorer women and those in lower income or rural areas have poorer access to or are less likely to use effective methods of contraception. Globally, more than 10% of all women do not have access to or are not using an effective method of contraception, with much higher proportions in LMIC countries. Less than half of those in the WHO African Region had their contraceptive needs met (WHO 2016a). It is estimated if unmet need for contraception was met, it could decrease maternal deaths by nearly a third (United Nations Development Programme 2015).

Most maternal health complications are preventable if women enjoy sufficient economic resources to satisfy educational and informational and health needs and are able to delay age at first pregnancy. The main direct causes of maternal morbidity and mortality include obstetric haemorrhage, hypertensive disorders, and sepsis during pregnancy (WHO 2016a). Indirect causes include the following: Women with untreated AIDS-related health conditions have an eightfold increased risk of maternal death than HIV negative women (Kendall et al. 2014, p. S251). In the absence of HIV approximately 281,500 global maternal deaths could have been avoided in 2008 (Hogan et al. 2010). Inadequate access to skilled maternal healthcare, especially emergency obstetric care is a major problem. This is due to unavailability of adequate maternal health services, distances, costs in travelling to maternal health services, and inadequately skilled healthcare providers.

Unsafe abortion's impact on maternal health

Unsafe abortion is a 'preventable pandemic' (Grimes et al. 2006, p. 1). Unsafe abortion is on a continuum unsafe care, with abortions conducted either by unskilled individuals or in an unsafe medical environment (Sedgh and Adewole 2016). Unsafe abortion contributes significantly to maternal morbidity and mortality. An estimated 19–20 million unsafe abortions occur annually, with 97% in LMIC. An estimated 68,000 women die annually from unsafe abortion and millions have complications, often with long-term, poor maternal health consequences. Key outcomes from unsafe abortion are haemorrhage, infection, and poisoning from substances used in induced abortions (Grimes et al. 2006, p. 1). There has been a decline in abortions, in Eastern Europe, but no significant decreases in LMIC (Singh et al. 2017, p. 5). An estimated 55% were safe; 31% less safe and 14% least safe. Countries

with the most restrictive abortion laws were responsible for the majority of unsafe abortions (Singh et al. 2017, p. 7).

Men and maternal health

While maternal mortality and morbidity affects only women physically and emotionally, it should not be regarded as only a women's health issue. The importance of men as partners in maternal health (attending antenatal, childbirth, and postnatal care) cannot be overemphasized (Brittain et al. 2015; Sibanda et al. 2017; Konje et al. 2018) (Box 10.2.12).

Box 10.2.12 Key messages

- Maternal mortality highlights health inequity between women in different world regions.
- Most maternal deaths are preventable through good quality, skilled maternal care, and availability of emergency care.
- Improved access to contraception and safe abortion would decrease maternal deaths.
- Men as partners in maternal health should be promoted.

Interventions and initiatives to address women and men's health

Biomedical interventions

HIV

Biomedical interventions to decrease HIV infection have been the focus of much research. These include promotion of male and female condoms as barrier methods to protect against HIV acquisition.

Biologically, uncircumcised men have higher female-to-male HIV infection risk than circumcised men. Randomized controlled trials in Kenya, Uganda, and South Africa show that medical male circumcision can provide partial protection against risk of female-male HIV transmission by up to 60% as well as to penetrative partners in same-sex male intimate relationships. The WHO and UNAIDS have recommended medical male circumcision as part of an HIV prevention strategy for men, particularly in

countries with a high HIV prevalence and low circumcision rates (WHO/UNAIDS 2008). ART's critical role in HIV treatment and in 'treatment as prevention', through pre-exposure prophylaxis, reducing HIV infectivity and transmissibility. People living with HIV (PLWH) with undetectable viral loads, have minimal risks of transmission (McNairy and El-Sadr 2014). Research for a microbicide, applied to the vaginal or anal tract to reduce HIV transmission, has had limited success in women, over the past 30 years. However there is active ongoing research (Karim et al. 2010; Doggett et al. 2015). This has highlighted HIV prevention's gender-related factors—gender hierarchies in sexual decision-making and gender norms influencing younger women's lack of adherence to microbicides (Doggett et al. 2015). There is also research for a vaccine to prevent or ameliorate the effects of HIV transmission (Bekker and Gray 2017).

CVD

Key changes that have occurred to address gender issues in CVD. These include addressing knowledge among individuals and in communities and important health system changes in the delivery of care by health professions. In the United States in 2014, overall male mortality from CVD overtook female mortality for the first time since 1984. This is attributable to increased awareness of women's symptoms, presentation, and appropriate treatment for possible heart attacks (Aggarwal et al. 2018, p. 2). Primary and secondary prevention has been largely responsible for a decline in CVD over the past decades (Appelman et al. 2015). Since 2014, an American Heart Association consensus statement has recommended the full battery of non-invasive diagnostic tests for women with suspected heart attack symptoms (Aggarwal et al. 2018, p. 4).

Maternal health

Measures addressing poor maternal health have been introduced at an individual, community, and health systems level. These include improving knowledge of skilled care antenatally, during birth and postnatally at an individual, partner, and community level; and training of health professionals, particularly in rural areas to deal with complications and emergency care and ensuring emergency care facilities are available and well-functioning. Programmes like *Momconnect* in South Africa (Barron et

al. 2016); and Maternal Waiting houses for pregnant women, operating in a variety of LMIC settings such as Lesotho, Cambodia, Malawi, Nigeria, Papua New Guinea, Timor, and Zambia (WHO 1996; Wild et al. 2012; Siv et al. 2014) are examples of health systems initiatives to improve maternal healthcare. Given that apart from HIV and respiratory illnesses, health-system-related causes are the commonest preventable maternal deaths causes, health system initiatives need to be prioritized.

Mental health

Numerous medical and pharmaceutical interventions are effective in treating MNS problems. However psychological and social interventions are important to prevent and treat MNS disorders (Patel et al. 2016).

Transformative gendered initiatives to improve women and men's health

Multiple theories and interventions of change to address the impact of gendered factors on health have emerged. Gupta's (2000) work on HIV introduced interventions along a continuum, to address the gender aspects of the epidemic. These include interventions that are: (1) gender exploitative; (2) gender neutral; (3) gender sensitive, or accommodating; or (4) gender transformative (Rolleri 2014). An example of gender exploitative programming in HIV prevention is one that uses an aggressive image of masculinity to promote condoms, taking advantage of patriarchal masculinity norms, reinforcing gender stereotypes (Rolleri 2014). Gender-neutral programmes take account of specific needs of women or men but miss opportunities to address gender determinants of health. An example is where fidelity messages are promoted to prevent HIV, without reference to gendered power relations in many women and men's intimate sexual relationships (Gupta 2000). Gender-sensitive approaches address specific needs, such as introducing male-friendly reproductive healthcare services at convenient times for men. They recognize and respond to gender norms and inequities, but do not work structurally changing harmful norms or power imbalances (Rolleri 2014). Gender transformative programmes aim to increase awareness of inequitable gender norms, question these and promote, individually and structurally, equitable gender norms, and relations (Rolleri 2014). An example is changing inequitable norms in which men hold power

in decision-making in sexual relationships to those in which women and men engage in equitable decision-making (Greene and Levack 2010).

Individual agency

Some women living in contexts in which hegemonic patriarchal patterns prevail, engage in a variety of individual actions to assert their agency (Jewkes and Morrell 2012; Stern et al. 2016). Jewkes and Morrell's (2012) research in rural South Africa shows that women resist male control and potential male IPV. Some women avoid initiating such relationships, while others accommodate them but simultaneously seek respect and non-violence. Some women in countries such as South Africa and Botswana avoid formal marriage, in part to avoid male control over their lives (Cooper et al. 2013).

While many men conform to dominant masculinity associated with high risk sexual behaviour, some have adopted health-seeking behaviours protective towards their own and their partners' health (Stern and Cooper 2014; Morrell et al. 2016). As not all masculinities are equally powerful, some men go against prevailing gender norms even if they face sanction. Some men act out their masculinity individually through reflecting discomfort with harmful hegemonic forms through caring fatherhood (Morrell et al. 2016). A study among 18–49-year-old men in South Africa found 84% reported helping their children with school homework; only just over half (54%) reported discussing personal matters with their children. Men who were more gender egalitarian in their attitudes were more likely to be caring fathers (Morrell et al., 2016, p. 81).

Structural changes

Sexual and Reproductive Rights are a fundamental human right. Less restrictive abortion laws decrease unsafe abortions. The South African Choice of Termination Act of 1996 is a good example of this, with abortion-related morbidity and mortality decreasing by 91% between 1997 and 2002 (Cooper et al. 2016). Legalizing abortion is a first step, with social stigma, political will for implementation and healthcare provider unwillingness to provide abortions, remaining major problems (Harries et al. 2014). As the US and South African experience show, it is important even when abortion is legal to prevent rolling back gains made (Cooper et al. 2016). In all countries, but particularly those where abortion is illegal, post-abortion care

is crucial in protecting women's health (Singh et al. 2017). A 16-country study showed that factors most influencing access to safe abortion services were having abortion services integrated into comprehensive SRH care, strong country-based women's rights organizations, supported by international agencies and professional medical associations; involvement of non-governmental organizations in provision of services; task sharing among providers so that provision of abortion services is more 'normalized'; and availability of new and less complicated techniques (such as the use of misoprostol and misoprostol-mifepristone in medical abortion). Political will was a key factor for legalization, provision, and ensuring access to abortion services (Chavkin et al. 2018). Although the need for abortion will always remain, better knowledge and access to contraception is critical in preventing pregnancy in the first place.

A number of social interventions prevent and treat MNS problems. Initiatives with good results include legislation measures to restrict access to means of self-harm/suicide and reduce the availability of and demand for alcohol. At health service and community levels, parenting programmes and life skills training in schools can be effective in building social and emotional competencies. At the health service level, self-management, web-based psychological therapy for depression and anxiety disorders; and primary care and community outreach programmes are positive initiatives. This may include psychological and pharmacological management for specific conditions.

Hospitals play a role in providing specialist services for MNS disorders, providing for severe emergencies and for integrating mental healthcare into broader other healthcare services. At a specialist care level, the management of complex and severe cases of MNS disorders, and the integration of primary care level interventions in other medical care platforms, such as maternal and HIV care have shown positive results. The PRIME programme has focused on a district health systems level. It involved partnerships with stakeholders in Ethiopia, India, Kenya, Nepal, South Africa, and Uganda. It developed a district health framework for dealing with mental health problems. Research to test implementation of pilot projects and estimate costs and evaluate their outcomes and processes was conducted. It was aimed at health ministries' scale-up of mental health services at district level in order to improve individuals' and communities' psychological well-being. It has prioritized LMICs, where there is a significant gap in addressing

prevention, treatment, and care for mental health problems (Lund et al. 2016, p. S1). These would be cost-effective interventions, if scaled up. Less than 1% of development assistance for health and government spending on health is allocated to MNS problems, estimated at US$1–2 per capita per year in LMIC, and US$ 3–5 per capita in upper-middle-income countries. National Health Insurance or Universal coverage policies should include addressing these issues through allocation of public health resources (Patel et al. 2016, p. 1).

Advocacy and group/community initiatives

HIV and GBV

A number of examples of gender transformative programmes have been introduced to address HIV and violence against women.

A gender transformative HIV and GBV prevention programme, the *Stepping Stones* programme (Welbourn 1995), was developed in Uganda and adapted and used in 40 countries. Targeting women and men, it sought to improve sexual health through building stronger, more gender-equitable relationships (Jewkes et al. 2007). A randomized controlled trial evaluating the *Stepping Stones* programme in rural South Africa among young men and women (15–26 years old), showed of short term success in reducing sexual risk-taking and violence perpetration by young male participants. Similar changes did not occur among young female participants. This speaks to the difficulties women face in implementing individual behaviour change, in the absence of community or structural changes in gender norms and relationships (Jewkes et al. 2007).

The International AIDS Alliance strategy (2016–2020) on HIV, health and rights conducts a programme based on a ‘people centred’ approach. It works through community action in partnership with PLWH, based on the premise that they are best able to assess their own needs. It promotes equity through focusing on those systematically excluded or marginalized; activities that are criminalized (such as women who use drugs in Kenya and sex workers); and people with diverse sexual orientations or gender identities. It analyses the social determinants, including gender’s, effect on peoples’ lives, and health (International AIDS Alliance 2017, p. 1). Its Vihaan project in India, promotes community-based organizations and PLWH taking a leadership role in care, treatment, and support programmes (International AIDS

Alliance 2017, p. 3). In Kenya work with women using drugs involves issues of concern for young women as lovers, mothers, keeping safe, HIV, SRH and rights and childcare (International AIDS Alliance 2017, p. 2).

Recent transformative research interventions aimed at girls involve cash transfer programmes to address one of the root economic HIV vulnerabilities in young women. These were implemented and evaluated in South Africa (Cluver et al. 2013) and other southern and eastern African countries affected by HIV (Samson 2009). They showed some success in encouraging younger women to complete schooling, be economically independent and engage in more positive sexual health behaviours.

Over the past few decades, a substantial number of male-oriented initiatives have addressed the gender effects of HIV and GBV. These focused on changing patriarchal masculinities among men that are harmful to men and women's health.

Examples of transformative individual, community, and structural initiatives that engage primarily with men on GBV, HIV, and fatherhood include the *Sonke Gender Justice Network* and *Primundo* (Dworkin et al. 2012; Ricardo et al. 2011). Sonke Gender Justice Network's the 'One Man Can' campaign, is a rights-based gender equality health initiative, recognized as best practice by the WHO. Its programme has been translated into over 10 languages and subsequently implemented across the African continent (Van den Berg et al. 2013). It organized men's community-based workshops to reflect on human rights, women's rights, how masculinities are defined and practised and can be more caring (Dworkin et al. 2013). It assisted establish community action teams to address GBV and HIV (Dworkin et al. 2012). Evaluations showed increased actions among male participants against GBV, engaging in safer sex and accessing HIV testing and ART (Dworkin et al. 2013).

Pharmaceuticals and patent laws—structural initiatives

In India, people living with HIV struggled and won changes in India's medicine patent laws to allow access to cheaper antiretroviral medication (People's Health Movement 2018). The Treatment Action Campaign in South African launched and won a similar struggle as well as pressurizing the government into providing antiretroviral treatment in public sector health facilities (Colvin 2014). These initiatives confronted structural determinants

of health and involved the support of health professionals and healthcare providers.

Mental health

The ‘Emerging mental health systems in LMICs’ (Emerald) programme has aimed at improving health outcomes of people with MNS problems in Ethiopia, India, Nepal, Nigeria, South Africa, and Uganda. It generated evidence that was used to boost health system performance in providing improved mental healthcare and enhance the capacity of policymakers, and planners. It focused on strengthening health service use and caregiver capacity to support efforts within mental health systems. The programme sought to deal with stigma and discrimination as key barriers to health-seeking behaviour and provision of mental health services (Semrau et al 2015).

Other informative initiatives that could inform women and men’s health

The *Genuino Clandestino* is an Italian network of collectives, associations, and individuals engaged in dealing with the struggles for food and control over land. Founded in 2009, with origins in small-scale producers of food, it links its activities to the specific needs of local communities, promotes small-scale organic food markets, certification of products, self-organized kitchens, and land access. Its strong grassroots community base has enabled it to take on local struggles important to female and male nutrition and land issues and to confront the interests of large multinational food and land companies (People’s Health Movement 2018).

Changing gender power relations

There has been ongoing tension on place of men and boys in changing gender power relations (Tolhurst et al. 2012). Initial approaches for male involvement stressed their strategic importance for women’s health. This raised questions about whether gender was only about women’s interests. Later approaches emphasized male involvement as important in its own right and to improve female health (Tolhurst et al. 2012). These approaches argued that transforming gender relations acts in the interests of both women and men’s health. Yet others have drawn critical attention to women and men

not being equally vulnerable or privileged. Hence addressing gender inequity in power relations likely involves the relinquishment of personal and structural hegemonic patriarchal forms of power and privilege, vested in institutions such as the legal, political, and economic system (Box 10.2.13).

Box 10.2.13 Key messages

- Biomedical interventions have been important in HIV, CVD, mental health, and maternal health improvements.
- There are multiple theories of gender change, with gender transformation being the most far-reaching.
- Individual agency, structural changes and advocacy and community initiatives are important in transforming gender power relations that can improve women and men's health and healthcare.
- Several evaluated transformative initiatives have shown promise in improving women and men's health.

In conclusion

Researchers, practitioners, policymakers, and policy implementers should recognize health as a complex interplay between many determinants, of which gender is one key social determinant. These operate at individual, interpersonal, systems (such as the healthcare system) and structural levels. This has key implications for how we conceptualize health problems, how we address them, how we approach research and design a health system and services. It involves work intersectorally to promote facilitators of health and engage in advocacy activities to transform the legal, policy, social, political, and economic structures, in which health is embedded.

ACKNOWLEDGEMENTS

Huge appreciation goes to Tanya Jacobs and Courtney Sprague who previewed this chapter at different stages and provided invaluable informal reviews and comments. We cannot thank you enough for your insights and encouragement.

Our thanks to:

Ntobeko Nywagi who assisted in searching for data on Life expectancy and Cardiovascular disease;
To Prof. Finn Diderichsen for permission to adapt his and his colleagues framework that appears as figure 2.2 in Sprague (2018, p 67), for use in Figure 10.2.2 in this Chapter;
To Hillevi Sellen for her patience in extending deadlines for the chapter.

The first author wishes:

To thank to Justine Evans for beginning to teach me when and how to say 'no' or 'I need a deadline extension'!

I express my huge appreciation to Jon, Tara, and Mikey for encouraging me to believe 'I can do this' in writing this chapter.

Child health

Tyler Vaivada, Amira Khan, Omar Irfan, and Zulfiqar A. Bhutta

Current situation of child health globally

Within the life course, the period of life before attaining adulthood is divided into three age subgroups based on epidemiology and healthcare needs: the first 5 years (*under-5 children*), the next 5 years (*older children*), and the second decade of life (*adolescents*). The first 5 years of life are further subdivided into the neonatal period (the first 28 days of life), infancy (the first year of life), and preschool years (from 1 to 5 years). This chapter focuses on the health of under-5 children, in addition to older children from 5 to 10 years.

The most important indicators of health status of children relate to their mortality, morbidity, nutrition, growth, and development. Poor health and survival are linked to social and economic development and child mortality is one of the most sensitive barometers of this relationship. An overview of the health situation and inequalities among children in the world is presented in this section.

Global burden and epidemiology of mortality in children under 5

There has been remarkable progress in the reduction of the under-5 mortality burden, with the under-5 mortality rate (U5MR) decreasing from 93 per 1,000 livebirths in 1990 to 39 per 1,000 livebirths in 2017; a reduction of nearly 56% (UN IGME 2018). Much of this success in reducing under-5 deaths is attributable to falling infectious disease mortality. Despite progress made, 5.4 million children died in 2017—a staggering 2.5 million of them were neonates. Nearly half of under-5 deaths occur within the first month of

life, and the risk of death is the highest on the day of birth; it then decreases over the subsequent days, months, and years. Unfortunately, as compared to the 60% reduction in the 1–59-month mortality between 2000 to 2017, mortality in the neonatal period has only decreased by 41% (UN IGME 2018).

More than 80% of all under-5 deaths are clustered in just two regions of the world: sub-Saharan Africa and South Asia. Sub-Saharan Africa leads with the highest global U5MR of 76 deaths per 1,000 live births in 2017 with the chances of an under-5 child dying being 1 in 13. It is noteworthy that globally 50% of all under-5 deaths are concentrated in six countries: India, Nigeria, Ethiopia, Democratic Republic of Congo, Pakistan, and China.

Most children eventually die from only a small number of diseases and conditions. Globally, the leading causes of under-5 mortality are those occurring in the neonatal period, such as preterm birth complications (18%), intrapartum-related events (12%), and neonatal sepsis or meningitis (7%). Although global data on preterm birth rates are sparse, in 2014, an estimated 10.6% (14.84 million) of live births occurred before 37 weeks' gestation, of which 80% were in sub-Saharan Africa and South Asia (Chawanpaiboon et al. 2018). Birthweight is a key indicator of maternal and foetal health during pregnancy, and in 2015, an estimated 14.6% (20.5 million) of newborns had low birthweight (LBW), defined as less than 2500g (Blencowe et al. 2019). LBW can be the result of intrauterine growth restriction, preterm birth, or both. Children born too soon or too small are at considerable increased risk of mortality and morbidity. Pneumonia (16%), diarrhoea (8%), and malaria (5%) are the leading causes of infection-derived post-neonatal under-5 mortality (UN IGME 2018).

The so-called epidemiological transition has a complex, dynamic course which reflects changes in demographic, socioeconomic, cultural, biological, technological, and environmental domains. As a result, important modifications are seen in the patterns of causes of death that usually shift from acute infectious diseases and deficiency-related conditions to non-communicable diseases (NCDs), leading to a relative increase in conditions such as perinatal causes (prematurity, birth asphyxia, and trauma), congenital abnormalities, and injuries. The World Health Organization (WHO) estimated that, between 2000 and 2012, childhood measles, diarrhoea, and

pneumonia mortality reduced by 80, 50, and 40%, respectively (WHO 2018a).

Poverty, maternal health and education, gender, race, and poor-quality healthcare are some of the underlying determinants of under-5 deaths. Levels, trends, and progress in both infant and under-5 mortality are unequally distributed between and within communities, regions, and countries. The likelihood of a child dying in the poorest household, before their fifth birthday, is nearly double that of the most affluent. Similarly, those in rural areas have a 1.5 times greater chance of under-5 death than children in urban settings. More than one-third of under-5 mortality is concentrated in the least developed countries. Unless this inequity is addressed, it is estimated that between 2016 and 2030, 69 million under-5 children will die with nearly half of them in sub-Saharan Africa (Watkins et al. 2016). Figure 10.3.1 illustrates the distribution of under-5 deaths by cause in 2016. Figure 10.3.2 shows trends in child mortality rates.

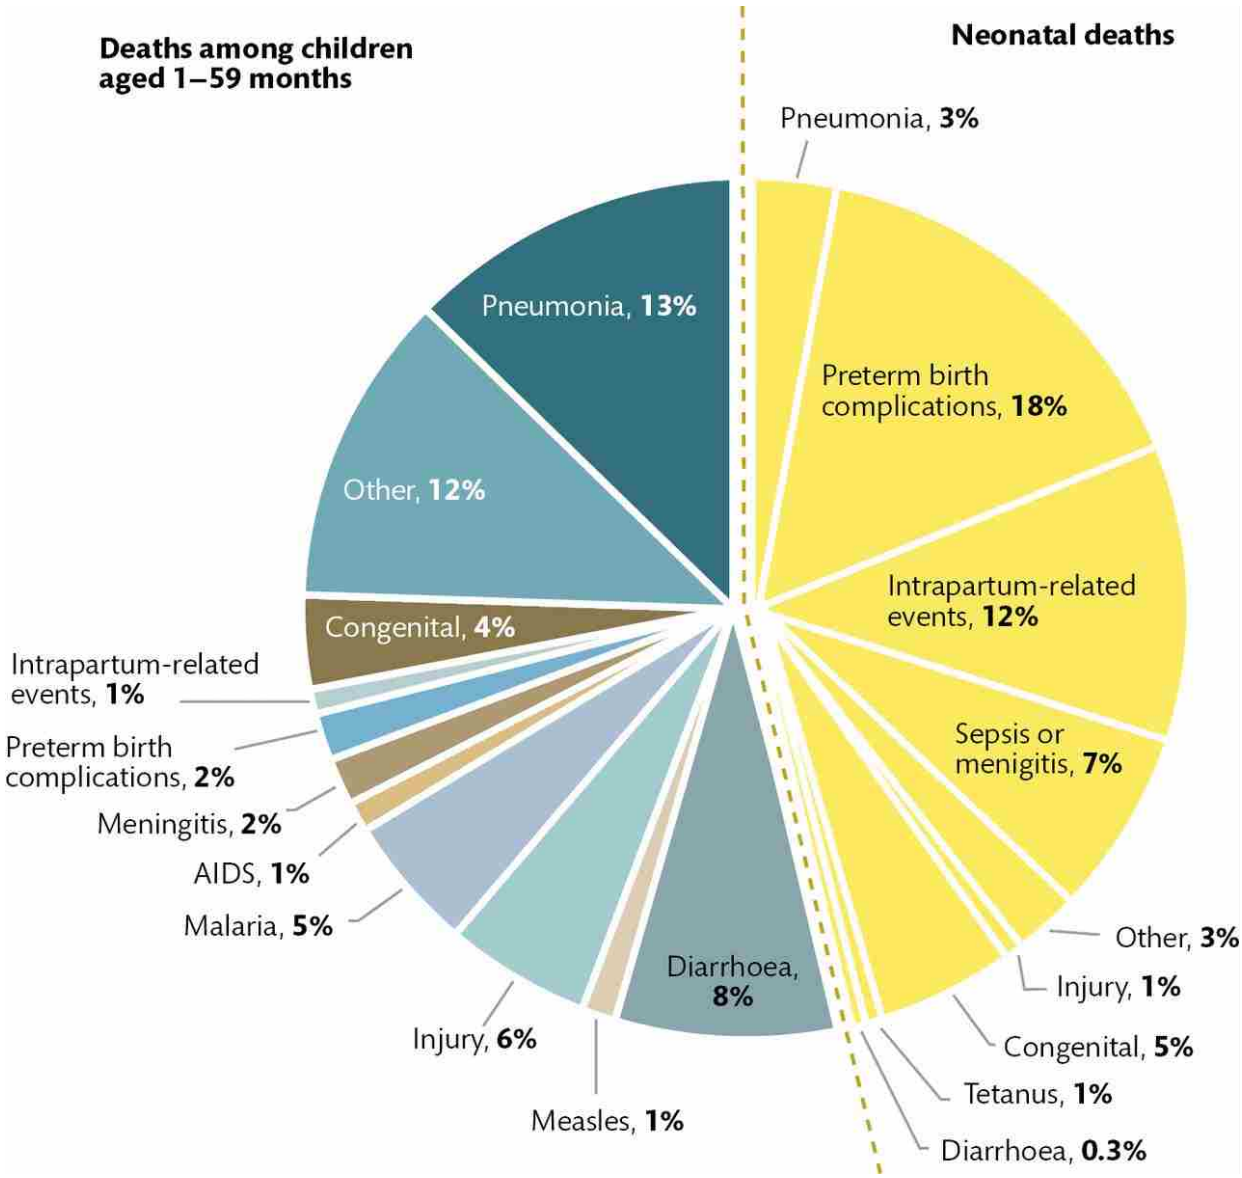

Fig. 10.3.1 Global distribution of deaths among children under-5, by cause, 2016.

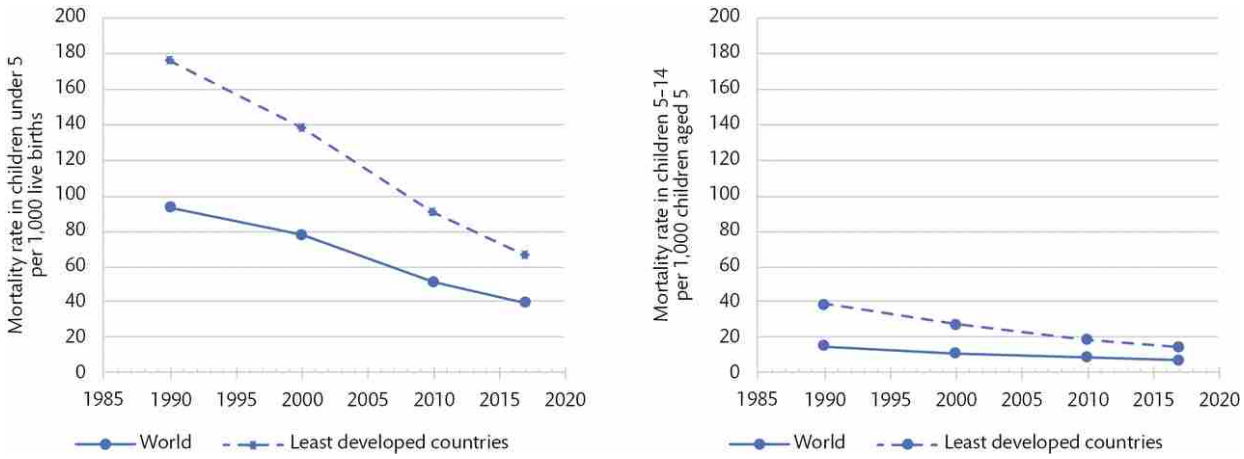

Fig. 10.3.2 Trends in child mortality rates, 1990–2017.
Source: data from Levels and Trends in Child Mortality Report 2017. (2017). [online] United Nations Inter-agency Group for Child Mortality Estimation (UN IGME). Available at: https://www.unicef.org/publications/files/Child_Mortality_Report_2017.pdf [Accessed 14 May 2019].

Global burden and epidemiology of morbidity in children under 5

Measurement of morbidity is more complex than that of mortality, thus data on the distribution of morbidity burden among the under-5 population is scarce. Despite data limitations, it is known that the main causes of morbidity highly correlate with the major causes of death in under-5 children (Table 10.3.1). Pneumonia, the second-leading cause of under-5 mortality is the leading cause of under-5 deaths in sub-Saharan Africa—nearly 490,000 annually. The global incidence of pneumonia in the 0–4 age group is nearly 0.19 episodes per child per year, with the highest incidence in Southeast Asia (0.26) and Africa (0.27) (Walker et al. 2013). In 2010, 120 million episodes of pneumonia occurred in children less than 5 years of age, of which 14 million progressed to severe illness (Fischer Walker et al. 2013).

Recent estimates of diarrheal disease burden show that diarrhoea incidence and mortality decreased by nearly 6 and 21%, respectively, between 2005 and 2015 (GBD Diarrhoeal Diseases Collaborators 2017). Of the 1.3 million deaths caused by diarrhoea in 2015, nearly 0.5 million were in children under-5, accounting for 8% of the total under-5 mortality. Nearly 90% of these diarrhoeal deaths in children occurred in South Asia and sub-Saharan Africa. Persistently high rates of diarrhoea morbidity have long-term detrimental effects on child growth and cognitive development.

Incidence of both pneumonia and diarrhoea are closely associated with poor home environments, undernutrition, and lack of access to health services. The prevalence of pneumonia and diarrhoea can be more than twice as high among the poorest children as among the richest ones. Malnutrition is an underlying determinant of nearly 45% of all under-5 deaths. With changing environments and lifestyles, rates of childhood overweight and obesity are rising. In many instances, overweight and obesity coexist with undernutrition and stunting, thus giving rise to the double burden of malnutrition.

Table 10.3.1 Estimated numbers of deaths caused by infections in neonates and children aged 1–59 months, at the global level in 2000–2015

	2000	2015*
Neonates		
Pneumonia	0.296 million	0.161 million
Sepsis/meningitis	0.532 million	0.402 million
Tetanus	0.161 million	0.034 million
Diarrhoea	0.04 million	0.018 million
Children (1–59 months)		
Pneumonia	1.4 million	0.76 million
Meningitis	0.284 million	0.115 million
Diarrhoea	1.2 million	0.509 million
Measles	0.485 million	0.074 million
Malaria	0.725 million	0.306 million
AIDS	0.22 million	0.086 million
Pertussis	0.056 million	0.054 million

* Neonatal sepsis/meningitis, neonatal pneumonia, neonatal tetanus, childhood pneumonia, childhood diarrhoea, meningitis, diarrhoea, measles, malaria and AIDS all showed >30% decline in mortality rates from 2000 to 2015

Source: data from: Liu, L., Oza, S., Hogan, D., et al. (2016). Global, regional, and national causes of under-5 mortality in 2000–15: an updated systematic analysis with implications for the Sustainable Development Goals. *The Lancet*, *388*(10063), 3027–35.

Global burden and epidemiology of mortality and morbidity in school-age children

Although a great deal of progress has been made since 1990, there are still considerable differences in the risk of mortality between younger and older children (Fig. 10.3.2). The disparities in child mortality between the least developed countries and the global average have also narrowed, but a substantial gap remains that can be addressed by evidence-based interventions targeted at highly marginalized groups. Between 1990 and

2016, the global mortality rate for children between 5 and 10 years decreased from 10.3 to 4.5 deaths per thousand children (Masquelier et al. 2018). Despite this global trend, the mortality rates of older children remained high in 2016 in sub-Saharan Africa at 11.9 deaths per thousand. In 2016, there were still an estimated 585,000 deaths globally among children 5–9 years, with approximately 351,000 and 192,000 occurring in sub-Saharan Africa and South Asia, respectively.

Mortality rates are substantially lower, and the breakdown of causes of mortality in children over the age of 5 are quite different from that of younger children, with NCDs and injury-related causes increasing in importance to different degrees between countries (Fig. 10.3.3). The relative proportion of total mortality due to these causes increases in adolescence, and in higher income countries. A high proportion of infection-related mortality, characteristic of early childhood, extends into later childhood for those countries with higher levels of under-5 infectious morbidity. For example, the nutritional and communicable disease-related death rate of children 5–14 in India in 2016 was 32.6 and 26.2 per 100,000 for girls and boys, respectively, but the same rates for China were only 1.7 and 1.5 (Fadel et al. 2019). Furthermore, while NCDs and injuries in this age group were the principal causes of death in China, Brazil, and Mexico, India still experienced higher mortality rates due to these causes. Here, the typical epidemiological transition has not yet occurred, resulting in a substantial double burden of communicable and NCDs in older children, putting significant strain on health systems.

While their mortality risk is lower, older children bear the consequences of ill health and adversities that were experienced in their earlier years. Early and continued nutritional deficits and recurrent infections can lead to poor school performance, in addition to predisposing children to deleterious metabolic changes. The main causes of morbidity and mortality in children under 5, including respiratory infections, diarrhoea, and malaria, remain a significant burden for school-age children in the poorest low- and middle-income countries (LMICs). NCDs that become increasingly prominent and cause significant morbidity and disability include hemoglobinopathies, asthma, rheumatic heart disease, and sensory and neurological disorders. Additionally, school-age children experience a higher burden of injuries caused by drowning, road traffic accidents, poisoning, burns, and maltreatment.

Fig. 10.3.3 Breakdown of the causes of mortality among children 5–14 in Brazil, China, India, and Mexico from 2005 to 2016.

Source: data from Fadel, S.A. et al (2019). Trends in cause-specific mortality among children aged 5–14 years from 2005 to 2016 in India, China, Brazil, and Mexico: an analysis of nationally representative mortality studies. *The Lancet*, 393(10176), pp.1119–27.

Determinants and indicators of child health and well-being

The determinants of child survival, growth, and development can be broadly categorized as the social and physical environment in which a child resides, or their biological characteristics. Social and environmental determinants constitute the underlying risk factors further up the causal chain that can influence child health status. Biological determinants are often directly related to these underlying risks and include maternal risk factors (which influence a child's health even before they are born), birth conditions, and the health and nutritional status of child. The key adversities that have the highest impact on child health vary along the life course but are most critical in infancy and early childhood when most preventable child deaths occur. It is important to note that these risk factors affect entire populations of children to varying degrees, and those that contribute to a proportion of child deaths also contribute to a spectrum of morbidities, disabilities, and suboptimal growth and development trajectories in a much larger proportion of children.

Social and environmental determinants of child mortality and morbidity

Economic marginalization and poverty are the underlying determinants of much of the inequity in child health globally. Household food insecurity and reduced access to a diverse range of nutritious foods is strongly associated with poverty and predisposes children to malnutrition. When parents lack the means to provide a nurturing environment for their children, the risk of child mortality rises, child health suffers, and the consequences extend through adulthood and into the next generation. Parental educational achievement, particularly of the mother, is strongly linked to child health through multiple pathways. Community and household living conditions are also important determinants of childhood exposure to infectious diseases, chiefly water quality, sanitation infrastructure, and hygiene practices. Children raised in a

safe, secure, and stimulating home environment, with responsive caregivers, early educational opportunities, and good access to health services, are best placed to survive to adulthood and achieve their developmental potential. Supporting optimal child health is necessary to optimize human capital development within a population. When a child cannot reach their full intellectual and social potential, lifetime educational achievement and earnings are reduced, and the intergenerational cycle of poverty is perpetuated.

Gender and women's empowerment also play a key role in child health, the impacts of which begin even before birth. Adolescent girls who enter marriage and become pregnant at an early age are at higher risk for malnutrition, and subsequent foetal growth restriction and poor birth outcomes. Although female infants have a biological advantage over male infants in early life (who generally experience higher mortality rates than female infants in most regions of the world), inequitable gender preferences can put infant girls at a disadvantage with regards to infant feeding and care practices. These discriminatory parenting practices reflect societal gender inequality that manifests itself at the earliest stages of life.

Geographical disparities in child health stem, in part, from inequitable access to food, health services, and education—particularly in rural regions. Geography also dictates the physical environment in which children and their families live, and to which pathogens and pollutants they are exposed. Climactic conditions and agricultural productivity can affect household food security, especially in regions susceptible to the effects of climate change. Children are especially vulnerable to environmental shocks that disrupt the normal functioning of infrastructure, health systems, and food distribution. Migration, political instability, conflict, and natural disasters create adversities in the living conditions of children that increase the risk for malnutrition and disease.

Biological risk factors for child mortality and morbidity

There are several key maternal risk factors in the context of pregnancy that influence child health. Adolescent pregnancy is associated with poorer birth outcomes, and untreated infectious diseases in expectant mothers can cause serious birth complications or child death. Adequate maternal nutrition status, both before conception and during pregnancy, are required for

optimal growth and development of the foetus. Preterm birth and intrapartum-related complications such as birth asphyxia, in addition to severe neonatal infections, cause the majority of neonatal deaths. Those infants that survive are at substantially increased risk for developmental delay and disability (Mwaniki et al. 2012). Early childhood malnutrition and exposure to pathogenic organisms are the immediate causes of the majority of preventable child mortality, morbidity, and poor growth and development beyond the neonatal period. The subclinical condition known as environmental enteric dysfunction, or environmental enteropathy, is characterized by intestinal inflammation and changes to the intestinal lining. It is linked to poor sanitation conditions and chronic pathogen exposure, primarily through the repeated ingestion of faecal matter, and is proposed to represent an important link on the causal pathway to child stunting and suboptimal cognitive development, though the exact mechanism by which this occurs is still being investigated (Keusch et al. 2014).

Nutrition and growth in childhood

The nutritional status of under-5 children is usually assessed through three standard indicators: stunting, wasting, and underweight. In the case of stunting, a child's linear growth falls below minus two standard deviations (−2 SD) from the median height-for-age of the WHO Child Growth Standards (WHO 2006a). Stunting is usually a result of chronic undernutrition over a lengthy period of time, often in the context of a high burden of infectious pathogens that are associated with enteric dysfunction and nutrient malabsorption. A child is considered wasted when they fall below −2 SD from the median weight-for-height of the WHO Standards. Wasting usually reflects an acute nutritional deficiency, due either to reduced food consumption or acute weight loss during an illness. A child is said to be underweight if his/her weight falls below −2 SD from the median weight-for-age of the WHO Standards, which can be a result of stunting, wasting, or both. Conversely, overweight is defined as 2 SD above the median weight-for-height of the WHO Child Growth Standards.

While childhood malnutrition is a consequence of risk factors related to the social determinants of health, poor nutritional status itself is strongly associated with vulnerability to disease, delayed physical and mental development, and increased mortality risk. Undernutrition is usually

associated with inadequate maternal education and reduced child well-being. Despite declines in recent decades, in 2018, 21.9% (149 million) of children under 5 years globally experienced stunted linear growth, down from 32.5% (198.2 million) in 2000. In 2018, 5.9% (40.1 million) were overweight, up from 4.9% (30.1 million) in 2000. In 2018, an estimated 7.3% (49.5 million) of children under 5 experienced wasting (UNICEF/WHO/World Bank 2019). These global metrics mask striking inequities between regions; in 2018, 14.6% of children under 5 in Southern Asia experienced wasting, representing more than half of all wasted children globally. In Eastern Africa, 35.2% (24 million) of children under 5 were stunted (UNICEF/WHO/World Bank 2019).

An increasing number of countries are experiencing a ‘double burden’ of malnutrition, in which high rates of undernutrition, and overweight and obesity coexist. While Asia and Africa account, respectively, for 55 and 39% of all stunted children under 5, they also account for 47 and 24% of all overweight children under 5. Obese children are at increased risk for adult obesity, diabetes, liver disease, and poor social and economic performance in later life.

Micronutrient deficiencies are also a concern in children, sometimes causing serious deficiency-related morbidity, and affecting growth, development, and immune function. Deficiencies in iron (one cause of anaemia), vitamin A, iodine, and zinc are particularly harmful to child health, and are common in LMICs.

The nutritional status of children over 5 years globally is insufficiently measured and studied compared to the under-5 group. In addition to malnutrition and growth deficits that are carried forward from early childhood, micronutrient deficiencies such as iron deficiency anaemia can contribute to poorer school performance in school-age children.

Early child development

The first years of life provide the greatest opportunities for optimizing developmental trajectories. Young children have maximum plasticity of neuronal systems and are highly vulnerable to the negative effects of poor environments, and thus can benefit the most from interventions aimed at addressing risk factors in the critical period of early childhood. Estimates using stunting and poverty as proxy measures suggest that 43% (250

million) children under 5 in LMIC are at risk of not achieving their developmental potential (Lu et al. 2016; Black et al. 2017). Large regional disparities exist, with 66% (94.8 million) of children in the sub-Saharan African region at risk, versus 18% (9.7 million) in Latin America and the Caribbean.

A child's environment and activities while growing shape their cognitive, motor, and socioemotional development. Optimal child development can only occur with adequate nutrition, prevention and timely management of illness, responsive caregiving, and adequate psychosocial stimulation. Chronic malnutrition, poverty, illness, disability, and severe psychosocial deprivation represent key adversities that hamper a child's optimal development. Children experiencing these adversities have more difficulty learning, are less active, and may be less able to receive the attention needed from those who care for them. Later in childhood, school performance may suffer, and subsequent educational attainment and future earnings may be reduced.

Effective interventions that impact child development are available along the life course, and aim to improve maternal health and birth outcomes, caregiver–child interactions, responsiveness, and stimulation through play and communication. Through stimulation and interactions, these interventions intend to enhance the child's ability to learn socially and intellectually and grow physically. The frequent contact of mothers, their babies, and young infants with health services provides a unique opportunity for these services to actively promote and support early child development.

Key supportive actions for child health

Actions to improve child health do not exist solely within the health sector. This section briefly outlines a package of intersectoral and cross-cutting actions, rights frameworks, and policy improvements that support child health at the structural level. These actions address the most basic and distal social and environmental determinants of child health and are completely essential if actions within the health sector are to be effective.

Cross-cutting actions and supportive interventions to address the social determinants of health

There are a host of actions that must be taken at the national and subnational level to help to address the basic and underlying risk factors for child mortality and morbidity, and suboptimal development across the life course (Box 10.3.1). These include policies and programmes that aim to address poverty, food insecurity, illiteracy, gender inequality, poor infrastructure, unsafe home and community environments, suboptimal caregiving practices, and barriers to health service access. When specifically tailored and targeted with marginalized populations in mind, these actions have high potential to impact child health at the population level and should be the foundation of national strategies for improving child health and well-being across the life course.

Box 10.3.1 Key cross-cutting actions, programmes, and policies supporting child health, and health throughout the life course

- Poverty alleviation and cash transfer programmes
- Social protection services and safety nets
- Health insurance schemes
- Infrastructure and education for improved water, sanitation, and hygiene
- Improving living conditions and housing quality
- Reducing indoor and outdoor air pollution and exposure to toxins (e.g. lead, arsenic, aflatoxin)
- Food fortification with micronutrients
- Agricultural policies supporting food security
- Education and empowerment for women and girls
- Improved access and quality of health services
- Improved access to parenting programmes and comprehensive early child development services
- Universal primary education

Recognizing the rights of the child

Efforts to ensure effective accountability for children's health are further enhanced by the recognition that availability of and access to health information and services for children and their caregivers are basic human rights. Recognition of need for legal entitlements of every child, regardless of his/her status or situation, elevates associated responsibilities and political commitments to legal obligations. This paradigm shift thus enables the

establishment of not merely a normative but indeed legal foundation for addressing the health needs of children.

The UN Convention on the Rights of the Child (CRC), adopted in 1989 and ratified by all but two UN Member States, is the principal legal instrument for the protection of children's well-being, and outlines the core obligations of States in relation to children's health. Article 24 directly addresses the child's right to health and healthcare, while other provisions refer to the many underlying determinants of children's health. The CRC thus provides a valuable holistic blueprint of all essential needs and legal entitlements of children needed to ensure their survival, health, and optimal development.

Governance

Supportive laws and policies are prerequisites for strengthening the health sector's capacity to provide quality healthcare to a population. Governance in the context of a functional health system involves developing strategic policy frameworks, regulation, and system design and accountability. Examples of evidence-based policies that play a role in child health and that are currently being promoted in countries to tackle the burden of ill health and excess mortality are (WHO 2012b):

Maternity protection in accordance with the International Labour Organization Convention 183.
Policy on midwives authorized to administer a core set of life-saving interventions.
Policy on postnatal home visits in the first week of life.
The International Code of Marketing of Breast-milk Substitutes.
Policy on community treatment of pneumonia with antibiotics.
Policy on low osmolarity oral rehydration salts and zinc supplementation.
Policy on rotavirus and pneumococcal vaccines.

In order to facilitate the effective implementation of these policies in countries, advocacy and policy dialogue with a wide range of stakeholders is needed. Both public funding of healthcare and the quality of governance matter for the reduction of childhood mortality but remain inadequately monitored and evaluated. Some policies gain wide adherence rapidly while others lag behind. For example, among the 75 countries with the highest

burden of maternal and child mortality, the number of those with a policy allowing community health workers (CHWs) to treat pneumonia has more than doubled from 18 to 38 between 2008 and 2012. CHWs with appropriate training and supervision, and access to essential drugs and supplies have contributed significantly to improved pneumonia treatment (Kalyango et al. 2013). In contrast, by 2017 less than a third of the 81 Countdown countries had fully adopted the legislation on International Code of Marketing of Breast-milk Substitutes, which was endorsed in 1981 with consensus by the member states of the WHO.

Key child health issues, critical periods, and age-specific health sector interventions for prevention and management

Children living in resource-poor environments require protective interventions to prevent the major causes of mortality and morbidity summarized in prior sections. There are two main types of interventions: first, health promotion for morbidity reduction and prevention of specific disease conditions; second, case management interventions to treat disease, help reduce illness severity, and improve child health and survival. Key interventions are reviewed in the following text for each of the major causes of child mortality and morbidity, and summarized in Table 10.3.2

Table 10.3.2 Summary of key interventions to address risk factors for the major causes of child mortality, morbidity, and suboptimal growth and development

Important causes of child mortality and morbidity	Preventive interventions	Case management interventions
Maternal and Newborn (<1 Month)		
Newborn conditions: • Preterm birth • Perinatal asphyxia • Neonatal sepsis • Low birth weight • Congenital conditions	*Preconception:* • Maternal iron-folic acid or multiple micronutrient supplementation • Nutritional supplementation with balanced protein-energy in mothers at risk for undernutrition • Counselling on cessation of smoking, alcohol, and other substances • Delaying age at first pregnancy, and promoting optimal birth spacing *Antenatal care:* • Routine antenatal care visits • Maternal vaccination • Intermittent preventive treatment of malaria in pregnancy (IPTp) • Infectious disease screening and treatment • Prevention of Rhesus disease *Labour and childbirth care:* • Skilled care during labour and birth • Care at the time of birth: warmth, delayed cord clamping, hygienic cord care, and early initiation of breastfeeding *Postnatal care:* • Care during the first days and weeks after birth: exclusive breastfeeding, warmth, hygienic skin and cord care, vaccination, and prompt care-seeking for illness	• Detection and management of hypertension, diabetes, and foetal growth restriction during pregnancy • Tocolytics and antenatal corticosteroids for preterm labour (in appropriate populations) • Antibiotics for preterm premature rupture of membranes • Detection and management of maternal group B streptococcus (GBS), helminthic, malaria, tuberculosis, and HIV infections • Kangaroo Mother Care, and additional care of preterm and low birthweight infants (addressing feeding, warmth, and breathing problems) • Caesarean section or assisted vaginal delivery in case of foetal distress • Resuscitation if unable to breathe after birth • Diagnosis and treatment of neonatal sepsis and local infections
Infancy (<1 Year) and Early Childhood (1–5 Years)		

Important causes of child mortality and morbidity	Preventive interventions	Case management interventions
Pneumonia	• Immunization against *Pneumococcus*, *Haemophilus influenzae*, pertussis, diphtheria, and measles • Exclusive breastfeeding up to 6 months; continued breastfeeding with safe and appropriate complementary feeding at least up to 2 years • Reduction in environmental risk factors—e.g. indoor air pollution, overcrowding	• Treatment of pneumonia with amoxicillin • Treatment of severe pneumonia with parenteral antibiotics, oxygen, and other supportive treatment
Diarrhoea and enteric infections	• Early and exclusive breastfeeding up to 6 months; continued breastfeeding with safe and appropriate complementary feeding at least up to 2 years • Preventive vitamin A and zinc supplementation • Immunization against measles, rotavirus, cholera, and typhoid • Improved water and sanitation; hand washing with soap	• Oral rehydration therapy to prevent dehydration • Zinc treatment for 10–14 days during diarrhoea • Antibiotics for dysentery and typhoid
Malaria	• Vector control • Use of long-lasting insecticide-treated bed nets • Intermittent preventive treatment in infants (IPTi)	• Treatment of non-severe malaria with oral antimalarial drugs recommended for the area • Treatment of severe malaria with parenteral antimalarial drugs

Important causes of child mortality and morbidity	Preventive interventions	Case management interventions
HIV/AIDS	• Primary prevention of HIV and of unintended pregnancies in HIV-infected women • Antiretrovirals (ARVs)—treatment of pregnant women when indicated, prophylaxis for others for the prevention of mother-to-child transmission of HIV • Exclusive breastfeeding with ARVs or replacement feeding for HIV-positive mothers • Co-trimoxazole prophylaxis for HIV-exposed and HIV-infected children	• Antiretroviral therapy (ART) for children who are eligible for it
Malnutrition	• Early initiation of breastfeeding within 1 hour of birth • Exclusive breastfeeding up to 6 months of age • Continued breastfeeding with safe and appropriate complementary foods for at least 2 years • Preventing vitamin A, iron, iodine, and zinc deficiency through supplementation, food fortification, and dietary diversification • Community-based screening for severe acute malnutrition using mid-upper arm circumference (MUAC) measurements, and growth monitoring and promotion strategies	• Community-based management of children with severe malnutrition without complications • Hospital management of severely malnourished children with complications
School Age (5–10 Years)		
Overweight and obesity	• Education on healthy eating habits • Promotion of physical activity • Improving the local food environment	• Anthropometric screening, management, and treatment of comorbidities

Important causes of child mortality and morbidity	Preventive interventions	Case management interventions
Non-communicable diseases Sickle cell disease Asthma Rheumatic heart disease Epilepsy	• Improving air quality • Prompt detection and treatment of streptococcal pharyngitis and rheumatic fever	• Treatment of sickle cell disease with hydroxyurea • Screening, ongoing treatment, and supportive care for congenital and chronic conditions
Communicable diseases	• Vaccination for HPV and tetanus • Vaccination for typhoid, cholera, dengue where indicated • Catch-up on missed routine vaccines • Improved water and sanitation; hand washing with soap • Prevention of other infectious diseases from early childhood described earlier	• Deworming • Detection and case management of other invasive infections from early childhood described earlier
Unintentional injuries Drowning Road injuries Burns	• Swimming lessons • Helmet use • Improved cookstoves	• Emergency ambulance services • Trauma care

Maternal and newborn care interventions

Although neonatal mortality rates have reduced by 51% between 1990 and 2017, accelerated efforts are still needed to achieve Sustainable Development Goal targets for 2030 (Hug et al. 2019). Improved coverage and quality care along the continuum from pregnancy, childbirth, and the newborn period, into childhood and adolescence are critical for optimizing newborn health and survival. Such goals must focus on the most effective evidence-based interventions and intentional investment and implementation, which has so far been insufficient. Newborn health

interventions can be classified into those relevant for all mothers and newborns, and those relevant for those newborns with conditions that require additional care (Table 10.3.2).

Routine care for mothers and newborns

Improving newborn health and survival necessitates addressing social determinants, the education and empowerment of women in society, and especially the health and well-being of girls. This includes education and nutrition, prevention of harmful practices such as female genital mutilation, delaying age at first pregnancy, prevention and treatment of sexually transmitted infections, enhancement of pre-pregnancy nutrition status and optimization of interpregnancy intervals. Routine care during pregnancy holds particular importance for newborn survival and well-being. Evidence-based interventions for newborn health (Bhutta et al. 2014) provided during antenatal care include maternal vaccination (*Haemophilus influenzae* type b, influenza, pneumococcal), infection prevention, screening, and treatment, prevention of Rhesus disease, and maternal nutrition enrichment in populations with inadequate dietary intakes.

Antenatal care provides the platform for continued care during and after childbirth by planning for skilled birth attendance, preparing for any unforeseen complications, and by helping the family prepare for immediate newborn care practices, such as early initiation of exclusive breastfeeding.

The presence of skilled birth attendants and the provision of immediate obstetric care represent the cornerstone of modern obstetrics. A Delphi process involving expert consultation suggested that basic emergency obstetric care could reduce neonatal deaths during the intrapartum period by 40% and comprehensive emergency obstetric care could do so by 40% (Lee et al. 2011).

Skilled childbirth care in first-level health facilities, with the backup of a hospital that can manage complications, should be available and accessible to expectant mothers 24 hours a day, every day, as the complications that may occur cannot be predicted and may very rapidly become fatal. It is crucial to have access to a skilled attendant and a companion who can stay with the mother and child for the first 12–24 hours to ensure a successful home birth. Knowledge and recognition of maternal and newborn danger signs is crucial for women and families who cannot access a skilled

attendant, and a plan needs to be in place for a clean delivery and early care-seeking.

Vaccines are highly effective and cost-effective prevention tools for the prevention of morbidity and mortality in early life. Given their proven benefits, availability and accessibility of routine neonatal vaccines should be a public health priority. Several key vaccines are mentioned in Table 10.3.2.

Care for newborns at the time of birth and during the period that follows includes several relatively simple and effective interventions that do not require advanced technology (Table 10.3.2). The most critical time to deliver these interventions is immediately after birth and in the first 24 hours of life as a large proportion of maternal and neonatal mortality is reported during this window. Hence, at least one additional contact with a health provider within the first week, is required.

Care of at-risk and sick newborns

Fifteen million premature babies are born every year of which nearly 1 million die due to complications of preterm birth. About 75% of these deaths could be prevented if current cost-effective measures are made available to all (Liu et al. 2016). Such key interventions include tocolytics to delay birth, antibiotics for preterm premature rupture of membranes, and corticosteroids given to eligible mothers during preterm labour to promote lung maturation of the baby. Additional care of preterm and LBW infants is critical for improving newborn survival. Basic newborn care packages should involve identification of LBW infants within the first hours after birth. In settings where measuring birth weight is not feasible, such as for home births, all newborns perceived to be ‘small’ should receive additional care, much of which can be provided at home and in first-level health facilities. However, care for babies weighing less than 1,500 g, who have difficulty feeding or breathing due to lung immaturity, is best provided in a hospital.

In addition to basic newborn care, LBW infants need more attention, including immediate drying, adequate nutrition, provision of warmth, hygiene, early detection and management of infections, vitamin K administration, and growth monitoring. Kangaroo mother care or skin-to-skin contact is supported by strong evidence to reduce mortality and improve breastfeeding. Mothers who are unable to breastfeed directly should be taught to express breast milk and to feed from a cup.

Perinatal asphyxia is responsible for 10% of all under-5 deaths. Monitoring of progress and feto-maternal well-being in labour using a partograph has been proven to help reduce morbidity and mortality due to perinatal asphyxia. When foetal distress is suspected, assisted vaginal or Caesarean birth may be needed, which requires functional referral mechanisms. The second key intervention for prevention of asphyxia-related mortality and morbidity is neonatal resuscitation. All birth attendants should be skilled and equipped to perform neonatal resuscitation, which can include positive pressure ventilation, use of endotracheal intubation and laryngeal mark, in addition to thorough drying and stimulation.

The timely detection and optimum treatment of suspected neonatal bacterial infections, such as pneumonia and sepsis can substantially reduce neonatal mortality. It is therefore important to have community- and health-facility-based activities which focus on screening and management. Newborns with severe infections should receive parenteral antibiotics, along with intravenous fluids or alternative feeding methods and other supportive therapy such as oxygen in a hospital. Although the evidence for the use of injectable and muscular antibiotics in community settings has shown significant reductions in mortality in the infected newborns, implementation at scale has been scarce.

Care during Infancy and early childhood

The first 5 years of life is a critical period of rapid growth and development when children are particularly sensitive to adversity. The focus during this period is on supporting optimal nutrition, minimizing the burden of infectious diseases, and providing a nurturing, responsive, stimulating environment to optimize growth and development.

Malnutrition

The World Health Assembly (WHA) has declared 2016–25 as the ‘decade of nutrition’ and the Sustainable Development Goal (SDG) 2 aspires to end hunger, achieve food security, and eliminate all forms of malnutrition by 2030. Interventions to prevent malnutrition include promotion of optimal feeding of infants and young children, prevention and treatment of illness, and amelioration of micronutrient deficiencies in the diet. Early initiation of

breastfeeding, exclusive breastfeeding up to 6 months of age, and continued breastfeeding along with complementary foods up to at least 2 years of age are key interventions to combat undernutrition. Early initiation of breastfeeding, ideally within the first hour after birth, is associated with a reduced risk of neonatal mortality (Khan et al. 2014) and exclusive breastfeeding during the first 6 months of life is associated with a significantly lower risk of all-cause and infection-related mortality compared to those who were predominantly, partially, or not breastfed (Sankar et al. 2015). Safe and appropriate complementary feeding started at 6 months of age can reduce the prevalence of malnutrition and contribute to reduced mortality. Promotion of safe and appropriate complementary feeding has been shown to significantly improve weight-for-age and height-for-age scores (Lassi et al. 2013).

Prevention and management of acute malnutrition

Malnutrition, as a term, covers both being undernourished or overweight. Acute malnutrition is characterized by an acute loss of weight as a result of inadequate food intake or disease. However, there are many underlying and basic causes that contribute to the development of undernutrition. Several social factors such as decreased access to care, poor living conditions, inadequate care and feeding practices, and household food insecurity exacerbate this issue. In low-resource settings, children experiencing wasting are particularly vulnerable to infections, such as diarrhoea, pneumonia, and malaria, which can worsen malnutrition and further increase risk of disease, creating a vicious cycle of deteriorating health. The risk of mortality in acutely malnourished children is elevated, and nutrition-related factors directly or indirectly contribute to 45% of deaths in children under 5 years of age (Black et al. 2013).

To improve the nutritional status of children and prevent them from becoming severely malnourished, the dietary management of moderate acute malnutrition (MAM) (weight-for-height between –3 and –2 SD of the median of the WHO Child Growth Standards or 11.5 cm $\leq$ mid-upper-arm circumference [MUAC] < 12.5 cm) should be based on optimal use of locally available nutrient-dense foods. Inadequate nutrient content of habitual diets can be augmented through a number of approaches, including dietary diversification and fortification of certain staple foods with vitamins

and minerals. Supplementary feeding in children with MAM should be complemented with essential nutrition actions such as breastfeeding, nutrition counselling, and addressing the underlying social determinants of undernutrition.

Severe acute malnutrition (SAM) in children 6–59 months of age is defined as weight-for-height criterion less than −3 SD below median WHO Growth Standards, or MUAC less than 11.5 cm, or the presence of bilateral oedema. For infants less than 6 months, there is no agreed cut-off value for MUAC. Children with SAM should be clinically assessed for presence of medical complications and for their appetite. Children who pass the WHO-defined appetite test and are clinically well and alert are treated as outpatients while those with medical complications, danger signs, or who fail the appetite test should be treated as inpatients. Young infants less than 6 months with SAM are always treated as inpatient. Outpatient management involves providing the child with therapeutic feeding, micronutrient supplementation, antibiotics, and regular monitoring.

Inpatient management is generally organized in two phases: the stabilization phase (usually 3–7 days) includes careful evaluation and management of hypoglycaemia, hypothermia, dehydration, infections, electrolyte imbalance, and feeding initiation; and the rehabilitation phase (usually 4–6 weeks) which consists of the provision of nutritional and psychosocial support to achieve full nutritional recovery. Therapeutic feeding should start early in the stabilization phase and include giving a low-protein milk-based formula diet with additional vitamins and minerals such as the WHO-recommended F-75 (75 kcal/100 mL). In the rehabilitation phase, a milk formula with higher protein and energy content such as F-100 should be given and additional iron is needed to address deficiencies. Ready-to-use therapeutic foods (RUTFs) have replaced liquid F-100 in a variety of settings because they do not contain free water and can therefore be used without risk of bacterial contamination. Most RUTFs are lipid-based pastes combining milk powder, electrolytes, and micronutrients to meet recommended nutritional values and offer the malnourished child the same nutrient intake as F-100. RUTFs also contain 10–14 mg/100 g of iron, therefore no additional intake of iron is necessary.

In combination with community-based screening, RUTFs are highly effective in the treatment of SAM in children 6–59 months of age without complications (WHO 2013c). These children can be managed in the

community without the risks of nosocomial infections or any other disruptions regarding hospital care to the family. Often ignored is the sensory stimulation component of management where it is recommended that children with SAM be provided with structured play therapy and tender loving care in the rehabilitation phase.

In children less than 6 months of age who have SAM, care should focus on managing sepsis and other underlying complications and on re-establishing breastfeeding where this has been ineffective.

Prevention and management of chronic malnutrition

Chronic malnutrition in children is a global public health concern that is strongly linked to poverty. The process of nutritionally associated linear growth faltering begins *in utero* in the presence of maternal malnutrition, contributing to intrauterine growth restriction and low birthweight. During infancy, chronically suboptimal feeding practices, deficits in macronutrient and micronutrient intake, and a high burden of infectious diseases contribute to poor growth. A high prevalence of linear growth stunting within a population of children is a visible and easily measurable indicator of widespread chronic malnutrition. Children who experience this growth delay also suffer both higher mortality and suboptimal cognitive and motor development. Chronically malnourished children are at substantially higher risk of dying from common childhood infections such as diarrhoea, pneumonia, and malaria. Nutrition-related factors directly or indirectly contribute to 45% of deaths in children under 5 years of age, with an estimated 17% of mortality in children under 5 years attributable to stunting (Black et al. 2013).

The exact causes of stunting within a population are multifactorial, and still not well-understood. As such, a broad spectrum of interventions to prevent and address both undernutrition and high infectious disease burden is necessary to minimize the risk of growth faltering. This includes the promotion of optimal infant and young child breastfeeding and complementary feeding practices described earlier, ensuring adequate micronutrient intake in those at risk of deficiency, and high coverage of the infection prevention strategies described in the following sections.

Analyses of cohort data have shown that every unit increase in height-for-age z-score in children ≤2 years was associated with a 0.22 SD improvement

in measures of cognitive function at 5 to 11 years (Sudfeld et al. 2015), demonstrating the lingering effects chronic malnutrition in young children. This has serious implications not only for population health in countries with a high burden of chronic childhood malnutrition, but also for the fulfilment of their intellectual and economic potential. Countries that prioritize the implementation and scale-up of nutrition-sensitive and nutrition-specific policies and programmes stand to make the greatest improvements in human capital development and economic productivity, as these actions generally have very high benefit-cost ratios (Hoddinott et al. 2013).

Micronutrient deficiencies and hidden hunger

Sometimes described as 'hidden hunger', common micronutrient deficiencies such as those of vitamin A, iron, iodine, and zinc, both at clinical and subclinical levels, contribute to illness, suboptimal growth and development, and mortality in children. Strategies to prevent these deficiencies include supplementation (WHO 2011a, 2011b, 2016c), point-of-use fortification (WHO 2016d), mass food fortification of staple foods (WHO 2016e, 2018c), and dietary diversification (Pan American Health Organization and WHO 2003; WHO 2005b). See Table 10.3.3 for a summary of nutrition-specific and nutrition-sensitive interventions for the prevention and treatment of micronutrient deficiency in mothers and children, as recommended in the 2013 *Lancet Series on Maternal and Child Nutrition* (Bhutta et al. 2013; Ruel et al. 2013).

Table 10.3.3 Summary of interventions to prevent and treat micronutrient deficiencies in mothers and children.

Individual level	Population level
• Education and support for optimal infant and child breastfeeding and complementary feeding practices • Promotion of dietary diversification • Point-of-use fortification of complementary foods (e.g. micronutrient Sprinkles) • Single micronutrient supplementation (e.g. vitamin A capsules) • Multiple micronutrient supplementation (MMN) • Balanced energy protein supplementation (BEP) • Lipid-based nutrient supplements (LNS) • Delayed cord clamping • Deworming • Improved water, sanitation, and hygiene	• National nutrition-sensitive policies and programmes • Mass food fortification with micronutrients (e.g. salt iodization) • Biofortification • Cash transfer programmes • Social safety nets

Acute respiratory infections

Acute respiratory infections (ARIs), particularly pneumonia, are the second-leading cause of under-5 mortality, causing 16% of all child deaths worldwide. However, in children beyond the neonatal period, pneumonia continues to be the leading killer, responsible for nearly 13% of these deaths (Liu et al. 2016). Half of all childhood pneumonia deaths are attributable to *Pneumococcus* and *Haemophilus influenzae* type b (Hib). Other common causative organisms include viruses, most prominently respiratory syncytial virus, in addition to bacterial infections with *Staphylococcus aureus* and *Klebsiella pneumoniae*. *Pneumocystis jirovecii* is a significant cause in areas with high HIV burden. Interventions to control ARIs can be divided into preventive interventions such as immunization against specific pathogens, improvements in nutrition, reduction in household air pollution, and case management interventions.

Widespread use of vaccines against *Pneumococcus*, *Haemophilus influenzae*, pertussis, diphtheria, influenza, and measles has the potential to substantially reduce the incidence of ARIs in children in LMICs. Two particularly important vaccines are those against *Pneumococcus* and Hib pathogens, as they account for the largest burden of disease. *Pneumococcus*

and Hib were estimated to cause more than 300,000 and 30,000 under-5 deaths, respectively, in 2015 (Wahl et al. 2018).

Two types of pneumococcal vaccines are currently being used internationally: a polysaccharide vaccine effective against 23 different strains of *Pneumococcus* (primarily recommended for adults) and different formulations of polysaccharide-protein conjugate vaccine (PCV), of which WHO recommends the use of the 10- and 13-valent types (PCV10 and PCV13, respectively), for all infants. The serotypes included in these vaccines account for the majority of serious pneumococcal disease in children worldwide. PCVs are increasingly available in low-income, high-mortality countries, but gaps in vaccine uptake within countries could reduce their impact. A total of 141 countries have included the vaccine in their national immunization programmes; these include 7 of the 10 countries with the highest burden of pneumococcal disease.

The use of Hib conjugate vaccines in developed countries has resulted in the virtual elimination of invasive Hib disease (meningitis and bacteraemic pneumonia) because of immunity in vaccinated children and a herd effect in those not vaccinated. There are several Hib conjugate vaccines available, all of which are effective when given in early infancy and have virtually no side effects. The success of these vaccines is seen in most low-income countries which have introduced Hib vaccines. Recent research has estimated that the use of PCV has prevented 250,000 pneumococcal deaths from 2000 to 2015 (90% of these after 2010), while Hib vaccine prevented 1.2 million deaths in the same period (Wahl et al. 2018).

Vaccination should be seen as complementary to other strategies for pneumonia control, such as improved care-seeking and case management, better nutrition (including exclusive breastfeeding for the first 6 months of life), hand washing promotion, and measures to reduce indoor air pollution. Many studies have shown that young children exposed to smoke from the use of household biomass fuel had twice the risk of developing acute lower respiratory infection than unexposed children. A systematic review on household air pollution control strategies for child survival concluded that reducing exposure could reduce the risk of fatal pneumonia, especially if WHO guidelines are followed (Bruce et al. 2013).

Diagnosis and clinical guidelines for ARI case management rely on two simple clinical signs: fast breathing and lower chest wall indrawing. Chest indrawing is the inward movement of the lower chest wall when a child

breathes in. As per the revised WHO classification, children 2–59 months, with cough and/or difficult breathing plus fast breathing and/or chest indrawing are now classified as non-severe pneumonia that can be treated at home with oral amoxicillin (WHO 2014a). Severe pneumonia can be recognized by the presence of one or more danger signs (such as central cyanosis, severe respiratory distress, inability to drink, lethargy, or convulsions), and such cases must be managed in a hospital with parenteral antibiotics and supportive care including oxygen therapy. The updated guidelines to manage 'chest indrawing' pneumonia (previously labelled 'severe pneumonia') at home is significant, especially in settings when referral is difficult and also in reducing the use of unnecessary parenteral antibiotics. The role of CHWs in identifying and treating non-severe pneumonia is critical, especially in low-resource settings with poor access to facilities (Bhutta et al. 2013).

Diarrhoea

Diarrhoea remains one of the leading causes of under-5 child mortality in LMICs that lack sufficient resources and a strong infrastructure. Strategies for the control of diarrhoeal diseases have remained substantially unchanged since the early 1980s. A package of proven prevention and treatment measures is available that, if taken to scale, will lead to a significant reduction in the morbidity of diarrhoeal disease. It consists of a seven-point plan for diarrhoea control and includes promotion of early and exclusive breastfeeding, vitamin A supplementation, rotavirus and measles vaccinations, promotion of hand washing with soap and improved water supply quantity and quality, community-wide sanitation promotion, fluid replacement to prevent dehydration, and zinc treatment (UNICEF and WHO 2009). The package should be implemented as part of a concerted process alongside targeted and integrated behaviour change strategies which aim improve uptake by families and communities.

Exclusive breastfeeding for the first 6 months of life reduces the risk of infection-related neonatal mortality when compared to partial or no breastfeeding (Gülmezoglu et al. 2016). Components of breast milk such as antibodies, hormones, and growth factors provide optimal protection to the growing child. It is recommended that appropriate complementary feeding be introduced at 6 months of age alongside continued breastfeeding until at

least 24 months. This improves the nutritional status of infants and young children, optimizing physical and cognitive development and immune function.

Rotavirus is the leading cause of diarrhoea mortality among children younger than 5 years. It is estimated that introduction of the rotavirus vaccine was responsible for a 2.6% decrease in diarrhoea-related mortality in children younger than 5 years between 2000 and 2016 (Troeger et al. 2018). The international market has two rotavirus vaccines: the monovalent (RV1) and the pentavalent (RV5), which show 80 to 90% efficacy against severe infection in countries with very low or low mortality, and 40 to 60% efficacy in countries with high mortality in children and high or very high mortality in adults. WHO recommends the first dose of rotavirus vaccine be administered as soon as possible after 6 weeks of age, along with diphtheria-tetanus-pertussis (DTP) vaccine. RV1 and RV5 are administered in 2 dose and 3 dose schedules respectively, with 4 weeks each between the doses (WHO 2013a, b).

An estimated 800,000 children die each year from preventable diseases caused by lack of quality water, sanitation, and proper hygiene (Mills and Cumming 2016). Human faeces are the primary source of diarrhoeal pathogens. Water filtration and disinfection, and hand hygiene can significantly reduce diarrheal disease risk (Darvesh et al. 2017). However, behaviour change components are complex and often difficult to sustain. Poor-quality and quantity of water, sanitation, and hygiene (WASH) and related measures can hinder linear growth in children under 5 years of age (Dangour et al. 2013). Thus, resources should also be directed towards extending and sustaining water, sanitation, and hygiene services at the community level. SDG 6 includes targets for universal access to drinking water, sanitation, and hygiene.

Most diarrhoea-related deaths are due to dehydration, and dysentery (bloody diarrhoea) and electrolyte imbalance in severe cases. Management of diarrhoea includes:

Oral rehydration salts (ORS) solution administration to replenish fluid loss, or an intravenous electrolyte solution in cases of severe dehydration.
Mothers and health workers should supplement children with 20 mg per day of zinc for 10 to 14 days (10 mg per day for children under the age of 6 months).
Continuing or increasing breastfeeding during, and increasing feeding after, the diarrhoeal episode.
Using antibiotics only during episodes of bloody diarrhoea.

The use of oral rehydration solution has shown to reduce diarrhoea-specific mortality by 93% (Munos et al. 2010). Two noteworthy advances in the management of acute diarrhoea are: zinc supplementation, and newly formulated ORS containing lower concentrations of glucose and salts. Over the years, ORS formulation therapy has proven safe and effective in the prevention and treatment of dehydration. However, acceptance of standard ORS by mothers and health workers has been suboptimal because watery stools persist, and the duration of diarrhoea is not reduced. Efforts over the past decades have led to the development of a new ORS formulation with reduced osmolarity (low sodium and glucose). This new formulation reduces stool output, vomiting, and the need for any intravenous therapy. The new ORS is safe and effective in both non-cholera diarrhoea and cholera in children and adults. WHO and UNICEF now recommend the use of ORS containing 75 mEq of sodium and 75 mmol of glucose per litre (total osmolarity of 245 milliosmol per litre) everywhere (WHO 2005a). In addition to fluid replacement, optimal nutrition status can enhance fluid absorption and strengthen immune function.

A recent review of relevant clinical trials from areas with prevalent zinc deficiency showed benefit of zinc supplementation in children aged 6 months or more by reducing the duration of diarrhoea (Lazzerini and Wanzira 2016). Moreover, studies from India show that supplementing zinc in the management of acute diarrhoea can reduce the rate of hospital admissions for diarrhoeal disease (Mazumder et al. 2010). The addition of zinc to ORS in the treatment of diarrhoea has also increased the compliance of ORS and has reduced unwarranted use of prescription drugs of unknown identity and antibiotics (Bhandari et al. 2008).

Dysentery is an inflammatory disorder of the lower intestinal tract with a clinical picture of abdominal cramping, fever, and severe diarrhoea, often accompanied by the passage of bloody and mucoid stools. *Shigella* is the

leading and most severe cause of bloody diarrhoea. The primary treatment for shigellosis is the use of antibiotics, which can decrease dysentery-related mortality by more than 99% (Traa et al. 2010).

Antibiotic resistance is an emerging challenge in the management of shigellosis, and with ciprofloxacin-resistant strains already emerging, this increases the urgency for the development of a *Shigella* vaccine. Ciprofloxacin is the current treatment drug of choice due to its effectiveness, safety, ease of oral administration, short course, and low cost. For severe cholera cases, WHO recommends the use of oral antibiotics to which strains of *Vibrio cholerae* in the area are known to be sensitive; possible choices include tetracycline, erythromycin, doxycycline, co-trimoxazole, and chloramphenicol. Antibiotic treatment of cholera has shown a 63% reduction in rates of clinical failure and a 75% reduction in rates of bacteriological failure (Das et al. 2013).

Enteric infections and neglected tropical diseases

Neglected tropical diseases (NTDs) are a group of bacterial, parasitic, and viral infections highly endemic to the poorest regions of the world, where NTDs caused over 500,000 deaths per year (Naghavi et al. 2017). Several conditions disproportionately affect children compared to adults, who are often infected with multiple pathogens. Some of these infections are chronic, and contribute to substantial and prolonged illness and disability.

The WHO recognizes 17 core NTDs: rabies, trachoma, dengue, Chagas disease, Buruli ulcer, endemic treponematoses, human African trypanosomiasis (HAT), leprosy, echinococcosis, leishmaniasis, taeniasis/cysticercosis, dracunculiasis, trematodiases, lymphatic filariasis, schistosomiasis, onchocerciasis, and soil-transmitted helminthiases. From a programmatic point of view, WHO classifies NTDs into two groups: preventive chemotherapy and transmission control (PCT) NTDs, and innovative and intensified disease management (IDM) NTDs. The most prominent examples of PCT group NTDs are lymphatic filariasis, onchocerciasis, schistosomiasis, and soil-transmitted helminthiasis; they are mainly controlled by the administration of drugs to entire at-risk populations. IDM focuses on NTDs that lack appropriate tools for large-scale use. These include Buruli ulcer, Chagas disease, HAT, and leishmaniasis. Climate change is contributing to the intensifying spread of

many vector-borne infections, including malaria, dengue fever, Chagas disease, leishmaniasis, onchocerciasis to name a few (Mitra and Mawson 2017).

Disease control strategies, in line with WHO's 5 general strategies may involve: (i) prevention, including combined and concurrent preventive chemotherapy; (ii) improved access to clean water and sanitation; and (iii) control of insect vectors by use of environmentally safe insecticides, treated bed nets, and other personal protective measures, vegetation clearance, and improved sanitation to disrupt breeding sites (Mackey et al. 2014).

Food-borne enteric infections are also major causes of morbidity and mortality in LMICs, with outbreaks of *Salmonella*, *Escherichia coli*, and spongiform encephalitis occurring due to suboptimal sanitation, hygiene, and food processing practices. Typhoid and paratyphoid fevers are caused by infection with *Salmonella typhi* and *paratyphi*, respectively. After malaria and diarrhoea, typhoid fever is the most common cause of death in older children. An estimated 14.3 million cases of typhoid and paratyphoid fevers occurred globally in 2017, with 12.6% of cases reported among children younger than 5 years, and 55.9% among children less than 15 years. The highest mortality rates were reported in South Asia, accounting for 69.6% of worldwide mortality from typhoidal illness in 2017 (Stanaway et al. 2019). Antibiotics such as cephalosporins and azithromycin are primarily used in the affected regions. In December 2017, WHO endorsed the first conjugate vaccine for typhoid. This new vaccine has longer-lasting immunity than older vaccines, requires fewer doses and can be given to younger children. Provision of safe water and adequate sanitation, good hygiene among food handlers, and vaccination are all effective in preventing typhoid fever.

E. coli are normal inhabitants of the human intestine. Virulent strains are responsible for diarrhoea, neonatal meningitis, sepsis, and urinary tract infections. Transmission occurs via contaminated food and water or direct contact with an infected individual. Outbreaks have been associated with ground beef, exposure to animals in public settings, and contamination of water in recreational areas. Children who are suspected of having a systemic infection with *E. coli* should receive intravenous antibiotic therapy after diagnostic culture of the organism. Aminoglycoside or a third-generation cephalosporin is recommended as the empirical therapy. Preventive measures for *E. coli* infections involves hand hygiene, food safety, and contact isolation of infected individuals.

Dengue virus is estimated to infect 50 to 100 million people worldwide and is a significant cause of childhood morbidity and mortality (WHO 2013d). It is endemic to more than 125 countries across all WHO regions (excluding Europe) and has increased in incidence about 30-fold in the past 50 years. The factors that facilitate local outbreaks are shared with other NTDs, and include a lack of vector control, rapid urbanization, climate change, global travel to endemic regions, and social infrastructure weaknesses. Its arthropod vector is the *Aedes aegypti* mosquito. Public health interventions for dengue focus on vector and environmental management. Complications can lead to dengue haemorrhagic fever (DHF), which in some severe cases, such as in those who suffer from dengue shock syndrome (DSS), can be fatal.

Soil-transmitted helminths (STH) are a group of worms transmitted through soil contaminated with infected human faeces. Of particular importance are the hookworm *Necator americanus*, the roundworm *Ascaris lumbricoides*, and the whipworm *Trichuris trichiura*. Most STH infections result from ingestion of contaminated soil or through skin penetration. Endemic to tropical regions worldwide, STH infections are particularly burdensome in poorer areas of Asia, Africa, and Latin America, with most cases occurring among the extreme poor living in some of the large LMICs of Asia, such as India, Bangladesh, China, and Indonesia. Children usually suffer from *Ascaris* and *Trichuris* infections, whereas hookworms can be seen among both children and adults. In sub-Saharan Africa, an estimated 50 million children are infected with hookworm alone, and in Southeast Asia nearly 120 million preschool and school-age children require treatment for STH infections (Hotez et al. 2015). The predisposing factors include poor personal hygiene and sanitation, poverty, and overcrowding. Infections can result in anaemia, growth retardation, and impaired cognitive development, and are also responsible for school absenteeism and a substantial burden of disability-adjusted life years (Vandemark et al. 2010). A recent study reported deficits in children's cognitive development as a result of untreated STH infections (Pabalan et al. 2018). According to the WHO, administration of drugs like albendazole and mebendazole, education, and adequate sanitation are required for STH infection management.

Schistosomiasis is caused by schistosomes that penetrate the skin of those that have frequent contact with contaminated water bodies, which are often children and adolescents. More than 90% of schistosomiasis cases occur in

Africa alone. *Schistosoma* infection and non-treatment is significantly associated with educational, learning, and memory deficits (Ezeamama et al. 2018).

Malaria

Malaria accounts for 5% of child deaths worldwide. More than 300,000 children under 5 (1–59 months) were killed by malaria in 2015 (Liu et al. 2016), accounting for nearly two-thirds of all malaria deaths. The African region bears 90% of the global malaria burden, however from 2000 to 2015 the leading cause of under-5 mortality in sub-Saharan Africa shifted from malaria to pneumonia. Chapter 8.15 describes malaria interventions in greater detail.

Owing to effective preventive measures, the global malaria death rate has decreased by 60% since 2000. Vector control remains the most effective measure to prevent malaria transmission in all ages. Insecticide-treated bed nets (ITNs), and more specifically long-lasting insecticidal bed nets (LLINs), are particularly effective in reducing uncomplicated malaria incidence and parasite infection prevalence in pregnant women and young children. The WHO's Global Technical Strategy for Malaria 2016–2030 aims for universal coverage with effective vector control using LLINs or indoor residual spraying (IRS) of all households at risk for malaria (WHO 2015).

Prompt parasitological confirmation by microscopy or alternatively by rapid diagnostic tests in all patients suspected of malaria should happen prior to treatment. Treatment solely on the basis of clinical suspicion should only be considered when a parasitological diagnosis is inaccessible. Once diagnosed, the child should be treated early with a safe and effective antimalarial medicine as delaying treatment could result in progression to severe disease, which is associated with a high case-fatality rate.

Malaria case management has been greatly affected by the emergence and spread of chloroquine and sulfadoxine/pyrimethamine resistance. To counter the threat of drug resistance of *Plasmodium falciparum* to monotherapies and to improve treatment outcomes, the use of artemisinin-based combination antimalarials is recommended for treatment of uncomplicated malaria. In areas with poor access to health facilities, early recognition, prompt, and appropriate treatment require treatment in the home or

community. The development of new chemical formulations to target mosquitoes and the upcoming first global malaria vaccine (WHO 2018b) hold potential to reduce the burden of malaria further.

HIV and AIDS

In 2017, an estimated 1.8 million children under 15 globally were living with HIV, with just over half receiving antiretroviral (ARV) treatment. In 2015, HIV/AIDS accounted for about 1.4% of under-5 deaths globally (Liu et al. 2016), the vast majority of which occurred in sub-Saharan Africa. Although the proportional mortality due to HIV/AIDS among children under 5 remains unacceptably high in some African countries, it has declined significantly in the last decade due to scaling-up of interventions to prevent infections in children. In 2015, an estimated 45% of new HIV infections among children occurred in Central and West Africa. In children less than 18 months HIV infection diagnosis is established by the presence of HIV DNA through HIV nucleic acid-based testing (NAT) and beyond this age by detecting antibodies to HIV through an enzyme-linked immunosorbent assay. This is because maternal antibodies to HIV can pass through the placenta and remain present in HIV-exposed but uninfected children until the 18 months of age.

About 90% of HIV-infected children are infected through the mother-to-child transmission (MTCT), which may occur during pregnancy, birth, or through breastfeeding. Without any interventions, there is risk of transmission between 20 to 45%, but this can be reduced to less than 2% with a combination of evidence-based interventions (WHO 2010a). Antiretroviral (ARV) drug interventions given to pregnant HIV-infected women are very effective at preventing peripartum MTCT and also protects the health of the mothers (WHO 2010a). In 2013, about 49% of women continued to take antiretrovirals (ARVs) while breastfeeding, compared to 62% of women who took them during pregnancy. This demonstrates the urgent need to increase awareness about the importance of continuing treatment after birth.

Postnatal ARV interventions are now recommended to reduce the risk of maternal HIV transmission through breastfeeding. ARVs can be given either to the mother (Shapiro et al. 2010; Kesho Bora Study Group 2011) or to the infant (Coovadia et al. 2012). Based on the strength of this evidence and

programmatic considerations, national authorities are advised to support one infant feeding practice for HIV-infected mothers, namely, either breastfeeding while on ARVs or to avoid breastfeeding altogether and use replacement feeds (WHO 2010b). In settings where diarrhoea, pneumonia, and malnutrition continue to be significant causes of child mortality, breastfeeding is likely to give HIV-exposed infants the greatest chance of HIV-free survival (Kagaayi et al. 2008; Peltier et al. 2009). Mothers should exclusively breastfeed their infants for the first 6 months of life, introducing appropriate complementary foods thereafter, and continue breastfeeding for at least the first 12 months of life, and up 24 months and beyond while being actively supported for ARV adherence (WHO 2016a). It has been challenging to achieve high coverage of these interventions in resource-poor countries. Moreover, CD4 count testing to establish which pregnant women are eligible for lifelong ARV treatment or prophylaxis has hindered scale-up in many settings. There is recognition that women in high-burden countries are likely to have repeated pregnancies that would each require ARV interventions, either prophylaxis or treatment. To this end, and to protect mothers, several national programmes have opted to start all HIV-infected pregnant women on lifelong treatment (e.g. Centers for Disease Control and Prevention 2013). The questions of whether all affected pregnant women will want to start lifelong regimen and how best to support women to remain in care and achieve high rates of adherence remain unanswered.

In countries where infectious diseases and malnutrition do not contribute significantly to child mortality, mothers known to be HIV-infected may be advised to give their infants replacement feeds and avoid all breastfeeding. Commercial infant formula milk should be given as the replacement feed to the HIV-uninfected infants only when the following specific conditions are fulfilled:

Clean water and sanitation are assured at the household level and in the community, and
The mother or other caregiver can reliably provide sufficient infant formula milk to support normal growth and development of the infant; and
The mother or caregiver can prepare it cleanly and frequently enough so that it is safe and carries a low risk of diarrhoea and malnutrition; and
The mother or caregiver can, in the first 6 months, exclusively give infant formula milk; and
The family is supportive of this practice; and
The mother or caregiver can access healthcare that offers comprehensive child health services.

Pneumocystis jirovecii (previously known as *carinii*) infection often occurs before HIV status has been confirmed, and can cause life threatening pneumonia in HIV-infected or exposed individuals. Co-trimoxazole is a fixed-dose antimicrobial combination of sulfamethoxazole and trimethoprim targeting a broad range of aerobic Gram-positive and Gram-negative organisms, fungi, and protozoa including *Pneumocystis*. The drug is widely available in both syrup and solid preparations at a low cost, even in resource-limited settings. Regular prophylaxis with trimethoprim-sulfamethoxazole (co-trimoxazole) has been shown to reduce mortality of HIV-infected children by up to 40% even in the absence of ART (Chintu et al. 2004). Co-trimoxazole prophylaxis may also reduce the risk of malaria-related mortality in both HIV-infected and exposed children (Sandison et al. 2011), though its role in HIV unaffected children is questionable. Because of difficulty in diagnosing HIV infection in infants, co-trimoxazole prophylaxis is recommended for all HIV-exposed children around 4 to 6 weeks after birth and continuing until HIV infection has been cleared and the infant is no longer at risk of acquiring HIV through breastfeeding (WHO 2014b).

HIV-exposed and HIV-infected children should receive all childhood vaccines as early in life as possible, except Bacillus Calmette–Guérin (BCG) and yellow fever vaccines. In asymptomatic children, the decision to give late BCG should be based on the local risk of tuberculosis. Infants with symptomatic HIV infection should not receive yellow fever vaccines.

Antiretroviral therapy (ART) can substantially improve survival of HIV-infected children. The availability of ARV drugs with other formulations such as ‘sprinkles’ make earlier initiation and adherence to treatment by children more convenient. The particular needs of adolescents infected with

HIV such as access to adolescent-friendly sexual and reproductive health services are increasingly recognized as priorities.

The Global Health Sector Strategy on HIV for the period 2016–2021 (WHO 2016b) suggests the health sector response to HIV as critical for achieving universal health coverage, which is a key target of the SDGs. The strategy proposes a set of global targets aligned with the multisectoral UNAIDS strategy. It also identifies five strategic directions: strengthening national HIV programmes; defining a package of essential interventions; adapting services for underserved populations for equitable coverage; implementing funding mechanisms to reduce costs to patients; and embracing innovation.

Prevention and management of suboptimal development and disability

Experiencing repeated adversities between conception and early childhood disrupts normal brain development, social functioning, and learning. Developmental delay or disability can result from repeated exposure to infection or malnutrition, and from adversities related to insufficient stimulation, trauma, and maltreatment. Global data on direct measures of child development are still very sparse, although it is known that many children are at risk for poor development due to the conditions of poverty and chronic malnutrition.

The Nurturing Care Framework (Black et al. 2017) outlines five key domains for intervention that must be addressed in order to ensure children reach their full developmental potential: good health, adequate nutrition, responsive caregiving, safety and security, and early educational opportunities. The efforts of parents, families, and communities, within an enabling environment, make this possible. Many of the evidence-based interventions supporting child health and nutrition discussed in prior sections have the potential to support healthy development through a reduction in risk factors for suboptimal development (Britto et al. 2017; Vaivada et al. 2017). Interventions in multiple domains of the Framework can also be packaged together for delivery, such as combined stimulation and nutrition interventions to support optimal development.

It is imperative to provide extra support for children with motor, developmental, and learning disabilities, especially in LMICs, where these

children are particularly vulnerable (WHO 2012a; 2010b). Primary care providers are well placed to support child development in LMICs, as they are often the only health service providers that have contact with young children and families. There is a notable lack of research examining the effectiveness of interventions for prevention of developmental delay in early childhood.

Strengthening integrated service delivery

Despite the fact that effective interventions exist against all major conditions from which children die, the coverage of these interventions generally remains low. The key to achievement of substantial child mortality reduction is quality universal coverage of the interventions previously described.

Before the mid-1990s, child health programmes in LMICs focused on immunization, control of diarrhoeal diseases, ARIs, and nutrition. Their implementation led to reduction in under-5 mortality in many countries, but this approach encountered limitations. The narrow focus on single interventions has failed to consider the child in a holistic manner, leading to many missed opportunities for care in contacts with a health practitioner. It was also difficult to resolve upstream health-system constraints such as management or human resource policies using this approach. Solving these problems involves ensuring access to an integrated package of interventions that are organized around the continuum of care. It also means that care should span across the home, community, health centre, and hospital. The advantages of delivering interventions as packages include the following:

Many interventions go naturally together because they are delivered by the same person at the same time.
Packaging is more cost-effective in terms of training, implementation, and supervision.
Packaging meets the needs of the individual caregiver and the child much better than isolated and uncoordinated single-intervention delivery, thus reinforcing the continuum of care.

Potential obstacles to packaging of interventions may be related to policy, programmes, and the organizational structure of ministries and health services. For example, managers responsible for single issue-focused programmes may feel that packaging their interventions with other maternal

and child health services lessens their delivery efficiency. Another concern about packaging interventions is that vulnerable groups may not get any of the interventions if insufficient attention is given to equitable delivery of the package.

Delivery platforms relevant to child health ideally target the specific health needs of children at different stages of life with tailored packages of interventions for health promotion, prevention, screening, and treatment. Community delivery platforms aim to address the health needs of mothers and children where health facilities are sparse, often through the use of CHWs to facilitate outreach services, initiatives such as women's groups, and campaigns such as Child Health Days. Financial platforms such as conditional cash transfers can incentivize health seeking behaviours and school attendance, and user fee removal can increase health service utilization. School-based platforms target the needs of school-age children with vaccinations, nutrition interventions, and health education. Digital and technology-based platforms leverage the broad reach of mobile phones and the Internet to deliver both health messaging and healthcare. A tailored and context-specific mixture of these delivery strategies is necessary to achieve optimal coverage of essential interventions for child health.

Integrated management of neonatal and childhood illness (IMNCI) and integrated community case management (iCCM)

Integrated management of childhood illness (IMCI) was developed as an integrated delivery approach to managing common childhood diseases based on the principles of primary healthcare (PHC) as set out in the Alma Ata Declaration. Focusing on countries with a high under-5 mortality burden (>40/1,000 live births), the approach aims to enhance health workers' skills in treatment of common childhood diseases, strengthen health systems for appropriate management of childhood illnesses, and improve family and community practices to promote child health.

Over the years the approach has been expanded to include newborn care —IMNCI and integrated community case management (iCCM). Recognizing the key role CHWs can play when appropriately trained, equipped, and supervised, the equity-focused iCCM strategy involves training these workers to identify and treat children in remote areas for pneumonia, diarrhoea and malaria using appropriate treatment methods such

as ORS and zinc, oral antibiotics or artemisinin-based combination therapy (ACT) (WHO 2017b). A Cochrane review on the impact of IMCI concluded that the implementation of IMCI, especially with the neonatal care component, led to a decrease in infant and under-5 mortality rates (Gera et al. 2016).

Health system building blocks

It is crucial to address the challenges that affect health systems in many low-income countries in order to effectively scale-up child health interventions. The programmes which address newborn and child health are implemented through 'complex public and private organizations that rely on systems to provide medicines, finance health services, assure quality, and efficiency of care, manage the health workforce, and generate information needed for effective operational decisions' (Countdown Working Group on Health Policy and Health Systems et al. 2008). Key input components to the health system include an adequate and skilled health workforce, evidence-based policies, and sufficient health funding—critical determinants of access, quality, and demand for effective interventions. Improving child health services globally relies heavily on decisions made using health information systems (HIS). However, in most resource-limited settings, HIS are prone to lack of coverage, incomplete record-keeping, poor data quality, limited analysis, and fragmented systems that can hamper delivery of quality health services. Service delivery, together with medical products and technologies, reflect the immediate outputs of the health system: the availability and distribution of care (WHO 2010c).

Over the past two decades, increasing economic hardships and financial crises have disrupted healthcare delivery in many countries. Due to deteriorating infrastructure and a resource-limited public health sector, subject to structural adjustment and macroeconomic ceilings, challenges faced by healthcare sectors persist. As a result, human resources in the health sector have been destabilized and undermined. In many countries, households spend considerable amounts on healthcare and out-of-pocket expenditures for health services, sometimes two to three times greater than the total health expenditure by governments and donors. To establish an efficient, functional health system, it is important to address inequality in access to health services and provide financial risk protection. As part of the

SDGs and universal health coverage (UHC) agendas, many developing countries have implemented health programmes to improve access to basic health services for all and provide financial risk protection to reduce out-of-pocket (OOP) health expenses.

The higher the proportion of health-related user payments, the greater the relative financial burden on the poor, rendering many unable to afford necessary healthcare services. Household expenditure surveys show that more than 150 million individuals globally face severe financial crisis each year due to healthcare costs. The full assessment of such financial burden needs to evaluate a multidimensional framework to examine the broader impacts of illness or injury on the household economy, such as loss of work (Ruger 2012). Prepayment systems involve collection of funds in advance through tax-based insurance or social health insurance schemes. Both provide financial risk protection and promote equity through prepayment of healthcare costs and pooling of health risks. OOP expenditures should be gradually added into prepayment schemes, including community finance programmes.

Health workers are ‘all people engaged in actions whose primary intent is to enhance health’. This includes health service providers such as doctors, midwives, nurses, pharmacists, and CHWs. It also includes health management and support workers who dedicate all or part of their time to improving health (WHO 2006b). The availability of a competent workforce is vital to successfully delivering healthcare services. Critical shortages, inadequate skill mix, and uneven geographical distribution of the health workforce are major barriers to achieving global goals for child health. The minimum threshold necessary to deliver essential maternal and child health services is estimated as 23 doctors, nurses, and midwives per 10,000 population. Countries that fall below this threshold struggle to provide adequate skilled care at birth to pregnant women, as well as emergency and specialized services for newborns and young children, influencing the burden of women and children mortality directly. Among countries categorized as low-income economies by the World Bank, only five met this minimum threshold in 2010.

In almost all countries, a poor mix of the types of health workers and their range of individual skills, combined with a shortage of qualified health workers in remote and rural areas, impedes access by women and children to life-saving interventions and services. To address these challenges, countries

are exploring and applying different solutions. Community-based health workers can provide a number of life-saving child health interventions, such as management of non-severe pneumonia and immunizations. As a result, governments in various countries are instituting new cadres of CHWs or upgrading the skills of existing community resource persons to deliver an essential package of health services that include child health interventions. Similarly, midwifery personnel are enabled to perform life-saving interventions such as resuscitation of the asphyxiated baby. The process of sharing tasks at various levels of service delivery, sometimes referred to as task-shifting, is being investigated and applied in a number of countries.

Supporting children in humanitarian emergencies and conflict settings

The total number of people affected by humanitarian emergencies has been on the rise. In 2017 alone, there were an estimated 65 million forcibly displaced people, over half of whom were less than 18 years old (UNHCR 2018). A recent analysis commissioned by Save the Children was conducted by the Peace Research Institute in Oslo (PRIO) which mapped the numbers of children living in areas affected by armed conflict globally (Østby et al. 2018). The research reported that in 2017, 420 million children were living in areas defined as ‘conflict zones’ or ‘conflict-affected areas’—nearly one in every five children worldwide. Armed conflicts violate children’s rights, as established in the United Nations Convention on the Rights of the Child (UNCRC) (Hodgkin and Newell 2007).

Environmental factors, including climate change, can encourage conflict and intensify the severity of natural calamities (IPCC 2014). Large-scale disasters and warfare can increase the probability of family separation dismantling any existing support systems, putting children at risk for abuse, violence, and neglect. Such emergencies can create economic hardship and create further vulnerabilities for children. In Lebanon, over one million Syrian refugees have been registered with the United Nations High Commissioner for Refugees (UNHCR 2017), and child labour and marriage have been reported as families face financial insecurity (Bartels et al. 2018). Moreover, children in situations of economic and physical instability are also at increased risk of sexual abuse, human trafficking, and recruitment by extremist groups or armed forces.

The consequences of armed conflict on children can be both direct and indirect. Direct effects include physical injury or disability, developmental delay, mental health sequelae, or death. Armed violence has the intended and unintended consequence of killing and maiming children. Indirect effects are associated with the destruction of resources required by children for their optimal survival and growth, in addition to effects on the social determinants of health, such as living conditions, education, nutrition and health of caregivers (Guha-Sapir and D'Aoust 2011). Such conflicts can also displace children, and about 68.5 million people globally were forcibly displaced in 2017, with 25 million being refugees; over half of these refugees were children (UNHCR 2018).

The UN Security Council identifies six grave violations against children in situations of armed conflict (United Nations 2013):

killing and maiming of children
recruitment and use of children as soldiers
sexual violence against children
abduction of children
attacks on schools and hospitals
denial of humanitarian access

Given the prevalence of armed conflict globally and its deleterious effects on children, it is critically significant that child health experts respond both domestically and globally. Child health professionals should recognize children's traumatic life experiences and respond to the consequences of such trauma on children's health and well-being by providing holistic, multidisciplinary, culturally acceptable, and age-appropriate services that reflect children's need for physical, mental, emotional, and sexual and reproductive healthcare (Marsac et al. 2016).

Governments should develop systems to register all children at birth, so that no child remains stateless, and children separated from family have opportunities to reunite. A plan needs to be in place to regularly review plans for children in custody of the State. Doing so overcomes the barriers to accessing health services, education, and employment. There is a need to facilitate dialogue between states, the UN, NGOs, and non-state armed groups to protect children. It is important for the governing bodies to support international mechanisms to prosecute cases of children's rights violations in conflict.

Educational opportunities for children affected by armed conflict should be provided ensuring their swift reintegration into society. There is strong evidence supporting the role of education for boys and girls at all levels in reducing political violence (Østby and Urdal 2010). Interventions for optimal feeding including breastfeeding become even more critical for survival in humanitarian emergencies. During such displacements children may face risks from diarrhoeal diseases, pneumonia, and undernutrition. Moreover, unhygienic water and sanitation, overcrowding, food insecurity, and overburdened health facilities can further exacerbate the worsening situation for children.

Children should be protected from landmines, small arms, and light weapons through strict control on their ownership, sale, and safe storage. Environmental hazards, such as landmines, injure and kill children long after conflicts have ended. As a complement, initiatives for child protection may also take the form of direct implementation, such as the establishment of 'Child Friendly Spaces (CFS)' that allow children safe zones to play, parent trainings that emphasize alternatives to physical punishment and reunification for separated children. Domains for further research include the physical, developmental, and psychosocial health consequences of armed conflict exposure on children; the associations if any, between social determinants and these effects; the burden of child morbidity and mortality attributable to armed conflict; interventions; and child health assessments for humanitarian response.

Global initiatives to accelerate progress on child survival, good health, and optimal development

Several global initiatives related to specific causes of child mortality have been launched to help accelerate progress in closing the gap in child health outcomes between high-income countries and LMICs. Countries that have rapidly increased coverage for multiple interventions across the continuum of care have accelerated child survival. Their success can mainly be attributed to improvements in service quality—bringing them closer to home and expanding access to essential care.

The UN has launched the updated Every Woman Every Child's Global Strategy for Women's and Children's Health for the period 2016–2030

(WHO 2017c). The aims of this ‘Global Strategy’, which are universal in scope, are to end all preventable mortality for mothers, newborns, and children, and promote this vision as part of a plan for accelerating progress in achieving the SDGs. The strategy has helped catalyse new attention and investment to some of the most frequent causes of women’s and children’s mortality. Other recent global initiatives and events are tackling different aspects of implementing the ‘Global Strategy’, including the Child Survival Call to Action, The Family Planning Summit, and the UN Commission on Life-Saving Commodities for Women and Children, Every Newborn Action Plan, and the Global Action Plan for Pneumonia and Diarrhea.

To accelerate progress and achieve improved health outcomes for all children, it is important to ensure universal access to good-quality basic care, clean water, sanitation, and other social sector services such as education. This also includes creating the national legal, policy, and budget frameworks to promote the realization of children’s rights to these services.

School-age children

Children between 5 and 10 years of age normally attend primary school, and thus can be targeted by school-based health programmes. School feeding programmes and targeted micronutrient supplementation are effective strategies to prevent malnutrition. Education and messaging regarding the lifelong benefits of healthy eating habits and an active lifestyle can begin in this age group, coupled with supporting a healthy food environment. The school setting also provides an opportunity for the promotion of good oral hygiene practices and oral health screening. Furthermore, vision screening and the provision of corrective lenses for those children that require them help them learn more effectively. The WHO Health Promoting Schools initiative provides a framework of preventive actions that aim to promote healthy living habits and better learning conditions, and provide a safe learning environment with access to health services for schoolchildren.

Overweight and obesity

An estimated 38.3 million children under 5 worldwide were overweight or obese in 2017. Nearly half of these children live in Asia and about a quarter in Africa (WHO/UNICEF 2018). Past the age of 5, obesity rates climb even

further: 340 million children and adolescents between 5 and 19 years experienced overweight or obesity in 2016. Overweight and obesity increases a child's risk of developing type 2 diabetes, hypertension, asthma, and liver disorders. Moreover, they have a higher likelihood of suffering from depression and low self-esteem.

To assess, prevent, and manage childhood obesity, the WHO recommends primary care providers take anthropometric measurements for all young children to determine weight-for-height and assess the presence of wasting or overweight (WHO 2017a). They should also counsel caregivers on optimal infant and young child feeding, promote intake of healthy food and adequate physical activity, and develop a management plan for children identified to be obese. As childhood stunting raises the risk of becoming overweight or obese, it is not recommended to provide formulated supplementary foods to children who are only moderately wasted or stunted, unless there is household or community food insecurity or other medical considerations.

Non-communicable diseases and injuries

With the global epidemiological transition and change in lifestyles, NCDs are on the rise globally, especially in industrialized countries. Contrary to common perception, NCDs and their risk factors have a significant impact on the health of children and adolescents. Congenital disorders, diabetes, cancer, sickle cell disease, epilepsy, chronic respiratory diseases such as asthma, and rheumatic heart disease are some key NCDs that affect children and require a functioning health system providing quality care to effectively detect and manage. Childhood overweight and obesity, unhealthy diet, exposure to pollution, certain infectious diseases, and epigenetics can all increase the risk of developing an NCD in the short- and long-term.

While many NCDs are chronic and require ongoing management, some preventive actions do exist. Preventing obesity is a key strategy to prevent the development of several NCDs, both during childhood and later in life. Improving indoor and outdoor air quality can help prevent asthma exacerbations. Prompt detection and treatment of rheumatic fever can help prevent progression to rheumatic heart disease.

Supporting positive developmental progress, resilience, and self-efficacy is vital for children to achieve their full potential. As mental disorders can

begin to surface in childhood, routine screening and counselling for conditions such as anxiety, depression, and conduct disorder should be provided.

As rates of unintentional injuries rise as children become older, injury prevention is key to reducing injury-related mortality and disability. This includes requiring the use of helmets on bicycles and mopeds, and seatbelts in automobiles. Swimming lessons and education on water safety provided to children can reduce the risk of drowning. Burns can be prevented through the use of safer types of improved cookstoves, compared to open flames. Improving access to emergency services and trauma care in the event of injury is necessary to minimize injury-related mortality and morbidity.

Communicable diseases

Ensuring complete and up-to-date vaccinations status in school-age children is the most effective prevention strategy for infectious diseases. For children 5–10 years, these include universal vaccination for human papilloma virus (HPV) (age 9+) and tetanus, targeted vaccination for typhoid, cholera, dengue where indicated, and catch-up and booster vaccines as needed. Routine deworming treatment in endemic regions is also recommended for reducing the risk of anaemia. Improving WASH conditions in the school setting as well as the household also remains crucial for preventing infection transmission. School-age children also still require many key interventions that are carried over from the under-5 period for specific high-burden conditions, including ARIs, diarrhoea, and malaria. Typhoid fever in particular becomes increasingly prevalent in older children and requires prompt screening and treatment.

Child health in the SDGs era

In 2015, the 2030 Agenda for Sustainable Development was adopted by all United Nations Member States (UNGA 2015), representing a comprehensive plan for peace and prosperity, not only for people, but also for the planet. As part of this agenda, 17 SDGs (Box 10.3.2) were agreed upon, building on the legacy of the prior Millennium Development Goals (MDGs), whose purview ended in 2015. The MDGs contained specific targets for reductions in maternal and under-5 mortality, emphasizing massive inequities between low

and high-income regions, and were successful in bringing the global health and development community together with a common goal. Countries that have rapidly increased coverage for multiple interventions across the continuum of care have accelerated child survival. The most pronounced falls in under-5 mortality occurred in four regions: Latin America and the Caribbean; East Asia and the Pacific; Central and Eastern Europe and the Commonwealth of Independent States (CEE/CIS); and the Middle East and North Africa. All have more than halved their regional rates of under-5 mortality since 1990. Their success was attributed mainly to improvements in service quality—bringing them closer to home and expanding access to essential care.

While all of the SDGs are relevant to child health from a societal and environmental perspective, two specific goals contain ambitious and explicit targets for key indicators of child health. These include achieving global targets for stunting and wasting reduction by 2025, ending all forms of malnutrition by 2030 (Goal 2.2), and ending preventable newborn and under-5 deaths by 2030 (Goal 3.2), with targets for neonatal and under-5 mortality of 12 and 25 per 1,000 live births, respectively.

Box 10.3.2 The Sustainable Development Goals

- Goal 1. End poverty in all its forms everywhere
- Goal 2. End hunger, achieve food security and improved nutrition and promote sustainable agriculture
- Goal 3. Ensure healthy lives and promote well-being for all at all ages
- Goal 4. Ensure inclusive and equitable quality education and promote lifelong learning opportunities for all
- Goal 5. Achieve gender equality and empower all women and girls
- Goal 6. Ensure availability and sustainable management of water and sanitation for all
- Goal 7. Ensure access to affordable, reliable, sustainable, and modern energy for all
- Goal 8. Promote sustained, inclusive, and sustainable economic growth, full and productive employment, and decent work for all
- Goal 9. Build resilient infrastructure, promote inclusive and sustainable industrialization and foster innovation
- Goal 10. Reduce inequality within and among countries
- Goal 11. Make cities and human settlements inclusive, safe, resilient, and sustainable
- Goal 12. Ensure sustainable consumption and production patterns
- Goal 13. Take urgent action to combat climate change and its impacts*
- Goal 14. Conserve and sustainably use the oceans, seas, and marine resources for sustainable development
- Goal 15. Protect, restore, and promote sustainable use of terrestrial ecosystems, sustainably manage forests, combat desertification, and halt and reverse land degradation and halt biodiversity loss
- Goal 16. Promote peaceful and inclusive societies for sustainable development, provide access to justice for all and build effective, accountable, and inclusive institutions at all levels
- Goal 17. Strengthen the means of implementation and revitalize the global partnership for sustainable development

Measuring progress in child health

The Countdown to 2030 initiative aims to provide a framework through which to improve the monitoring and measurement of child, women, and adolescent health. The main focus is on measuring and reporting, at the national level, on the coverage of many of the key interventions described in this chapter, in addition to highlighting geographic and socioeconomic inequities in this coverage within countries.

There are 81 countries tracked as part of the Countdown initiative, and despite progress in recent years towards universal coverage, there is still a large gap in coverage of essential interventions along the continuum of care (Boerma et al. 2018). In order to achieve the ambitious targets set out by the SDGs, a great deal of investment is still required. Countdown aims to provide accurate data on coverage, quality, and inequalities so as to guide these investments towards those countries, regions, and populations who

have the greatest need. To this end, efforts to strengthen the collection of high-quality vital statistics data are required to improve accountability to commitments made to improve child health. Furthermore, developing a deeper understanding of the drivers of this coverage change, through quantitative analysis of coverage data coupled with assessment of national policy impacts, is also needed to develop evidence-based recommendations tailored to each Countdown country context. Ideally, this involves strengthening individual countries' capacity for conducting these analyses.

Conclusion

ARIs, diarrhoea, malaria, and injuries are the main causes of illness and death in children 1–59 months. Among newborn babies, most deaths are the result of preterm birth complications, intrapartum-related events such as birth asphyxia, and infections. Undernutrition is associated with 45% of all under-5 deaths. Despite the substantial progress made in reducing under-5 mortality, 5.4 million children under 5 died in 2017, 2.5 million of these being neonates.

Poor health and survival are linked to social and economic disadvantages. Child deaths are unequally distributed in the world. Within countries, child morbidity and mortality tend to be higher in the rural areas and within the poorer and least educated families. Poorly nourished, LBW, sick, and disabled children all are at particular risk of adverse outcomes and have special needs for care. Global progress in child health is attributable to a broad range of factors that include high coverage of good-quality, effective interventions, development programming, and strategic integrated delivery of packaged health services, along with improvements in education, child protection, respect for human rights, and economic gains in developing countries.

Key points

Approximately two-thirds of under-5 deaths could be prevented by universal coverage of a small set of existing interventions that do not require expensive technology. Among these interventions, the promotion of breastfeeding, management and prevention of neonatal conditions, ARIs, diarrhoea, malaria, and HIV infection, in addition to improved feeding, have the highest impact in reducing child mortality.

Reducing stillbirths and neonatal mortality requires high-quality coverage of key interventions delivered during pregnancy, childbirth, and in the postnatal period.

Many more children today survive infancy yet remain in impoverished conditions. Infections and chronic malnutrition during infancy and childhood delay growth and development, and thus promoting interventions for survival alone is inadequate.

Supporting early child development during critical time periods facilitates optimal developmental trajectories in which children grow into adults that can realize their full potential.

Coverage of key interventions remains unacceptably low. Integrating interventions into packages of care organized along a continuum through pregnancy, birth, the neonatal period, and childhood, and delivered at all levels—from the home and community to first-level facilities and hospitals—would contribute to improved efficiency in intervention delivery and to the achievement of high coverage.

Strengthening health systems is a prerequisite for increasing the coverage and quality of health interventions.

The development of an operational plan to which programmes can be held accountable, along with a good financing and human resource strategy, will yield long-term benefits for the child and the health system at large and is an essential element to follow the development of a child survival strategy.

10.4

Adolescent health

George Patton, Peter Azzopardi, Natasha Kaoma, Farnaz Sabet, and Susan Sawyer

Introduction

The current generation of 10- to 24-year-olds is the largest in human history. Their health and well-being are increasingly shaped by the global forces of urbanization, migration, global communications, economic development, and the sustainability of planetary ecosystems. Over the past two decades we have come to new understandings of adolescence as a critical developmental phase in life for achieving human potential (Patton et al. 2016). It is characterized by maturation of all physiological systems including reproductive, musculoskeletal, cardiometabolic, and neurocognitive. Health during adolescence shapes patterns of growth and the acquisition of social and emotional capabilities, sets trajectories for health across the life-course and, because this is the next generation to parent, lays a foundation for the healthy development of the next generation (Patton et al. 2016). Thus investments in adolescence have the potential to bring a 'triple dividend', an understanding that has brought a fresh prominence to adolescent health in global policy (Every Woman Every Child 2015). However, the challenge for governments in investing in adolescent health is a relative lack of capacity extending from the health workforce to healthcare systems, monitoring frameworks and evidence base for policy and programming, and processes relative to other fields of health (Patton et al. 2016). This chapter outlines current understandings of adolescent health, growth, and development, the available evidence for effective interventions and priorities for research, and technical investment.

Concepts of adolescence

Adolescence is generally conceptualized as the phase of life that spans childhood and adulthood. It is a phase of major growth with neurocognitive maturation extending well into the third decade. Through history, adolescence has been considered to begin with puberty and end with transitions into marriage and parenthood (Worthman and Trang 2018). In today's contexts, the endpoint is often less clear-cut, particularly in higher income and urban settings where the adoption of other adult roles such as the transition to employment, financial independence, as well as the formation of life partnerships commonly mark the end of adolescence. These events occur at different ages in different parts of the world influencing local cultural concepts of adolescence, which vary greatly.

Sawyer et al. recently reviewed the range of different English terms have been used to describe the adolescent phase of life or parts of it (Fig. 10.4.1) (Sawyer et al. 2018). Within the UN system, adolescence has been generally defined as the second decade from 10 to 19 years and youth commonly refers to 15 to 24 years. The terms 'adolescents and young adults' and 'young people' are also used to refer to the 10–24-year-old age group (World Health 1989; Sawyer et al. 2012).

The Convention on the Rights of the Child defines a child as below the age of 18 years unless, under the laws applicable to the child, majority is attained earlier (Assembly 1989). Eighteen is commonly viewed as the legal age of majority, the point at which an individual is considered an adult in many countries, although not universally. In law there is no single definition of adulthood but rather a collection of laws that at differing ages, for different activities, bestow the status of adulthood. These include laws that have major consequences for health and health risks including those related to the age of consent to sexual intercourse or medical treatment, the minimum age that young people can legally work, leave school, drive, buy alcohol, marry, and be held accountable for criminal actions. In addition to 'young adults', 'emerging adulthood' is a term that has been used to describe the phase of life from the late teens to the late twenties when an individual acquires some of characteristics of adulthood without having necessarily reached the milestones that historically define fully-fledged adulthood.

This chapter focuses on this age range from 10 to 24 years, coinciding with the major years of physical, cognitive, and social development and the key social role transitions that mark adulthood. When we use the terms

‘adolescence and young adulthood’, or simply ‘adolescence’, we are referring to these years.

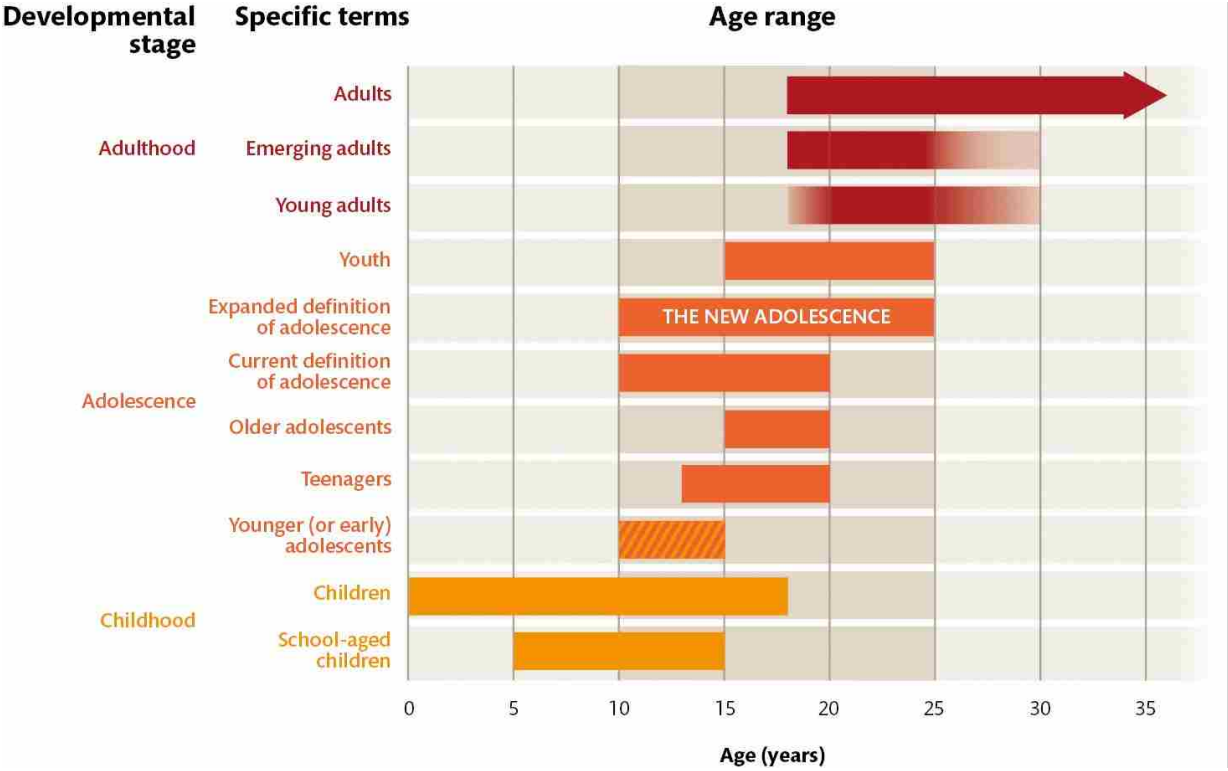

Fig. 10.4.1 Different terms used to describe the adolescent and young adult years.

Adolescent growth and development

Timing of adolescent growth and development

Later childhood and adolescence are increasingly viewed as sensitive developmental phases where an individual’s interaction with the physical, nutritional, social, and cultural environment shapes patterns of physical, social, and emotional growth (Patton et al. 2016). These aspects of the environment affect the timing and form of puberty. The effects of this changing environment are evident in secular trends in the age of menarche in girls. Over the past 150 years there has been a fall in the age of menarche of

around 4 to 5 years in Western Europe and North America, which is thought to arise from better childhood health from improved nutrition and reduced infectious disease (Worthman and Trang 2018). Occurring over a shorter period, similar trends have been observed in countries undergoing rapid economic development or in children whose families have moved from low-resource to high-resource settings (Houghton et al. 2014). In high resource settings the mean age for menarche is now 12–13 years, although the onset of puberty occurs much earlier with adrenarche (adrenal maturation) on average occurring around the age of 7–8 years and thelarche (breast budding) around 10 years (Patton and Viner 2007).

The timing of puberty predicts later life health as early puberty increases risks for premature all-cause mortality, cardiovascular deaths, type II diabetes and some mental disorders (Day et al. 2015). During adolescence, early puberty is also associated with higher rates of common mental disorders in girls; a mismatch between the social and sexual roles that accompany physical maturity and an individual's underlying cognitive–emotional capabilities is one possible explanation (Brooks-Gunn and Warren 1989).

In pre-industrial societies, the adolescent transition from puberty to adult roles, as defined by the transition to parenthood, ranged from around 2 years in girls to 4 years in boys (Schlegel and Barry 1991). In today's developed economies, longer periods of education and the availability of effective contraception means that adolescence commonly persists for well over a decade. The lengthening of adolescence means that it occupies a greater proportion of the life-course than ever before. It is also associated with a more diverse set of influences on adolescent health, growth, and development in many places. These include a longer duration of education and training, with the acquisition of professional capabilities and independence increasingly being hallmarks of adult status (Patton and Viner 2007; United Nations Children's Fund 2012). So too relationships with an adolescent's family of origin have shifted in many places with an extension of time living at home into the third and even fourth decade in many places. Opportunities for engagement with the peer group and cultural influences beyond the local neighbourhood have also changed with the growth of mass media, and more recently, digital and social media. For these reasons, influences on adolescent health differ markedly today from those in previous

generations. Equally the opportunities for using new platforms for health interventions have also expanded.

Psychosocial development

Early adolescence (10–14 years) is dominated by puberty and the effects of the rapid rise in pubertal hormones on body morphology, and sexual and brain development. It is accompanied by a remodelling of the brain's reward system, a sensitivity to peer influences, low levels of future orientation and altered risk perceptions, sometimes leading to risk-taking behaviour. It is a time of identity formation and development of new interests including sexual and romantic relationships. School and family environments have major effects on growth and development and are therefore important settings for health intervention.

Mid-adolescence (15–19 years) is characterized by continued pubertal maturation, particularly prominent for males, whose growth spurt starts later and continues for longer. Brain development continues with maturation of the prefrontal cortex and increased connectivity between brain networks enhancing executive and self-regulatory skills. It is a phase of greater autonomy and, in poor resource settings where there are limited opportunities for educational engagement, a common point of transition into marriage and parenthood for girls. In higher resource settings, this phase of development is accompanied by a greater future orientation and an ability to weigh up the short- and long-term implications of decisions. Education settings are influential for those who remain in school: for those who leave school, work settings have a growing influence on health, particularly in hazardous work environments in low-income settings.

Later adolescence or young adulthood (20–24 years) is accompanied by maturation of the prefrontal cortex and greater planning and self-regulation. It marks the end of a period of high brain plasticity. It often corresponds to the adoption of adult roles and responsibilities, including entering the workforce or tertiary education, marriage, childbearing, and economic independence.

Adolescent health in the global context

Demographic and epidemiological transitions

The demographic transition from high birth and early-life death rates to low fertility and longer life expectancy has reshaped the relative proportion of adolescents in high-income countries since the post-war years. The demographic transition is now proceeding rapidly in most other countries with different countries at very different points in that transition (World Bank 2007). This acceleration of the demographic transition has resulted in today's adolescent generation being the largest in history relative to other age groups. With a population of 1.8 billion, 10–24 year olds comprise over a quarter of the global population. Nearly 90% live in low- and middle-income countries where they may comprise more than a third of the population (Fig. 10.4.2). In contrast, in a growing number of high-income countries the proportion of 10- to 24-year-olds is now under 15%. Projecting forward to the end of the century, around a half of the world's adolescents will be growing up in sub-Saharan Africa.

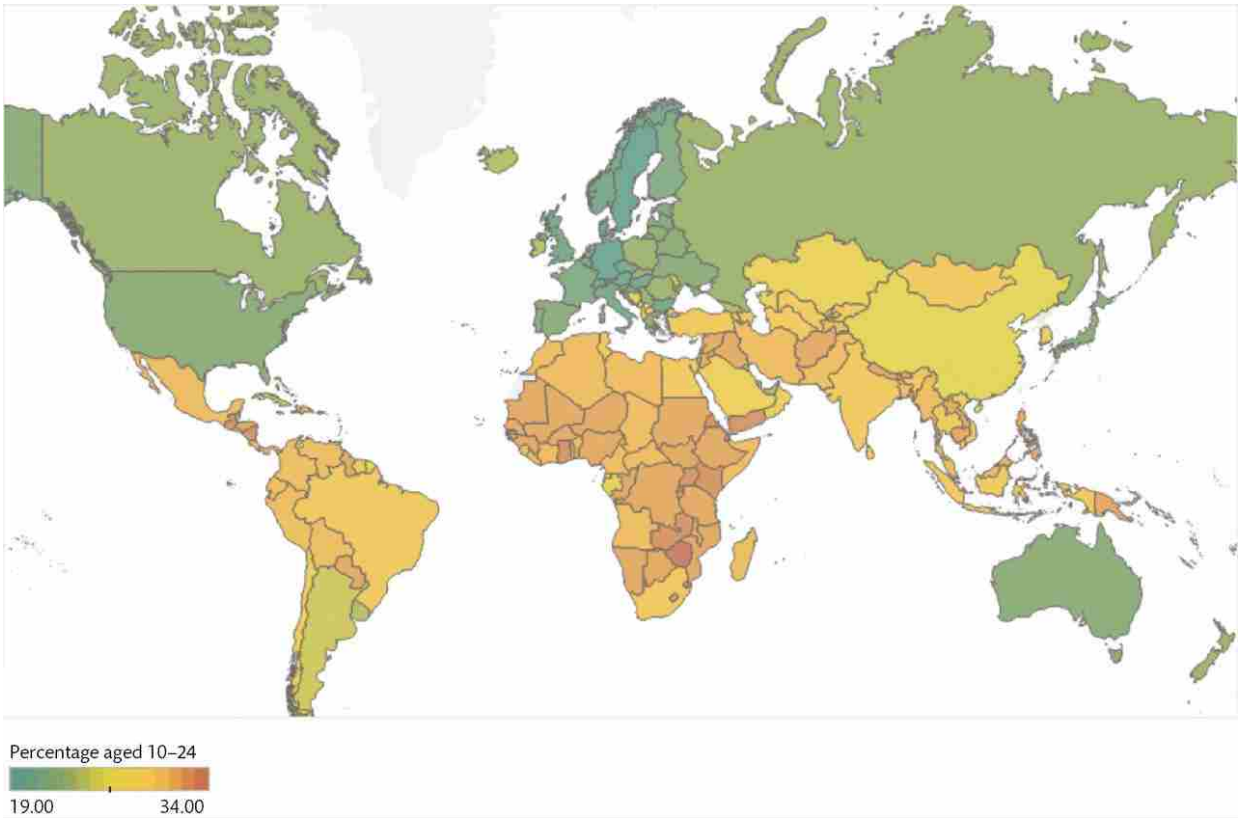

Fig. 10.4.2 Percentage of the population aged 10 to 24 years across countries in 2020.

Better childhood health and nutrition, extended time in education, delays in family formation and access to new technologies theoretically offer a prospect of this being the healthiest generation of adolescents ever. Indeed, many more adolescents are now growing up in non-communicable disease (NCD)-predominant countries with lower levels of reproductive health problems, infectious disease injury, and violence. Yet uneven demographic change means that across Asia and Africa many more young people are growing up with high risks for multiple health problems in the adolescent years (Azzopardi et al. 2019).

The demographic transition has been accompanied by epidemiological and nutritional transitions with profound implications for adolescent health and health risks. The nutritional switch towards greater consumption of foods that are high in added sugars, salt, and unhealthy fats, and low in important micronutrients is fuelling a global rise in obesity but with continuing high levels of micronutrient deficits. Further global trends in youth unemployment, less stable families, environmental degradation, armed conflict, and mass migration also pose new threats to adolescent health.

The epidemiological transition, that commonly accompanies the demographic transition and economic development, has changed health profiles for all age groups. Many adolescents have benefited from better control of infectious diseases including diarrhoeal disease, lower respiratory tract infections, tuberculosis, and malaria. Adolescent girls and young women in many settings have benefited from gains in maternal health, particularly in settings where early pregnancy has fallen markedly. However, the epidemiological transition has brought an increase in other health problems for adolescents, including road traffic injuries and suicide. In some countries and contexts, such as Latin America and Eastern Europe, these problems have extended to homicide, mostly in young males (Patton et al. 2009). A link to broader economic conditions was evident in the rise of mortality and alcohol-related disease burden in Eastern European countries following the fall of the Soviet Union in 1991 and is likely to be a factor underlying more recent civil unrest and armed conflict across the Middle East, North Africa, and sub-Saharan Africa (Yair and Miodownik 2014).

Other adolescent health problems have become more prominent with the epidemiological transition, including more persistent mental and physical health problems. For these reasons, self-harm and suicide have assumed greater significance in adolescent health in recent decades, particularly in high resource settings (Collishaw 2015). Mental disorders have a particular significance in adolescent health as they commonly have their onset in late childhood and adolescence. Because many persist into adulthood, adolescent mental disorders make a greater contribution to adult disease than ever before (Patton et al. 2014).

HIV is a further reason why adolescents and young adults, particularly in southern and eastern sub-Saharan Africa, have to date seen fewer benefits from the epidemiological transition. To a large extent, the burden of HIV has fallen on the young; new infections are concentrated in adolescent girls and young adults; the effectiveness of new antiretroviral medication has also brought the survival into adolescence and adulthood of a generation affected by maternal–child transmission. In this context of continuing high prevalence, adolescents and young adults have not had the same mortality declines as other age groups (Murray et al. 2014).

With ageing populations and a convergence to a disease burden dominated by NCDs in later life, adolescent-prevalent NCDs and adolescent-onset NCD risks assume greater significance (Jamison et al. 2013). In part, the relatively

high prevalence of adolescent NCDs reflect greater survival into adolescence of diseases that were previously fatal in early childhood (e.g. cystic fibrosis and childhood cancers): in part it reflects a changing epidemiology of mental and physical disorders with higher incidence rates in the adolescent years in developed settings, e.g. allergy and autoimmune conditions (Mayer-Davis et al. 2017). NCD risks that commonly emerge during adolescence include tobacco use, physical inactivity, obesity, alcohol, and illicit substance use and poor diets. Without specific policy interventions, the combination of increasing wealth and unrestrained marketing will see adolescent health risks continue to rise in prevalence.

Adolescent health by region

We have adopted the conceptual model from the 2016 Lancet Commission on Adolescent Health and Well-being to describe global and national patterns of adolescent health (Fig. 10.4.3). The model considers:

Current causes of disease burden and death across the adolescent years;
Health risks that emerge during adolescence with consequences for health during these years, for later adult health and/or a healthy start to life for the next generation; and
Important and structural determinants of health that affect health growth and development across the adolescent and young adult years (Sawyer et al. 2012). These include education and employment; marriage and parenthood; marketing and digital media; and the quality of universal health coverage.

The model also depicts the corresponding responses to adolescent health problems and their determinants. The most effective actions for adolescent health and well-being are intersectoral, occur at multiple levels, and with multiple components. They may include structural, media, community, online, and school-based elements as well as the provision of preventive and treatment health services. Intersectoral coordination has, for example, been prominent in countries that have made progress in reducing road traffic injury. In addition to the specific interventions outlined earlier, essential underpinning elements have included strong information systems, clear governance, civil society advocacy and a capacity to implement effectively within different sectors (Jamison et al. 2013).

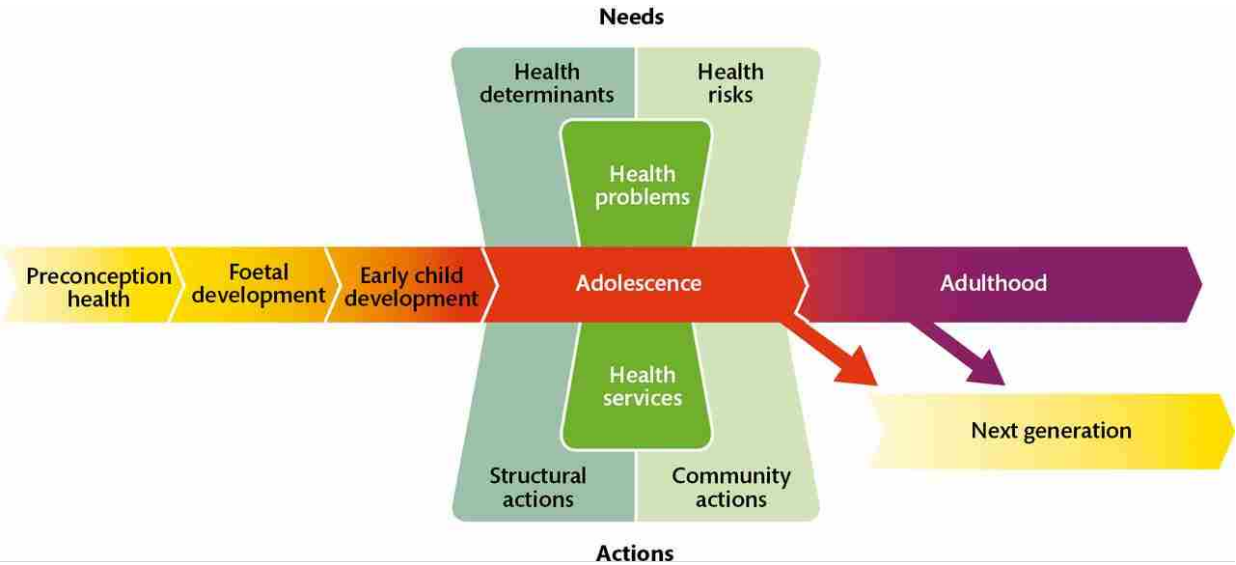

Fig. 10.4.3 A conceptual framework for adolescent health.

Disease burden across adolescence

Disease burden and mortality rates generally increase across the adolescent years into young adulthood, with those increases particularly marked for sexual and reproductive health problems and common mental disorders in females, and for injuries, violence, and substance use disorders in males.

This is in turn reflected in increases in mortality across the adolescent years with particularly marked increases in deaths due to injury, violence, suicide in males and maternal causes for females in later adolescence and young adulthood (Patton et al. 2016). In comparison to younger children, adolescents have had lesser reductions in mortality in recent decades. In a study of 50 countries with longitudinal data, the mortality of children had declined by over 80% in the last 50 years (Grazzi 2004). In contrast, mortality among adolescents had improved only marginally. Indeed, there has been a reversal of historical mortality patterns in which early childhood mortality exceeds adolescent deaths. Over that time causes of death in adolescents have changed with a fall in infectious disease deaths in most high- and middle-income countries and a rise in deaths due to injuries, that now account for around 40% of all adolescent deaths globally.

Azzopardi et al. recently populated 12 headline indicators presented in the 2016 Lancet Commission on Adolescent Health and Wellbeing to examine trends in adolescent health over the past quarter century together with differences between countries and regions (Azzopardi et al. 2019). In that analysis, disability-adjusted life years (DALYs) estimates were used to assess variations in disease burden by country with disease burden grouped into three categories: group 1 conditions (infectious diseases, maternal health problems, undernutrition, and/or HIV) common in low-resource setting; injury and violence; and the NCDs of adolescence (chronic physical illness, mental disorders, and substance use disorders). Countries were classified as multiburden if they had high disease burden from all categories of disease: injury excess with high rates of injury and NCDs; and NCD predominant where the major disease burden around from chronic mental and physical health problems (Fig. 10.4.4).

Injury excess
NCD predominant

Fig. 10.4.4 Changing disease burden from 1990 to 2016 in 10- to 24-year-olds in countries classified as multiburden, injury excess, and NCD predominant.

Reprinted from Azzopardi, Peter S, et al. (2019), 'Progress in adolescent health and wellbeing: tracking 12 headline indicators for 195 countries and territories, 1990–2016', *The Lancet*, under a CC BY 4.0 License.

Figure 10.4.4 illustrates the extent of change in adolescent disease burden over the last 25 years. Particularly notable has been a reduction in adolescent injuries and violence in many places, with a majority of injury-excess countries in 1990 having become NCD predominant. There has been relatively less success in ensuring the transition of countries with a multiburden disease profile. Many of these countries are the countries that have seen the greatest increase in their adolescent population. For this reason the number of adolescents growing up in multiburden countries in 2016 was 35% greater than in 1990, suggesting that the challenges for health service systems in these places have become substantially greater.

Adolescent health risks

Although adolescent health risks contribute to disease burden during the adolescent and young adult years, their greatest contribution is often towards disease burden later in life or in relation to adverse consequences for the health growth and development of the next generation. Tobacco use is illustrative. It overwhelmingly has its onset in adolescence but causes little or no disease burden during these years. However, it is a major risk factor for NCDs in older adults and maternal smoking during pregnancy is a well-established risk factor for poor foetal growth and later life illness in offspring (Patton et al. 2018).

Overall tobacco use has declined in adolescents globally since 1990 in part due to the implementation of the Framework Convention on Tobacco Control. However, progress has been mixed. Rates of daily smoking remain above 15% in 10–24-year-olds across many European countries with one in four smoking daily in the Russian Federation. Across countries, tobacco use is almost always more common in adolescent males than in females. A number of countries in sub-Saharan Africa, Eastern Europe, and the Middle East have seen rises and in some low-resource countries (e.g. Indonesia and Papua New Guinea), rates of tobacco use are unacceptably high. Notably, non-signatories to the Framework Convention on Tobacco Control have generally seen lesser falls in adolescent and young adult tobacco use.

Alcohol use disorders typically begin during the young adult years, with a younger age of drinking onset being particularly hazardous (Bonomo et al. 2006; Viner and Taylor 2007). Alcohol use carries risks for injury, violence, suicide, and unwanted pregnancy during adolescence, is linked to a range of NCDs in adulthood (cancers, cardiovascular disease, liver disease, and pancreatitis) and greater use in pregnancy has prominent intergenerational harms (Riley and McGee 2005). Both alcohol use and binge drinking are generally more prevalent in males. Although still more common in resource rich countries, binge drinking is becoming prevalent in other places with the actual number of adolescent binge drinkers having increased slightly in recent decades (Azzopardi et al. 2019).

Overweight and obesity increase markedly across adolescence and young adulthood with very high persistence, particularly for obesity (Patton et al. 2011). The risks in later life include premature mortality, chronic disability, type 2 diabetes, ischaemic heart disease, hypertension, and cerebrovascular disease. Preconception maternal (adolescent) obesity increases risks for miscarriage, gestational diabetes, operative delivery, pre-eclampsia, infant perinatal mortality, and macrosomia (Yu et al. 2006). Adolescent overweight and obesity have increased markedly in prevalence across almost all countries since 1990, with dramatic annual increases of around 10% in China and Vietnam. The prevalence of overweight and obesity is around one in five young people in NCD Predominant and Injury Excess countries and is continuing to increase in all places. Since 1990, the increase in overweight and obesity in NCD-predominant and injury-excess countries has been 120% (Azzopardi et al. 2019).

Sexual and reproductive health risks also typically emerge during adolescence, with risks shifting in an environment of greater access to digital technology and social media (e.g. sexting, higher risk sex with multiple partners). Globally there have been strong trends towards reduced adolescent fertility, but these trends are less prominent in sub-Saharan Africa and Latin America. Rates of women giving birth before 18 years remain high across much of sub-Saharan Africa, and for a number of countries in South Asia. Overall around one in five women in multiburden countries report giving birth by the age of 18 years.

There is continued debate around the extent to which adolescent mothers are at greater risk of adverse maternal and infant outcomes. Some recent reports using verbal autopsy methods have failed to find differences in

mortality in young mothers (Blanc et al. 2013; Nove et al. 2014). However, a recent World Health Organization (WHO) multicountry survey of pregnancy complications found much greater pregnancy-related morbidity in adolescent mothers (Ganchimeg et al. 2014) and country level studies continue to report higher maternal mortality in young mothers, particularly from causes such as unsafe abortion that may be sensitive to reporting bias in household surveys. An estimated 22 million unsafe abortions occur annually, of which about 15% are among adolescent girls. Young women have a higher risk of abortion-related deaths than in those over 25, are more likely to terminate pregnancy after the first trimester, and are more likely to use unregulated providers (Woog et al. 2015). Even after controlling for various sociodemographic factors, knowledge of the legal status of abortion and partner support, adolescents had 77% lower odds of obtaining a safe abortion compared with women aged 30 and older.

Beyond adolescent birth rates, limited information is available on adolescent sexual and reproductive health in many countries. Across sub-Saharan African and Latin American countries with available data, between 10% and 20% of 15–24-year-olds report having first sexual intercourse before the age of 15 years. Condom use in the context of having had two or more partners in the past year shows great variability between countries, but remains under 50% for adolescents in multiburden countries where rates of adolescent pregnancy, HIV, and sexually transmitted infections (STIs) are high and access to contraception and facilities for menstrual management are low.

Data around adolescent mental disorder and mental health risks is perhaps some of the weakest in global health. One recent estimate of coverage of minimally sufficient data for estimating the prevalence of six major mental disorders of children and adolescents reported an overall global coverage of 6.5%; 124 countries had no usable data at all (Erskine et al. 2017). Yet mental health problems and mental health risks appear common in almost all places. Self-harm, for example, is a risk factor for premature death from suicide and accidental injury; in later life adolescents who self-harm also have higher mortality from cancer and cardiovascular disease (Bergen et al. 2012). At least 1 in 20 adolescents in the mid-teens in high-income countries report some self-harm, typically self-laceration, or self-poisoning, in the previous 12 months (Hawton and James 2005). Other risk factors for mental

disorders including bullying, sexual, and physical abuse and intimate partner violence are rarely monitored in adolescence.

Responding to adolescent health needs

Health services

Health services for adolescents play a number of roles ranging from acute healthcare such as the management of trauma; preventive healthcare such as the provision of preconception and antenatal care to young women; and the management of chronic health problems or health risks including HIV, mental and substance use disorders, and chronic physical illnesses.

Adolescents and young adults commonly fail to access healthcare at the same level as other age groups. Unmet versus met need for contraception are potentially useful indicators of the extent to which adolescents are able to access a sensitive health service. Just under two-thirds of young women aged 15–24 years have their demand for modern contraception satisfied with modern methods, with rates substantially higher in NCD-predominant countries than in multiburden countries where around half of young women have their needs met. Given the rate of demographic change in multiburden countries, the actual numbers of young women with unmet need have substantially increased, suggesting that health services have not kept pace with rapid population growth, particularly in sub-Saharan Africa. To a large extent, data on met need for contraception comes from girls who are married. Far fewer data are available on sexually active unmarried adolescents, particularly in the many countries where prescribing contraception to unmarried girls under the age of 18 years is illegal.

Health service interventions may differ in their effectiveness in adolescents in comparison to older adults for a range of reasons (Cipriani et al. 2016). Rates of contraceptive failure are, for example, higher in adolescents than in older women, with younger women more likely to abandon contraception despite ongoing need (Blanc et al. 2009). Reasons include poor understanding of pregnancy risks, concerns about the effect of contraceptives on health or fertility and opposition from partners. Lack of knowledge of services, cost, shyness, stigma around early sexual activity and judgemental providers are further barriers. One study in the United States found contraceptive failure was almost twice as high in under 21 year olds

using oral contraceptive pills, transdermal patches, or the vaginal ring. In contrast, the failure rate of long-acting reversible contraceptives (LARCs) is extremely low in all age groups (Winner et al. 2012). Yet despite increased use of LARCs in the United States since 2007, 15–24-year-olds remain less likely to use them than 25–39-year-old women (Finer et al. 2012).

Notwithstanding their increased prevalence across adolescence, most adolescents and young adults with mental health problems do not receive treatment from health professionals. One European study of mental healthcare in adults showed that about 6% of the sample was in need of mental healthcare but nearly half reported no formal healthcare use. Those aged 18–24 reported the least use of services (Alonso et al. 2007). Actions to reduce barriers include promoting mental health literacy and combatting stigma, particularly in LMIC where the scaling up of mental health services has not yet been a priority (Patel et al. 2007).

Barriers to healthcare

Two sets of barriers diminish access to quality healthcare for adolescents. One set are external to health services and include legal frameworks governing health actions, out of pocket costs, and cultural and community attitudes. Though not unique to adolescents, these barriers assume greater importance in the young.

Legal and financial barriers to health service access are greater for adolescents than other age groups and are increasingly out of step with the health risks that adolescents face. One example is lack of access to contraception in many countries for unmarried girls under the age of 18 who are sexually active. Even when national legislation allows a particular health response, provider attitudes and beliefs about the appropriateness of an action in the context of age, marital status, or partner/parental consent may affect their response to an adolescent (Calhoun et al. 2013). Financial barriers arise from adolescents' limited independent eligibility for tax and insurance-based funding schemes. Where health insurance exists, it is often through parents (or partners), presenting risks to confidentiality when accessing healthcare for sensitive problems, e.g. mental health, contraception, or substance use (Waddington and Sambo 2015). Socially marginalized adolescents often fall outside of financing systems for healthcare and are particularly vulnerable to catastrophic medical events.

Further barriers to access arise more from the developmental context of adolescence, including adolescents being less experienced users of healthcare. Adolescence brings an increasing desire for privacy and confidentiality, with embarrassment, shame, and fear of being judged presenting barriers to healthcare. In the United States, a leading concern of adolescents who had foregone healthcare was not wanting their parents to find out (Schoen et al. 1998). Inexperience in turn leads to many adolescents not appreciating that problems such as substance use, bullying or overweight can be discussed with health professionals (Sanci 2011).

Adolescents value respect, good coordination of care, appropriate provision of information, high-quality communication, involvement in decisions about care, and healthcare providers listening to their needs (Luxford et al. 2010). As such, the skills of clinicians differ from those needed for the healthcare of younger children which is typically mediated through parents. One important task for health professionals is to set expectations with adolescents and parents about an adolescent taking greater responsibility for healthcare. With increasing age, providers need to explicitly engage the young person themselves, which ideally includes consulting with them alone which is difficult in many cultural settings.

Improving access to quality healthcare requires actions beyond the health service sector. For making sexual and reproductive health services more adolescent-responsive, training of health workers alone does little to improve access or contraception use. However, high-quality training, combined with the provision of adolescent-responsive facilities, strategies to change community norms, and greater availability of LARCs can bring major shifts in access and quality (Chandra-Mouli et al. 2015). Further elements within a multifaceted approach might include promotion of adolescent health literacy, engagement of community leaders, having an appropriate package of services, monitoring provider competencies, promoting equity and non-discrimination, collecting data for quality improvement and engaging adolescents around practice policies (Nair et al. 2015).

Ultimately access to healthcare depends on the availability of platforms which are responsive to the life context of adolescents. School-based health services will have greater relevance as secondary education participation grows in many countries. Service models range from fully equipped and permanently staffed school centres with medical, nursing, and counselling staff to clinics sited near schools but with strong links. The predominant

focus of many school-based and school linked health services has been on provision of sexual and reproductive healthcare but there is clearly an opportunity for these services to extend to mental healthcare, treatment, and prevention of infectious diseases, management of anaemia, and other chronic physical health problems. Web-based technologies also have the potential to improve access to health services (Kauer et al. 2014).

Education settings as platform for health action

Education is a powerful determinant of health and human capital and socioeconomic progress, one in which the adolescent years are central (Viner et al. 2012). Those who are more educated live longer lives with less ill-health (Cutler and Lleras-Muney 2012). In high-income countries (HICs), the benefits are generally greater for women in terms of mortality, self-reported health, mental health, and obesity (Miyamoto and Chevalier 2010). Among adolescents in low- and middle-income countries (LMICs), higher education is associated with reduced teenage births and older age at marriage. The health and well-being benefits of expansion of secondary education accrue through multiple mechanisms, including healthier behaviours, greater cognitive capacity, and longer productive adult lives for the current generation, better health, and lower mortality among their children and overall greater productivity in the future workforce. Education brings profound intergenerational benefits; improved education for women may account for up to half of the global improvement in child mortality since 1970 (Patton et al. 2018).

With primary education now widespread in LMICs, expansion of participation in secondary education offers an achievable strategy for improving health across the life-course and into the next generation (Miyamoto and Chevalier 2010). In countries that already have high secondary education participation, facilitating schools to more explicitly promote health has the potential for leverage above and beyond the health benefits of educational participation alone.

However, many forces operate to divert adolescents from secondary education. Prominent among these are the costs of education and the opportunity costs to families of the loss of adolescent labour, especially in rural areas. For these reasons, poor adolescents in LMICs are less likely to attend secondary school. Early marriage accounts for higher drop-out rates

in girls in LMICs. Most interventions to increase access to and retention in education in these setting have been in younger adolescents, largely in primary schools. Scholarships, school fee reduction or removal, cash transfers conditional on remaining in school, providing school uniforms, decreases in grade repetition, school proximity, and mother tongue education are cost-effective strategies in different contexts for promoting school retention (Glewwe and Kremer 2006; UNICEF 2015). Addressing gender disparities in access, social norms around girls' participation in education, and targeting resources to the poorest regions as well as to disadvantaged students are important elements of increasing adolescent educational engagement in the poorest groups. There is also value in greater non-formal or flexible learning strategies for adolescents without access to mainstream education (e.g. child labourers and married adolescents who have left school) (Yasunaga 2014). Health interventions complement these strategies to promote educational engagement: these might include comprehensive sexuality education, providing access to modern contraception, treatment of micronutrient deficiencies and anaemia and management of mental disorders (Rosenberg et al. 2015).

The traditional way in which schools address health and health risks has been through health education delivered in classrooms. This approach can bring small to moderate benefits in knowledge and attitudes but implementation is often patchy and the effects are generally not sustained (Foxcroft and Tsertsvadze 2011). In contrast, the ways that schools operate more widely have great effects on health, behaviour, and well-being (Patton et al. 2003). For this reason actions that address the school ethos and environment have become much more a focus of recent evaluations and policy attention (Patton et al. 2006; Shinde et al. 2018). A school's environment extends to the physical and social environment, management, and organization, teaching, discipline, pastoral care, school health services, whole-school health promotion, and extracurricular activities. Positive effects from these interventions extend to student substance use, violence, and victimization, and mental health, particularly in groups facing discrimination and disadvantage (Shackleton et al. 2016).

The most effective actions for health in school settings will commonly be multicomponent with curriculum elements, a focus on a school's social and physical environment (e.g. around water, sanitation, and menstrual management facilities), together with engagement of families and/or the

community (Harden et al. 2009). These approaches consistently show positive outcomes for adolescent sexual health, violence, and tobacco smoking and may be beneficial for other health risks (Harden et al. 2009; Blank et al. 2010).

Peers, media, and marketing

The emergence of strong peer relationships is a central feature of early adolescent development (Viner et al. 2012). Such relationships may have either positive or negative effects on health. Peer connection, peer modelling, and awareness of peer norms can be protective against violence, mental health problems, substance use, and sexual health risks (Salazar et al. 2009). Equally, peers may also increase risks, with peer participation in risk behaviours likely to increase smoking initiation and persistence, alcohol initiation and use, self-harm, sexual risks, and violence (Fisher et al. 2007; Kretman et al. 2009). Other peer characteristics, such as sexual partner communication and negotiation skills, influence risks of unwanted pregnancy, STIs, and HIV (Taffa et al. 2002; Salazar et al. 2009).

Modern adolescent peer relationships differ markedly from a pre-industrial social context in both the number and diversity of peers. Prolongation of education and later marriage and parenthood have effectively expanded the role of peers within the lives of adolescents. Peer education, or the promotion of healthy behaviours *for* young people *by* young people, is one popular strategy adopted by the health sector. Such interventions have certainly shown positive outcomes for the young people conducting the programming (i.e. the peer educators themselves) (Maticka-Tyndale and Barnett 2010). Peer promoters themselves have greater self-confidence, improved communications, leadership and interpersonal skills, higher aspirations, and lower rates of health risk behaviours. However, there has been little testing of their effectiveness in changing health outcomes for the broader population of young people they are meant to reach, leading to suggestions that peer education is ineffective (Chandra-Mouli et al. 2015). This reflects a tension in resource-constrained settings between a wish to scale up promising approaches and the value of undertaking smaller scale interventions with rigorous methodologies (Maticka-Tyndale and Barnett 2010).

Mass media and more recently social media are further expanding the role of peers and youth cultures in the lives of adolescents in all places (Larson 2002). Online spaces have changed adolescent developmental tasks such as relationship and identity building which were previously mainly negotiated in face-to-face engagement with peers. For many adolescents, identity formation incorporates local influences with new elements derived from global cultures. There is continued debate over whether exposure to digital media, including a greatly expanded social network, may adversely affect adolescent social, emotional, and cognitive development (Bell et al. 2015). To date, the development of the new media has been so rapid that research efforts to understand their effects have failed to keep pace.

Few studies of the health effects of marketing to adolescents have extended either to LMICs or to new media. Much marketing through digital media extends beyond national borders and is more tailored to individuals. Given that marketing is likely to become even more powerful and increasingly cross-national borders, policy responses at both national and global levels will be needed. To date most research has been around mass media, where the effects on risks ranging from tobacco and alcohol use, to choice of diet and body image norms are clear. There are also good examples of interventions using mass media to promote adolescent health. The South African multimedia 'edutainment' programme Soul City, for example, helped change social norms around HIV/AIDS and domestic violence, contributed to increased individual knowledge about condom use and domestic violence and to the empowerment of local communities (Moyer-Gusé 2008).

While trends in using digital media are global, the means of accessing information varies widely (e.g. mobile phones, personal or public computers). In sub-Saharan Africa growth in access to mobile phones has meant that digital media have become available even in remote places (Lester and Karanja 2008). Young people are generally the earliest adopters of information and communication technologies (ICT) such as mobile phones, instant messaging, the internet, and social media, a phenomenon seen in LMICs as well as in HICs. These new media have the potential to provide a powerful voice for adolescents and young adults to actively engage with each other and their communities. Even in disadvantaged groups and remote locations mobile phones may offer a platform for communication and engagement around health (Alami et al. 2019). These

tools provide a platform for health education in their own right as well as the capacity to augment healthcare delivery and other preventive actions including those within schools. Social media offer the potential to reach diverse groups including those who are geographically isolated or facing discrimination and disadvantage.

Community interventions

The lives of young people are affected by the behaviour, norms, and values of adults and other adolescents in their communities. Community interventions commonly involve local government, families, youth-focused and religious organizations, and schools. Positive youth development (PYD) broadly refers to experiences that provide optimal preparation for the attainment of adult potential and well-being. These programmes are often community based and seek to promote life skills and positive attitudes including self-confidence and empowerment, social and emotional skills, and good problem solving. They aim to build the agency of young people so that they can positively influence the environments in which they live, learn, and play. The strategies employed range from sport and outdoor education to theatre, music, and art, survival skills, leadership training, and mentorship. Certain interventions, such as the promotion of sport in girls, have the potential to bring benefits in physical health and fitness, as well as empowering girls to deal with harmful gender norms (Saavedra 2009). PYD programmes aim to strengthen assets and skills, increasing youth agency and contribution, and foster an enabling environment. The most effective have generally built on available community structures, used good information on adolescent health and well-being, adopted a multicomponent strategy and monitored progress. One example has been the Communities that Care (CTC) framework that has been trialled in a number of United States sites with clear benefits and evidence for cost-effectiveness (Catalano et al. 2012).

One strength of PYD as a framework for intervention in LMICs is that it can be applied in different countries and contexts. One recent systematic review suggested that across LMIC, these programmes achieved gains across a range of youth outcomes, including education, sexual risk behaviour, early marriage, violence, and job skills and employment (Catalano et al. 2019). Several of the approaches also demonstrate promise that PYD increases gender equality.

Conditional cash transfer programmes (CCT) are another example of a community-based intervention that commonly targets adolescents. Examples include payment of school fees and supplemental cash to poor parents on the condition that they send their child to school. Trials in Malawi and Kenya found reduced self-reported sexual activity, pregnancy, and marriage in one or both countries, and reduced school drop-out among girls and young women who received the CCTs (Baird et al. 2010).

Structural interventions

Legislation, taxation, and implementation of policies bringing investment in families, communities, schools, and health services are essential elements of adolescent health action in all places. Laws commonly govern both access to resources for health and protection from hazards. Some specifically address health (e.g. access to healthcare including effective contraception); others address health risks (e.g. consumption of alcohol, access to tobacco); and others address social determinants of health (e.g. age of marriage, protection from hazardous work). Inadequate and inconsistent legal frameworks undermine the health, rights, and potential of adolescents and young adults. Particularly significant are laws that penalize groups facing discrimination and disadvantage where adolescents are more vulnerable that older age groups. One example are laws that diminish the rights of lesbian, gay, bisexual, transgender, and intersex (LGBTI) adolescents and young adults with particularly punitive laws in Nigeria, Somalia, and Sudan.

It was not until the twentieth century that more consistent international legal frameworks emerged for adolescents. The 1989 United Nations Convention on the Rights of the Child (UNCRC) recognized children as bearers of human rights rather than parental property, with liberties and responsibilities appropriate to their age (United Nations General Assembly 1989). The overwhelming majority (195) of countries have signed and ratified the UNCRC, with the United States the only exception. The UNCRC embodies adolescent development suggesting that where freedoms and liberties are restricted, this should be consistent with human rights principles and evolving capacities (Ruck et al. 2016). As adolescents acquire greater competency and maturity, there is a lesser need for adult guidance and an increased capacity for autonomy.

Despite these important developments in international legal frameworks, there remains great diversity in the laws that affect adolescents. Laws often fail both in their framing and implementation, reflecting neither the principles of the UNCRC or an understanding of adolescents' actual capacities. Rather, they mirror historical economic, social, cultural, and sometimes religious priorities (Lansdown 2015). In areas where legislation has a proven role in protecting health (e.g. minimum age to smoke tobacco, working age), laws commonly do not exist. In others, such as legal frameworks around sexual and reproductive health, there is little consistency between countries in the age of marriage, access to contraception, availability of safe abortion, and legality of same-sex relationships.

Child marriage jeopardizes the health, growth, and development of girls in many countries. Around 15 million girls around the world marry each year before 18 years and in lower-income countries, one-third of girls are married before 18, and one in nine before 15 years (UNICEF 2013). Too early marriage results in diminished opportunities for education, greater sexual exploitation, and violence that can sometimes extend to enslavement. Child brides are also exposed to health risks from early pregnancy, have greater maternal and infant mortality, and heightened vulnerability to HIV/AIDS and other STIs (Klugman et al. 2014).

The Convention on the Elimination of All Forms of Discrimination Against Women (CEDAW) requires states to ensure that men and women have equal rights to enter into marriage and to freely choose a spouse with their free and full consent. Yet 34 countries permit girls to marry below 18 years. Some still permit marriage below 15 years, and a few specify no minimum age (Forum on Marriage and the Rights of Women and Girls 2015).

More rational legal frameworks governing adolescents would take greater account of evolving adolescent cognitive and emotional capacities. With access to knowledge, adolescents from the age of 14 years demonstrate similar or even greater cognitive capacity than adults to make good judgements in calm and emotionally neutral contexts (Steinberg 2007). Yet in emotionally charged situations of stress or excitement, particularly with peers, emotions are more likely to drive decision-making (Steinberg 2007; Van Duijvenvoorde and Crone 2013). Legal frameworks would ideally take both factors into account in framing legislation around age of consent. Restricting an adolescent's right to smoke would therefore be justified from

their greater vulnerability to poor decision-making in emotionally charged contexts with peers, as well as from a still evolving capacity to understand the future health consequences. Such approaches would also support and promote adolescent autonomy. Thus voting from 16 years both empowers adolescents and promotes civic engagement. Permitting access to effective contraception including LARCs for sexually active adolescents is one example of how the law can take development into account in protecting an adolescent's health.

Investments in adolescent health should ideally extend from those directed towards conspicuous health problems to health risks that emerge during these years and the broader social determinants of health (Fig. 10.4.3). This ideal is rarely achieved as a result of major barriers to health action, whether through health services, community platforms, or structural initiatives. Adolescents and young adults are the age group with the poorest level of universal health coverage (Tylee et al. 2007). Social, structural, and environmental determinants of adolescent health lie largely outside the health service sector (Viner et al. 2012). There are shifts in these determinants as young people mature through adolescence, such that strategies suited to younger adolescents may be inappropriate or ineffective with young adults. So too strategies that are effective and appropriate for girls may be less effective for boys. The settings for health actions mirror those of determinants and extend from health services, schools, and education settings, to families and communities, places of employment, road transport, media, legal, and policy environments.

Youth engagement and empowerment

The United Nations defined youth participation as 'the active and meaningful involvement of young people in all aspects of their own, and their communities' development, including their empowerment to contribute to decisions about their personal, family, social, economic and political development' (United Nations (DESA) 2007). It embodies the ideas that adolescents and young adults make essential contributions to the design and implementation of programmes and policies that affect them and that meaningful engagement will lead to more equitable communities (Suleiman et al. 2006). In essence, meaningful engagement is not only a fundamental right but essential to capture the unique contributions of youth (Ruck et al.

2016). Developmental perspectives further support meaningful engagement as essential for positive social and emotional development during adolescence. Adolescents are emotionally 'primed' to engage so providing the structures, processes, and support for meaningful engagement itself shapes positive trajectories of development (Dahl 2004). Even though the rationale for youth engagement around health is strong, there has been little systematic research into models of youth engagement, leadership and participation, and their effectiveness.

The sociologist Karl Mannheim wrote early in the twentieth century about the capacity of youth to inspire social change and how the focus of efforts shifts across generations (Mannheim 1970). In recent years, adolescents and young adults have led movements for democracy in Asia and the Middle East, for lesbian, gay, bisexual, and transgender (LGBT) rights, for gender equality, and for action on climate change. Conversely, where opportunities for positive engagement are absent, we have seen adolescents and young adults drawn into violent extremism and gang violence with catastrophic health and societal consequences (Dahl 2004).

Successful engagement emphasizes the capacities of adolescents and young adults to work in partnership with adults. This generally requires both processes to promote active youth participation ('training young people to speak') and the responses of adults ('training adults to listen') (Patton et al. 2016). Adolescents and young adults depend on systems and structures for engagement that are put in place and supported by adults. To engage most effectively, youth need resources (including financial), training, ongoing mentorship, sensitization to political and management processes. They also need platforms and mechanisms for engagement. Existing models range from tokenism to those that are completely youth-led (Wong et al. 2010). More egalitarian relations between young people and adults are essential for meaningful engagement but decisions are still often taken through an adult lens that overlooks young people's perspectives (Gibbs et al. 2010). In general, the greater the level of youth control and responsibility, the greater is the effectiveness of engagement, whether around their own health or around policies and programmes that affect others (Wong et al. 2010).

Youth engagement in health-related advocacy has increased over the past two decades, fostered at a global level by the UN and other international organizations. Similar processes have occurred at country and community levels within organizations delivering services to young people.

There are reasons to be optimistic about the scope for extending meaningful youth engagement around their health and well-being. The growth of social networking and digital media make it possible to access information, communicate and mobilize with other advocates, as well as draw in resources in unprecedented ways. New media promote more active engagement as adolescents and young adults can independently generate their own content (Kaplan and Haenlein 2010). These possibilities allow broader collaboration which in turn can generate political leverage. Time, privacy, and the need to convince adolescents that their voices will be heard remain barriers. For these reasons capitalizing on these new possibilities is likely to require a shift in approaches to communication for both government and civil society organizations. Attitudes of adults towards young people and their capabilities, together with young people's lack of confidence in engagement processes, are a common barrier (Coates and Howe 2014). Attitudinal barriers commonly arise from cultural contexts where young people are perceived as subordinate to adults, that exclude young women and that further stigmatize socially marginalized groups (Harden et al. 2001; Iwasaki 2014). Inflexible bureaucratic arrangements, insufficient investment to support ongoing engagement, and restrictive policies, such as limiting the participation of adolescents in research, may be further limiting factors (Villa-Torres and Svanemyr 2015).

For these reasons, most youth engagement in health falls short of sustainability, and top-down, adult-driven approaches remain the most common.(Gibbs et al. 2010) In programmes that do engage young people, those selected are often already 'confident, articulate and naturally identified leaders'. In practice, few efforts meaningfully involve the most marginalized adolescents, who may include ethnic minorities, HIV-positive youth, married adolescents, youth with disabilities, LGBT youth, youth living in poverty, those with lower educational levels, and very young adolescents (Paterson and Panessa 2008). In many circumstances, adolescent girls and young women face inequitable systems and structures which limit their participation.

The investment case and accountability

There is also growing evidence for both cost-effectiveness and high benefit–cost ratios from investments in adolescent health. In the US, the benefits

from evidence-based prevention programmes were estimated to range between $2 and $42 for every dollar invested (Catalano et al. 2012).

A recent analysis of the investment case for adolescence in LMICs highlighted both high benefit–cost ratios from five investments (education, HPV vaccination, reducing rates of child marriage, prevention of road traffic injury and provision of youth-friendly healthcare) and their affordability even in low-resource setting (Sheehan et al. 2017). In providing health services for physical, mental and sexual health, an investment of US$4.65 per capita per annum had an unweighted mean ratio of benefit to costs (BCR) of over 10; for the prevention of road traffic injuries a BCR of 5.9 could be achieved through an annual per capita investment of US$0.60. Programmes to reduce child marriage (US$1.5 per capita per annum) showed a mean BCR of 5.7, with the benefits greatest in lower-income countries. Investment to improve secondary schooling were more expensive with a per capita investment of US$22.6 per annum generating a mean BCR of 11.8 (Sheehan et al. 2017).

Yet recent analyses of developmental assistance for health across the life-course suggests that there is scant investment in 10–24-year-olds (Skirbekk et al. 2017; Li et al. 2018). Only 1.6% of developmental assistance for health is targeted to 10 to 24-year-olds, despite this age band making up 30% of the population in low-income countries. Overwhelmingly the investments have been in HIV and reproductive health with little or no investment in adolescent nutrition, mental health, or injury prevention (Li et al. 2018).

The *2030 Agenda for Sustainable Development* and the *Global Strategy for Women's, Children's and Adolescents' Health* has outlined the need for better data to drive accountability for countries (United Nations 2014). Ideally, data should allow comparisons over time and tracking of inequalities within and between countries. In reality existing global data systems for adolescents remain poorly coordinated, inconsistent in coverage and timing, inadequately disaggregated, missing large groups of adolescents (e.g. out of school adolescents) and fail to deal with the spectrum of adolescent health problems and their determinants (Patton et al. 2012).

The implementation of adolescent health policies often requires engagement across government ministries. In many countries, this extends to international agencies and global funders and ideally includes civil society groups outside of government (Bhamra et al. 2015). The relevant constituents include professionals working with adolescents, academics and

private industry with young people and youth-focused organizations essential stakeholders in the implementation of effective policies and programmes. Their meaningful engagement can ensure a proper understanding of what data mean, inform the feasibility and appropriateness of potential actions, and support broader buy-in.

The most effective actions for adolescent health and well-being are often intersectoral and multicomponent, tailored to local needs and capacities. Ideally such interventions will have been adapted and trialled in similar contexts. Yet in some areas such as mental disorders, nutritional interventions, and sexual and intimate partner violence, there are not yet clearly effective and scalable actions for adolescents. In other areas, health actions such as comprehensive sexuality education have been evaluated in HICs, but neither adequately adapted nor evaluated in LMICs. Many innovative approaches have been piloted and sometimes rolled out on a larger scale but without evaluation. Examples include interventions based on digital media that offer great promise but in the absence of more systematic evaluation their broader utility remains uncertain (Patton et al. 2016).

Conclusion

Adolescent health now has a presence in global health and international development. The challenge now is to take responses to scale. We now have a good understanding of many approaches that are effective including the strategies for re-orienting health service responses to adolescents, intersectoral actions, and the value of partnerships with young people themselves. Next steps to more effective and accountable systems for adolescent health will need to include better information systems, development of a stronger evidence base for action and ensuring effective policy action around those facing the greatest levels of discrimination and disadvantage. The benefits will extend well beyond adolescence to health in later life and lay a foundation for the best possible start to life for the next generation.

Intersectional and social epidemiology approaches to understanding the Influence of race, ethnicity, and caste on global public health

Jennifer Beard, Nafisa Halim, Salma M. Abdalla, and Sandro Galea

Introduction

Health at the individual, interpersonal, and community level is a product of multiple, intersecting characteristics that comprise identity and contribute to privilege and vulnerability. Health, illness, well-being, and misery for all humans are shaped by a confluence of biological, social, and cultural factors. While traditional epidemiological approaches have measured associations by considering variables in isolation, there is growing recognition that multiple variables are important determinants of identity and, therefore, of health and well-being.

Social epidemiology, in particular, has aimed to more fully understand how multiple intersecting factors influence population health (Bowleg 2012; Bauer 2014; Larson et al. 2016). Social epidemiology the science of measuring the ways in which variables like race, ethnicity, sex, gender, sexual orientation, and physical ability are associated with illness and health at the population level (Berkman et al. 2014). It seeks to examine the role of material, behavioural, and psychosocial pathways which influence social inequality and health disparities over the life course, looking at early exposure to social toxins like racism and poverty (as well as biological toxins such as lead or air pollution) and their cumulative influence on health later in life (Cable 2014). Although the traditional methods of epidemiology remain limited to measuring single variables and their association with single outcomes, newer approaches have emerged that aim to understand the complexity of forces that shape health in populations (Galea, Riddle, et al. 2009; Diez Roux 2011). These innovations in social epidemiology are akin

to intersectional approaches to understanding health disparities within and across populations.

An intersectional approach challenges and complements traditional epidemiological methods by asserting the need to measure the impact of multiple, interlocking variables on the health of individuals and populations. As Amroussia et al. (2017) explain, 'The intersections of these categories create a complex web of social inequalities that are all experienced together by individuals. It is not possible to explore inequalities grounded in each category in isolation from each other, since that is not the way they are experienced by individuals' (Amroussia et al. 2017). Privilege, disadvantage, and bias exert pressure, influencing individual agency and power. These external forces are shaped by ambient societal factors like cultural and social norms, economic and political structures, institutions, and laws. For example, a Hispanic woman living in the US faces greater social inequities than a Hispanic man. That same man may face more social challenges than a White woman, particularly if he is poor, Black, or gay. Intersectionality takes all these ascribed, achieved, and external forces that shape identity and influence agency into consideration within a specific cultural, social, and historical context.

This chapter examines the ways in which the individual characteristics we are born with or acquire over the course of our lives intersect to offer us privileges or hamper us with disadvantages that dictate our positions in the social hierarchy and our health. We define common terminology and explore the intersections between social determinants and health outcomes in an illustrative case focused on India. Finally, we offer recommendations for making intersectionality central to social epidemiology and global health.

Terminology and definitions

Many of the concepts featured in this chapter (race, ethnicity, privilege, racism) are widely understood and used in common parlance, yet each is also abstract and nuanced. The following definitions aim to provide common understanding of the overlapping social positions and processes that contribute to individual and population health.

***Race and ethnicity*:** The Oxford English Dictionary (OED) defines 'race' as 'a group of people, animals, or plants, connected by common descent or origin. In its widest sense the term includes all descendants from an original

stock, but may also be limited to a single line of descent or to the group as it exists at a particular period' (Oxford English Dictionary Online 2018). The breadth of this basic definition, referring to vague categorization of all living entities based on context and other subjective criteria may startle first-time readers. Most of us have deeply ingrained ideas about race as an objective system grouping human beings according to intrinsic physical characteristics including skin colour, facial features, and hair texture. Yet, researchers unravelling the human genome have concluded that these external markers have very little grounding in genetic difference (Rosenberg et al. 2002; Yudell et al. 2016). This conclusion is consistent with decades of sociological theory and research (Berger and Luckmann 1966). Race is a social construct built on and enforced by differences that have no biologic grounding (Scott and Marshall 2009). James Scott and Gordon Marshall, editors of the Oxford Dictionary of Sociology, describe it as a term that should always be marked by inverted commas to indicate that 'this manner of categorizing individuals and population groups is not based on any biologically valid distinctions between the genetic make-up of differently identified "races'' (Scott and Marshall 2009).

The OED defines 'ethnicity' as 'status in respect of membership of a group regarded as ultimately of common descent, or having a common national or cultural tradition; ethnic character' (Oxford English Dictionary Online 2018). This definition closely mirrors that of 'race' but with emphasis on culture and other shared external identifiers such as country of origin, history, language, religion, and tribe. For many scholars and activists, 'ethnicity' is a more useful term than 'race' because it is free of biological connotations. But ethnicity is also a complex social construction dependent on external factors ranging from geopolitical boundaries to personal identification. For example, many Americans take great pride in their ancestors' pre-migration national heritage and identify as Irish or Italian even though they have never been to said country and have no personal connections there. Ethnicity, like race, also has a long history of being used to justify social exclusion and brutality.

Birth-ascribed status: The concept of birth-ascription is helpful for understanding aspects of identity into which one is born and upon which one is ranked within the social hierarchy. These demographic identifiers include race, ethnicity, sex, and caste. Gerald Berremann explains birth-ascription as a 'consequence of birth or ancestry and hence immutable', conferring a

‘societally defined and affirmed worth which is regarded as intrinsic to the individual that cannot be repudiated, relinquished, or altered’ (Berremann 1972). Birth-ascription, he suggests, is a prison without walls in which ‘everyone is sentenced for life to a social cell shared by others of like birth, separated from and ranked relative to all other social cells’ (Berremann 1972).

Raj Bhopal has described race and ethnicity as ‘complex, intertwining, and important concepts used by societies to identify and evaluate social groups and individuals’ (Bhopal 2015). His use of the word ‘evaluate’ is apt. Birth-ascribed status is a form of social evaluation imposed by those with privilege and power. In the US, being identified as Black, Hispanic, or more broadly as ‘not-White’, functions as a form of social evaluation used to justify slavery, brutality, codified social exclusion, and both explicit and implicit bias. In India, caste and sex are the primary drivers of social hierarchy.

Achieved status and agency: Achieved status, is a sociological term referring to ‘any social position held by an individual as a result of his or her personal accomplishments in open formal or market competition with others’ (Scott and Marshall 2009). Achievement refers to education, profession, income, marriage, parenthood, and other social positions that one earns, accomplishes, or chooses. The Oxford Dictionary of Sociology notes that the distinctions between achieved status and ascribed status are not absolute as one’s place within the social hierarchy based on race, ethnicity, gender, and caste further or limit opportunities for and scope of accomplishment. Agency or the ‘the capacity for willed (voluntary) action’, can be bolstered or diminished by education, social network, family relationships, professional path, and income (Scott and Marshall 2009). A Dalit woman living in a poor, rural region will face more barriers than her counterpart living in an urban area that will limit her agency or ability to transcend the social rank into which she was born.

Social position and identities: Social identity theory posits that individuals develop their sense of identity based on groups to which they belong. The development of social identity is a three-part process that starts with social categorization of the people around you as ‘us’ or ‘them’ (Tajfel and Turner 985). Step two, social identification, involves assuming the identities of the different groups to which we belong. Step three, social comparison, is the impulse to define oneself and one’s group as different

from and better from other groups. Brenda J. Allen outlines six primary identity groups: gender, race, social class, sexuality, ability, and age (Allen 2011). Some groups (male, White, wealthy, heterosexual, able-bodied, and adult) are typically more powerful than others and have historically built their identity around subjugating others.

Intersectionality: Intersectionality was first articulated by women of colour as a critique of the feminist, civil rights, and anticolonial movements of the last half of the twentieth century (Collins and Bilge 2016). Kimberlé Crenshaw, a Black feminist legal scholar, is generally credited with first using the term 'intersectionality' in 1989. Mainstream feminism in the US, she argued, was a movement created by and for White middle-class women. And the civil rights campaign to end racial discrimination likewise erased the compound sex- and race-based subordination of Black women with its focus on middle-class Black men (Crenshaw 1989). Although Crenshaw is often credited with first articulating the need for an intersectional approach to understanding 'multiply-burdened marginalization' (Crenshaw 1989), she was by no means alone. Her voice was one in a global chorus of women of colour frustrated with the binary thinking of social change movements that categorized marginalization as race- *or* gender-based, without considering what Patricia Hill Collins and Sirma Bilge describe as the 'many axes that work together and influence each other', enhancing the privilege and power of some and deepening the oppression of others (Collins and Bilge 2016).

Figure 10.5.1 illustrates intersectional identities as a cluster of interlocking ascribed, achieved, and geopolitical identities that lock together to form the position of each individual. Privilege, disadvantage, and bias exert pressure influencing each individual's agency and power. These external forces are shaped by ambient societal factors like culture, norms, economic and political structures, institutions, and laws.

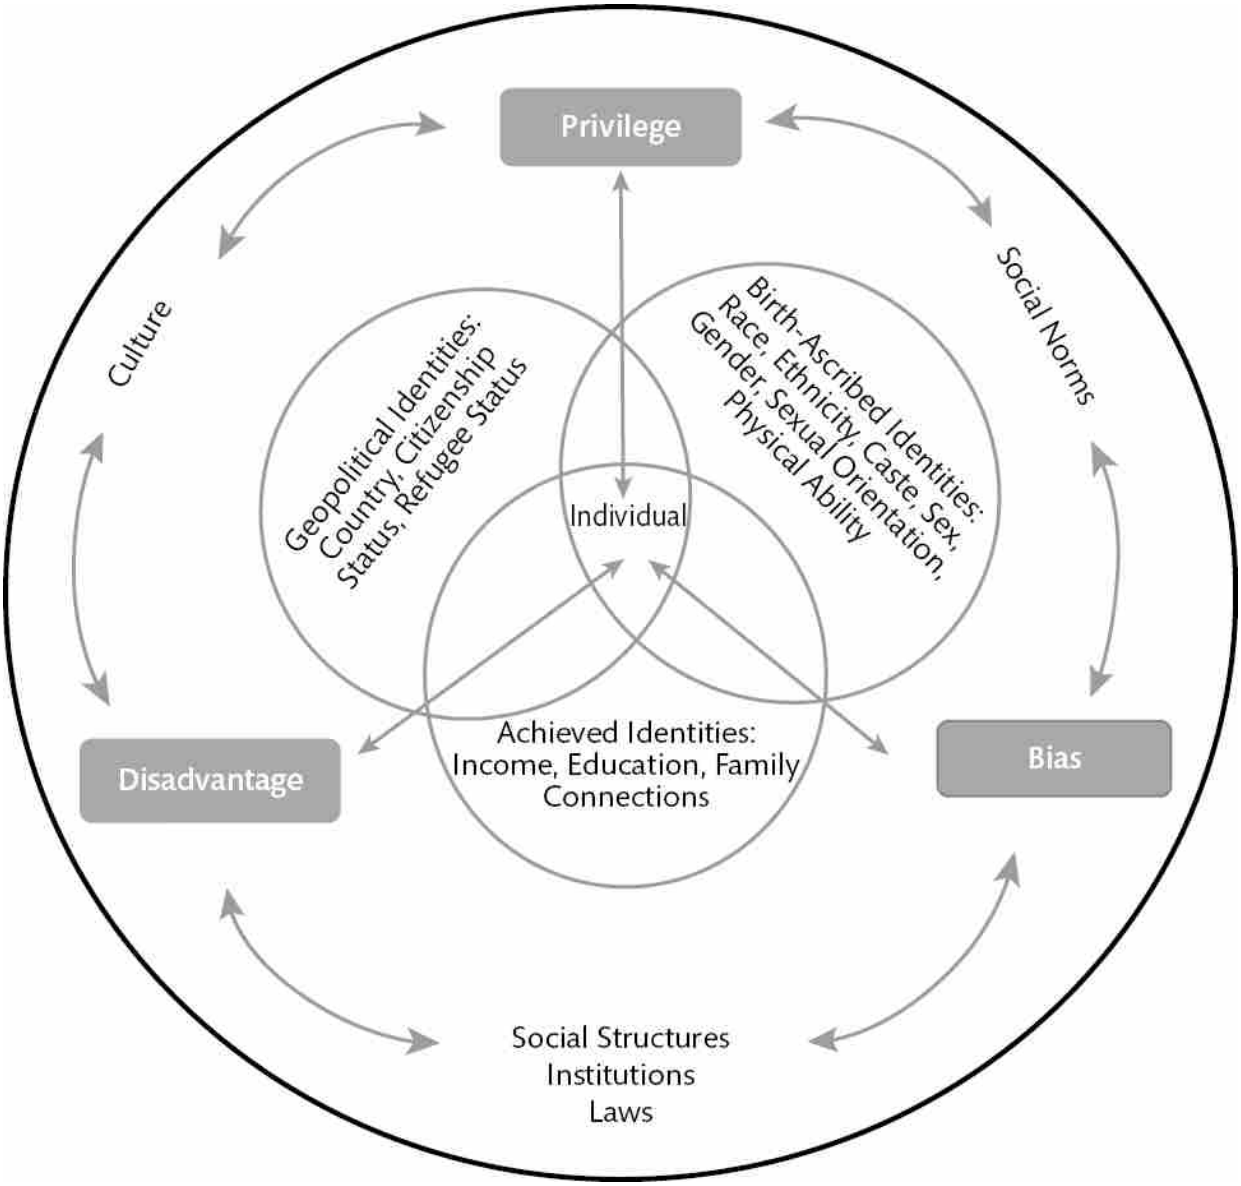

Fig. 10.5.1 Intersectional identities.

Racism and racialization: The Oxford English Dictionary definition of 'racism' provides a detailed overview of discriminatory social processes, beliefs, and actions based on race, ethnicity, an other defining characteristics:

> A belief that one's own *racial or ethnic group* is superior, or that other such groups represent a threat to one's cultural identity, racial integrity, or economic well-being; (also) a belief that the members of *different racial or ethnic groups* possess specific characteristics, abilities, or qualities, which can be compared and evaluated. Hence: *prejudice, discrimination, or antagonism directed against people of other racial or ethnic groups* (or, more widely, of other nationalities), esp. based on such beliefs. (Oxford University Press 2018, emphasis added)

From this broad perspective, skin colour and other physical features are inadequate as universal determinants of racialized discriminatory behaviour.

Racialization is the imposition of a 'racial interpretation' on groups of people seen as other, even when both parties share similar physical and social characteristics. In European and United States migration history, Caucasian Jews, Irish, and Italians have been depicted and shunned as separate and inferior races despite similar White skin and other physical attributes. In colonial Rwanda, Tutsis were favoured by German and Belgian colonizers over the more 'African' Hutus. Both ethnic groups are Black, but colonial rulers promoted the former as being closer to White because of their lighter skin, tall and slim stature, and facial features. Racialized discrimination has played out in its most extreme forms in, for example, the genocides in Europe, Rwanda, and Darfur, ethnic cleansing of the Rohingya from Myanmar, and tribal violence in Kenya. In India, the caste system has imposed discriminatory social stratification rendering millions 'untouchable' (Berremann 1972). In the US, structural racism is sometimes described as a caste system that has led to mass incarceration and police shootings of unarmed Black men (Alexander 2010; Sampath 2015; Demby 2018).

Privilege and disadvantage: Social privilege and disadvantage are the unearned consequences of birth-ascribed rank. Many variables are at play in the ratio of advantage and disadvantage each of us carry, including skin colour, religion, sex, gender, sexual orientation, body-type, and physical ability. The degree to which these qualities confer unearned advantage or disadvantage is dependent on the biases and norms of the context in which we live. In the 1989, Peggy McIntosh famously used the analogy of an 'invisible knapsack' filled with free passes, passports, and licences to describe White privilege and male privilege (McIntosh 1989). Intersectional approaches to understanding oppression shed light on many other determinants of privilege, power, disadvantage, and oppression. As McIntosh explained more recently: 'We are all put ahead and behind by the circumstances of our birth. We all have a combination of both. And it changes minute to minute, depending on where we are, who we're seeing, or what we're required to do' (Rothman 2014).

Social determinants of health: The US Centers for Disease Control and Prevention define social determinants of health as 'conditions in the places where people live, learn, work, and play that affect a wide range of health risks and outcomes' (Centers for Disease Control and Prevention 2018).

These daily conditions of life include the houses we live in, the type of food we eat, the schools we attend, the amount of money we have to meet our needs, the way we are treated by our parents as children, the degree to which we feel socially accepted, and more (Commission on Social Determinants of Health 2008). Likewise, race-based privilege, oppression, and other birth-ascribed attributes like ethnicity, sex, and caste are critical factors contributing to the health of individuals and populations. In the US, for example, infant mortality is two times higher for Black babies (11.7 deaths per 1,000 births) compared to White (4.8 per 1,000) (Riddell et al. 2017). And, in Brazil, low-birth weight is significantly higher among infants of African ancestry (12.4%) compared to Brazilians with European-only ancestry (8.10%) (Nyarko et al. 2013).

Intersectionality in global health research: conceptual framework and methodologies

Figure 10.5.2 illustrates the pathways connecting intersectional identities and health status across the life course. As articulated in Section 2, an individual's social position depends on his/her birth-ascribed and achieved attributes. Further, the individual's birth-ascribed attributes depend on his/her own characteristics (i.e. gender, birth-order, skin tone, sexual orientation) and the characteristics of his/her parents (wealth, income, religion, caste, race, and ethnicity). Intersectional theory posits that 'multiple social categories (e.g. race, ethnicity, gender, sexual orientation, socioeconomic status) intersect at the micro level of individual experience to reflect multiple interlocking systems of privilege and oppression at the macro, social-structural level (e.g. racism, sexism, heterosexism)' (Bowleg 2012). Birth-ascribed attributes largely shape an individual's achieved attributes later in life. Individuals are endowed with privileges and disadvantages along different dimensions, the net of which determine each individual's social position. History, culture, and social and economic context determine the identities associated with privileges and those with disadvantages.

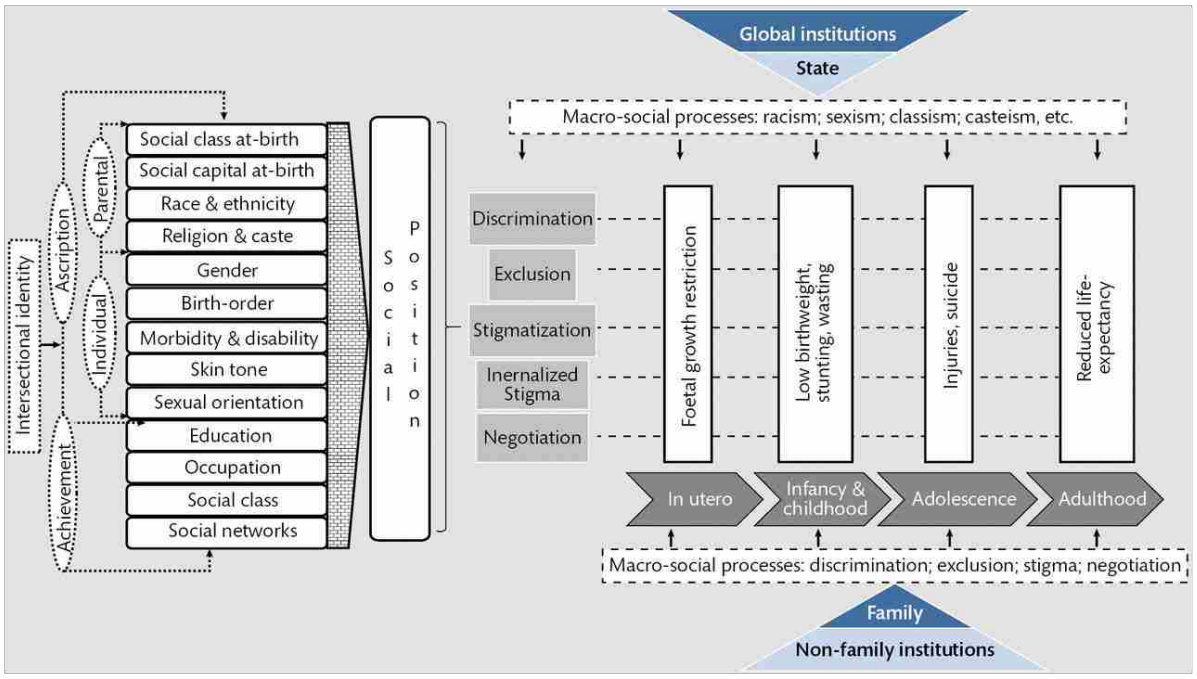

Fig. 10.5.2 Pathways linking intersectional identity and health outcomes throughout the life course.

Social positions affect health and well-being across the life course, as illustrated in the constructs on the far left in Figure 10.5.2. Depending on social position, each individual will or will not experience bias and discrimination in interactions with healthcare providers, educators, employers, and others. For example, clinicians influenced by unconscious bias may make assumptions and care decisions about poor patients, patients of another race or ethnicity, patients of a different caste, patients who are gay or lesbian, or patients with non-binary gender. Parents may rely on internalized social norms to make decisions on whether to invest in daughters as much as sons. And, educators or employers may perceive members of their own race or religion as having more positive attributes (e.g. cooperative, competent, honest, compliant, hard-working, ‘pure’) than those of another race or caste with whom they may associate negative qualities (e.g. competitive, incompetent, dishonest, deviant, lazy, ‘polluted’). These decisions or interactions can lead to discrimination and exclusion over the life course, affecting foetal growth, birth outcomes; childhood nutrition and development; sexual contraception choices and contraception use during adolescence, and pregnancy outcomes or life expectancy during adulthood.

The extent to which clinicians, educators, employers, and others engage in discriminatory practices will be shaped by the enactment and enforcement of national and international laws criminalizing discrimination. Whether or not a Black pregnant woman in the US and many other countries with a history of institutional racism or a low-caste pregnant woman in India and other South Asian countries will be able to leverage or negotiate respectful treatment will depend on her position. Leveraging or negotiating refers to using advantages along some social positions to compensate for disadvantages along others. For example, a wealthy Black pregnant woman in the US or a Brahmin pregnant woman in India will be better able to demand respectful treatment than a poor woman who is Black or from a Scheduled Caste. The more disadvantages individuals have, the less ability they will have to leverage power in social interactions. The ratio of disadvantages to privileges one carries, influences stress burden, perceived agency, and, ultimately, health and well-being.

Study design, measurement, and modelling

The advantages of incorporating intersectional approaches in health research have been widely acknowledged (Hankivsky et al. 2010; Bowleg 2012; Bauer 2014; Lopez and Gadsden 2016; Larson et al. 2016; Green et al. 2017). Yet, intersectionality frameworks have been underutilized due to limited progress in developing methodologically sound approaches for applying intersectionality in health research. Intersectional theory challenges and offers nuance to standard epidemiological methods for measuring associations between variables like race, ethnicity, caste, gender, economic status, and health outcomes by placing each individual at the centre of a busy thoroughfare with multiple roads leading in from all angles. Another helpful image is that of a knotted tangle of many strands of yarn in which each is spun from multiple types of fibre representing social identifiers and varying levels of access to privilege and power. The traditional methods of social epidemiology stop short of measuring and analysing what Lisa Bowleg has described as ‘multiple and interlocking social identities’ (Bowleg 2012), which is the goal of an intersectional approach.

Applying an intersectional approach to population health research requires using analytical methods that examine the complex characteristics of individuals that blur the fixed lines that define a population (Green et al.

2017). A number of social epidemiologists have incorporated intersectionality into their research, using it to inform study design, determine variables to measure, approach measuring multiple social positions, and analyse data (Weber and Parra-Medina 2003; Schulz and Mullings 2006; Warner 2008). An overview of some intersectional approaches to population health research follows:

Study approach/design: Eco-epidemiology is a methodological parallel to the intersectionality framework concerned with the determinants of disease in individual cases as well as the social contexts within which individuals live. To measure how race produces ill-health, for example, an eco-epidemiology approach takes into consideration that study subjects experience of racism at individual (i.e. internalized racism), interpersonal and community (discrimination and exclusion), and societal levels (institutionalized racism). Similarly, an eco-epidemiology approach to data analysis incorporates contextual factors pertinent to neighbourhoods and states:

Neighbourhood factors include violence rates, incarceration rates, income/wealth inequality, affordable housing, housing occupancy rates, and liquor outlet density;
State factors include public funding for healthcare and social programmes, human rights protections, discriminatory laws or policing practices, and employment protections.

Eco-epidemiology generally requires a large sample size, with samples organized across multiple levels (individuals; neighbourhoods; etc.) of the socioecological spectrum (Bauer 2014).

Operationalization of intersectional social positions: Intercategorical and anticategorical intersectionality are two methods researchers have used to measure multiple, interacting variables and their possible influence on health (McCall 2005; Wemrell et al. 2016; Green et al. 2017; Wemrell et al. 2017). The intercategorical approach uses traditional social categories such as race and gender as proxies of the social forces of racism or sexism. The anticategorical approach, emphasizes ‘the inherent fluidity and malleability of social categories, as. . . socially contingent constructions rather than mirrorings of fixed realities’ (Wemrell et al. 2017).

Wemrell et al. adopted the ‘anticategorical’ approach to measuring intersectional social positions and risk for ischaemic heart disease by

combining categories such as immigration status (yes, no), socioeconomic status (high, medium, low), marital status (yes, no), and mental illness (yes, no) separately for men and women. The research team constructed 48 variables, 24 for men and 24 for women (Wemrell et al. 2017). These variables included:

Males who had been registered inhabitants of Sweden for at least 10 years, had high income, cohabitated, and had been prescribed psychotropic medication.
Females who had been registered inhabitants of Sweden for at least 10 years, had high income, cohabitated, and had not been prescribed psychotropic medication. (Wemrell et al. 2017)

Modelling: Eco-epidemiologists primarily alternate between two approaches to model health effects of intersectionality. Green et al. (2017) advocate use of multilevel modelling approaches, which entail setting up the data in a way that nests individuals (level 1) within each intersectional identity (level 2) (Green et al. 2017). The authors suggest adding two sets of covariates to regression models: individuals' (a) gender, race, and other dimensions of social identity; (b) intersectional identity. This differs from traditional approaches of modelling intersectionality. In a traditional approach, a researcher uses an interaction variable for an intersectional identity (e.g. an interaction variable indicating being both Black and female) along with two variables, each for one identity (i.e. a variable indicating being female, and another indicating being Black).

Complementary use of complex systems approaches has strong potential utility for dealing with the complexities associated with intersectional health production processes (Galea et al. 2009). Individual and societal factors influence one another in the process of the production of health. For example, an individual's alcohol use and residence in a neighbourhood with a high density of alcohol shops can each adversely influence health. Yet, individuals who tend to engage in high levels of alcohol use may choose to live in neighbourhoods where alcohol outlets are easily accessed. Or, neighbourhoods where alcohol outlets are readily available may influence moderate or non-alcohol users to increase their use to the point of alcohol addiction. Each situation is an example of individual and neighbourhood-level factors influencing each other, and thereby confounding the associations estimated by regression models between single-level factors and

health outcomes. Such relationships between determinants are commonly referred to as dynamic relationships.

Individual, interpersonal, community, and societal indicators can be consequences as well as the causes of health outcomes. An individual's health can be a consequence as well as a 'complicating cause' of alcohol use disorder (Galea et al. 2009). An individual living with a chronic disease may turn to alcohol dependence among other harmful behaviours as a coping mechanism. Or many individuals' high demand for alcohol may influence availability of liquor stores in the neighbourhood. This phenomenon is commonly referred to as 'reciprocity' between health exposures and outcomes.

Complex systems computational models have the potential to simulate dynamic reciprocal interactions and interrelations between individuals, exposures, and outcomes that change over time and across the life course (Galea et al. 2009). Computer simulations that specify rules by which individual agent's interactions can be used to observe how intersecting variables at the individual level can translate into population health outcomes. In model specifications, researchers can let agents be adaptive (i.e. agents change their behaviours over time) or prescriptive (i.e. agents behave using pre-set rules). Agents may interact based on spatial proximity or memberships within a social network; can be clustered into groups at different levels (i.e. households, neighbourhoods, states); and, can be influenced by group-level factors (Galea, Riddle, et al. 2009; Galea, Hall, et al. 2009; El-Sayed et al. 2012).

Case study: intersectionality and health inequities in India

India is home to 1.2 billion people, ranked hierarchically by gender, religion, caste, and economic class, among other axes of power (World Bank Group 2017). Steady economic growth of 3–4% annually replaced the stagnation of the British colonial era, making famines a distant memory (Drèze and Sen 2013). India's economic growth has accelerated over the last three decades at an annual rate of 9%, making it one of the world's fastest growing economies (Paul and Mas 2016).

At independence in 1947, after two centuries of British colonial rule, India committed to using legislative policy within the framework of a representative democracy to improve the lives of women and historically

disadvantaged minority groups. To reduce caste-based inequalities, India has adopted a number of progressive laws designed to reduce structural inequities and equalize political representation. All 30 states have set aside 22.5% of seats in the legislature and government-sponsored educational institutions and public-sector jobs for the Scheduled Castes (16–17% of the population) and the Scheduled Tribes (7–8% of population) (Deshpande 2000; Pande 2003). Further, India enacted a number of laws and regulations aiming to eliminate gender-based discrimination and, thereby, improve women's status in society.

The 2006 Prohibition of Child Marriage Prevention Act criminalizes child marriage and imposes a jail sentence or fine. The 1994 National Pre-Conception and Pre-Natal Diagnostics Techniques (PNDT) Act bans sex-selective abortions. And, since 1993, Indian states have been constitutionally required to reserve for women one-third of all chief positions (Pradhan) in local village councils (Gram Panchayats). Notably, in a landmark ruling in 2014, India's Supreme Court recognized transgender people as members of a third gender, which shows the country's gradual progress toward gender inclusiveness.

Still, Amartya Sen has argued that health in India is in 'dire straits' due to severe underinvestment (India Express News Service 2017). In 2011, India spent 3.9% of its gross domestic product on health, a 28% decrease from 1995. India's health inequalities by gender, caste, and class are glaring, and particularly at the intersection where all three meet. A child from a Scheduled Caste, for example, is twice as likely to die in the first year of life compared to a Brahmin child (Thresia 2018). A female child is 1.7 times more likely to die in the first year than a male child (Chowdhury et al. 2017). Infants and children from the lowest standard of living quintile respectively have 2.73 and 4.61 higher odds of mortality than those from the highest quintile (Subramanian et al. 2006). Even Kerala, the southern-most Indian state with health indicators comparable to those in high-income countries, is beset by pervasive health inequalities (Thresia 2018).

Positions

Caste, gender, and class are the most salient axes of social position and power in present-day Indian society. Table 10.5.1 compares race in the US and caste in India as systems of social stratification.

Table 10.5.1 Race vs. caste comparisons

	Race in the US	Caste in India
Context of origin	Western colonialism and capitalism	Hindu society
Status assignment	At birth	At birth
Recognizable by:	Overt characteristics: skin colour; hair texture, facial features; stature, name	Overt and covert characteristics; skin tone; name; occupation; place of residence; etc.
Structural characteristics	Hierarchical	Hierarchical
	Endogamy* practised	Endogamy, a social norm
	Occupation, not race based	Occupation caste based
Social function	Maintains social order by reducing transaction costs	Maintains social order by regulating completion
Social meaning	Imposition of worth based on in or out-group membership	Imposition of worth based on in or out-group membership
Rationalized by:	Economic status and law	Religio-philosophical ideology
Affirmative action	Quotas	Quotas
Lived experiences	Differential access to goods; services; livelihood, respect, self-determination, peace of mind, pleasure, and other valued things including nourishment, shelter, health, independence, justice, security, and long life	

* Endogamy refers to marriage within one's own group based on kinship and/or shared customs, values, and beliefs (such as tribes or castes).

Ancient Hindu society stratified the population into four mutually exclusive, exhaustive, birth-ascribed, and endogamous castes (varna) (Desai and Kulkarni 2008; Vaid 2014), each associated with a type of occupation:

Brahmin (priests and teachers),
Kshatriya (rulers and warriors),
Vaishya (traders)
Shudra (artisans and manual labourers).

Each caste is further stratified into many smaller subcastes (*jatis*), and each subcaste into even smaller sub-sub castes (Vaid 2014). Scheduled Castes, the lowest in the hierarchy, tend to be employed in occupations considered profane (e.g. skinning animal carcasses, butchering animals, removal of human waste, attendance at cremation groups, washing clothes, fishing). The historical justification for 'untouchability' is 'they are so low that they do not deserve to be assigned a caste' (Desai and Kulkarni 2008).

The ritual of purity-pollution underlies the religious rationale for the caste system. Dharma (right conduct), karma (just deserts) and rebirth are the philosophies rationalizing caste assignments. At nearly 3,000 years, India's caste system is among the world's oldest forms of social stratification (Beteille 1969; Von Fürer-Haimendorf 1982; Galantar 1984; Omvedt 1993). Caste discrimination was legally abolished in 1950, but continues to vitally affect opportunities, rewards, and social roles. India's gender-based social stratification entitles men to more rights, resources, and responsibilities compared to women, regardless of ability. India's gender stratification and preference for sons has resulted in many families adopting sex-selective abortion skewing pro-male sex-ratio at birth and neglect of female infants and children (Miller 1989; Jeffery and Basu 1996; Murthi et al. 2018).

Patrilocality (i.e. a married couples living near or with the husband's parents), patrilineality (i.e. names and property pass to the next generation through male descendants), the role of sons in religious rituals, old-age support from sons, the dowry system, and desire to protect female safety and purity are the key cultural factors legitimizing gender stratification (Jayachandran 2015).

Intersectional processes

Returning to Figure 10.5.2, gender and caste interact in complex ways affecting illness and health in India. For the purpose of illustration, consider gender and caste as simple dichotomies. Compared to Priya, a Brahmin woman, Amitabh, a Brahmin man will likely be less vulnerable and susceptible to health risk factors. He will have better access to assets and

services that promote good health, and he will suffer fewer consequences of illness, violence, or disability. On the other hand, Priya will likely perform better than Prakash, a Scheduled Caste/Schedule Tribe (SC/ST) man, who will likely perform better than Anju, an SC/ST woman. While Amitabh and Anju hold extreme social positions on a continuum of intersecting gender and caste identities, Priya and Prakash belong to the middle group. Amitabh has only privileges accorded to him due to his male and Brahmin identities and Anju has only disadvantages. Priya can leverage her caste privileges to compensate for her gender disadvantages. And Prakash can leverage his gender privileges to partially compensate for his caste disadvantages. Although, both Priya and Prakash exist in the middle of the social continuum, Priya belongs to a dominant middle group and Prakash to subordinate middle group since gender identity is more fluid than caste identify in present-day India.

Intersectional health research in India

To date, only a handful of studies have adopted an intersectionality framework to explain health disparities in India. Sen and Iyer (2012) used household survey data on health seeking behaviour from 60 villages of Koppal district, Karnataka. They found that, of the six groups based on two categories of gender (male, female) and three categories of class (poorest, poor, and non-poor), middle-groups (non-poor women and poor-men) shared striking similarities in key health outcomes (Sen and Iyer 2012). Using the National Family Health Surveys of India 1992/93—2005/06, Joe found severe immunization shortfalls among SC/ST children from rural areas, particularly for girls (Joe 2015). Using the National Family Health Surveys of India 1992/93–2005/06, Mukhopadhyay (2015) found that ‘class inequality dominates caste inequality and caste inequality dominates gender inequality’ in childhood stunting in rural North India (Mukhopadhyay 2015). Finally, Scaria (2017) used data from a household survey from Wadakkanchery village of Kerala and found that morbidity is highest among women from Scheduled Castes and Tribes, followed by women from Other Backward Classes, and Christian and Muslim women (Scaria 2017).

Looking forward: embracing intersectional social epidemiology

Intersectionality offers social epidemiologists an opportunity to explore innovative research methods for exploring the systems driving health inequalities. It also offers a pathway for using our research to improve the underlying social and structural conditions contributing to disparate health outcomes (Galea 2013; Galea and Link 2013; Bauer 2014).

Embracing intersectionality will require a range of approaches, from ecological thinking to systems thinking. Complex systems approaches will require data tracing multiple positions and processes within and across levels (Galea 2017). At a minimum, we need to maximize our access to data on social positions (e.g. race, ethnicity, caste, etc.) and social processes (e.g. privilege/disadvantage, racial discrimination/racialization) across multiple levels of social-ecology. Big data from social media, consumer health-record platforms, and troves of administrative and corporate records presents unique opportunities to explore causes of disease, factors that protect health, and sources of resilience.

The conceptual nuance of measuring the contribution of multiple intersecting identities to both individual and population health offers social epidemiologists an opportunity to embrace theory and deepen our understanding of historical, structural, social, and cultural drivers of health and illness (Galea and Link 2013). Finally, and, perhaps most importantly, social epidemiologists need to continue to ask questions of consequence (Galea 2013). This means continuing to pursue knowledge of disease causality but not simply for the sake of knowing. Rather, we need to pursue this knowledge with the aim of intervening to mitigate or enhance individual and community-level factors driving health outcomes, both good and bad.

Conclusion

Global health activists and practitioners have been using intersectional approaches since at least 1978 and the Alma-Ata Health for All Declaration, which urged the world to eliminate ‘gross inequality in the health status of the people, particularly between developed and developing countries as well as within countries’ by promoting ‘maximum community and individual self-reliance and participation in the planning, organization, operation and control of primary healthcare’ (WHO and United Nations Children’s Fund 1978). As defined by Alma-Ata, primary care put equal emphasis on addressing social drivers of health and access to healthcare.
